Proof. Within b, every transaction is executed based on the same world state and no one updates any key until they all complete execution. If tx is re-executed on node i, then tx must change its read/write sets (Line 8 in Algorithm 2) or read/write a new key $key' \in all_keys$ (Line 5 in Algorithm 3). Then obviously node j should also re-execute tx because the read/write sets of each transaction are obtained during speculation and agreed upon by consensus. □

With Lemma 1, in the following we only consider the transactions that are not re-executed. We discuss the cases without and with an improved replay strategy, respectively.

Lemma 2. *(With a simple re-execution strategy in Algorithm 2) The execution results of each batch are equivalent to the same serial order on every node.*

Proof. For any two transactions tx and tx' in the same batch, they should not have WAW dependency, nor should they have both WAR and RAW dependencies (Line 34 in Algorithm 1). Without loss of generality, we assume the serial order of transactions in the batch is: $\cdots \rightarrow tx' \rightarrow \cdots \rightarrow tx \rightarrow \cdots$. We then discuss three cases:
Case 1: If they are non-conflicting, they are serializable. And we determine their order based on the order of their indices.
Case 2: If tx WAR-depends on tx', then since the result of execution will only be committed after all transactions in the batch finish execution, tx' cannot read the value written by tx, they are serialized as tx' happens before tx, the assumed serial order is satisfied.
Case 3: If tx RAW-depends on tx', their execution is equivalent to tx happens before tx' (i.e., re-ordering), so the serialized order can be changed to $\cdots \rightarrow tx \rightarrow \cdots \rightarrow tx' \rightarrow \cdots$. Also note that tx in this case must have no WAR dependency with any other transaction, so no dependency circle will be generated in the same batch.

In all cases, the execution results of all the transactions within each batch are equivalent to a certain serial order. It is also trivial to see that every node proceeds based on the same world state and consensus-provided information. So their execution results should be equivalent, □

Lemma 3. *(With an improved strategy in Algorithm 3) The execution results of each batch are equivalent to the same serial order on every node.*

Proof. With the proof of Lemma 2, we only need to discuss the following three cases.
Case 1: Neither tx nor tx' reads a new key that is (newly) written by some transaction. In this case, both tx and tx' are committed by following the serial order extracted from DAG (Line 14 in Algorithm 3). Even if tx and tx' newly write the same key key', there is no RAW-dependency between them, so their execution results are still equivalent to the serial order.
Case 2: tx reads a new key key' that is also (newly) written by some transaction, while tx' does not. In this case, tx' gets committed before tx (Line 14), while tx is executed again and committed (Line 16). Even if tx' also writes key', tx can read the update of key' if necessary. Anyway, tx' is executed before tx in the serial order.
Case 3: both tx and tx' read some new keys, say key' and key'', that are also written by some transactions. In this case, both tx and tx' are executed (sequentially) again and committed. Without loss of generality, tx is executed before tx' in the serial order. □

With Lemma 1, every node re-executes the same set of transactions sequentially. With Lemma 2, Lemma 3 and every node executes batches one after another, the execution results of all transactions are equivalent to the same serial order.

Shoal++: High Throughput DAG BFT Can Be Fast and Robust!

Abstract

Today's practical partially synchronous Byzantine Fault Tolerant consensus protocols trade off low latency and high throughput. On the one end, traditional BFT protocols such as PBFT and its derivatives optimize for latency. They require, in fault-free executions, only 3 message delays to commit, the optimum for BFT consensus. However, this class of protocols typically relies on a single leader, hampering throughput scalability. On the other end, a new class of so-called DAG-BFT protocols demonstrates how to achieve highly scalable throughput by separating data dissemination from consensus, and using every replica as proposer. Unfortunately, existing DAG-BFT protocols pay a steep latency premium, requiring on average 10.5 message delays to commit transactions.

This work aims to soften this tension, and proposes Shoal++, a novel DAG-based BFT consensus system that offers the throughput of DAGs while reducing end-to-end consensus commit latency to an average of 4.5 message delays. Our empirical findings are encouraging, showing that Shoal++ achieves throughput comparable to state-of-the-art DAG BFT solutions while reducing latency by up to 60%, even under less favorable network and failure conditions.

1 Introduction

This paper presents Shoal++, a novel partially synchronous DAG-based Byzantine Fault Tolerant (BFT) consensus protocol that matches the throughput of contemporary DAG-BFT protocols while significantly reducing latency, narrowing the gap with the theoretical optimum.

BFT consensus offers the attractive abstraction of a single, always available server, that remains correct even as a subset of replicas may fail arbitrarily. Fueled by recent advances to simplicity and practicality [15, 19, 35, 47], interest and adoption of BFT protocols is skyrocketing: it is at the core of aspiring multi-national projects such as the digital Euro [2], confidential data sharing frameworks [6] and the growing Web3 industry [1, 5]. Already today, numerous blockchain companies [40–42, 44] are actively deploying BFT protocols [16, 22, 31, 34, 35], supporting millions of daily worldwide users.

Following the seminal PBFT [15] protocol, most traditional BFT consensus protocols [24, 28, 47] operate in a primary-backup like regime in which a single, dedicated leader replica proposes an ordering of commands, and follower replicas vote to ensure consistency and durability.

*The work was done while the authors were interns at Aptos Labs.

As demonstrated by PBFT, this approach can enjoy excellent latency in fault-free executions, requiring only three message delays (md) to order a leader's proposal, the optimum achievable for BFT protocols. A dedicated leader, however, poses not only a single point of failure, but constrains the achievable throughput to the processing and networking bandwidth available to a single server. To improve scalability, and meet the high throughput demands of modern applications, recent proposals emphasize maximizing resource utilization and balancing load across *all* replicas.

Initial approaches propose multi-log frameworks [37] that partition the request space, and operate multiple consensus instances in parallel (each led by a different replica) whose logs are carefully intertwined. More recent designs take scalability a notch further by entirely separating data dissemination and consensus. Pioneered by Aleph [21] and DAG-Rider [26], and made practical by Narwahl [19] a new class of so-called DAG-BFT protocols have risen to popularity.

DAG-BFT protocols employ a structured, highly parallel, asynchronously responsive data dissemination layer as a backbone, and layer consensus atop. Data dissemination proceeds through a series of *rounds* in which each replica proposes new transaction batches via reliable broadcast (RB); each proposal (DAG *node*) references a subset of preceding proposals (DAG *edges*), resulting in a Directed Acyclic Graph (DAG) of temporally (or *causally*) ordered proposals. The consensus layer reaches agreement on prefixes of the DAG, and derives an ordering for all causally referenced proposals.

State-of-the-art DAG protocols [34, 35] avoid running an explicit consensus protocol, and instead embed the consensus process onto the DAG directly: they ensure that all replicas converge on the same view of the DAG, and interpret it's structure locally to implicitly determine commitment. Consensus simulates leaders by assigning pre-determined "fixpoint" nodes in the DAG (henceforth *anchors*) and confirms agreement of an anchor by waiting until it has gathered sufficient references in future DAG rounds that guarantee its durability.

Upon committing an anchor node, all of its causally referenced proposals are implicitly committed and ordered. Such design is appealingly simple – it requires no additional communication for consensus and avoids the notoriously complex view change logic inherent to traditional BFT protocols. It is also very resource efficient – each replica acts as a proposer, thus allowing high throughput with a large number of replicas. As a result, DAG-BFT has prompted swift adoption by several large blockchain systems [42, 44].

However, today's DAG protocols fall short in terms

of latency. They require several rounds, each consisting of reliable broadcasts to *certify* DAG nodes, to commit a transaction. Bullshark [35] for instance requires, even in fault-free cases, up to 4 rounds to commit a proposal (12md in expectation, §3.2); recent advances made by Shoal [34] reduce it to 3 rounds (10.5md expected, §3.2). A far cry from the 3md possible by traditional BFT protocols!

This work proposes Shoal++: a novel DAG-based BFT system that achieves near-optimal latency while maintaining the high throughput and robustness of the state-of-the-art certified DAG construction.

We begin by analyzing sources of end-to-end (e2e) latency in DAG protocols (§3.2); at a high level, it can be broken down into three stages. (i) DAG proposals happen only at regular intervals (rounds), and transactions that narrowly miss inclusion (e.g. arrive just after a node is formed) must wait for the next round. We refer to the time a transaction must wait to be included in a DAG proposal as **Queuing Latency**. (ii) In order to be committed, a proposed DAG node must be referenced by a committed anchor. Unfortunately, in existing DAG protocols [34, 35], at most one anchor is scheduled per round[1]. This results in additional **Anchoring latency**, the time until a node is referenced by the next committed anchor. (iii) Finally, in existing DAG protocols, an anchor requires *at least* two more DAG rounds to be committed; we refer to this as **Anchor Commit Latency.**

Key ideas. To reduce end-to-end consensus latency, Shoal++ employs three techniques, respectively addressing each latency stage. First, Shoal++ identifies and optimizes an inefficiency in the existing Bullshark commit rule to reduce common case Anchor Commit Latency to only 4md. Next, we configure Shoal++ to dynamically attempt to make *every* node an anchor, thus eliminating Anchoring Latency. Shoal++ builds on Shoal's idea to dynamically re-interpret the anchor assignment at each commit, and introduces small timeouts to help replicas advance rounds in lock-step to ensure that future rounds sufficiently reference anchor candidates. Finally, to minimize Queuing latencies, Shoal++ orchestrates *multiple* staggered DAG instantiations in parallel, and intertwines their resulting logs; this allows transactions that miss inclusion to simply board the new round of the next, staggered DAG.

Put together, these techniques allow Shoal++ to reduce expected end-to-end consenus latency to only 4.5md, shaving off 6md compared to Shoal, the state of the art DAG-BFT.

We've implemented a prototype of Shoal++ and evaluated it empirically against two popular DAG-BFT protocols (Bullshark [35] and Shoal [34]), a concurrent DAG-BFT protocol (Mysticeti [12]), and a traditional BFT protocols (Jolteon [22]). Our results are promising, demonstrating matching throughput of existing DAG BFT solutions while reducing latency by up to 60% over Bullshark in the common case and by up to 10x over Mysticeti in the failure case.

[1]Bullshark [35] schedules an anchor every second round; Shoal [34] improves it to every round.

2 Model

We adopt standard BFT assumptions [15, 47]. We refer to participants that follow the protocol as correct, and those that deviate as faulty (or *Byzantine*). There are a total of $n = 3f+1$ replicas, of which at most f may be faulty at any time. We make no assumptions on the number of faulty clients. We assume the presence of a strong, yet static adversary that may arbitrarily delay messages and coordinate all faulty particpiants, but may not break standard cryptographic primitives such as signatures. We denote signed messages using $\langle m \rangle_\sigma$. We assume that all signatures and Quorums are validated, and henceforth omit explicit mention.

The goal of BFT consensus is to establish a common totally ordered log across all correct replicas. We operate under the partial synchrony model [20]. The system is safe at all times – no two correct replicas ever disagree on a committed prefix of the log. Liveness is not guaranteed during periods of asynchrony, but eventually there arrives a Global Stabilization Time (GST) after which the network (temporarily) behaves synchronously, and progress is guaranteed.

3 Dissecting DAG-BFT

Before we present Shoal++, we provide a brief background on the core mechanisms of DAG-BFT, and analyze the latency breakdown of existing protocols. We implicitly focus on *certified* DAG protocols derived from Narwahl[19]. Although some recent works propose uncertified DAGs [12, 27] in an effort to save latency, this comes at the cost of reduced robustness and introduces new sources of unwanted latency (§3.2).

3.1 DAG core

At the core of DAG-BFT is the round-based certified DAG structure proposed in Narwahl [19]. Replicas proceed through a series of structured rounds, in which replicas continuously propose new nodes containing batches of transactions. Each replica maintains their own local view of a DAG.

A replica adds another replica's proposal as node in its local DAG once the proposal is *certified*. Proposals in round r must reference $n-f$ certified proposals from round $r-1$ to be considered *valid* candidates, and each replica may propose and certify at most one candidate per round. To certify a proposal a replica follows a simple Reliable Broadcast procedure.

1. It broadcasts a signed proposal $P := \langle r, B, edges \rangle_\sigma$ for round r containing (i) a batch B of transactions, and (ii) $n-f$ unique proposal certificates from round $r-1$ (*edges* for short).
2. Upon receiving a valid proposal, a replica checks whether it has already received a different proposal from the same author for round r. If it has, it ignores

the proposal; if it has not, it casts a signed vote $S := \langle r, d = hash(P) \rangle_\sigma$ back to the proposing replica.

3. A replica waits for $n - f$ matching signatures for its proposal P and aggregates them into a certificate $C := \langle r, d, \{S\} \rangle$ that it broadcasts to all replicas.
4. Upon receiving a proposal certificate a replica adds a node to its local DAG.

Figure 1 illustrates a DAG of certified nodes as it appears in a local view of one of the validators. We note that because proposals are certified, no replicas can produce two conflicting nodes for the same (round, replica) position. Thus, all replicas eventually converge on the **same** local view of the DAG.

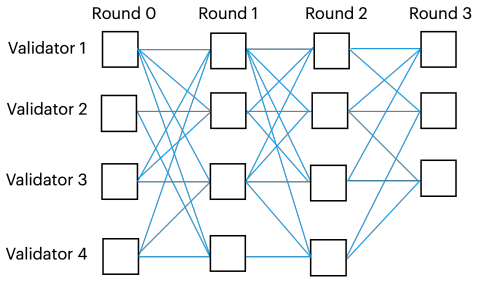

Figure 1: Narwhal's round-based DAG from a validator's local point of view.

3.1.1 Consensus core.

By itself, the DAG is no more than a scalable and robust mempool. It continues to grow at the pace of the network (i.e. *responsively*), and, by virtue of being certified, ensures that all disseminated transaction batches are reliably available. A consensus layer is needed to establish agreement. It can be modularly layered by running an **external** consensus blackbox that commits views of the DAG (e.g., Narwhal+Hotstuff [19]), or logically **embedded** into the existing DAG messages without the need for additional messages (e.g., Tusk [19], Bullshark [35], or Shoal [34]). The rest of the paper focuses on embedded DAG-BFT protocols as they are more efficient.

Embedded consensus. At a high level, consensus is projected onto the DAG structure by designating specific DAG nodes as fixpoints (henceforth *anchors*) that simulate a leader, and interpreting DAG edges as votes for a leader. Upon committing an anchor, all of its causal history can be implicitly committed as well; an ordering can be derived using any deterministic function, e.g. using a topological sort.

Anchor nodes are chosen deterministically in advance (much like leaders in traditional BFT protocols) and placed at regular intervals. Bullshark [35], for instance, uses a round-robin scheme to select anchor candidates and places an anchor candidate per every other round of the DAG. Figure 2 illustrates the anchor commit logic in Bullshark.

An anchor in round r becomes committed as soon as $f+1$ nodes in a round $r' > r$ link to it (**Direct Commit Rule**). The

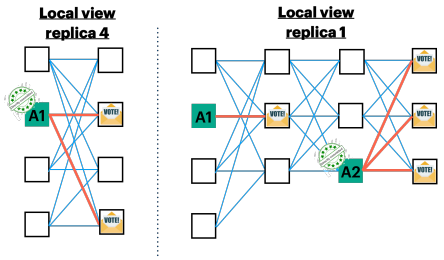

Figure 2: Bullshark Commit example. Replica 4 observes $f+1=2$ votes for anchor A1, and directly commits it. Replica 1 observes only one vote ($< f+1$), and cannot directly commit A1; it commits A1 indirectly upon committing A2 and its causal history, ordering A1 before A2.

safety intuition is straightforward: (i) all nodes are certified, and thus every anchor is equivocation-free, and (ii) all nodes in rounds $r'' > r'$ must include an edge to at least one of the nodes that link to the anchor, and thus the anchor is durable.

In particular, every future committed anchor must link to all previously committed anchors, thereby establishing a consistent total order amongst anchors. Upon committing an anchor, a replica recursively traverses the anchor's causal history, and first commits all preceding anchors (**Indirect Commit Rule**). Conversely, if an anchor candidate is *not* in a committed anchors causal history, then it could never have committed, and it is safe to skip it. Intuitively, the Indirect Commit Rule ensures that, even if a replica does not invoke the Direct Commit rule on some anchors (e.g. because its local DAG view is temporarily out of sync), all correct replicas will agree on the same sequence of committed anchors.

We note that while this design is always safe, it relies on conservative timeouts to ensure liveness (similarly to traditional BFT protocols). Since nodes include only $2f+1$ edges, anchor candidates are not guaranteed to receive the $f+1$ links required to commit. In the worst-case, candidates are repeatedly skipped, thus stalling commit progress.

To reduce the expected latency, Shoal [34] optimizes Bullshark in two ways. First, it leverages the deterministic anchor commit sequence to dynamically re-interpret the anchor schedule upon every commit. Rather than placing anchors every other round, this approach allows for an anchor to be placed every round. Second, it introduces an anchor reputation scheme to attempt to select as candidates only the fastest and well-connected replicas; such candidates are more likely to be included as edges. This allows Shoal to avoid timeouts in all but extremely unlikely scenarios.

3.2 Latency breakdown

We breakdown different sources of latencies present in DAG-protocols, and analyze their respective costs in Bullshark and Shoal. We denote as the e2e consensus latency of a transaction the time between a replica first receives the transaction, and the time that the transaction is ordered. We separate the e2e latency of certified DAG-BFT protocols into three components:

1. **Queuing latency:** the time it takes for a transaction to be proposed in a DAG node.
2. **Anchoring latency:** the time it takes for a non-anchor node's proposal to be "picked up" by an eventually committing anchor.
3. **Anchor Commit latency:** the time it takes to commit an anchor proposal.

Queuing Latency. The DAG advances in a series of synchronized rounds, and each replica may issue at most one proposal (containing a batch of transactions) per round. Each round requires a Reliable Broadcast to certify a proposal, for a total of 3md. Consequently, a transaction that narrowly misses inclusion in the current round proposal must, in the worst-case wait up to 3md before being broadcast; assuming transactions arrive at a uniform rate, the average Queuing Latency is 1.5md.

Anchoring latency. A proposal becomes "anchored" once it is referenced by an eventually committing anchor. Anchoring latency depends on two factors: (i) the frequency of anchor candidates, and (ii) the reliability with which said anchor candidates are committed (i.e. not skipped).[2] Bullshark has anchor candidates in every odd numbered round (i.e., only every second round). Consequently, the best-case inclusion latency of non-anchor proposals in even rounds is 1 round (3md), and 2 rounds (6md) in odd rounds; a best-case average of 4.5md. Shoal increases candidate frequency to every round, and thus improves the inclusion latency of non-anchor proposals to one round for all (3md). The practical reliability of commitment cannot be easily quantified by pen-and-paper, and is best left to empiric analysis as it depends on network configuration and message delivery patterns. Shoal demonstrates that the use of a reputation can aid significantly in ensuring that anchor candidates are reliably included [34].

Anchor Commit latency. In both Bullshark and Shoal, an anchor becomes committed upon either (i) being references by $f+1$ nodes in the next round (Direct Commit Rule), (ii) or being subsumed in the causal history of future committed anchor (Indirect Commit Rule). The Direct Commit Rule requires at least 2 rounds: one to certify the anchor proposal, and one to certify $f+1$ proposals that reference it, for a total of at least 6md. The latency of indirectly committed anchors can be broken down into their own Anchoring Latency to a future anchor, plus the future anchors Commit Latency.

Putting all latency stages together results in a best case average latency of 12md (1.5md + 4.5md + 6md) for Bullshark, and 10.5 for Shoal (1.5md + 3md + 6md).

3.3 A note on uncertified DAGs

A class of recent DAG-based designs [12, 27, 29] proposes to replace DAG nodes with uncertified proposals that are disseminated with best-effort. At first glance, such designs holds promise by reducing latencies across the stack. However, removing certificates makes the DAG brittle: it can introduce a significant amount of unwanted synchronization on the critical path and increase susceptibility to timeout violations [23]. Edges to uncertified, yet locally unavailable proposals must be validated by fetching missing data (at least 2 additional md per round) *before* advancing to avoid losing liveness in the face of Byzantine fabrications or unstable networks. In practice, we find that even occasional message drops can significantly degrade overall latency (§8.3). In contrast, Shoal++ demonstrates that certification is *not* the root-cause of high latencies, and that latency can be significantly reduced without sacrificing robustness.

[2] The proposals of non-anchor candidates are subject to both factors; the proposals of anchors candidates themselves are subject only to the latter.

4 Shoal++ Overview

Shoal++ strives to reduce latency across each of the three latency stages; it employs three different ideas that respectively address Queuing, Anchoring, and Anchor Commit Latency. Together, Shoal++ is able to reduce total e2e expected latency close to an average of 4.5md. We briefly outline each idea in sequence.

Faster anchors. The first observation Shoal++ makes is that the Bullshark Direct Commit rule can be optimized when anchors are referenced by a supermajority of uncertified nodes. Intuitively, a replica may eagerly commit an anchor as soon as $2f+1$ *proposals* that link to an anchor node are observed, as this implicitly guarantees that eventually the Direct Commit Rule is satisfied. Since this is an even stricter condition that may not be fulfilled, Shoal++ (i) retains the existing Direct Commit Rule as backup, and (ii) leverages Shoal's reputation mechanism to reliably trigger the Fast Direct Commit Rule. This allows Shoal++, in practice, to reduce Anchor Commit latency to 4md.

More anchors. Next, Shoal++ takes Shoal's idea of increased anchor frequency one step further, and tries to turn as many nodes into anchors as possible. Doing so requires striking balance. On the one hand, increasing the number of anchors increases the opportunities to avoid incurring the anchoring latency. On the other hand, it introduces also opportunity for more uncommitted anchors, which can stall progress. Adopting the reputation scheme proposed by Shoal can help identify a reliable subset of candidates, but is not enough to streamline progress in practice. Shoal++ (i) slows down round advancement to put the DAG into lockstep and avoid missed anchors, and (ii) dynamically re-interprets the tentative anchor schedule to skip anchors that are no longer needed.

More DAGs. Finally, Shoal++ minimizes Queuing latency by operating not one, but multiple DAGs in parallel. DAGs are staggered using a small offset, allowing waiting transactions that miss a round to quickly be included in the *next* DAG.

This simultaneously improves throughput via better resource utilization: proposals are sent more frequently, batches are smaller and can be sent and processed more efficiently (in a streaming fashion) than less frequent, large batches.

5 Shoal++ In-Depth

Shoal++ uses as starting points the DAG-core of Narwahl [19], and Consensus-core of Bullshark [35] outlined in §3. For the sake of brevity, we do not duplicate the pseudocode that is available in previous works and, in particular, omit a detailed description of the DAG construction (i.e., node broadcasts, transaction submission, node fetching, garbage collection, and so on). We defer to the original papers for an in-depth discussion and correctness proofs.

Algorithm 1 summarizes the DAG API and node structure. We abstract away the node certification process, and the commit logic. PROCESS_NODE and PROCESS_CERTIFIED_NODE respectively involve checking that a node proposal is valid and voting for it, and adding a new confirmed node to the DAG, triggering commit rules. RUN_BULLSHARK performs an instance of the Bullshark commit logic to determine (given a starting point) the first anchor to be ordered (§3.1.1).

Upon committing an anchor, all of its (yet-to-be-ordered) causal history is deterministically ordered as well. Helper functions CAUSAL_HISTORY and GET_ANCHORS aid, respectively, in identifying the causal history of a node (necessary for both commit and ordering logic), and the anchor candidate schedule. Shoal++ adopts and extends Shoal's [34] reputation logic; GET_ANCHORS returns, for each round, a vector of eligible anchors.

Algorithm 1 DAG interface

```
DAG API:
    PROCESS_NODE(v: Node)
    PROCESS_CERTIFIED_NODE(v: Node)
    CAUSAL_HISTORY(v: Node) → Vec<Node>
    RUN_BULLSHARK(anchor: Node) → Node
    GET_ANCHORS(round: int) -> Vec<Node>

struct Node n:
    n.round                    ▷ the associated round in the DAG
    n.source                   ▷ the replica proposing n
    n.parents                  ▷ n−f nodes from round v.round−1
```

Algorithm 2 summarizes the core protocol additions made by Shoal++ in an effort to reduce Anchor Commit, and Anchoring latency. We now discuss both in detail in turn.

5.1 A faster Direct Commit rule

As described in §3.2 it currently takes, in the best case, 6 message delays to commit an anchor using the Bullshark Direct Commit Rule. One DAG round is required to certify the anchor node itself, and a second DAG round is required

Algorithm 2 Core Shoal++ utilities

```
    Local variables:
        dag: DAG                              ▷ Initially empty
        weak_votes: Vec< Vec<int> >           ▷ Initially empty
        round: int                            ▷ Initially 0
        anchors: Vec<Node>                    ▷ Initially empty

 1: procedure NEXT_ORDERED_NODES()
 2:     while true do
 3:         if anchors.IS_EMPTY() then
 4:             round++
 5:             anchors ← dag.GET_ANCHORS(round)
 6:         anchor ← anchors.POP()
 7:         anchor_to_order ← select
 8:                             FAST_COMMIT(anchor)
 9:                             dag.RUN_BULLSHARK(anchor)
10:         if anchor_to_order ≠ anchor then
11:             SKIP_TO(anchor_to_order)
12:         return dag.CAUSAL_HISTORY(anchor_to_order)

13: procedure SKIP_TO(anchor: Node)
14:     round ← anchor.round
15:     anchors ← dag.GET_ANCHORS(round)
16:     anchors.REMOVE(anchor)

17: procedure FAST_COMMIT(n: Node)
18:     while true do
19:         if weak_votes[n.round][n.source] ≥ 2f+1 then
20:             return n

21: upon receiving node n do
22:     r ← n.round
23:     s ← n.source
24:     if n is the first node revived from s in round r then
25:         for each parent ∈ n.parents do
26:             weak_votes[r][parent]++
27:         dag.PROCESS_NODE(n)

28: upon receiving certified node cn do
29:     dag.PROCESS_CERTIFIED_NODE(cn)
```

to collect sufficient votes. A replica can directly commit an anchor upon observing $f+1$ certified nodes that link to the anchor (i.e. include the anchor in their parent set).

Shoal++ makes the following simple observation: if sufficiently many DAG *proposals* link to the anchor, the anchors fate is already set in stone, and we need not wait for round certification to complete. Recall that the certification process consists of three message exchanges, a proposal step, a voting step, and a certificate forwarding step (§3). Shoal++ allows replicas to FAST_COMMIT (Alg. 2) as soon as it observes $2f+1$ proposals that link to an anchor (Fig. 3). To do so, replicas simply additionally keep track of *weak votes* for each round that correspond to the proposals observed. Weak votes are not guaranteed to survive certification. For instance, a faulty proposer may equivocate, and produce a node certificate containing a different proposal that does not link to the anchor. However, out of any $2f+1$ weak-votes, at least $f+1$ must be cast by correct proposers that will never equivocate. Consequently, the presence of $2f+1$ weak-votes guarantees that eventually

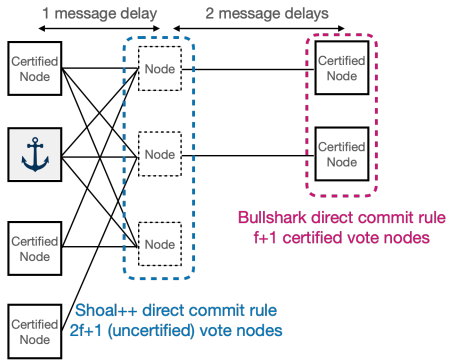

Figure 3: Bullsharks's direct commit rule requires f+1 certified vote nodes, while Shoal++'s direct commit rule requires $2f+1$ (uncertified) node proposals.

$f+1$ certificates linking to the anchor must be formed, thus ensuring safety. Using the Direct Fast Commit rule allows replicas to commit an anchor in only 4md: 3md to certify the anchor, and 1md to broadcast and receive proposals.

We note, however, that this rule places a *stronger* requirement for liveness; f additional proposals are (tentatively) required to link to an anchor. We thus retain the existing Direct Commit rule as backup, and allow replicas to commit using whichever rule is satisfied first. In some cases, it may be faster (and more reliable) to commit using $f+1$ certified nodes. For instance, when the network is unstable or point latencies are asymmetric, the fastest $f+1$ replicas might advance much more quickly than the fastest $2f+1$.

In our empirical evaluation, we find that this case is rare (§8) and that replicas are, most of the time, able take advantage of the Fast Direct Commit rule. Shoal's reputation scheme ensures that eligible anchor candidates are typically well connected, making it exceedingly commonplace for future round proposals to link to an anchor.

5.2 Increasing anchor frequency

In order to reduce Anchoring latency, Shoal++ tries to dynamically designate as many nodes as possible as anchors. Intuitively, if all nodes were anchors that become committed, no node would experience any Anchoring latency.[3] Safely operating more than one anchor per round requires additional orchestration. To ensure a consistently ordered log across all correct replicas, parallel anchors must be committed in a predefined order. One easy way to visualize parallel orchestration is by mapping anchors to fixed slots; much like parallel proposals in traditional BFT protocols such as PBFT [15]. Figure 4 shows a simple example in which there are four anchors in one round (all n nodes are anchors). Each anchor employs its *own* consensus instance that may proceed in parallel, and out of order, but anchors can be committed only in sequence.

[3]We note that such an approach is briefly discussed in the closing remarks of Shoal [34], but is neither implemented nor carefully evaluated for practical considerations.

Each consensus instance operates a one-shot Bullshark instance, augmented with the Fast Direct Commit Rule. We remark that each Bullshark instance operates its own tentative anchor schedule (e.g. the yellow anchor in Fig. 4 is considered the next anchor in the instance started by the red anchor), but terminates as soon as the initial anchor is resolved.

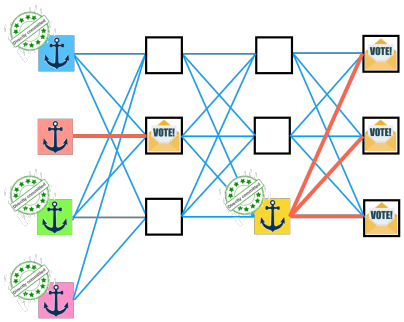

Figure 4: An illustration with four anchors in round 1, using the pre-assigned order: blue, red, green, pink. The blue anchor commits directly; it has $\geq f+1$ references from nodes in round 2. The red anchor is only indirectly committed upon directly committing the yellow anchor in round 4. The green and pink anchors must wait to be ordered until the red anchor is resolved.

While simple, a straightforward instantiation of this design is not robust, and may, in practice negate (or even hurt) any latency benefit. By treating every node as an anchor, progress is, in particular, bottlenecked on the *slowest* anchor. We illustrate such an unwelcome scenario in Figure 4: although the green and pink anchors have sufficient support to commit, they must wait until the preceding red anchor becomes committed or skipped. Unfortunately, the red anchor is slow and does not have any immediate links; it is indirectly committed only two rounds later via the next anchor in its consensus instance (yellow anchor). In worse circumstances, an anchor might never commit. In this case, we must wait for confirmation that the anchor is skipped, and fill its assigned slot with a no-op. Such scenarios are not fringe outliers, but expected by design: since DAG nodes include only $2f+1$ edges, rounds are privy to advancing based on the fastest $2f+1$ nodes, and leaving the remainder behind. Thus, with high probability, *at least* one anchor per round will not receive sufficient direct votes.

Adopting the reputation mechanism proposed by Shoal can help ameliorate, but not remedy the concern. We leverage reputation and modify GET_ANCHORS(r) to limit the set of eligible anchors per round only to those associated with historically fast and well-connected replicas. Unfortunately, we find that in practice leveraging reputation alone is insufficient, and does not reliably enough exclude slow replicas. While past performance is a helpful indicator, network instabilities in geo-distributed systems make it hard to accurately predict *future* performance, and we observe that the set of "slow" replicas changes very dynamically. To improve robustness further, we add two additional techniques that, respectively, try to (i) avoid unnecessarily classifying nodes as slow, and (ii) dynamically skip likely obsolete anchors.

Round Timeouts. Reputation alone is overly harsh in categorizing nodes as slow. Since DAGs advance with the fastest $2f+1$ replicas, to maximize the likelihood of anchors that commit directly, reputation *pessimistically* caps the eligible anchors per round to include only the (estimated) fastest $2f+1$ nodes. (i.e. $\frac{2}{3}$ of total nodes). In reality, however, ineligible nodes may only be fractionally slower, and arrive imminently. To avoid discriminating against such nodes, Shoal++ makes the conscious choice to, in each round, additionally wait for a small timeout beyond the first $2f+1$ nodes observed, and include any momentarily received nodes as additional edges. While this slightly slows down individual rounds, it encourages replicas to operate in lockstep, resulting in a more densely connected DAG. This allows us, in turn, to optimistically increase the set of eligible anchors back to include all n nodes, thus reducing *overall* latency.

We note that timeouts are not necessary for liveness, and are purely optimizing performance. They can thus be configured very aggressively, and are, in practice, negligible compared to the 3 network delays required to certify a node.

Skipping Anchor Candidates. Although round timeouts increase the reliability of the Direct Commit Rule, they cannot guarantee its success. Occasionally, replicas may fail or experience high networking delays, resulting in missing, or unconnected nodes. In such cases, all subsequently pre-ordered anchors must wait until the current anchor is resolved. Recall that an anchor $A1$ in round r is only resolved only upon committing, in its local consensus instance, an anchor $A2$ in a future round $r' > r$: $A1$ is committed if it is present in the causal history of $A2$ (Indirect Commit), or skipped if it is not. In practice, we expect indirectly committed anchors to be rare. Anchors that are merely slow, are likely to be committed thanks to the round timeout. Crashes, in turn, predominantly result in skips. Byzantine abuse can unfortunately not be avoided, and we must rely on the reputation scheme to avoid such anchors; fortunately, such faults are exceedingly rare in most practical deployments.[4]

We note that, even though $A2$ has been committed, it cannot be ordered before all preceding anchors in the pre-defined schedule have resolved their respective consensus instances (i.e. commit or skip). This is undesirable: such anchors are (i) likely already included in the causal history of $A2$, and (ii) may be subject to further latency delays. Unfortunately we cannot avoid this scenario if $A1$ is committed; another replica may have committed it directly, and resolved (and applied) the output of the next scheduled anchor $B1$. We can, however, sidestep the resolution of preceding anchors' Bullshark instances if $A1$ is skipped. For any given consensus instance, all replicas necessarily agree on the order of *all* committed and skipped anchors. Thus, in particular, they agree on the *first* committed anchor (in this case $A2$, since $A1$ is skipped). Let the round of this anchor be r'. Shoal++ opts to *skip* all tentative anchor candidates in rounds $< r'$.

Instead of pre-assigning anchors to fixed slots, Shoal++ considers all but the first anchor in each round *virtual*, and dynamically materializes them as it sees fit. At any given time, there is only a single materialized consensus instance (with an anchor every other round); upon resolving the current instance, Shoal++ re-evaluates where to sensibly place the next anchor. Only then it begins evaluating the associated consensus instance. Since all replicas resolve each instance identically, each locally re-interprets and materializes the same anchor schedule. Consider a slight modification of the example in Figure 4, in which the yellow anchor does **not** extend the red anchor. The blue anchor commits directly, and Shoal++ dynamically materialized the red node as the next anchor to evaluate. The red anchor, however, will be resolved as skipped upon committing the yellow anchor. Shoal++ thus skips evaluating the virtual green and pink anchors, and instead tries to materialize as anchor the first node *after* the yellow anchor.

5.3 Operating multiple DAGs in parallel

Finally, in an effort to minimize Queuing latency, Shoal++ chooses to operate k concurrent DAG instances, and interleave their outputs to construct a single, totally ordered log. Intuitively, staggering multiple DAGs, in a pipline-like manner, allows transactions to be proposed quicker. Instead of waiting (up to 3md) for the next DAG round to begin, a transaction simply joins the next round of the *next DAG*. This reduces the expected Queuing latency from 1.5md to $1.5/k$ md. In practice, we deploy Shoal++ with three DAGs, each offset by one message delay. Since each DAG round requires 3md to certify a node proposal, this ensures that a some DAG's proposal is available every 1md. We find that 3 DAGs offer a good sweetspot between theoretical Queuing latency and batch sizes; additional DAGs offer diminishing returns as proposals carry increasingly smaller batches.

Algorithm 3 summarizes the algorithm. Each DAG instance runs as a black-box, isolated from the others. In order to create a consistent total order, we must interleave their outputs. Each time a DAG commits an anchor, it outputs a new log segment.Shoal++ rotates across DAGs in round-robin fashion, and appends, in each round, exactly one available segment to the log. If, for whatever reason, one DAG commits more frequently, then its excess available segments must wait to be ordered until the other DAGs to make progress. Importantly, the individual DAGs themselves never block, and progress unimpeded. We note that segments also may not (and need not) be of equal size; each segment corresponds to a newly committed anchor, each of which may order varying sizes of causal histories.

Operating additional DAGs incurs additional messages and associated processing overhead. However, we find that in practice, this does not negatively affect performance.

[4] Blockchain systems [42, 44] report observing zero Byzantine faults in over a year of deployment. Reported faults are typically benign crashes.

Algorithm 3 Shoal++

```
    Local variables:
        d1,d2,d3: DAG instances                          ▷ Initially empty
1:  loop
2:      for i=1 to 3 do
3:          output di.NEXT_ORDERED_NODES()
```

In fact, throughput increases because smaller batches are proposed more frequently which helps amortize bandwidth and processing, resulting in better resource utilization. In theory, messages from different DAGs can be overlayed in order to share signatures. For instance, a node-proposal of DAG $i \in \{0,1,2\}$ can easily be combined with the certified-node-broadcast message of DAG $(i+1)\%3$.[5] This too, we find not to be worth it in practice as (i) signatures are not the bottleneck, and (ii) message stages have assymetric latencies, and artificially aligning them increases Queuing latency.

5.4 Discussion

The combination of the above techniques allows Shoal++ to, in the common, fault-free case, reduce average e2e latency to only 4.5md: 4md to commit anchors, and 0.5md queuing latency. In the presence of faults or bad network behaviors, additional anchoring and commit latency will be incurred to resolve anchors via the Indirect Commit/Skip Rule.

We note that Shoal++ uses a *linear* star-based communication pattern to ceritfy nodes, while protocols such as PBFT [15] leverages *quadratic* all-to-all communication. If desired, Shoal++ can adopt all-to-all communication, reducing latency by 1md (to 3.5md total) at the cost of increased message complexity. We also remark that although Shoal++ incurs a small additional queuing latency, every replica acts as proposer, and clients need only contact their *local* replica (in absence of faults). Single leader designs, in contrast, require clients to contact possibly remote leaders, introducing additional "queuing" latency. Finally, we note that Shoal++ consumes more resources—such as CPU, memory, and disk space—than Shoal due to the multiple DAGs technique. However, this approach enables Shoal++ to reduce queuing latency and makes better use of the available network bandwidth.

6 Correctness

We now prove the Safety and Liveness of Shoal++. We separately prove each augmentation Shoal++ introduces through a reduction to the Safety and Liveness proofs of Bullshark [35] and Shoal [34]. To formalize the arguments, our proof relies on the following three properties:

Property 1. *For any node n, the call* CAUSAL_HISTORY*(n) returns the same vector of nodes to all replicas.*

[5] In theory, votes can also be overlayed, though typically it is favorable to send them as fast as possible, rather than synchronizing.

Property 2. *All replicas commit the same anchors, and in the same order.*

Property 3. *For any given round r the leader reputation mechanism ensures that* GET_ANCHORS*(r) return the same vector of nodes at all replicas.*

Property 1 holds true for all Narwhal-based DAGs, and follows directly from the fact that all nodes in the DAG are certified; Properties 2 and 3 follow, respectively, from the safety proofs of Bullshark and Shoal.

Fast Direct Commit Rule. Since Shoal++ can commit using both the Fast Direct Commit Rule and the existing (Bullshark) Direct Commit Rule, Liveness follows directly from Bullshark. We prove that the Fast Direct Commit rule is safe:

Lemma 1. *For any anchor a, the procedures* FAST_COMMIT*(a) and* RUN_BULLSHARK*(a) never return contradictory values.*

Proof. By the code, FAST_COMMIT(a) can only return a. Thus we need to prove that if FAST_COMMIT(a) triggers, then RUN_BULLSHARK(a) also returns a. FAST_COMMIT(a) implies that the replica received $2f+1$ (uncertified) node proposals from different replicas that reference a. Since there are at most f faulty replicas, at least $f+1$ of these proposals were broadcasted by correct replicas and will eventually be certified. Since $f+1$ such certified nodes exist, some replicas may directly commit the anchor a via the Bullshark logic. It follows from P.2 that in this case, the RUN_BULLSHARK(a) call returns a to all replicas. □

Multiple Anchors per Round. Liveness follows directly from Bullshark. We show that Shoal++'s dynamic anchor mechanism retains Safety.

Lemma 2. *We assume all correct replicas are initialized with the same state (*round *and* anchors*). Then, all correct replicas' invocations of* NEXT_ORDERED_NODES *(Alg 2) return the same result.*

Proof. By the lemma assumption and Property 3, anchors.POP() returns the same anchor in the first iteration of the while loop to all replicas (Line 6). By Lemma 1, all correct replicas agree on which anchor to order (Line 7). It follows, from the determinism of NEXT_ORDERED_NODES and P.1 that all replicas return the same vector of nodes to be ordered in their first NEXT_ORDERED_NODES call (line 12). In addition, by the determinism of NEXT_ORDERED_NODES, all replicas end up with the same state (*round* and *anchors*) after the calls return. Therefore, by applying the argument above inductively, it is easy to show that all replicas also return the same vector of nodes in all future calls. □

Theorem 1. *The Shoal++ protocol Algorithm 3 satisfies Safety and Liveness.*

The Liveness and Safety proof of each DAG is given above. Since DAG outputs are interleaved deterministically, Safety and Liveness of the composed system follow immediately.

7 Practical Considerations

We briefly discuss some implementation considerations.

Inline data streaming. Narwahl [19] proposes, in addition to the DAG construction, to further decouple, and horizontally scale data dissemination using an additional "worker"-layer. Workers disseminate batches optimistically a-priori, and DAG proposals contain only hash references. This construction is extremely throughput-friendly in the best case, as data is streamed continuously, and consensus carries only metadata. In practice, however, much like with uncertified DAG-BFT protocols [12, 27], other replicas might not have the data behind the hashes (or the references in the case of uncertified DAGs) when the proposal is received and thus additional 2md latency is required for fetching. Shoal++ opts to forgo the worker layer in order to avoid this latency, and chooses to disseminate transaction batches inline with DAG proposals. Operating staggered DAGs allows Shoal++ to nonetheless achieve throughput competitive to that of Narwahl (with a single worker), as smaller batches are sent more frequently, thus amortizing bandwidth close to a streaming design.[6] Finally, we note that inline data streaming simplifies data fetching as it avoids an additional indirection needed to dereference digests.

Efficient fetching. DAG edges in Shoal++ contain only certified nodes, allowing Shoal++ to efficiently fetch missing nodes and resolve inconsistencies across replicas. Replicas whose DAG views are out of sync, may validate and vote on proposals *without* locally observing the proposed node's causal history. This streamlines the certification process, and ensures that the DAG operates at predictable rates. Any missing causal histories can be inferred asynchronously, off the critical path. We remark that this is not possible in uncertified DAGs; to ensure liveness, replicas must fetch all missing data *before* processing a new node. This results in unsteady processing times, and may significantly increase e2e latency. Certified edges, additionally allow us to balance data fetching load: since at least $f+1$ correct replicas must have observed any certified node, replicas missing the node may request it from different replicas to balance load.

Distance-based priority broadcast. We observe that in systems with large n, message broadcasting consumes considerable CPU times. When sending messages in a fixed order (e.g. first to $R1$, then to $R2$, ...) can unintentionally cause replicas to consistently receive messages with delay, making their nodes subject to falling behind in the DAG. To circumvent this issue, Shoal++, periodically records point latencies between replicas, and adjust broadcast send-orders to prioritize farther away replicas. This results in a more balanced message distribution, increasing the homogeneity of node certification pace.

[6] Scaling throughput by employing more workers is typically not worth it in existing BFT deployments, as single-worker ordering throughput in existing protocols already far exceeds execution bandwidth.

8 Evaluation

Our evaluation seeks to answer three questions:

1. **Latency reduction:** How much does Shoal++ reduce Latency compared to state-of-the-art alternatives?
2. **Latency breakdown:** How much does each of the augmentations introduced in Shoal++ contribute to the latency reduction?
3. **Robustness:** How well does Shoal++ tolerate faults?

We implemented Shoal++ into an open-source code base of Aptos, one of the major blockchain projects. Our prototype is written in Rust and utilizes the Tokio [10] asynchronous runtime. It uses BLS [14] implemented over BLS12-381 curves for signatures, RocksDB [9] for persistent storage of consensus data, and Noise [8] for authentication. We disable the execution and ledger storage components of the original blockchain in order to isolate consensus performance. Each data point represents the 50 percentile (median) with error bars representing the 25, and 75th percentiles.

Baselines. We compare Shoal++ against three popular high throughput DAG-BFT consensus protocols, Bullshark [36], Shoal [34], and Mysticeti [12], as well as one traditional low-latency BFT protocol, Jolteon [22]. Bullshark and Shoal represent state-of-the-art *certified* DAG-based protocols, while Mysticeti [12] is a concurrent work to Shoal++ that proposes an *uncertified* design to reduce latency. Jolteon [22] is a state-of-the-art leader-based BFT protocol, which improves Hotstuff [47] latency by 50%. A variant of Jolteon is currently deployed on Aptos [42]. Sui [44] recently replaced Bullshark with a Mysticeti deployment. For an apples-to-apples comparison, we re-implemented Bullshark, Shoal, and Jolteon according to the papers' description in the same codebase as Shoal++. For Mysticeti we run the publicly available source code [7] referred to in the latest version of the paper; its prototype too is written in Rust, using Tokio, but forgoes writing consensus data to persistent storage, making it less production-realistic. To minimize latency, we opt to disable the Narwhal [19] worker layer for both Bullshark and Shoal. However, for a fair throughput comparison with Shoal++, we additionally augment both systems with Shoal++'s proposed parallel-DAG strategy ("Bullshark/Shoal More DAGs", Fig. 5).

Experimental setup. We use the Google Cloud Platform [4] to mimic the deployment of a globally decentralized network. Our testbed consists of 100 replicas spread evenly across 10 regions around the world: we choose two regions in the US (us-west1 and us-east1), two in Europe (europe-west4

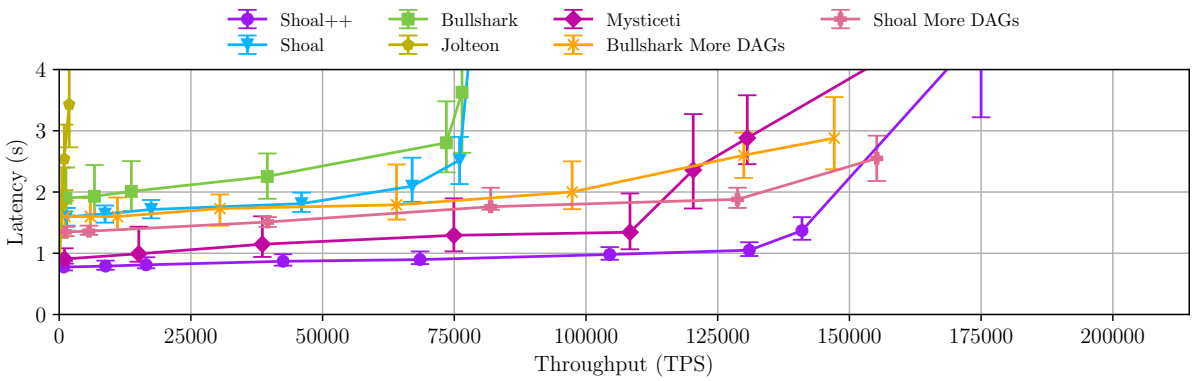

Figure 5: No failures with 100 replicas.

and europe-southwest1), three in Asia (asia-northeast3, asia-southeast1, and asia-south1), and, respectively, one each in South America (southamerica-east1), South Africa (africa-south1) and Australia (australia-southeast1). The round-trip times between these regions range between 25ms and 317ms. We use `n2d-standard-64` virtual machines, containing 64 vCPUs and 256 GB of memory [3]. We provisioned a 2TB network attached disk to each machine to guarantee enough IOPS for persistence. This spec is similar to those used by production blockchains and qualifies as commodity grade.

Clients connect to a single (local) replica and issue a continuous stream of dummy transactions (310 random bytes). As is standard in blockchain deployments, we measure consensus latency as the time between when a transaction first arrives at a replica, and when the transaction is ordered and ready to be executed. We use a batch size of 500 transactions across all systems. In all DAG-based systems, each node proposal contains one batch; Jolteon proposals may contain up to 100 batches. We configure Jolteon to use a 1.5s timeout for view changes (the standard in existing production systems [42]), and use a round timeout of 600ms for Bullshark, Shoal and Shoal++; Mysticeti by default uses a 1s round timeout. We remark that timeouts in Bullshark, Shoal and Shoal++ serve different functions. Bullshark requires them for liveness, while Shoal manages to sidestep using timeouts for liveness all but edge cases; Shoal++ follows Shoal, but re-introduces a timeout only for improved performance. We note that the timeout is started at the *beginning* of a round, and thus typically introduces only a small additional wait past observing the first $2f+1$ certified nodes.

8.1 Failure-free case

Figure 5 illustrates throughput and latency under failure-free conditions. Shoal++ is the only system to sustain sub-second latency for throughput of 100k transactions per second (tps).

Jolteon offers low latency (900ms) at low load, but is unable to scale throughput beyond 2100 tps as it is bottlenecked by the leader's network bandwidth. Bullshark and Shoal support significantly higher throughput (up to 75k tps) but incur high latency: 1.9s and 1.45s, respectively, at low load, and 2.4s and 1.7s, respectively at 50k tps. This follows directly from their high average number of required message delays (§3.2). Throughput scalability in both systems is bottlenecked by network utilization.

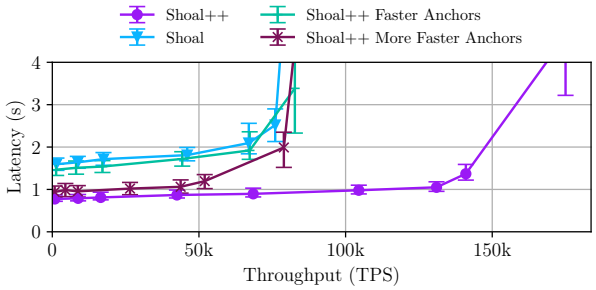

Figure 6: Shoal++ Breakdown. No failures with 100 geo-distributed replicas.

Shoal++ significantly reduces latency (775ms at low load), while simultaneously improving throughput scalability (up to ca. 140k tps). The parallel DAG construction allows Shoal++ to better utilize network and storage resources: rather than broadcasting and processing a large batch once per round, it broadcasts and processes three smaller batches at the same time. Applying the same technique to Bullshark and Shoal ("More DAGs") allows both systems to match the throughput of Shoal++ (while simultaneously improving queuing latency), without incurring the latency penalty of a Narwahl-style worker layer.

Mysticeti matches the throughput of Shoal++, but fails to match its latency, even at moderate loads. At high loads (upwards of 100k tps) Mysticeti notably incurs a signficant latency penalty as replicas may be temporarily out of sync, and must fetch missing data on the critical path of consensus.

8.2 Latency improvement breakdown

Figure 6 isolates the respective latency improvement of each Shoal++ augmentation compared to the baseline, Shoal.

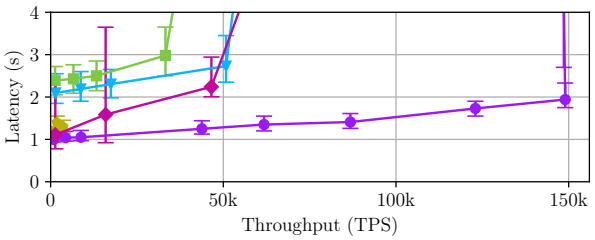

Figure 7: Latency/Throughput graph with 33 out of 100 crashed replicas.

Shoal++ *Faster Anchors* shows Shoal augmented only with the Fast Direct Commit Rule while Shoal++ *More Faster Anchors* additionally applies the multiple anchor augmentation. Finally, Shoal++ includes also the parallel DAG optimization.

The Fast Commit rule, in theory, improves anchor commit latency by up to 2md. In real, asymmetric network settings, however, it is not always 2md faster than the Direct Commit rule, and thus the practical latency improvement is smaller. The multiple anchor augmentation, in turn, improves latency significantly: (i) it saves, on average, 3md by eliminating the anchoring latency for most nodes (those that become anchors), and (ii) ensures that the anchoring latency for non-anchor nodes is typically only one DAG round because (with overwhelming probability) nodes are referenced by at least one of the (many) anchors in the next round. The parallel DAG framework improves latency further, by reducing queuing latency, but more importantly improves throughput scalability by approaching a data "streaming" effect; crucially, and unlike Narwhal-based worker designs, it does so *without* incurring additional latency.

8.3 Failure case

To quantify the robustness of Shoal++, relative to the baseline systems, we evaluate performance under two types of disruptions. First, we measure the performance of all systems while simulating crash failures of 33 (out of 100) replicas (Fig. 7). The performance of Jolteon remains largely unaffected, as its leader reputation mechanism quickly detects failures and subsequently elects only alive replicas. Shoal and Shoal++, likewise, swiftly adjust and elect only live anchors; latency, however, increases (up to ca. 2x at high load) as quorums must span more regions, increasing tail latency. Bullshark and Mysticeti, in contrast, suffer drastically increased latency since they do not employ a leader reputation mechanism to elect suitable anchor candidates, and thus must "wait" to commit until a non-faulty replica is elected as anchor.

Second, we measure the impact of sporadic message drops for Shoal++ and Mysticeti (Fig. 8). We inject network layer message drops for 1% of egress traffic in 5 nodes (out of 100 total), beginning at 60 seconds (red line). Under normal network conditions and a low-moderate load (18k tps) both Shoal++ and Mysticeti offer 700ms median consensus latency. Upon failure injection the latency of Mysticeti rises

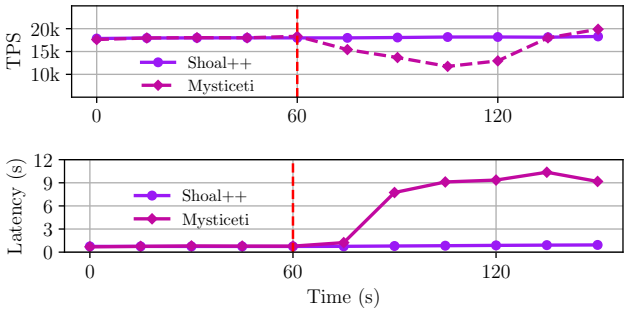

Figure 8: Impact of message drops in Certified vs Uncertified DAGs.

sharply (by a factor of 10x) as replicas scramble to perform critical-path synchronization on missing data (resulting, at times, in timeouts). As latency spikes, throughput initially drops as well, but recovers once the backlog of disseminated DAG proposals commit. Shoal++, in contrast, remains largely unaffected by message drops (latency rises to at most 1.3x). Because all nodes are *certified*, the DAG construction process in Shoal++ proceeds smoothly; any required synchronization is asynchronous and off the critical path.

9 Related work

Latency optimal BFT. Spurred by the seminal PBFT [15] protocol, a long line of systems [22, 24, 28, 30, 39] optimize for consensus latency. PBFT-based protocols designate a single leader to act as sequencer, and replace it only sporadically (e.g upon failure, or eagerly for fairness). This approach enjoys excellent latency. PBFT requires, when led by a correct replica, only 3 message delays (md); the optimum achievable latency in presence of faults, and optimal resilience of $n = 3f + 1$. Several followup works suggest optimistic Fast Paths [24, 28, 30, 39] that improve latency to only 2md in absence of faults, or by weakening resilience to $n = 5f + 1$. Unfortunately, single leader-based designs are fundamentally bottlenecked in throughput by the bandwidth and processing capacity of a single replica.

High throughput BFT. The key idea to scale beyond this bottleneck was realizing that networking resources must be fully utilized. Some works propose to decouple data dissemination from the consensus logic [11, 19, 46], while others [25, 37, 38] propose multi-log frameworks: these systems partition the request space and operate multiple parallel black-box instances of consensus protocols (e.g. PBFT) – each led by a different replica –, and carefully intertwine their outputs to construct a single, totally ordered log. This approach can achieve high throughput but requires complex coordination to deal with failures and re-configuration.

DAG BFT. More recently, a new class of so-called DAG-BFT protocols have emerged as the popular choice for high throughput BFT. At a high level, deployed DAG-BFT

protocols propose to explicitly separate data dissemination from consensus, and utilizing only a single common DAG data structure to implement consensus (§3).

HashGraph [13] was the first to propose a DAG-based consensus structure, and Danezis et al. [32] showed that any deterministic BFT protocol can, in theory, be embedded on a DAG. Aleph [21] and DAG-Rider [26] were the first to introduce additional rigidity to the DAG construction, leveraging a round-based structure to design asynchronous BFT protocols. Blockmania [18] was the first attempt to implement a DAG-BFT system, but fell short of adoption as it inherited a complex view change procedure, notorious to traditional BFT protocols such as PBFT.

Narwhal and Tusk [19] catapulted DAG-BFT to popularity by demonstrating that (i) (asynchronous) consensus can be embedded onto DAG-structures without the need for explicit view changes (Tusk), and (ii) throughput can be scaled nearly linearly through the addition of a horizontally scalable worker layer (Narwahl Mempool). Bullshark [35] improved upon Tusk by adopting partial synchrony and introducing a common case fast path during synchronous intervals; in a future iteration [36] Bullshark removed the asynchronous fallback, and established itself as the de facto partially synchronous DAG-BFT protocol.

Bullshark designates, at regular intervals (every two rounds), DAG-nodes to simulate a leader (anchor) akin to traditional BFT protocols, and commits them upon observing DAG patterns that ensure durable agreement of the leader. We refer to §3 for an overview of the Narwahl core DAG, and the partially synchronous Bullshark consensus protocol. Shoal improves the latency of Bullshark by (i) increasing anchor frequency to every round, (ii) utilizing a deterministic reputation scheme to select as anchors only the fastest, and best-connected replicas, and (iii) eliminating leader/anchor timeouts in all but extremely unlikely scenarios. Shoal, in a closing remark, briefly discusses the idea of multiple anchor per round; however, it does not provide detailed consideration.

Uncertified DAGs. A recent group of protocols propose the design of uncertified DAGs. Such constructions can, in theory, reduce latency, but are increasingly brittle as they are prone to data fetching on the critical path (§3.2). Cordial Miners [27] replaces the Reliable Broadcast (RB) in each round with best-effort broadcast (BEB), allowing anchors to (in the best case) commit within 3md; anchors are placed every other round, for an average latency of 4.5md. Similarly, BBCA-chain [29] replaces non-anchor nodes with BEB, and strengthens anchor nodes to single-shot pbft instances. Unfortunately, neither proposal has an implementation, and thus it is impossible to empirically evaluate practical performance.

Concurrent Latency reduction efforts. In concurrent efforts to Shoal++, several recent (non-peer reviewed) protocols suggest latency improvements, underlining the demand for high throughput systems with lower latency.

Sailfish [33] introduces an anchor commit rule that resembles the Fast Direct Commit Rule proposed in Shoal++. However, unlike Shoal++, it does not leverage the Bullshark Direct Commit rule as a potentially faster alternative. Furthermore, Sailfish does not employ the "more anchors" and "more DAGs" techniques, which enable Shoal++ to further reduce latency.

Mysticeti improves upon Bullshark's best case latency by transitioning to an uncertified DAG and implementing the Cordial Miners [27] consensus protocol. Mysticeti, like Shoal++, adopts Shoals high-level proposal to optimistically employ multiple anchors per round. Our evaluation demonstrates that Mysticeti almost matches Shoal++'s latency in the common case. However, as shown in §8, and independently corroborated by Autobahn [23], uncertified DAG constructions are prone to data fetching on the critical path, which negates the suggested latency benefits. A single Byzantine (or slow) replica, for instance, can impose at least 2 additional message delays *per* round in Mysticeti by not fully (or timely) disseminating its node proposals. In §8 we observed 10x latency degradation when 5 out of 100 nodes experienced 1% message drop.

Autobahn [23] introduces a promising DAG-*free* consensus approach in which replicas efficiently and reliably disseminate data independently in parallel "data lanes", and consensus commits only snapshot cuts of the lane states.

Leader reputation in BFT. To the best of our knowledge, leader reputation for BFT systems was first implemented in DiemBFT [43], and formalized by Carousel [17]. Shoal [34] and later Hammerhead [45] adopt leader reputation to DAG-BFT in an effort to exclude underperforming leaders from anchor candidacy. Shoal++ extends the approach to provide, in each round, a set of anchor candidates.

10 Conclusion

This work introduces Shoal++, a DAG-based BFT consensus protocol that offers high throughput, while significantly lowering e2e latency compared to current state of the art DAG-BFT protocols. Shoal++ takes as its starting point existing state of the art DAG-BFT protocols, and augments them in three key ways: (i) it reduces, in the common case, the commit latency of leaders (anchors), (ii) dynamically reinterprets anchor schedules to increase anchor frequency, and (iii) operates multiple parallel DAG instances to increase proposal frequency. This, in sum, allows Shoal++ to reduce the fault-free average e2e latency from 10.5 message exchanges (Shoal [34]) to only 4.5 message exchanges, within reach of traditional latency optimal (but throughput-inefficient) BFT protocols such as PBFT.

We note that the parallel DAG instances technique might be of independent interest, as this idea can be applied to any BFT algorithm to reduce its queuing latency.

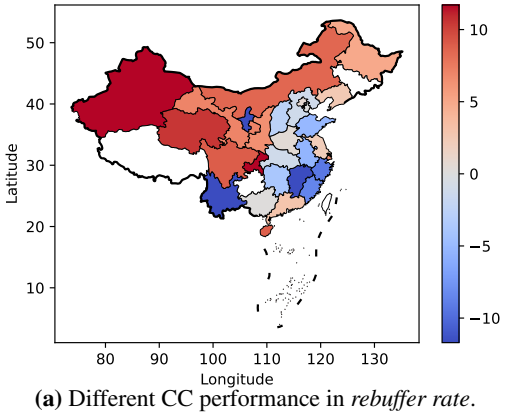
Abstract

Today's content delivery networks (CDNs) typically use static congestion control (CC) configurations, yet the diverse network environments preclude a universally optimal CC for all geographical regions, as evidenced by our extensive measurements. Current CC algorithms, limited by narrow applicability or high maintenance costs, struggle in large-scale CDNs. This work introduces ALICCS, the first CC Selection (CCS) approach tailored for production CDN, integrating fine-grained domain knowledge for learning to choose the best CC from existing, well-established ones. Through an over-one-year real-world deployment in Alibaba Cloud CDN, ALICCS has enhanced the Quality-of-Experience (QoE) by up to 9.31%, surpassing the competitive margin in the CDN market, and significantly reduced the retransmission rate by 25.51% to 174.36% across all provinces of China, leading to cost savings over 10 million US dollars. We also share key insights and experiences from deploying ALICCS at scale, highlighting traffic patterns in Alibaba Cloud CDN.

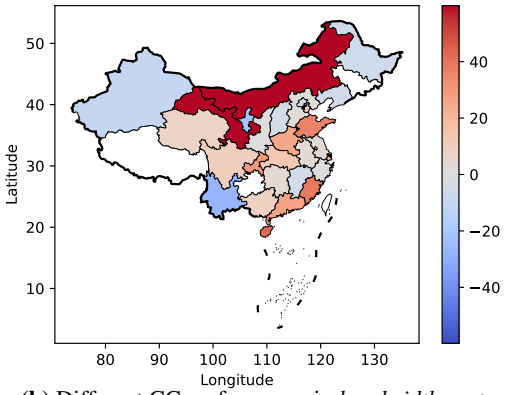
1 Introduction

Content Delivery Networks (CDNs) serve as the invisible backbone of the Internet, responsible for carrying over 70% of global traffic [4]. Enhancing Congestion Control (CC) in CDNs can significantly improve user experience by directly tackling network efficiency and reliability. It also achieves considerable cost savings for CDN operators, by offering a simpler, more resource-efficient alternative, compared to network or application layer modifications. Therefore, as a CDN provider, who has the greatest control and clearest visibility at the transport layer where CC is central, optimizing CC enables us to make more impactful changes that ISPs or application providers might not readily achieve (§2).

Currently, most CDNs still adopt the one-size-fits-all CC configuration [16, 32] across their geographically distributed regions, yielding a suboptimal overall QoE due to the vast diversity of CDN network environments. Conventional approaches either *fine-tune the parameters* of one type of CC or *invent a new CC*, targeting only specific network scenarios. Our experience shows that leading CC solutions exhibit significant variations in user QoE for content delivery services. No single CC scheme can always be the optimal choice across all regions of our CDN network, *e.g.,* ranging from rebuffer rate (Figure 1a) to bandwidth cost (Figure 1b)[1]. Given this complexity and variability, we raise a question: *How can we accurately select the best CC among well-established ones for distinct CDN nodes under dynamic network conditions?*



(a) Different CC performance in *rebuffer rate*.



(b) Different CC performance in *bandwidth cost*.

Figure 1: Performance comparison across 29 provinces in China. Red (Blue) means CUBIC (BBR) achieves better performance. A darker color indicates a bigger performance gap.

Machine learning (ML), with its widely proven proficiency in learning from diverse data, is particularly suited to address the dynamic and heterogeneous nature of CC Selection (CCS). It can adapt to varying CC performance across different factors. Despite this, extensive research on modifying CC, including learning-based approaches [14, 26, 45, 47, 49, 52], have not fully met the unique and stringent needs of production CDNs. From our experience, applying ML to CCS for large-scale production CDN presents the following key challenges, directly stemming from critical CDN requirements:

[*]These authors contributed equally to this work.

[1]Details on the fair A/B test of CUBIC and BBR are in Appendix §A.

Table 1: Comparison of ALICCS with state-of-the-art ML-based Congestion Control Selection methods.

	Optimization Goal	Granularity	Satisfy CDN req.[I]	Scales of CDN nodes, users/requests
Sage [49]	Throughput/latency related	N/A[II]	No	N/A
Disco [47]	Throughput/latency related	Per-connection	No	N/A (<10 servers and clients emulated)
Configanator [32]	Web performance (PLT)	Per-Network-Class	Yes	3 Global CDN PoPs, 8.2M requests
ALICCS	Rebuffer rate, latency	Per-connection	Yes	>1000 CDN nodes, 500M requests

[I] CDN requirements refer to those mentioned in §1: 1) scalability & generalizability, 2) interpretability, 3) managing inference overhead.
[II] N/A stands for Not Available.

- **Scalability and generalizability challenges.** Our CDN spans various geographical locations and network environments, necessitating distinct models for different nodes. However, managing individual models for the thousands of nodes in our global CDN is impractical due to extensive maintenance requirements. Moreover, most ML algorithms assume independent and identically distributed (i.i.d.) data between training and test domains, which may not hold true in practice. Developing a unified ML model that can efficiently scale and generalize across diverse data environments remains a crucial yet challenging goal.
- **Enhancing interpretability and accountability for deploying ML-based CCS.** Standard statistical tools alone do not suffice to evaluate ML models accurately due to potential sample selection bias and confounding factors [35]. It is therefore essential to integrate deep domain knowledge from our CDN with these tools to thoroughly assess the model's effectiveness and increase its interpretability before a full-scale CCS deployment in our production CDN.
- **Managing ML inference overhead without compromising CCS performance.** High performance of ML models often requires complex inference logic, leading to significant processing delays. Our real-world measurements reveal that non-optimized per-connection ML inference, *executed serially*, incurs significant overhead and undermines the queries per second (QPS) performance (refer to Table 3). Enhancing run-time efficiency with reduced ML inference delays is therefore vital to cost-effective CCS.

These challenges are not fully addressed by existing learning-based CCS efforts, summarized in Table 1. They do not incorporate the requirements and domain expertise of realistic large-scale CDN networks. Moreover, their reliance on methods like reinforcement learning [47,49] or online learning [32] necessitates handcrafted reward functions and immediate QoE feedback, both of which are impractical for the short video services supported by our CDN based on our experience.

To address the above challenges simultaneously, we introduce ALICCS, the first domain-specific, ML-based CCS scheme, tailored to *short video delivery*, a dominant workload in Alibaba Cloud CDN. ALICCS dynamically selects the most effective CC for each connection[2], aiming to (1) boost short video QoE, by reducing rebuffer rates and start-up delays, and (2) lower bandwidth cost, *e.g.,* retransmission ratio.

In developing ALICCS, we make the following contributions:

Firstly, it is crucial to define the right features and labels from usable data for ML models that predict key factors to optimize CCS, scale to numerous CDN nodes, and generalize to new environments. We reveal an observation (detailed in Figures 3 and 4) that network types decisively influence the best CCS. Therefore, our goal is to effectively learn a mapping from end-to-end TCP statistics to network types. However, this relation is *unstable* due to hidden states [35] like underlying network conditions. We then propose a decomposed Causal Graphical Model (CGM) using Generative Adversarial Networks (GAN) and domain knowledge, extracting features *that are invariant to the hidden states*. Additionally, we develop a hierarchical clustering algorithm to group a vast number of IP prefixes for model scalability improvement.

Secondly, to enhance the model's transparency and interpretability, we employ knowledge distillation to transfer insights from our complex, well-trained deep neural network (DNN) into a compact decision tree. This tree, developed using training data enhanced by the predictions of our DNN model, effectively replicates the DNN's decisions in a format that is easier to interpret. When we encounter performance degradation during online CCS inference, we substitute our large DNN model with this decision tree. This allows for precise tracking of any suboptimal predictions by identifying the specific features contributing to the inefficiency, providing better interpretability of our ML-produced CCS solutions.

Thirdly, we significantly reduce model inference overhead by constructing an IP-prefix based cache that leverages temporal and IP-prefix-specific similarities in the domain of the best CCS and network types. ALICCS has achieved 64.30× improvement in latency and 2.42× improvement in QPS for online CCS inferences. Moreover, we realize fine-grained CCS by implementing it in a per-connection manner. This also bypasses the complexity and QoE sensitivity issues in selecting the grouping granularity, which is inherent in existing CC control methods that rely on request grouping [32].

Deployment and experience. ALICCS has served Alibaba Cloud CDN's production for over one year. We train our model on labeled data from App #1[3], one of the leading short video companies in the world, obtained from about 30% of the CDN nodes supporting its services. The well-trained model serves online CCS inference in an over-one-year in-production deployment for both App #1 and App #2,

[2] Multiple requests can multiplex on each CDN connection.

[3] Partner apps are anonymized due to NDA of our company.

two major providers in the global short video market. ALICCS achieves 95.8%–99.0% Wi-Fi/4G prediction accuracy in about 400 nodes of three main ISPs in China and Southeast Asia, covering almost all provinces in China, demonstrating our ML model's generalizability. Combining our model's predicted network access type and the mapping to CC choices, we reduce the rebuffer rate by 4.76% and retransmission bandwidth by 25.51%–174.36%. In terms of run-time efficiency, ALICCS achieves CPU usage below 0.79% (at most two cores per CDN node) and maintains the minimum memory consumption below 2.90 GB (see Figure 11). In addition, it achieves 64.32× processing delay reduction and 2.42× maximum QPS improvement (see Table 3).

2 Background and Motivation

In this section, we detail our motivation for employing CCS in Alibaba Cloud CDN, focusing on short video services. We then share observations that drive ALICCS's design choices.

2.1 Overview of CDN at Alibaba Cloud

Alibaba's CDN spans over 70 countries with a total egress bandwidth exceeding 180 Tbps that serves over 120 EB (*i.e.,* 120×2^{60} Bytes) of data every year. In particular, it has 2800+ nodes in China and South Asia, covering a wide range of geographical regions and ISPs, where ALICCS is deployed. By caching content at edge servers, the CDN significantly reduces back-to-origin bandwidth and enhances user proximity. It offers diverse services, ranging from large file transfers to media streaming services, among which short video services take the most significant share of traffic demands.

CDN providers aim to deliver high-quality services cost-effectively, focusing on improving *user QoE* and reliability to stand out from competitors. *Bandwidth costs* constitute a major portion of operational expenses, which means even slight and relative reductions in data transfer can lead to significant absolute savings at scale.

2.2 Motivation: CCS for Short Video Services

Short videos, *e.g.,* supported by App #1 and App #2, have become a major workload of Alibaba Cloud CDN. The CDN should then be optimized to deliver short videos with high user QoEs while incurring minimum bandwidth costs.

QoE of short video delivery. Efficient content delivery for short videos in CDNs necessitates quick video start times and smooth playback. Traditional video streaming focuses on metrics like bitrate, resolution, and loading appropriate initial buffering video segments (typically 2-10 seconds) to ensure high-quality, continuous playback over longer durations. In contrast, short video services emphasize minimizing the rebuffer rate to reduce stalls and the initial buffering delay, typically less than 1 second for the first frame to load.

Why adjust CC? Extensive efforts have been made to improve video delivery QoE by refining application layer strategies like Adaptive Bitrate (ABR) algorithms and content pre-fetching. However, these are beyond the control of CDN providers and thus not considered in this work. In large-scale production CDNs, optimizing CC directly targets network bottlenecks, leading to immediate improvements in content delivery, especially for short video services. Besides, adjusting CC offers a straightforward and resource-efficient alternative to overhauling application layer configurations, including fine-tuning ABR [7, 30, 43] and content pre-fetching [17, 29] settings, or transitioning from HTTP/2 to HTTP/3 [5, 42].

Table 2: Performance comparison of different CCs for 4G networks (*CUBIC Agg.* means CUBIC tuned to aggressively trigger retransmissions to lower rebuffer rates).

CC Algorithm	CUBIC	CUBIC Agg.	BBR
Video Rebuffer Rate	1.13	1.05	1.0
Retransmission Rate	1.41	1.53	1.0

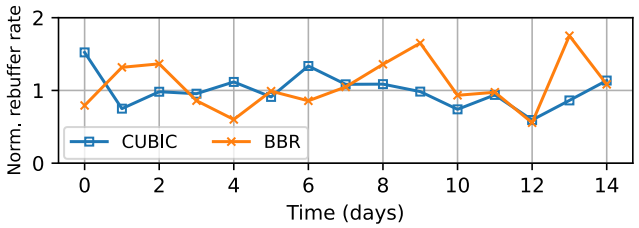


Figure 2: A two-week A/B test comparing BBR and CUBIC, serving short videos for App #1 in one CDN node.

Why CCS? While conventional approaches generally focus on parameter fine-tuning (*e.g.,* Bayesian Optimization) for a given CC [8], our experience has shown that the benefits of such tuning can be marginal in certain scenarios. This is because each CC algorithm has inherent limitations in how it identifies and reacts to congestion, which may fall short in situations violating their assumptions. For instance, in tuning CUBIC for 4G networks, a substantial increase in sensitivity to trigger retransmissions is necessary to match BBR's rebuffer rate in 4G. This adjustment, however, leads to an increase in the retransmission rate from 1.41 to 1.53 (see Table 2). Compared to the alternative of *inventing new CC algorithms*, our approach of selecting the best among long-living CC schemes, known for their effectiveness in variable scenarios, *provides robust worst-case performance*. It reduces potential revenue loss associated with inadequately tested CCs.

Why ML for CCS? Due to dynamic network conditions and user traffic in CDNs, *rule-based* CCS approaches are generally impractical. This is supported by our measurements showing volatile patterns of CC performances across both regions (Figure 1)[4] and time (Figure 2). Moreover, our choice of using ML for CCS is driven by our observations and domain knowledge, based on which CCS can be reduced to a classification problem, elaborated in §2.3. This problem reduction directly informs our model design, where we integrate supervised

[4]We find regional proximity does not yield network metrics' similarity, likely due to diverse traffic policies (*e.g.,* rate-limiting) in nearby regions.

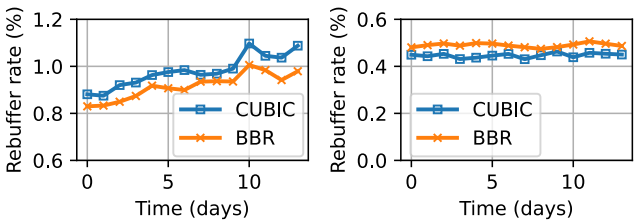

Figure 3: Contrasting advantages of BBR and CUBIC varying network types, *i.e.,* 4G (left) and Wi-Fi (right).

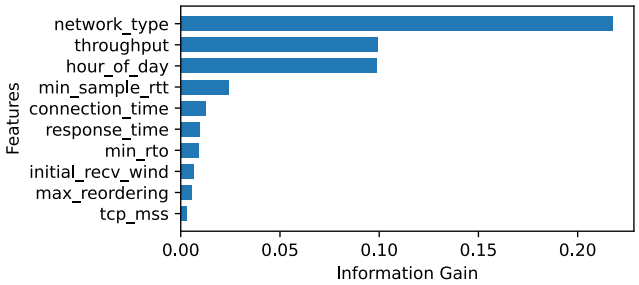

Figure 4: Top 10 features on our CDN with the highest information gain for predicting the best CC candidate. These features span four categories: transport layer (TCP) statistics (*e.g.,* retransmission rate and throughput), application layer statistics (*e.g.,* response time), link layer statistics (*i.e.,* network type) and timing (*i.e.,* hour of the day).

learning with fine-grained domain knowledge. Consequently, other ML choices, such as reinforcement learning [47, 49, 52] and no-regret (or online) learning [14, 32, 50] do not align well with our needs. They are in general tailored to sequential processes where data are gradually available, adding unnecessary complexity and inefficiency to CCS.

2.3 Key Observations

Our goal is to develop an ML system that selects the best CC algorithm from a set of candidates to enhance user QoE and reduce bandwidth costs for short video services across extensive CDN nodes.

Observation I: CCs' advantages vary regionally and temporally. Despite extensive efforts to optimize the performance of individual CC algorithms, we find that no single algorithm consistently outperforms others in all scenarios. Our Figures 1a and 2, illustrate that the superiority of BBR and CUBIC in rebuffer rate varies across regions and fluctuates over time, demonstrating that using a fixed CCS rule is generally impractical. This observation aligns with recent findings [49], which report similar fluctuations in the CC superiority.

Observation II: Network types decisively influence CC advantages. We compared short video rebuffer rates between BBR and CUBIC over 14 days, presented in Figure 3. Both groups, represented by the blue and orange curves respectively, use the same network type, *i.e.,* 4G for the left figure and Wi-Fi for the right. This reveals a strong correlation between network access and the best CC choices: BBR outperforms in 4G connections (left) while CUBIC wins under Wi-Fi (right). Other CCs like Vegas [11], Reno [23], and Westwood [40], exhibited significantly inferior performances (*e.g.,* 30%–40% higher rebuffer rate than CUBIC and BBR) for short video delivery in our production CDN, based on comprehensive pre-deployment measurements. To ensure performance reliability and stability, we choose CUBIC and BBR as the CC candidates. Moreover, we examine the impact of different features on CC selection. Figure 4 shows that network type has the highest information gain [3], vastly outweighing other features like retransmission rate and hour-of-the-day with information gain of 0.001 and 0.005 respectively[5]. This observation leads us to reduce the CCS problem by focusing on predicting the network type for each TCP connection, as it provides the most substantial predictive power of the best CC and keeps system complexity manageable. We then deterministically choose CUBIC for Wi-Fi and BBR for 4G to optimize short video QoE.

Observation III: ISP rate-limiting impacts CCs differently. Based on Observation II, we hypothesize that the contrasting performance of CUBIC and BBR varying network types is attributed to the ISP's traffic policies, particularly token bucket rate-limiting that may cause premature packet losses[6], which CUBIC misinterprets as congestion signals, significantly reducing throughput. To confirm this, we first utilize BBR's bandwidth probing mechanism to assess rate-limiting strength over months and then examine how CUBIC and BBR respond. We observe that 4G's rate-limiting generally increases from the start towards the month's end. During this, CUBIC's average throughput drops to less than 10% of that without rate-limiting (1472 Kbps vs. 8728 Kbps), and its average retransmission rate surges to 73× higher than its non-rate-limited performance. It highlights that CUBIC struggles in 4G rate-limiting conditions, while BBR's bandwidth probing technique can instead effectively identify the bandwidth constraints. Regarding BBR's inferior performance on Wi-Fi, it is primarily due to Wi-Fi's frame aggregation mechanism, which undermines BBR's bandwidth probing capabilities [18].

Observation IV: Network types need to be predicted dynamically. Obtaining network type via client reporting is impeded by software upgrade overhead and unreliable client data. Notably, labeled data from client accounts for only 5%–10% of total requests (see labeled data acquisition in §3). Additionally, private IP database solutions like MaxMind [2] offer limited coverage and accuracy of network type labels for our CDN network. Moreover, we observe that with 90% probability, a /24 IP prefix will significantly shift its proportion of dominant type (Wi-Fi or 4G) in 15 hours, necessitating dynamic network type prediction.

[5] Features like retransmission rate are analyzed but not shown in the figure, as they ranked outside the top 10.

[6] Packet losses can be categorized as transmission, congestion (from link contention), and rate-limiting loss. While the first two vary over time within the same network, the rate-limiting loss is consistently bound to 4G networks.

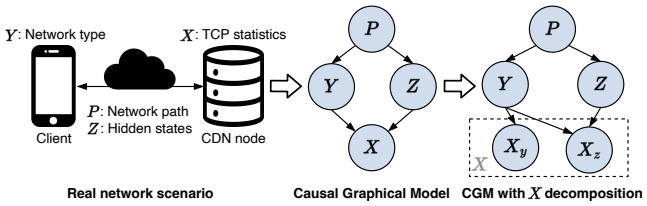

Figure 5: Illustration of decomposing features via CGM.

3 Design and Implementation

In this section, we outline the design of a unified ML model for all CDN nodes, enabling stable mapping from TCP statistics (additional features are listed in Appendix §B) to network types. One naïve solution would be to collect training data from all regions and train a comprehensive model. However, this method raises two significant issues: (1) The QoE performance in worst-case scenarios is not guaranteed, which is critical for production CDNs. (2) Regions that are underrepresented in the training data can impede model inference performance due to limited generalization. Essentially, weak network conditions and regions with fewer requests are often insufficiently represented in the training set. Training the model naïvely without eliminating the effects of these diverse network conditions, which are represented as underlying network characteristics, may lead to overfitting on good conditions or regions with ample requests. This, in turn, degrades model accuracy in poor network conditions or small regions, as evidenced in §5.4, undermining its capability to provide worst-case guarantees. Another straightforward CCS approach is to directly adopt the network type labels from datasets and then choose CUBIC for Wi-Fi and BBR for 4G. However, network types in the datasets are often unreliable and thus need to be predicted dynamically (refer to Observation IV).

3.1 Model Design and Training Method

Prior research on applying ML to networked systems often overlooks model generalizability under volatile network environments. In contrast, our model design aims to learn causal relationships between TCP data and network types[7], guided by our key observations (§2.3). This approach enhances prediction accuracy in new environments, crucial for generalizability. However, our measurements reveal that the relationship between TCP statistics and network type is generally *unstable*. This instability likely stems from end-to-end TCP statistics being influenced by network types as well as varying path-specific characteristics, such as buffer sizes and the number of competing flows across CDN nodes and IP prefixes.

Design overview. To tackle the instability in learning, our idea is to decompose the raw data features, which are TCP statistics ($\triangleq X$), into two parts, denoted by X_y and X_z respectively in Figure 5: one influenced solely by network types ($\triangleq Y$) and the other influenced by both Y and hidden state ($\triangleq Z$). Our goal is to create a model based only on features X_y for model stability. To do so, we construct a decomposed Causal Graphical Model (CGM) and tease apart the impact of network types Y and hidden states Z on TCP statistics X, by leveraging the one-to-one mapping between network paths ($\triangleq P$) and IP address prefixes observable on CDN servers. This ensures a stable model that maps X to Y while remaining *causally invariant to Z*. Finally, we incorporate domain knowledge as constraints and regularization terms, to ensure model scalability and reduce the noise.

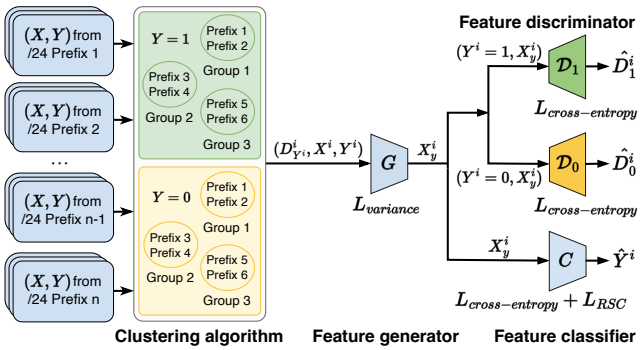

Figure 6: Overview of our ML model design.

Decomposing features via CGM. Ideally, to develop a generalized model for the diverse CDN nodes, we need to identify features for any TCP connection that have a stable relationship with our target Y. However, directly using X, the measured TCP statistics (*e.g.,* maximum congestion window size), is insufficient due to their dependence on both the network type Y and varying hidden factors Z (*e.g.,* path capacity), as depicted in the middle CGM in Figure 5. Different CDN nodes involve various paths P (interchangeable with connections) and thus different hidden factors Z, causing instability in the X and Y relationship. To address this, we leverage our decomposed CGM with X_y and X_z, the decomposed features of X (refer to Figure 5), and a condition satisfied by X_y: $Pr(X_y|Y,P) = Pr(X_y|Y)$. Therefore, our goal is *to identify features X_y for each connection that maintain a constant conditional probability distribution $Pr(X_y|Y)$ across all connections*. By training a classifier with these feature-target pairs $\{X_y^i, Y^i\}_{i=0}^m$, with a total of m samples, we can create a model that performs reliably on every CDN node. This is realized by integrating this decomposed CGM into a GAN, where a generator is trained to obscure the discriminator's ability of predicting the path from which the sample originates.

Learning path-invariant features via GAN. Through the above mathematical insights rooted in our decomposed CGM, learning a stable mapping from X to Y is converted to learning a path-invariant feature representation X_y given Y. Furthermore, leveraging the one-to-one mapping relationship between IP prefix and Internet path[8], the goal becomes *learning*

[7] The minor case of non-1:1 mapping between connection and network type is not yet addressed. Potential solutions are outlined in Appendix §C.

[8] The association between IP prefixes and Internet paths stays stable for several hours, despite occasional changes due to load balancers.

an IP-prefix-invariant feature representation for any specific network type. To achieve this, we adopt the GAN framework and construct two discriminators, marked by $\mathcal{D}_1$ and $\mathcal{D}_0$ in Figure 6, each outputting which /24-prefix group the sample comes from, for Wi-Fi ($Y=1$) and 4G ($Y=0$), respectively We then formulate two regularizers, R_{D_0} and R_{D_1}, based on the discriminators' predictions $\widehat{D}_0$ and $\widehat{D}_1$, corresponding to the ground-truth group labels D_0 and D_1, respectively[9]. These regularizers represent the classical cross-entropy-based classification loss of discriminators and are formulated as:

$$R_{D_0} = L_{cross-entropy}(D_0, \widehat{D}_0) \tag{1}$$

$$R_{D_1} = L_{cross-entropy}(D_1, \widehat{D}_1) \tag{2}$$

Scalability with domain knowledge-assisted clustering. Ideally, the outputs D_0 and D_1 correspond to the vectors indexing IP address prefixes. However, a scalability challenge arises: the discriminators need to distinguish which IP prefix each sample originates, among tens of thousands of candidates at each CDN node, causing intractable training complexity. To tackle this, we modify the discriminators' original outputs to be IP-prefix *groups* and introduce a domain knowledge-assisted clustering algorithm. As shown in Figure 6, we first separate the training data based on whether Y equals 1 or 0 and then adopt K-means clustering to group the IP /24 prefixes, with Euclidean distance adopted as the distance metric.

Labeled data acquisition. We collect labeled data through collaboration and coordination with one of the short video service's client end. The label of network type is piggybacked via http header extensions from client side. Note that due to the overhead associated with software development and client upgrades, the volume of labeled data obtainable from client side is limited between 5% and 10% of its total requests with limited region coverage in a limited period of time.

Feature selection. Our CDN spans nearly all provinces in China, handling numerous TCP connection features from user requests, requiring efficient feature selection due to significant data scale and diversity. We choose information gain as the selection criteria for its intuitiveness and broad applicability. However, a one-shot feature does not meet our production-level accuracy requirements. Therefore, we also periodically diagnose ALICCS's model performance by combining the knowledge-distilled decision tree and Shapley value analysis to tweak the feature sets, which will be elaborated in §3.2.

While the core of our ML model to predict network types, integrating a decomposed CGM with domain-specific GAN and clustering, it also demands meticulous handling of numerous corner cases. Below, we outline two additional techniques used in our production CDN for effective model training.

[9]In practice, to eliminate CC algorithm bias and obtain IP-prefix-and-CC-invariant features, we can instead cluster data by the combination of CC and IP-prefix, and re-define the outputs of $\mathcal{D}_1$ and $\mathcal{D}_0$ to be the combinations. Or, we can add another discriminator for it.

Diversified features for smaller ISPs. Through training with CDN data, we have learned that, while a universal feature representation generally works well, significant deviations in feature distribution exist, in particular for smaller ISPs compared to major ones. This discrepancy can cause a model to underperform with smaller operators. By identifying and transforming alternative features from smaller ISPs to align with the broader distribution, we can ensure a more robust and effective model. To enhance generalizability and avoid over-reliance on dominant features, our model employs the Representation Self-Challenging (RSC) method [22]. Unlike Dropout, which randomly deactivates features, RSC uses gradients to selectively mute predictive features, encouraging the model to utilize a broader range of features. Therefore, we integrate an RSC-based regularizer into our training loss, denoted as L_{RSC} (used later in Equation 5). This approach is particularly effective for data from smaller-scale ISPs, diversifying the model's focus and ensuring robustness across various scenarios that deviate from larger operators.

Noise reduction with domain knowledge. To reduce feature noises, we again utilize the domain knowledge that requests with the same IP /24 prefix usually follow identical IP paths. Thus, the extracted features from the same IP /24 prefix should align closely, sharing the same path-specific hidden states X_z and the desired X_y. We translate this insight into a regularizer $L_{variance}$. Let $\mathcal{S}_{prefix}$ denote the set of those X^j sharing identical IP /24 prefixes and $\overline{X}_{prefix}$ denote the average of $X^j \in \mathcal{S}_{prefix}$. We formulate $L_{variance}$, the sum of the variance of extracted features of each /24 prefix group, as follows:

$$L_{variance} = \sum_{prefix=i}^{n} (X^j - \overline{X}_{prefix})^2_{X^j \in \mathcal{S}_{prefix}}. \tag{3}$$

Training method. Utilizing Equations 1, 2, and 3, we construct the loss functions for training the discriminators, generator (G), and the classifier (C) according to the following:

$$L_D = R_{D_0} + R_{D_1}, \tag{4}$$

$$L_C = L_{cross-entropy}(Y, \widehat{Y}) + L_{RSC}, \tag{5}$$

$$L_G = L_{variance}, \tag{6}$$

$$L_{all} = L_C - \lambda_1 * L_D + \lambda_2 * L_G, \tag{7}$$

where L_D is the discriminator's classification loss, L_C is the classifier's classification loss, and L_{RSC} is a term inspired by RSC regularization. L_G represents the regularization term applied on the generator G. L_{all} is the overall training loss, with hyperparameters λ_1 and λ_2 balancing the trade-off between model fitting and generalization. Further details on the design trade-off can be found in Appendix §D. Adhering to the standard GAN training method, we alternate between two training phases. We initially train the discriminators using loss L_D, with fixed generator and classifier parameters. Subsequently, we train the generator and classifier using the combined loss L_{all}, while keeping the discriminators fixed.

3.2 Model Interpretability Enhancement

In addition to generalizability and scalability, it is essential to establish trust before deployment and understand the root cause of prediction errors. This is crucial for iterating and refining the model, especially during incremental deployment in a production CDN. Model interpretability entails two requirements: First, its behavior must be easily verifiable by operational engineers using their domain expertise. Second, it should accurately reflect the ML model's behavior. To this end, we have chosen a tree-based model, which satisfies these requirements and has proven to be particularly well-suited for networking problems that span local and global control [31].

Knowledge distillation with augmented features. We distill the knowledge of our GAN-based deep learning (DL) model into a decision tree-based model for performance diagnosis. We first input all features $\{X^i\}_{i=0}^m$ from the training set to the trained DL model to obtain the prediction probabilities $\{Y_0^i, Y_1^i\}_{i=0}^m$. Then, we combine them to create a distilled version of the training set, $\{X^i, Y_0^i, Y_1^i\}_{i=0}^m$. Next, we construct a multi-output regression decision tree and train it using the distilled training set. Each output in the tree corresponds to the predicted probability of one CC selection solution, *i.e.,* Wi-Fi and 4G. The utilization of feature-probability tuples (X^i, Y_0^i, Y_1^i) rather than the standard feature-label pairs (X^i, Y^i) reflects our domain-specific GAN-based model design, where we construct two discriminators for Wi-Fi and 4G network types respectively, leading to higher interpretability.

Using our decision tree in practice. The tree-based models enhance the robustness of ML models by enabling performance issue debugging and helping understand the model predictions to build trust. For instance, during the initial deployment phase, when encountering a low accuracy within a specific /16 IP prefix, we applied Shapley analysis [28] to the output of the decision tree for those examples. This combination allows us to quantify feature importance for predictions on subset of samples and understand the model predictions for certain IP prefixes. We then found that the model excessively relied on the TCP maximum segment size (MSS) feature from that specific /16 IP prefix. Therefore, we adjusted the model to reduce its reliance on MSS and broaden its feature usage, effectively boosting the accuracy. Beyond debugging, decision tree models also assist the production team in comprehending and gaining confidence in our ML model, which is essential for its deployment in production. It is crucial to note that the distilled decision tree is employed solely for performance diagnosis rather than online inference, for two primary reasons. First, our caching mechanism, discussed later in §3.3, effectively mitigates DL model's inference costs. Second, empirical observations reveal that the distilled model's accuracy is much lower than that of our DL model. Nevertheless, despite a 5%–7% accuracy drop, we find the distilled tree model still captures error-related features, by aligning its prediction with the DL model for most samples. For subsets with significant prediction discrepancies, we increase the tree depth and retrain the tree until the alignment passes a threshold.

3.3 Inference Pipeline at CDN Nodes

Integrating our ML model (§3.1) into the networking stack of CDN nodes poses two technical challenges: (1) The model inference time must be negligible compared to the normal request processing time to maintain high request processing rates (*e.g.,* approximately 10k QPS) for any CDN node. (2) Hardware costs need to be considered, as excessive use of additional CPU or GPU cores per CDN node can be impractical and costly, potentially outweighing the benefits. We develop an efficient inference pipeline to tackle these challenges.

Centralized vs. distributed inference deployment. To implement automatic and intelligent CCS across CDN nodes using a well-trained DL model, we evaluated two approaches: centralized model inference services and distributed model replication on each node. Empirically, the centralized approach offers more abundant hardware resources in a cluster to deploy the model, facilitating faster ML model inference. However, the network latency between the centralized cluster and geo-distributed CDN nodes can be prohibitively high, potentially causing millisecond-scale delays for serving each batch of requests. Therefore, we opted for the distributed approach, replicating and performing inference locally on each CDN node to achieve greater responsiveness and efficiency.

This decision to adopt a distributed approach leads us to an efficient inference pipeline, grounded by two key observations drawn from comprehensive empirical studies:

- **Temporal stability of the best CCS and IP-based caching.** Consistent with a previous study [47], we find that the best CC choices, influenced by network path characteristics, remain stable for several hours. Specifically, our measurement reveals that a /24 IP prefix stays dominated by either Wi-Fi or 4G type (purity over 90%) for more than 2 hours with 87% probability[10]. And it can remain dominated by one of these types for 15 hours or more with 10% probability. This stability allows us to cache inference results for requests from specific paths, enabling their reuse for subsequent requests from the same path and significantly reducing inference costs over time.
- **Consistent CC choices based on IP prefix similarity.** IP networks are typically organized in subnets, and IP routing is based on the longest prefix matching. As a result, requests from the same IP prefix often undergo similar path decisions at a given time. As shown in Figure 7, among the top 10K /24 prefixes with the most requests, 90% of them exhibit a *purity* (percentage of connections with the same network type) higher than 91%, and these prefixes account for 84% of the total requests seen by our CDN. This allows us to not only cache results for the last few hours but also aggregate the results of our predicted CC choices

[10] We infer these dynamics may stem from ISP's load balancing and management, but we lack visibility into ISP's network to validate such hypothesis.

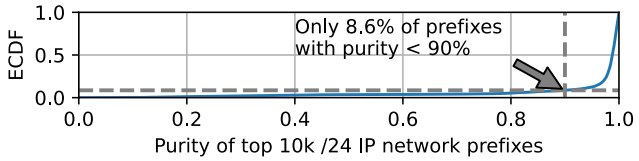

Figure 7: CDF of purity distribution of /24 prefixes.

under the same IP prefix into a single entry, leveraging their homogeneity in CC selection to save memory.

Inference pipeline. Figure 8 depicts the pipeline developed utilizing the above insights. We minimize the inference delay in the request processing pipeline by decoupling the process into online cache lookups (shown as the "Online processing pipeline" box) and periodic offline updates (shown as the "Offline processing pipeline" box). The latter records pairs of requests' IP addresses and the CC choices chosen given the predicted network types. The update is performed hourly to save computations, and also match the temporal stability of the best CCS. Every time a request server encounters a new client connection, it queries the mapping cache for the CC decision. This reduces the CCS latency from running a complex DL model inference to a lightweight cache lookup.

Efficient IP lookup cache. We implement an IP lookup cache using the Trie data structure [10,19,34,38,48], which provides O(1) lookup complexity with special hardware requirements. Instead of constructing a full Trie, which has high space complexity, we aggregate IP prefixes based on our previous observation on purity. We first construct a Trie at the /16 prefix level and examine the purity of each leaf node. Expansion stops if a node's purity surpasses a set threshold; otherwise, we expand until the node satisfies our purity standards or reaches the /32 prefix limit. A detailed algorithm is provided in Appendix §F, with further insights into threshold tuning available in Appendix §D. Even under /32 prefix granularity, requests of different network types are still observed. We speculate that the CDN only sees the public IP, which may be dynamically binded to various networks.

Empirical purity tuning. Tuning the aforementioned purity thresholds is crucial to model accuracy and space complexity. We adopt an empirical approach, starting with gathering online purity measurements, as shown in Figure 7. By analyzing the requests from the top 28 CDN nodes over one week, we find that only 8.6% of /24 prefixes have purity lower than 90%. By fine-tuning the threshold to aggregate IP addresses based on this observation and the available resources in each CDN node, the number of entries in the mapping cache is brought down from hundreds of thousands (*i.e.,* 10^5, the number of IP addresses seen by a CDN node in the last hour) to hundreds (*i.e.,* the number of /16 or /24 IP prefixes), resulting in a 614× memory saving without sacrificing prediction accuracy.

4 Experiences and Discussion

In this section, we discuss our deployment experiences and lessons learned in our real-world production CDN.

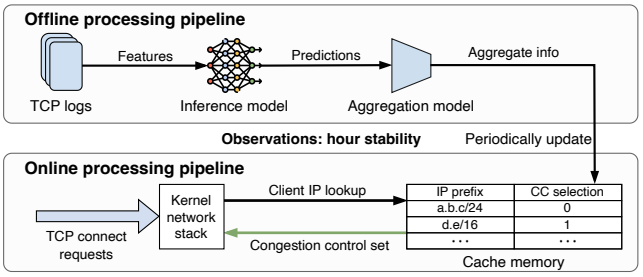

Figure 8: Inference pipeline at CDN nodes.

4.1 Deployment Experiences

ALICCS has served Alibaba Cloud CDN's production for over one year, supporting short video services for two major providers, spanning nearly all provinces in China. It reaches high network type prediction accuracy in around four hundred nodes of three main ISPs in China and Southeast Asia. We share some experiences in deploying ALICCS at scale.

Service-aware CCS. CDN requires tailored CCS strategies for different customers and services. This means that CCS can not be operated only in the kernel space where we are not aware of the service types and can not make customized decisions for different services. To better integrate with information from services and maintain flexibility, we decide to move AI processing mostly to user space.

TCPe (TCP extension) is our modular and customized TCP protocol stack implemented in the kernel space. Upon receiving each connection request from a client, it sends a query for the right CC decision to the mapping cache lookup using the client's IP address and then applies the query result of the CC algorithm accordingly in the kernel space. It also acquires TCP statistics from kernel space at a fine granularity, provided to the Log Server, which is responsible for collecting TCP statistics of CDN requests and send them to AI model for inference. We use the standard TCP socket's programming interface (*e.g.,* setsockopt) to set the CC algorithm.

AI Server, where the ML model resides, is not required to provide low latency, as it is decoupled from the online CCS service due to our designed Mapping Cache. We export the model trained in Pytorch in PMML format and load it into the AI server using the high-performance CPMML library. It continuously outputs predictions of network types using TCP logs from the Log Server, converts the predictions into CCs, and forwards them to the Aggregation Module.

4.2 Lessons Learned

We now share our lessons learned in deploying ALICCS.

What influences the QoE disparity of short video services under various CCs? Traditional CC design typically emphasizes maximizing throughput; however, our studies indicate that preventing frequent speed fluctuations is more critical, especially for short video services. Thus, while most CC mechanisms offer adequate throughput, optimizing *throughput stability*, a critical determinant of rebuffer rate perfor-

mance, emerges as essential for short video services. Beyond traditional network metrics such as RTT, loss, and bandwidth, our research also highlights the significant impact of network operators' traffic policies, such as rate limiting (refer to Observation III). Taking these policies into consideration is the key to optimal CC algorithm design. Furthermore, CCs customized for specific network types such as Wi-Fi and 4G, considering their unique physical characteristics, greatly enhance short video QoE (refer to Observation II).

Data cleaning. The massive number of CDN nodes requires careful data pre-processing via automatic data cleaning tools, augmented with our expertise in the patterns of TCP statistics and the prediction target, *i.e.,* network types. In our experience, data like RTT often incurs long-tail outliers that are extremely high but occur infrequently, thus violating the Gaussian assumption explicitly assumed by most deep-learning approaches, and impacting the efficiency of data normalization. Some abnormal RTT values can even skew the average RTT to seconds. Our current solution is to compress the data range by applying a logarithmic transformation (log), followed by standardization. This approach avoids the need for manually deciding the threshold to filter out outliers and significantly aids in accelerating model training.

Advantages of distributed inference for CDN networks. Our application of ML to CDNs indicates a distributed inference architecture is more beneficial for CDN networks. This approach offers two benefits: First, it enhances scalability by enabling edge nodes to independently serve requests, which alleviates bottlenecks and increases the network's capacity to manage high traffic volumes. Second, since CDN central servers often reserve processing power for video transcoding, offloading inference tasks to edges with surplus CPU cycles for peak demand is more cost-effective. In contrast, centralizing these tasks requires allocating an additional 2 CPU cores and 4 GB of memory to each of thousands of CDN nodes, resulting in significant expenses for CDN based on tests.

Enhanced gains of customized network services for IPv6. Our deployment experience shows that customizing network services using IP prefix aggregation reduces average rebuffer rates by 60% more in IPv6 networks than in IPv4 (7.6% vs 4.76%). This arises from two factors: First, IPv6 enhances predictability by reducing reliance on NAT and similar technologies used in IPv4. IPv6 network tends to assign a fixed IP prefix to a subnet over time, improving history-based predictions. Conversely, IPv4 with NAT may frequently change the mapping of IP prefix to underlying subnet, undermining these predictions. Second, the disparity in network characteristics between Wi-Fi and 4G is more pronounced in IPv6, with a ratio between mean retransmission rate of Wi-Fi over 4G being 2.1× in IPv4 and 2.9× in IPv6. These facts underscore the need for more tailored services to manage Wi-Fi and 4G disparities in IPv6 networks.

Deploying a fallback strategy for ML in CDN networks. When integrating ML system with CDNs, it is crucial to establish a robust fallback strategy when ML predictions are inaccurate. In practice, no ML system can perfectly address every scenario or maintain reliability in all situations. Therefore, it's essential to revert to a default strategy when ML predictions are uncertain. We employ a threshold-based scheme: if our ML-predicted network type has a logit exceeding 80% for Wi-Fi type and 60% for 4G type, it is trusted; otherwise, the system defaults to its original protocol set-up. The higher threshold for Wi-Fi reflects more cautious decision-making due to its large request proportions compared to 4G. This safeguard ensures that performance does not drop below the default configuration, thus enhancing reliability.

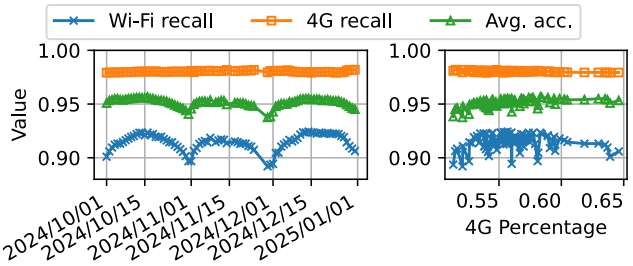

Figure 9: Model prediction accuracy varying date (left) and percentage of 4G traffic (right).

5 Evaluation

To ensure a smooth transition to full-scale deployment, we have focused our efforts on short video services. ALICCS has been applied to two major short video services on Alibaba Cloud CDN, with one of them contributing training data over 30% of our CDN nodes. We evaluate ALICCS's performance by addressing three key questions:

Q1: How accurate is our ML model in predicting the network types for large-scale, geo-distributed requests?

Q2: How efficient is our inference pipeline, particularly with the cache-based, online-offline decoupled design?

Q3: What's the QoE improvement for short video services using our production CDN?

5.1 Machine Learning Model Accuracy

Model prediction effectiveness. We validate our model's prediction accuracy across numerous CDN nodes handling high volumes of short video requests from major ISPs in China. To ensure statistical reliability, nodes with less than 5% of requests from 4G or Wi-Fi connections are excluded. Our ML model achieves an accuracy ranging from 95.8% to 99.0%, averaging an improvement of 1.58% and peaking at 3.4% on Wi-Fi networks of ISP #2. Remarkably, this is accomplished using only 30% CDN nodes for model training, confirming our model's generalizability.

Online validation of the ML model. Figure 9 presents our model's prediction accuracy in serving a large volume of short video requests over 3 months on a CDN node. The left figure depicts that our ML model achieves a remarkably high value of recall (*i.e.,* true positive rate of predicting each network

type), varying slightly between 89% to 93% for Wi-Fi, 97% to 98% for 4G, and an overall average ranging from 94% to 96%. Interestingly, the Wi-Fi recall exhibits a monthly cyclic pattern and remains stable over time. This phenomenon likely stems from ISP-enforced monthly 4G data caps, leading to a reduction in 4G usage as users hit their data limits towards the end of the month and a corresponding drop in Wi-Fi recall at the same times. This dependency is due to our model being trained on a balanced dataset (*i.e.,* 50% of the data is 4G), not reflecting the actual distribution of 4G usage at the beginning and end of the month. Previous studies, such as in reference [39], have shown that when the proportions of category (like 4G) shift, classification accuracies decrease. The impact on Wi-Fi recall is more noticeable due to its smaller absolute number. Additionally, our model prediction accuracies for both Wi-Fi and 4G are robust to varying percentages of 4G connections, as demonstrated in Figure 9 (right), confirming ALICCS's generalizability. We continuously monitored the model's performance by checking a domain name whose requests have been labeled by App #1 short video service provider. We see that the model maintains a high recall rate of over 90% for each network type for at least 6 months, from March 2024 to August 2024.

ML model prediction comparison. To evaluate the effectiveness of our ML model design, we conduct ablation studies, evaluating ALICCS's different components, and compare with Configanator, an advanced learning-based CCS scheme, and a baseline named Vanilla ML, where we directly feed training data into an MLP (multi-layer perceptron) network without extra generalization optimization. As shown in Figure 10, Configanator shows similar average performance as Vanilla ML but exhibits significantly more performance variance. This is due to Configanator's method of aggregating samples by network class, resulting in overfitting when the number of samples is small. Our GAN-based design significantly reduces variance across CDN nodes, an essential feature for large-scale deployments that demand reliability in worst-case scenarios. This is potentially due to our tailored regularizers in the loss functions, which leverage domain knowledge to boost model robustness by promoting learning from a universal set of features. For instance, incorporating RSC improves average performance by encouraging diverse feature use, and our regularizer $L_{variance}$ reduces feature noises, thereby improving average prediction accuracies.

5.2 Implementation Framework Efficiency

Superiority of our offline-online decoupled inference. In Table 3, we compare our decoupled online-offline inference method with the baseline, which executes *serial per-request online inference*. In the experiment, we set 32 Nginx workers to fully utilize available CPUs of 32 cores on the machine, emulating a CDN node at maximum QPS. The baseline method incurs a 10417ns processing delay and handles a maximum of 7.6k QPS only, while our system significantly reduces the processing delay to 162 ns and achieves 18.4k maximum QPS, representing 64.30× and 2.42× improvements respectively. Consequently, our decoupled framework drastically cuts AI inference delays and substantially increases QPS capacity, which is critical for managing high user demand efficiently.

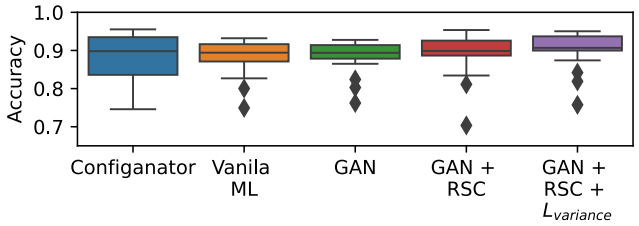

Figure 10: Ablation studies for evaluating different components of ALICCS and comparison with Configanator [32].

Table 3: Comparison with non-optimized online inference.

	Processing delay	Max. QPS
Baseline: online inference	10417 ns	7.6k
Online-offline decoupled	162 ns	18.4k
Improvement	64.30×	2.42×

CPU and Memory usage patterns. As Shown in Figure 11, the CPU overhead of ALICCS grows slowly with the number of connection requests, reaching a maximum of 200% at 17k QPS (refer to the left figure). This indicates our system requires no more than 2 cores, which is less than 1% (2 out of 256 cores) of the total CPU resources per CDN node, to handle peak traffic. Additionally, ALICCS's memory usage remains conservative, never exceeding 2.9GB (refer to the right figure), over a seven-day period in our measurements. These results underscore ALICCS's minimal resource impact on the overall CDN resource availability and its significant run-time efficiency. Additionally, our results also reveal interesting usage patterns in short video service: People tend to watch more short videos at noon, evidenced by the CPU usage being proportional to request volume and the 2 minor daily peak patterns; After a slight decrease early in the afternoon, viewship steadily climbs until reaching the peak at 20 o'clock.

5.3 QoE and Retransmission Improvement

In this section, we present the improvement in both QoE (rebuffer rate) and bandwidth cost (retransmission rate) achieved by ALICCS, serving the two major short video services, App #1 and App #2, in our Alibaba Cloud CDN.

Evaluation setup. To demonstrate the QoE improvements from deploying ALICCS, we conduct a month-long Randomized Control Test (RCT), comparing rebuffer rates with and without CCS. To approximate the random assignment of client connections to both versions, for each connection request, we apply the Cyclic Redundancy Check (CRC) [36] hash function on the client's IP address. Depending on whether the hash code is odd or even, the request is assigned to the system with our CCS strategy or the default system without CCS.

Baseline. The baseline system (default) uses CUBIC for all

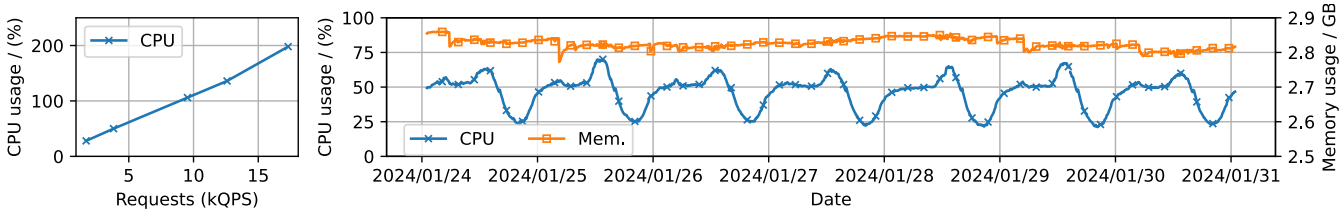

Figure 11: ALICCS's CPU overhead varying kQPS (left) and its seven-day usages of CPU and memory (right).

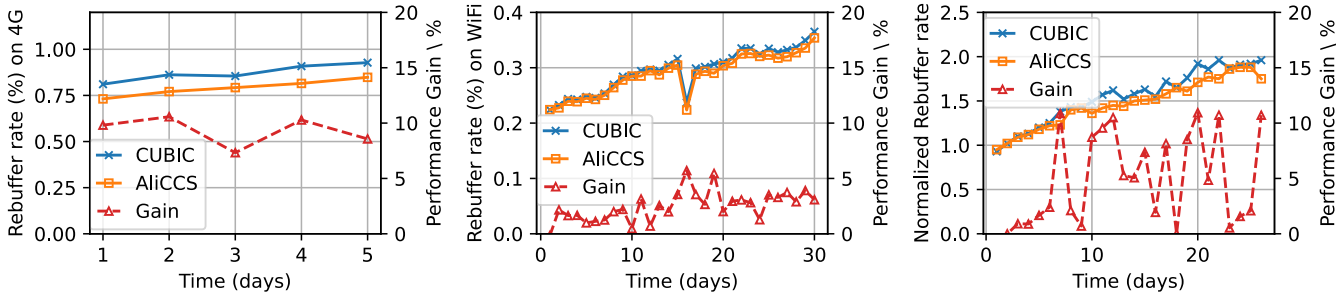

Figure 12: End-to-end rebuffer rate comparison of CUBIC and ALICCS.

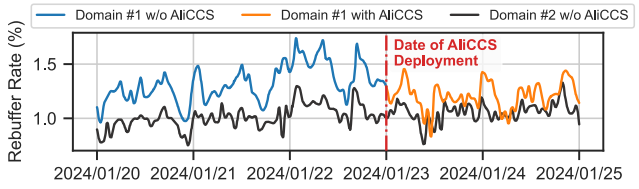

Figure 13: Rebuffer rates over time for two domain names with the same CDN nodes. The blue and orange curves represent the rebuffer rate for Domain #1 before and after ALICCS was applied. The black curve, associated with Domain #2, confirms stable CDN network conditions in this period of time.

requests given Wi-Fi's dominance in our CDN connections.

Real-world rebuffer rate improvement. As shown in Figure 12, ALICCS consistently achieves a lower end-to-end rebuffer rate, with improvements of 9.31% for 4G and 2.51% for Wi-Fi, along with a 4.76% gain across all connections *w.r.t.* deployment prior to ALICCS with all requests using CUBIC. This 5% reduction can boost our market edge in the fiercely competitive CDN industry, where even a 2%–3% difference in service quality matters, ensuring customer retention. Figure 13 zooms in on the results around the time when ALICCS was deployed, demonstrating the rebuffer rate reduction is attributed to the deployment of ALICCS.

Real-world retransmission rate improvement. As demonstrated in Figure 14, ALICCS achieves 59.24% improvement on App #1 and 61.28% on App #2, which translates into tens of million US dollars savings per year in terms of bandwidth cost for Alibaba Cloud CDN. To better understand the geographical diversity, we also investigated the performance gains across each province in China, as shown on the right side of Figure 14. ALICCS consistently achieves significantly lower retransmission rate in all provinces, with minimum, maximum, average, and standard deviation gains of 25.51%, 174.36%, 62.76%, and 36.28%, respectively. The results also lead to several interesting findings: Henan province tops the chart, possibly due to its high population density and heavy reliance on 4G networks; Performance gains in Guangdong province and Northeastern China exceed the average, in line with our observed widespread habit of streaming short videos on mobile devices in these areas. The smallest gain is seen in Qinghai province, likely attributed to inadequate 4G connectivity and lower population density.

5.4 Trace-driven Evaluation

Emulation setup. We also conduct an emulation study using short video traces collected over a day from one of Alibaba Cloud's highest-traffic CDN nodes. We compare ALICCS with two model-based CCS methods, Configanator [32] and Disco [47], both of which utilize the decision tree, as well as Pytheas [26], an online learning-based CCS (The rationale for the baseline selections is detailed in Appendix §E). We select CUBIC and BBR as CC candidates for evaluation due to their extensive testing, deployment, and worst-case assurance. Additionally, we construct the *best CCS* based on our trace, named Oracle, as a benchmark for CCS algorithm comparisons. We also define an aggregate QoE function, defined as a linear combination of rebuffer and retransmission rates, *i.e.*, $QoE = 1-\alpha \cdot rebuf - (1-\alpha) \cdot retrans$. Given our primary focus is on rebuffer rate over transmission costs, we set $\alpha = 0.8$ to prioritize minimizing stalls during short video streaming. Our emulation study employs a time-window-based mechanism [25, 27], where we construct unbiased estimates of CC's *outcomes*, *i.e.*, *QoE*, rebuffer rate, and retransmission rate metrics. For each /24 IP prefix group, we assign a time window for each CC to collect its corresponding outcomes. Oracle selects the CC with the best average *QoE* at the end of each window for each /24 IP prefix group. To simulate any

(a) QoE in good (right) and poor (left) network conditions. **(b)** Rebuffer rate. **(c)** Retransmission rate.

Figure 15: End-to-end improvement achieved by ALICCS in the trace-driven emulation.

algorithm's outcomes for CCs, including those that are not actually adopted by the real-world policy at a given timestamp in our trace, we use the average outcomes at historical times where the same CC is chosen under the same IP prefix group and network type.

Comparison with CCS state-of-the-arts. As shown in Figure 15a, all algorithms perform similarly in high QoE regions (right), *i.e.,* good network conditions where CC choice has minimal impact. In contrast, ALICCS performs notably well in low QoE regions (left), *i.e.,* impaired conditions. For QoE metrics like rebuffer rate, samples from poor network conditions disproportionately affect the average, underscoring ALICCS's advantage in low QoE regions. We then compare baseline performance under poor network conditions. Figure 15b shows that ALICCS *achieves a 4.54% to 30.80% lower rebuffer rate in the 85th percentile and beyond.* In contrast, Configanator and Disco exhibit higher rebuffer rates, as they overfit to good network conditions, neglecting the importance of edge cases with poor network scenarios. Meanwhile, Pytheas performs sub-optimally due to the inherent exploration required during network probing. Figure 15c shows the retransmission rate results. While ALICCS slightly increases retransmissions to reduce rebuffering, it outperforms Configanator, Disco, and Pytheas in the long-tail distribution, achieving a 1.74% to 25.24% lower retransmission rate. While Pytheas achieves comparable performance to ALICCS, estimating its reward function (*e.g.,* rebuffer rates) in real-time poses significant challenges and could incur additional computational overhead compared to ALICCS.

6 Related Work

Congestion control (CC) is a longstanding and significant topic, featuring a multitude of meticulously designed CCs, including CUBIC [20], BBR [12], and Reno [23].

Automatic CC Configuration. Recent studies propose machine-generated CCs and automatic parameter adjustments, highlighting that handwritten CC policies are effective only in limited contexts. Remy [45] utilizes offline optimization to generate a new CC by searching from a certain design space, followed by Copa [9] with more theoretical insights. CherryPick [8] employs Bayesian Optimization, while CFA [25] exploits domain-specific insights. Such methods fail to leverage large-scale data available on CDNs, potentially limiting their accuracy and generalization performance.

Learning-based CC parameter tuning. To increase generalizability, ML has been adopted to adjust CC parameters. For instance, Orca [6], Aurora [24], Libra [15], and TCP-RL [33] adopts RL with handcrafted reward functions for learning parameters like congestion windows, sending rates, etc. A few others adopt online learning but generally favor scenarios with i.i.d. network and/or CC characteristics. For example, Pytheas [26] applies multi-armed bandits (MAB), Configanator [32] integrates MAB with decision trees, and PCC vivace [14] utilizes gradient-based online learning. Recent works also adopt imitation learning, *e.g.,* DuGu [21] and Muses [51]. Such methods often overlook crucial worst-case scenarios in production CDN. ALICCS, instead, uses GAN-based model to balance performance across scenarios and

tackles the often-overlooked inference latency.

Learning-based CCS. Recent works have advocated CCS, *i.e.,* selecting the best CC among existing schemes. Specifically, Rein [13] uses data-driven methods to mitigate the CC transitioning overhead. Disco [47] and Antelope [52] leverage RL-inspired reward functions, demonstrating the advantage of CCS over CC tuning. OPSBC [50] combines traditional flow scheduling methods with MAB-based CCS. Sage [49] employs offline DRL to learn a new CC from traces, despite the complexity in feedback collection and high training cost due to a large state-action space. DPO [1] from Akamai represents an industrial effort to optimize CCS. Unlike ALICCS, these works do not present large-scale network experimental results, nor do they incorporate CDN domain knowledge.

Domain adaptation aims to preserve model performance on a target domain with limited data by applying knowledge from a source domain, and has been applied in various networking problems. For instance, Genet [46] applies curriculum learning for network adaptation. AWARE [37] uses meta-learning and bootstrapping for cloud auto-scaling. Other works leverage knowledge from simulation settings [41] or smaller-scale networks [44]. These works shed light on our work, albeit from a high-level perspective. We instead adopt GAN and Causal Graphical Model (CGM), tailoring our design specifically for short video workloads and production CDNs. Our solution is deeply rooted in CDN-specific domain knowledge.

7 Discussion

Do the observations driving ALICCS' design remain valuable beyond the scope of short video services? We believe most of our measurement insights extend beyond short videos and can be significant for the broader community. Notably, Observations I, III, and IV in §2.3—highlighting the variability in CCs' advantages, the impact of rate limiting, and the dynamics of network types—apply in general and inform further research on intelligent CCS design for diverse services. Additionally, our lessons in §4.2 on data cleaning, distributed inference, IPv6 benefits, and the fallback strategy provide insights for designing ML-based CDN systems. However, Observation II on correlation between network types and the best CCS and the lesson on throughput stability, are more specific to short video contexts, which is likely tied to the low traffic volume of short videos and the dependency on rebuffer rate for QoE.

Can ALICCS' design be effectively applied outside of short video domain or Alibaba Cloud's CDN? Our GAN-based model (§3.1), which learns uniform feature representations across IP prefixes, can be applied to CCS prediction for any service, provided that there is sufficient A/B test data with relevant labels (*i.e.,* best CCS under an IP prefix). The interpretation technique (§3.2) can aid model debugging of any classification task. Moreover, the distributed inference pipeline (§3.3) should be widely applicable to many ML-based CDN systems to reduce latency with a few assumptions: the input/output features of ML model are temporally stable and similar under the IP prefix, which are commonly adopted in existing works [26, 32]. However, it is noteworthy that, as rate limiting affects CCS (§2.3), ISP policy differences may impact ALICCS' performance gains in other networks.

Does network contention among clients degrade ALICCS' prediction accuracy? ALICCS uses the GAN model to achieve balanced accuracy across diverse conditions, including contention. In fact, ALICCS outperforms existing works by reducing accuracy variance and 95th percentile rebuffer rate, likely associated with impaired conditions (see Figures 10 and 15). However, ALICCS does not strictly optimize accuracy uniformity, as we find this could degrade overall accuracy significantly. Instead, we fine-tune λ_1 in the training loss to balance accuracy uniformity and overall accuracy.

ALICCS's reliance on pre-deployment test and domain knowledge: The success of framing CCS as an ML classification task relies heavily on comprehensive pre-deployment tests and domain knowledge to identify a strong link between network types and best CCS. This framework eliminates the need for acquiring short video QoE training data directly from content providers. However, it is not always straightforward, for a new scenario, to establish a clear connection between model predictions and desired outcomes. Our approach, despite avoiding continuous observations and handcrafted reward functions like in RL approaches, demands deep domain knowledge and insightful observations.

8 Conclusion

In this paper, we introduce ALICCS, the first production-optimized CCS approach that has served Alibaba Cloud CDN for over one year. ALICCS exploits our insights from large-scale measurements that reveal contrasting CC performances for short video services in varying network access types. It employs a domain-specific ML model for scalability and generalizability across numerous CDN nodes and changing network conditions, with an efficient inference pipeline for runtime performance. Extensive results from our production CDN demonstrate that ALICCS achieves significant retransmission rate reduction and enhanced QoE for short video services, outperforming advanced ML approaches and the default rule-based CC. We plan to explore combining CCS with protocol parameter tuning in the future and assess whether this integration can yield further QoE improvements.

Appendices

Appendices are supporting material that has not been peer-reviewed.

A Methodology to Conduct A/B Test Comparing CUBIC and BBR

To conduct a fair A/B test to compare performance of CUBIC and BBR in short video services, for each new connection from a specific partner app, we hash the request's IP using CRC algorithm to randomly map it to either the CUBIC or BBR group, ensuring a fair workload and network environment. The measurement period lasted around two weeks, with average data collected on a regional and daily basis. We have checked and confirmed the consistency of the results over this period. To further valid the difference we observe is due to CC's assignment rather than inherent difference between the group, we have also reversed the A/B assignment (IP assigned to group A now assigned to group B and vice versa) for about another two weeks, and the results are consistent with the first test, which validates the fairness of A/B test and the difference we observed is due to CC's assignment.

B Input Features of Our ML Model

Our CDN network collects several dozens of metrics to support a wide range of applications and services. Among these metrics, we carefully pick twelve of them as input features for our ML model, as shown in Table 4.

Table 4: Input Features for the ML Model

Feature	Description
mss	TCP maximum segment size
connection_time	TCP handshake time
init_snd_wnd	receiver initially advertised TCP window
min_rtt	minimum RTT in a TCP connection
max_snd_wnd	TCP receiver advertised maximum window size
min_snd_wnd	TCP receiver advertised minimum window size
min_rtt_variance	min RTT variance
max_rtt_variance	max RTT variance
min_rto	minimum retransmission timeout
min_srtt	max smoothed version of RTT
max_srtt	max smoothed version of RTT
max_cwnd	maximum congestion window of a TCP sender

C Handle Non-1:1 Mapping between Connections and Network Types

When there is a connection migration from one network type to another, there could be non-1:1 mapping between Connections and Network Types. We dicuss potential solutions to it. In case the migration is transparent to CDN server (e.g., the migration is behind a mobile proxy server), we find changing the CC for a live connection is a heavy engineering task requiring significant kernel modifications, and such cases are in minority. So we decide they will not be handled by ALICCS. In case the migration is visible to CDN server, like in case where QUIC or MPTCP is applied, ALICCS can be applied independently for each sub-connection, leveraging two IPs to find the best CC for each sub-connection in its cache.

D Hyper Parameter Tuning and Experiences

We report below some details on the engineering decisions and parameter choices. We explain as well the key considerations and the rationale behind our decisions.

Hyper parameters in the loss function for DL model training. We aim to strike a balance between reducing the variability of prediction performance across CDN nodes and maximizing overall average prediction accuracy. Our experiments show that increasing the parameters λ_1, λ_2 encourages the model to extract more uniform representations, thereby reducing the variability of prediction accuracy across CDN nodes. However, strictly minimizing variability could hurt the over all average accuracy. To address this, we perform a grid search to determine the values of λ_1 and λ_2, achieving minimal variability of accuracy without significantly compromising overall accuracy.

Other hyperparameters in DL model design. While the best hyperparameter configurations provided in existing literature on GANs can serve as a a starting point, we observe that they do not deliver the expected performance boost in our scenario. This likely reflects domain differences between areas like computer vision and networking. Consequently, we rely on performing a grid search to obtain the best-performing hyperparameter set for AliCCS, tailored to its unique requirements.

Inference pipeline at CDN Nodes. To balance computational efficiency and prediction accuracy, we opted to decide update the cache on an hourly basis. For our IP prefix aggregation strategy, we employ differentiated thresholds: For IP prefixes with high request volumes, we set high thresholds to make the conditions more strict, in order to avoid incorrect predictions affecting a large number of requests. For IP prefixes with low request volumes, we apply low thresholds to encourage aggregation, reducing memory usage without significantly impacting prediction accuracy.

E Method Selection Rationale for Trace-driven Evaluation

In our trace-driven evaluation, several state-of-the-art methods were not selected for the following reasons. Adapting Sage [49], originally designed for new CC learning to a CCS scheme, presents challenges due to its inefficiencies for production CDNs. The impracticality stems from the extensive training data required, such as rebuffer rates and bandwidth costs, across various state configurations from short video providers, which is not applicable for us as a CDN provider.

Algorithm 1 Prediction Results Aggregation Algorithm

Input: Pairs of IP and predicted cc: $\{(IP_i, pred_res_i)\}_{i=1}^{m}$
Output: $hashtable : IP_prefix \rightarrow (pred_res, purity)$
Input Parameters: p_thresh_16, p_thresh_24,
// step1: aggregate at prefix /16
Initialize $D \leftarrow \{(IP_i, pred_res_i)\}_{i=1}^{m}$
$H \leftarrow$ AGGREGATE_AT_PREFIX_LEN$(D, 16)$
// step2: for prefix without sufficient purity, expand at prefix /24
$D_expand_24 \leftarrow \emptyset$
for all prefix_16 in $H.keys()$ **do**
    if $H[prefix_16].purity < p_thresh_16$ **then**
        $D_tmp \leftarrow$ { $IP_i, pred_res_i \mid IP_i$ matches prefix_16 }
        $D_expand_24 \leftarrow D_expand_24 \cup D_tmp$
        remove prefix_16 from H
    end if
end for
// step3: for prefix without sufficient purity, expand at prefix /32
$H_24 \leftarrow$ AGGREGATE_AT_PREFIX_LEN$(D_expand_24, 24)$
$D_expand_32 \leftarrow \emptyset$
for all prefix_24 in $H_24.keys()$ **do**
    if $H_24[prefix_24].purity < purity_thresh_24$ **then**
        $D_tmp \leftarrow$ (find all data under prefix_24)
        $D_expand_32 \leftarrow D_expand_32 \cup D_tmp$
        Delete prefix_24 from H_24
    end if
end for
$H_32 \leftarrow$ AGGREGATE_AT_PREFIX_LEN$(D_expand_32, 32)$
// merge the 3 hash tables
$H \leftarrow H \cup H_24 \cup H_32$
return H

procedure AGGREGATE_AT_PREFIX_LEN(D, $prefix_len$)
    Input: D: a subset of Pairs of IP and prediction result
        $prefix_len$: the length of prefix to aggregate at
    Output: $Map : IP_prefix \rightarrow (pred_res, purity)$
    Initialize $H \leftarrow \emptyset$ ▷ a 2-level hashtable
    for all $(IP, pred)$ in D **do**
        $ip_prefix \leftarrow$ COMPUTE_PREFIX$(IP, prefix_len)$
        $H[ip_prefix][pred] \leftarrow H[ip_prefix][pred] + 1$
    end for
    Initialize $H_res \leftarrow \emptyset$
    for all ip_prefix in $H.keys()$ **do**
        $pred_label \leftarrow \arg\max_{pred}(H[ip_prefix][pred])$
        $purity \leftarrow (fraction of pred_label under ip_prefix)$
        $H_res[ip_prefix].pred_res \leftarrow pred_res$
        $H_res[ip_prefix].purity \leftarrow purity$
    end for
    return H_res
end procedure

Both Disco [47] and Antelope [52] employ tree-based ML models for CCS prediction, with Antelope permitting mid-flow CC switching. However, in our trace-driven emulation where CCS is allowed only on a per-flow basis, the two approaches become nearly identical. Therefore, we implement only Disco as a representative model. Rein [13] was excluded from our comparative study due to its closed-source nature and its heuristic rules not being tailored for our short video service context.

F Prefix Aggregation Algorithm

We illustrate the prefix aggregation algorithm with a flow chart shown in Figure 16 as well as with Algorithm 1. Initially, we aggregate IP prefixes at the /16 level using a Trie and then assess the purity of this aggregation. Purity is defined as the ratio of the number of IP addresses with the most common label to the total number of IP addresses within the range. A high purity indicates that using the most common label to represent all IPs within the range results in minimal accuracy loss. If the purity is insufficient, we further refine the aggregation to /24 and /32 prefixes, as detailed in Steps 2 and 3 of the algorithm.

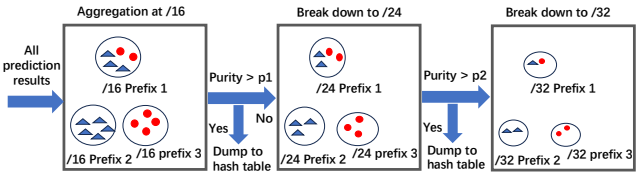

Figure 16: Trie-based prefix aggregation algorithm.

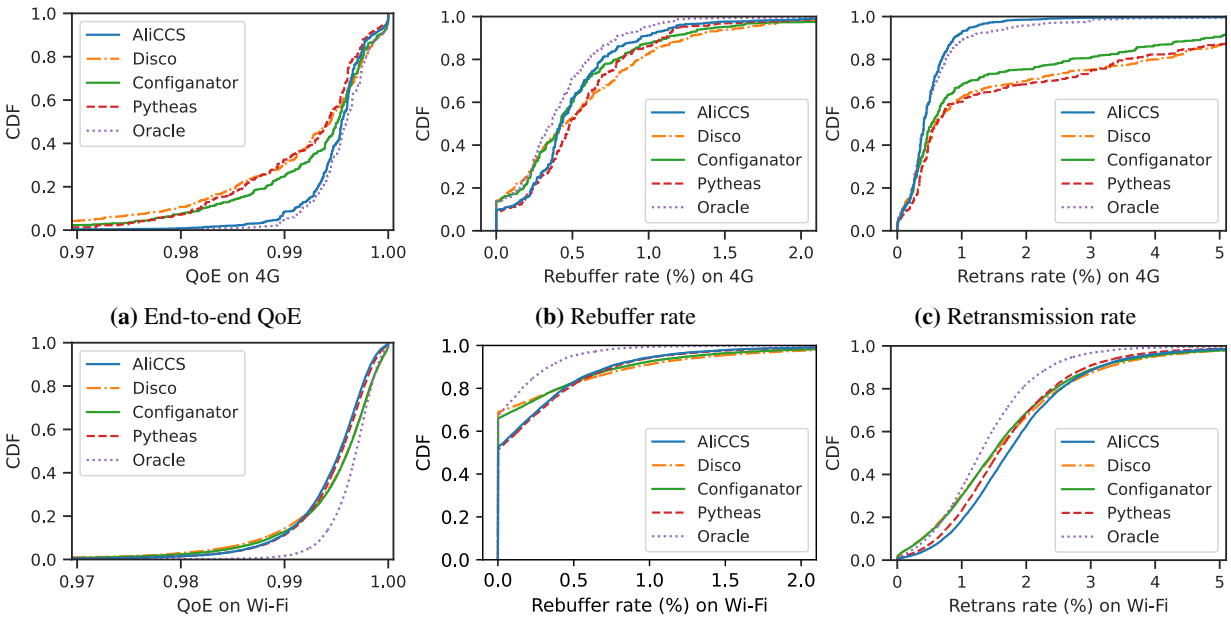
G End-to-End Performance

Figure 17 shows the end-to-end performance comparison of WiFi connections and 4G connections in terms of QoE, rebuffer rate, and retransmission rate.



(a) End-to-end QoE **(b)** Rebuffer rate **(c)** Retransmission rate

(d) End-to-end QoE **(e)** Rebuffer rate **(f)** Retransmission rate

Figure 17: The enhancement of ALICCS in trace-driven emulation is shown in terms of QoE, rebuffer rate, and retransmission rate. Figures 17a–17c show the results for 4G connections, while Figures 17d–17f show the results for Wi-Fi connections.

GPU-Disaggregated Serving for Deep Learning Recommendation Models at Scale

Abstract

Online recommender systems use deep learning recommendation models (DLRMs) to provide accurate, personalized recommendations to improve customer experience. However, efficiently provisioning DLRM services at scale is challenging. DLRMs exhibit distinct resource usage patterns: they require a large number of CPU cores and a tremendous amount of memory, but only a small number of GPUs. Running them in multi-GPU servers quickly exhausts the servers' CPU and memory resources, leaving a large number of unallocated GPUs stranded, unable to utilize by other tasks.

This paper describes Prism, a production DLRM serving system that eliminates GPU fragmentation by means of resource disaggregation. In Prism, a fleet of CPU nodes (CNs) interconnect with a cluster of heterogeneous GPU nodes (HNs) through RDMA, leading to two disaggregated resource pools that can independently scale. Prism automatically divides DLRMs into CPU- and GPU-intensive subgraphs and schedules them on CNs and HNs for disaggregated serving. Prism employs various techniques to minimize the latency overhead caused by disaggregation, including optimal graph partitioning, topology-aware resource management, and SLO-aware communication scheduling. Evaluations show that Prism effectively reduces CPU and GPU fragmentation by 53% and 27% in a crowded GPU cluster. During seasonal promotion events, it efficiently enables capacity loaning from training clusters, saving over 90% of GPUs. Prism has been deployed in production clusters for over two years and now runs on over 10k GPUs.

1 Introduction

Personalized recommender systems are the key infrastructure for many user-facing, revenue-generating web services, such as content streaming, e-commerce, social networks, and web search [12, 21, 47, 58]. These systems use deep learning recommendation models (DLRMs) to provide accurate, personalized recommendations to improve customer experience and increase user engagement. DLRM serving consumes the majority of the inference resources in today's AI cloud, with top recommendation models account for more than 79% of AI cycles, according to Meta [26].

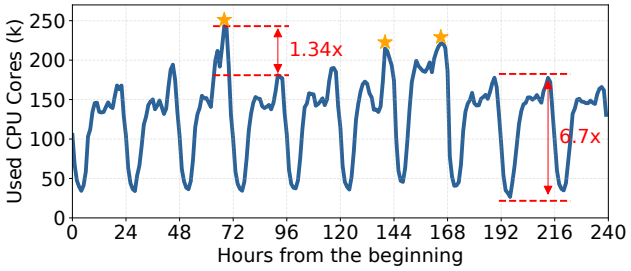

Figure 1: The CPU demands of DLRM services exhibit *daily* and *seasonal* variations; GPU demands follow the same trend. Trace collected from a production cluster, including three (starred) e-commerce promotion events.

However, serving DLRMs at scale faces aggravating challenges. DLRM serving has a stringent latency service-level objective (SLO), usually on the scale of tens of millisecond per request. In the meantime, DLRM serving needs to handle frequent spikes in demand. Meeting the latency SLOs often means provisioning for the peak load, which can be significantly higher than the average [28, 39]. Figure 1 illustrates the resource demands of Alibaba's DLRM services in a production cluster. We observe a distinct diurnal pattern with the peak-to-valley ratio over 6×; during seasonal promotion events, the peak load can be 1.3× higher than the regular peaks, which is in line with the previous report [68]. Provisioning for the peak load at such scale results in significant underutilization, making it economically unviable.

To reduce overprovisioning, a better strategy is to provision for the average load and enable *capacity loaning* during load spikes. Large companies like Alibaba own multiple purpose-specific infrastructures: some for training and the others for inference. When DLRM serving is in peak hours, it can temporarily loan GPU servers from training clusters as training jobs are less latency-sensitive and can tolerate interruptions. However, there is a mismatch between server configuration and DLRM's resource demand. Unlike training tasks that demand extensive GPU cycles, recommendation models exhibit low compute-intensity and are not bottlenecked on GPU. Instead, they perform sparse computations such as embedding [36, 37], which requires abundant memory for storing embedding tables and many CPU cores for table look-up and

pooling operations [26, 32]. As a result, running recommendation models in training servers quickly exhausts the servers' CPU and memory resources, leaving a large number of unallocated GPUs stranded. In our cluster, a typical DLRM service requests 48 CPUs and 1 GPU, while training servers commonly have ⟨96 CPUs, 8 GPUs⟩ (Figure 4). Deploying two DLRM inference instances occupies all CPUs on the host, leaving 6 unallocated GPUs unable to utilize by other tasks.

This paper presents Prism, a production DLRM serving system that addresses the resource mismatch problem with *GPU disaggregation*. Prism runs on a shared infrastructure where a fleet of CPU nodes (CNs) interconnect with a cluster of heterogeneous GPU nodes (HNs) through a high-speed RDMA network. Each CN has a large number of CPU cores and high memory but no GPU, while each HN is a typical training server with multiple GPUs but only a modest amount of CPU and memory resources. This infrastructure breaks down a cluster of monolithic servers with fixed configurations into two *disaggregated resource pools*, where CNs provide rich CPU and memory resources while HNs provide abundant GPUs. The two resource pools can be independently scaled to match the changing demands of dynamic workloads. Given a DLRM, Prism automatically divides its compute graph into two subgraphs, one containing CPU- and memory-intensive operators and the other GPU-intensive. The system then schedules the two subgraphs on the selected CN and HN for disaggregated serving and returns the results to users.

This paper describes the challenges, techniques, and lessons learned in building a disaggregated DLRM system at a production scale. First, the disaggregation needs to be *transparent to model owners*. Manually re-architecting models to a disaggregated version raises the risk of accuracy degradation and requires extra efforts from their owners, thus undesirable. Second, the system should *scale to thousands of servers* to handle excessive load spikes. Given the surging traffic, it should promptly schedule workloads to a large fleet of servers to achieve dramatic total throughput in a short period of time. Third, the system should *meet the stringent latency SLOs* of DLRM serving, in the presence of non-trivial communication overhead between CNs and HNs due to GPU disaggregation. Prism tackles these challenges with three major components: a disaggregation-optimized real-time prediction (RTP) framework that optimally partitions compute graphs between CNs and HNs (§4.1), a topology-aware resource manager that minimizes inter- and intra-server communication overhead (§4.2), and SLO-aware communication scheduling that ensures disaggregated serving within the target latency SLOs (§4.3).

Prism has been pilot deployed in late 2022 as the underlying infrastructure for a small number of production online recommendation services, with serving scale continuously increasing over the past two years. As of January 2025, Prism runs on over 10k GPUs, successfully decoupling the CPU and GPU computation demands of DLRMs without impacting service performance. Evaluations show that in daily high-allocation GPU clusters, Prism effectively reduces CPU fragmentation by 53% and GPU fragmentation by 27%; during seasonal promotion events, Prism efficiently enables capacity loaning from training clusters, saving over 90% of GPUs (§5). Our primary contributions are as follows.

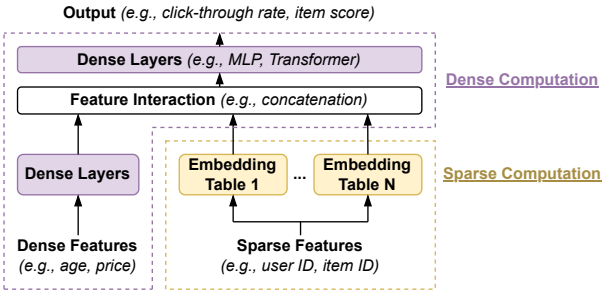

Figure 2: An architecture overview of DLRM.

- We identify the challenges in resource provisioning when deploying elastic DLRM services at a production scale and motivate the need for GPU-disaggregated serving.
- We design and implement Prism to harvest resources from CPU nodes and heterogeneous GPU nodes by means of disaggregated serving, alleviating the resource mismatch between the server configurations and DLRMs' resource demands, while still meeting latency SLOs.
- We evaluate Prism in production and demonstrate that it can effectively reduce resource fragmentation without compromising service performance, enabling efficient capacity loaning during promotion events.

We have released a production DLRM serving trace[1] as part of the Alibaba cluster trace program [3].

2 Background and Motivation

2.1 A Primer on DLRM

Modern recommendation models have a large feature set, separated into dense and sparse categories. Dense features, such as vectors and matrices, are processed by typical deep neural network layers, while sparse features are processed by indexing large embedding tables. Figure 2 illustrates a typical architecture of a DLRM [12, 47, 69]. The input comprises dense continuous features (e.g., user age and item price) and sparse categorical features (e.g., user ID and item ID). Sparse features are transformed into continuous embedding representations via a lookup operation in the embedding tables. These features are then fused and fed into a densely connected deep network, such as a multi-layer perceptron [12] or transformer [57], for prediction, eventually generating the model output, such as click-through rate or item score.

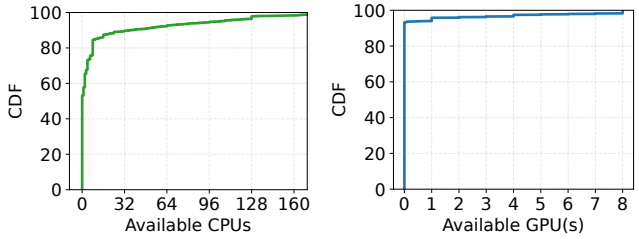

Figure 3: Resource allocation snapshot of a large-scale GPU cluster H with over 4k nodes, 640k CPU cores, and 11k GPUs.

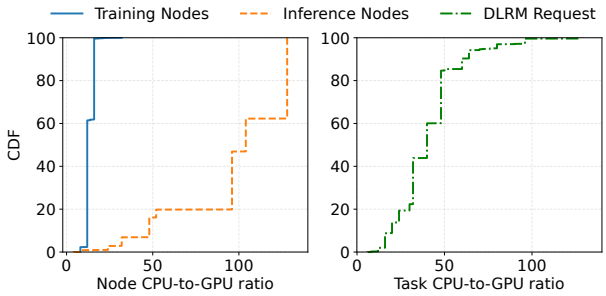

Figure 4: CDF of CPU-to-GPU ratio. The DLRM trace was collected over a period of one week from our production clusters, comprising of more than 25k instances.

DLRMs exhibit distinct computational and memory consumption characteristics compared to convolutional and recurrent neural networks [26, 30]. The embedding operations dominate the run-time of recommendation models. These operations are characterized by large embedding tables (typically on the order of tens to hundreds of gigabytes), low compute-intensity and little to no regularity, making them ill-suited to run on GPUs. In contrast, the model's dense network component is better executed on GPUs, which can achieve 10–44× speedup compared to running on CPUs, as shown in our experiments. Therefore, current DLRM serving systems decouple the sparse embedding lookup operations from dense computations. The former runs on a large number of CPUs, and the latter runs on a GPU.

2.2 Challenges in DLRM Provisioning

DLRM services serve a massive volume of requests with stringent latency SLOs and account for the majority of inference cycles in today's AI cloud [26]. These services feature dynamically changing requests with large *daily* and *seasonal* variations as shown in Figure 1. Instead of serving DLRMs in a dedicated cluster, which requires provisioning for the peak load and is economically unviable, at Alibaba we serve DLRMs along with other machine learning models in *shared clusters* in normal days; we additionally *loan* servers from training clusters to handle large load spikes during seasonal promotion events. However, this approach faces two challenges in practice.

C1: Resource fragmentation for daily DLRM serving. In shared clusters, frequently scaling DLRM provisioning based on the changing load results in severe resource fragmentation [64]. Figure 3 illustrates the distribution of available CPUs and GPUs of servers in a large GPU cluster, where both CPU and GPU allocation rates reach 90%. Despite having sufficient CPU and GPU quotas, DLRM service owners observe prolonged scheduling time or even scheduling failures [64]. From their perspective, the cluster has over 30k fragmented CPUs and more than 200 fragmented GPUs (detailed explanation in §5.4). The severe fragmentation is primarily due to the high CPU-to-GPU ratio of these inference instances (Figure 4, right), which cannot be accommodated using the servers' remaining resources. In practice, scheduling new DLRM instances often requires manually relocating running jobs to reduce fragmentation, which is time-consuming.

C2: Ineffective capacity loaning during seasonal load spikes. Throughout a year, Alibaba hosts several large-scale seasonal shopping festivals [68], during which DLRM services experience significant load spikes, exceeding the daily peak by more than 1.3× (Figure 1). To handle these transient, excessive load spikes, *capacity loaning* is often needed, which we elaborate as follows.

Production AI clouds are built from a large quantity of *heterogeneous servers* with configurations meant to support either training or inference tasks. Figure 4 (left) shows the distribution of the CPU-to-GPU ratio of the server nodes used for training and inference in a production cluster at Alibaba. In general, nodes suitable for training tasks are configured to have multiple advanced GPUs (e.g., 4 or 8 H800 GPUs) with high-speed interconnect (e.g., NVLink) but only a limited number of CPUs (e.g., 16 to 32 cores), thus having a low CPU-to-GPU ratio. In comparison, nodes optimized for inference tasks, especially DLRM serving, have a much higher CPU-to-GPU ratio, typically with a single GPU but a large number of CPU cores (e.g., 128 cores) to accelerate CPU-intensive operations, such as data preprocessing and embedding lookup. The presence of these heterogeneous servers essentially segregates a datacenter into two purpose-specific infrastructures, one for training and the other for inference. To improve utilization and reduce overprovisioning, capacity loaning between the two infrastructures should ideally be enabled. That is, when DLRM serving is in peak hours, it can temporarily loan training servers to handle excessive recommendation queries.

However, the mismatch between server configuration and resource demand renders capacity loaning ineffective. Figure 4 (right) shows the distribution of CPU-to-GPU ratio of the recommendation models deployed in our production clusters. Over 90% of DLRMs have CPU-to-GPU ratio greater

than 20, whereas *all* multi-GPU training nodes have a ratio below 20. As a result, running DLRMs on these training nodes quickly exhausts CPUs, leaving a large number of GPUs stranded, unable to utilize by other tasks.

2.3 GPU-Disaggregated DLRM Serving

Resource disaggregation [18, 23, 25, 53] holds tremendous promise in DLRM serving. This architecture allows decoupled independent scaling-out of CPUs and GPUs, thereby addressing the mismatch between server configuration and resource demands. Resource sharing is also made possible as GPU-intensive AI workloads, such as training, can run on the same infrastructure, together with recommendation models, significantly increasing the system utilization. Our design of a GPU-disaggregated DLRM inference service is motivated by two fundamental observations.

O1: Distinct characteristics of DLRMs. DLRMs exhibit a distinctive computational structure that naturally lends itself to graph partitioning based on operator-level resource affinity. Our analysis reveals that embedding table queries dominate CPU computation, while matrix multiplication accounts for the majority of GPU computational overhead (Figure 8). While DLRM services routinely update model parameters and embedding table values to reflect real-time user interaction, the underlying computational graph remains static. This architectural stability ensures that graph partitioning and disaggregation optimizations, once computed, remain optimal throughout the model's deployment lifecycle, eliminating the need for dynamic repartitioning.

O2: High-performance RDMA network. Modern RDMA network interface cards (RNICs) deliver bandwidth capabilities of 200–400 Gbps, matching or even surpassing that of PCIe 4.0 x16 interconnects (256 Gbps). RDMA's offload capabilities bypass the kernel networking stack, minimizing CPU overhead——a critical factor for inference workloads in disaggregated environments. Optimized RDMA networking can provide scalability, stability, and SLO guarantees for disaggregated inference scenarios (§5).

GPU disaggregation approaches. GPU disaggregation can be achieved using three approaches, as summarized in Figure 5. We compare these approaches and justify our choice.

1) API-level disaggregation: this approach intercepts program calls to CUDA APIs and redirects them to a remote GPU node for execution [2, 15, 16]. It requires only replacing the original CUDA library inside the container without any modification to the serving framework. However, its application agnostic nature offers little optimization opportunities. Future CUDA upgrades would also require considerable engineering effort in forward compatibility and performance tuning. Moreover, supporting heterogeneous AI accelerators (e.g., AMD GPUs) necessitates developing and maintaining distinct remoting layers for each platform.

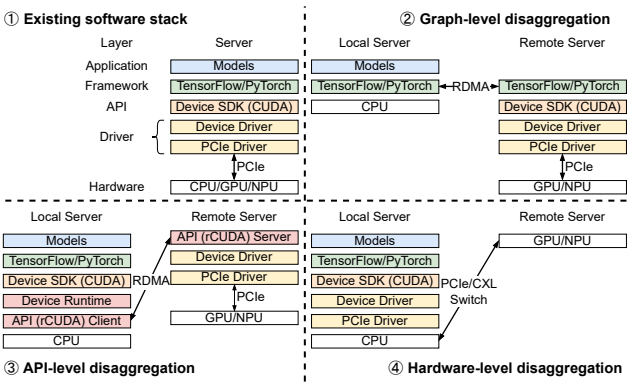

Figure 5: GPU disaggregation at different levels.

2) Hardware-level disaggregation: GPU disaggregation can be ideally enabled with specialized hardware, such as customized multi-hop PCIe switches [29, 42] and CXL technologies [1]. Hardware-level disaggregation requires no modification to software and incurs minimum I/O latency. However, it faces significant deployment barriers as it requires expensive infrastructure upgrade and customization. The disaggregation is also confined to a short distance (e.g., PCIe switches support disaggregation only within a rack).

3) Graph-level disaggregation: A DLRM is represented as a compute graph consisting of multiple operators running on CPU or GPU. Inspired by model parallelism, we can partition the compute graph into a CPU sub-graph and a GPU sub-graph (**O1**). The two sub-graphs can then be scheduled on selected CPU and GPU nodes for disaggregated execution, with communication over high-speed RDMA network (**O2**). Compared with the previous two approaches, graph-level disaggregation requires no specialized hardware and can achieve good performance with optimized partitioning, scheduling, and network transport. We hence consider it as a viable approach and base our system design on it.

3 Prism Overview

In this section, we present Prism, a large-scale DLRM system that enables GPU-disaggregated serving by means of graph partitioning. Prism has been deployed in our production clusters, serving as the underlying infrastructure for core recommendation services. As of January 2025, the system serves over 20k DLRM instances, utilizing more than 10k GPUs and 800k CPUs. As illustrated in Figure 6, Prism operates on a cluster where a fleet of heterogeneous GPU nodes (HNs) interconnects with a number of CPU nodes (CNs) via a high-speed RDMA network. A CN is configured with a large number of CPUs and high memory, while an HN is a multi-GPU node. This results in two disaggregated resource pools, a CPU pool provisioned by CNs and a GPU pool provisioned by HNs. Prism automatically partitions recommendation models for distributed inference on CNs and HNs.

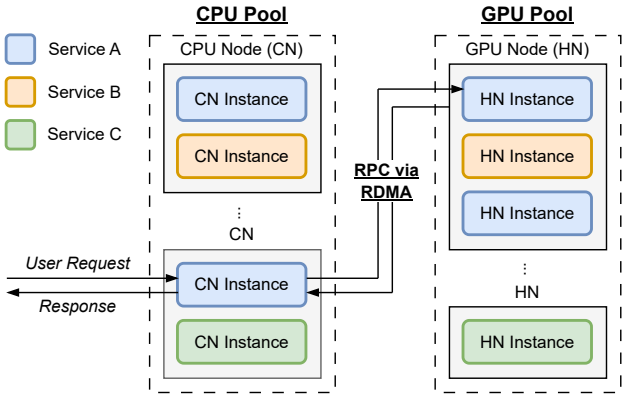

Figure 6: The cluster deployment of DLRM inference instances and request execution flow in Prism.

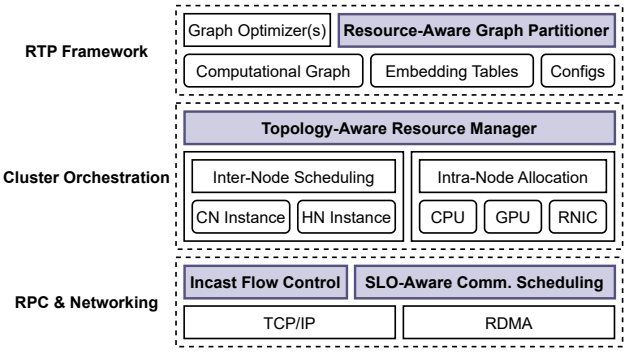

Figure 7: Prism overview and its key designs are in *purple*.

System architecture. Figure 7 provides an overview of Prism. The RTP framework (§4.1) takes input the compute graph, associated embedding tables, and configuration parameters (e.g., enabling/disabling custom optimizers). It divides a monolithic recommendation model into two subgraphs, one consisting of CPU-intensive operations and the other consisting of GPU-efficient operations. The resource manager (§4.2) then packages the two subgraphs into containerized CN and HN instances and places them onto the selected CN and HN nodes for disaggregated execution, by considering the network and node topology. The manager makes resource allocation decisions (e.g., CPUs, GPUs, RNICs) and dynamically scales CN and HN instances in response to the changing load. Once the CN and HN instances are placed on nodes, the communication scheduler establishes RDMA connections and performs incast control and SLO-aware request scheduling to meet latency SLOs (§4.3).

Execution flow. As illustrated in Figure 6, user requests are first routed to a frontend CN instances for embedding lookups and other CPU-intensive computations. Intermediate tensors are then transferred to the remote HN instance on a GPU node through RPCs over the RDMA network. After the HN instance returns results, the CN instance performs post-processing before sending the response to the user.

4 Prism Design

Prism is designed to meet three key requirements:

- *Transparency to model development and optimization:* For production deployment, it is important to make disaggregation transparent to model developers, without their cooperation to modify model architecture or implementation. It is hence essential to enable automated graph partitioning to support disaggregated inference for various recommendation models, without affecting users or invalidating original graph optimization strategies (§4.1).
- *Compliance to SLOs:* Disaggregation inevitably introduces performance overheads, necessitating a joint optimization approach across various system components to minimize the impact on service performance. For example, the compute graph must be judiciously partitioned and optimized to effectively separate the resource usage of different operators (§4.1). Furthermore, the node placement and resource allocation of instances require careful consideration to ensure good performance (§4.2).
- *Scalability*. In contrast to traditional recommendation services, GPU disaggregation introduces non-trivial communication overhead. Our system must ensure service performance remains unaffected, even under conditions of multiple server instances and high traffic loads in production environments (§4.3).

4.1 Resource-Aware Graph Partitioner

The most critical *first* step in decoupling CPU and GPU computation is to partition a model's original computation graph into two subgraphs, which are executed respectively by the CN and HN instances.

Retrofit for the existing workflow. In production DLRM systems, the recommendation framework provides model developers with a plethora of optional optimization techniques (e.g., JIT fusion, CUDA Graphs [22]) to enable or disable based on the model characteristics. These optimizers are typically applied in a *sequential manner*, iteratively rewriting the original computation graph and ultimately generating an optimized computation graph tailored for deployment. The

primary objective of our disaggregation approach is to minimize the impact on the service's inference performance. Thus, Prism introduces *graph partitioning* and *disaggregation optimization* as the final stages in the existing DLRM workflow, strategically waiting for all user-specified optimization strategies to be completed before meticulously reconstructing the computation graph for disaggregated serving.

Operator analysis of DLRMs. To gain deeper insights into the computational characteristics of DLRM services, we conducted a comprehensive profiling of the operators, as illustrated in Figure 8. The results unveil two key observations that serve as the foundation for our *resource-aware graph partitioning* algorithm: (1) Embedding lookup operators exhibit a dominant presence, accounting for over 70% of the CPU computation (Figure 8, left); consequently, we designate all embedding lookup-related operators as `CPU-intensive operators`. (2) Matrix multiplication computations emerge as the most significant contributor to GPU computation time. In more advanced models [11] incorporating transformers [57], the computation ratio of attention layers can even reach a staggering 40% (Figure 8, right); we categorize these operators as `GPU-efficient operators`.

Device placement. Leveraging the aforementioned observations, the RTP framework employs a heuristic approach to partition the GPU subgraph that necessitates computation on the HN instance: (1) `GPU-efficient operators` are selected as the initial seeds for the partitioning process. (2) Commencing from the seed operators, a Depth-First Search (DFS) coloring algorithm is simultaneously executed from both upstream and downstream directions, aiming to encompass the maximum number of operators feasible for GPU computation. (3) The DFS coloring process is terminated upon encountering `CPU-intensive operators`, ensuring an optimal balance between CPU and GPU utilization.

Optimization for disaggregation. To enhance the efficiency of distributed graph execution, we introduce two complementary strategies that achieve up to 50% reduction in inter-node data transfer volume: (1) We preserve and optimize constant subgraph execution. While constant operations constitute 10–20% of GPU computational workload (Figure 8, right), their optimization potential is often compromised when fragmented across different servers. By consolidating constant operations onto the HN instance, we maintain the structural integrity of constant subgraphs. This ensures that constant computations are executed exactly once and their results are cached for subsequent operations, eliminating redundant data transfers. (2) In cases where multiple derivative tensors are generated from a common source tensor and subsequently transmitted from the CN instance to the HN instance, we employ a size-aware transfer strategy. When derivative tensors' aggregate size exceeds the ancestor's magnitude, we optimize communication patterns by transmitting only the source tensor, thereby reducing the network bandwidth requirements.

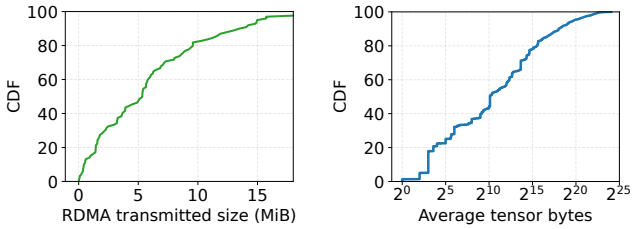

Figure 9: Statistical analysis of data transfer for top 100 disaggregated DLRM inference services. **Left**: Total volume of RDMA data transfers from a CN instance to a HN instance; **Right**: Distribution of transferred tensor sizes.

RPC for remote GPU execution. We develop a unified operator called `FusedGraphOp` for RPCs. This operator aggregates all tensors that require transmission from the CN instance and sends the requests to one of the remote HN instances. Upon completion of the remote GPU computation, the results are returned, marking the conclusion of the entire inference process. To minimize memory copies between the computational framework (e.g., TensorFlow) and the RPC system, we establish a unified memory pool where `FusedGraphOp` flags tensors requiring transmission and relinquishes control to the RPC system. By leveraging GPUDirect RDMA [7], these data are already stored in the RPC system's memory buffer upon creation, realizing defacto *zero-copy data transmission* [27, 67]. Experimental results demonstrate that this approach can yield performance improvements of 19–181%. The RPC system adaptively balances load using real-time processing latency of each HN instance [13].

Production deployment. We deploy Prism to evaluate DLRMs in production. In 80% of recommendation services, the data transfer size via the RDMA network is less than 10 MiB (Figure 9, left). Note that we focus on unidirectional data transfer from the CN instance to the HN instance, as the data sent back is typically *negligible* (e.g., approximately 100 KiB). The results presented in §5 demonstrate that, at this scale of transfer size, disaggregated inference can effectively separate resource requirements without compromising service performance. Interestingly, we observe a *bimodal* distribution in the size of transferred tensors. Only 11% of the tensors exceed 0.25 MiB, while a significant 44% of the tensors are smaller than 1 KiB (Figure 9, right). These findings motivate us to adopt a size-based approach when transferring tensors. For small tensors (e.g., $\leq$ 4 KiB), we directly employ RDMA send/recv operations, whereas for large tensors, we utilize RDMA write operations.

Implementation. Our implementation is built upon an optimized internal version of TensorFlow v1.12 [9], comprising approximately 2k lines of Python code for graph partitioning and disaggregation optimization, along with 3,500 lines of C++ code for the `FusedGraphOp` functionality. Prism rewrites

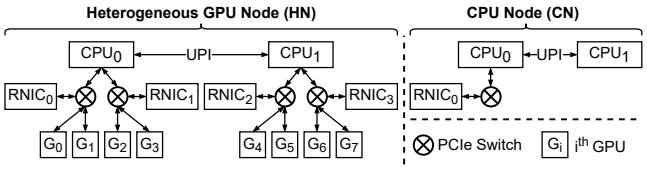

Figure 10: The hardware topology of a typical HN and CN.

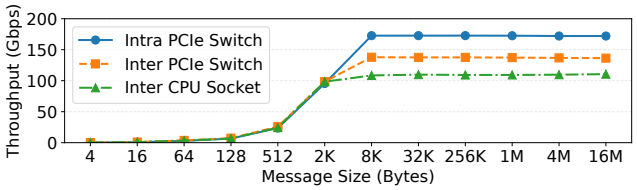

Figure 11: Performance comparison of GPUDirect RDMA across different GPU-RNIC interconnect topologies.

Algorithm 1: Topology-aware resource scheduling

Input: Cluster N, DLRM application id app, CN/HN instance $role$, resource requirements (cpu_num, gpu_num, mem_size, $disk_size$), deployment density d
Output: Selected node $node_id$, allocated resources (cpu_id, gpu_id, $rnic_id$)

1 Initialize node set $S \leftarrow \varnothing$
2 $N_{pod} \leftarrow N$.filter($N.cluster_topology, app$) ▷ Retain all nodes in the pod that runs the same app's existing instances
3 $N_{asw} \leftarrow$ get_asw_nodes(N_{pod}, app) ▷ Get nodes from ASWs with maximum instances
4 **parallel for** *node* $n \in N_{asw}$ **do**
5 **if** (*Insufficient resources* $\|$ $get_density(n, app) \geq d$) **then**
6 Return ▷ Filter out unavailable nodes
7 `// Prefer the shortest CPU/GPU-to-RNIC path`
8 **if** $role$ = *HN* **then**
9 $(cpu_id, gpu_id, rnic_id, topo_score) \leftarrow$ calc($n.topology$, GPU, RNIC, gpu_num)
10 **else if** $role$ = *CN* **then**
11 $(cpu_id, \varnothing, rnic_id, topo_score) \leftarrow$ calc($n.topology$, CPU, RNIC, cpu_num)
12 $S \leftarrow S \cup (n, cpu_id, gpu_id, rnic_id, topo_score)$
13 $node_id$, cpu_id, gpu_id, $rnic_id \leftarrow \arg\max_S topo_score$

the user-submitted model graph, where the CN subgraph receives the original model inputs (e.g., user attributes, candidate item lists), and the HN subgraph receives tensors sent via `FusedGraphOp`. If a tensor requires transfer via the RPC library and subsequent operator consumption, Prism replicates a new operator and delegates control to the RPC library. We also provide support for the PyTorch framework [49]. The subsequent experiments (§5) focus on TensorFlow versions to evaluate overall system performance.

4.2 Topology-Aware Resource Manager

The RTP framework disaggregates the model onto CN and HN instances, with the resource manager selecting nodes and allocating resources. To ensure recommendation service SLOs, the resource manager adheres to *topology-aware* node scheduling and resource allocation principles (Algorithm 1).

Inter-node scheduling. The cluster consists of a fleet of CNs and HNs (Figure 6). These nodes are grouped in a cluster unit called a pod (point-of-delivery), where nodes have one or more dual-port high-performance RNICs. Intra-cluster communication is achieved through a classic two-tier clos network [50]. Prism follows two principles for scheduling all CN and HN instances of the same DLRM service. First, all instances are confined within the same pod (Algorithm 1, Line 2), as *cross-pod RDMA connections induce over 50% performance degradation* in our evaluation. Second, co-locating CN and HN instances within the same ASW (Access Switch) offers superior performance. Therefore, we prefer this affinity and endeavor to pack these instances under the same ASW. If instances are distributed across multiple ASWs, Prism schedules new instances to the ASW with the most existing instances (Algorithm 1, Line 3).

Intra-node resource allocation. The hardware topologies of a typical HN and CN are depicted in Figure 10. The interconnect between GPUs and RNICs has a substantial impact on performance. Figure 11 shows that arbitrary bindings of GPUs and RNICs can induce 21–36% performance loss. Therefore, the resource scheduler prefers to assign RNIC and GPU on the same PCIe switch for each HN instance, mitigating data movement. Regarding CPU and RNIC topology, Prism mainly considers CPU-intensive CN instances. CN typically has only one RNIC, so the scheduler prioritizes the allocation of CPUs under the same PCIe switch connected to the RNIC (Algorithm 1, Line 8–11).

Production deployment. To ensure fault tolerance, online inference services deploy instances across multiple data centers. Simultaneously, to mitigate the effects of traffic peaks, the resource scheduler limits the deployment density of DLRM instances (Algorithm 1, Line 5). This scheduling policy avoids bursty resource consumption on the same node. During peak seasonal traffic periods, the scheduler incorporates additional instance density constraints at the NIC switch layer. These constraints are derived from the aggregate bandwidth capacity of distributed switches and predetermined safety thresholds (e.g., 80%). The scheduler dynamically allocates bandwidth quotas for each instance based on these constraints, thereby preventing network saturation.

Implementation. We develop topology-aware scheduling capabilities as a scoring plugin integrated within Kubernetes [4]. The device plugin deployed on each node and the central scheduler each implemented approximately 1,000 lines of code in Golang. The device plugins on individual nodes manage heterogeneous hardware topologies, reporting available GPUs and virtualized RNICs to the scheduler.

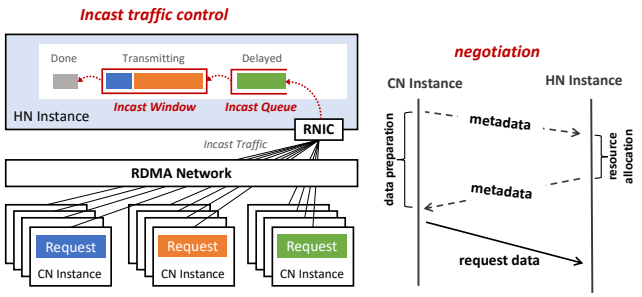

Figure 12: The incast control mechanism comprises of an incast window and queue. Only requests within the window can transmit parameters. The queue stores delayed requests.

4.3 SLO-Aware Communication Scheduler

Online recommendations demand stringent performance and stability guarantees. Empirical evaluations indicate that to adhere to stringent SLOs, the p50 and p99 latencies for transmitting 4 MiB model parameters must be below 3 ms and 6 ms, respectively. Notably, when a substantial number of CN instances concurrently transmit data to a limited number of HN instances, it generates a fan-in traffic pattern, also known as *incast*, as depicted in Figure 12. High-volume incast traffic can degrade overall performance, including long-tail latency and reduced throughput.

Incast flow control. As presented in Table 1, under various incast configurations, failing to impose restrictions on incast flows can result in request failures, which is unacceptable for a reliable online service. To meet the strict SLOs and mitigate the performance degradation caused by incast traffic, we propose an SLO-aware incast control mechanism. Incast control enhances communication performance by reducing the volume of incast traffic. As illustrated in Figure 12, incast control orchestrates the HN and CN instances to throttle incast traffic in a window-based manner. Initially, the CN instance sends a communication request before transmitting model data. Next, the HN instance verifies whether the incast window has the sufficient capacity to receive the model parameters. If space is available, the HN instance sends a communication response to initiate the data transmission. Otherwise, the HN instance defers processing the communication request in the incast queue until the incast window has the adequate capacity.

The *incast window size* and the *processing order of delayed requests* are crucial factors in determining the effectiveness of incast control in meeting SLOs, necessitating meticulous design. An undersized window leads to unnecessary delayed requests, while an oversized window renders incast control ineffective. Moreover, communication requests arrive with varying SLOs, and requests with more stringent SLOs might be impeded by other requests, resulting in SLO violations. We address these challenges through *adaptive incast window* and *SLO-aware communication request scheduling*.

Incast Size	Latency	% of Failed Requests
10	10 ms	≈ 33%
20	40 ms	≈ 50%
100	10 s	≈ 100%

Table 1: Incast statistics from our clusters. Incast size is the number of concurrent messages from different CN instances. Latency refers to the time for a HN instance to process 1,000 requests. The default message size is 8 MiB, typical for our services. Failed requests include timeouts or packet loss.

Algorithm 2: SLO-Aware Scheduling

Input: Newly-arrived communication request r' with its completion requirement $SLO_{r'}$ and message size $M_{r'}$, available network bandwidth B, requests in the incast queue R, current time t_{now}
Output: Scheduled communication requests R'

1 $d_{r'} \leftarrow t_{now} + SLO_{r'} - M_{r'}/B$ `/* calculate deadline */`
2 **foreach** r *in* R **do**
3 **if** $d_{r'} > d_r$ *and* r' *not in* R' **then**
4 R'.append(r')
5 R'.append(r)

Adaptive incast window. In Prism, the incast window size adapts to the congestion level of network links and PCIe links, as demonstrated in Figure 10. For PCIe link congestion, the traffic is stored in the RNIC receiver buffer. For network link congestion, the switch buffer stores the traffic. When the buffer occupancy of RNIC and switch surpasses a predefined threshold, the RNIC notifies the senders of congestion via Congestion Notification Packets (CNPs). Consequently, the number of CNPs serves as an estimator of the congestion level. The HN instance periodically collects the count of sent CNPs and calculate the congestion level by averaging CNP count by the number of f congestion requests. If the congestion level exceeds a predefined threshold T_{high}, the window sizes is increased. Conversely, if the congestion level falls below T_{low}, the window size is decreased. In Prism, the values of T_{high} and T_{low} are tunable based on the online workloads, preventing frequent fluctuations in the window size.

Deadline-aware request scheduling. Intuitively, Prism can process delayed requests held in the incast queue using a first-come-first-serve (FCFS) approach. Although straightforward to implement, FCFS is not SLO-friendly, as early-arriving requests with loose SLOs can obstruct requests that arrive later but have more stringent SLOs. To overcome this issue, the incast queue is designed to pop requests in a SLO-aware manner. Specifically, upon the arrival of a new communication request, Prism reorders the requests in the incast queue to maximize the number of requests meeting their SLOs. Based on this insight, we propose the early-deadline-first scheduling for delayed communication requests. The deadline of a communication request is defined as the latest time to initiate parameter transmission to meet the SLO. Prism calculates the deadline for the arrived request (Algorithm 2, Line 1) by

subtracting parameter transmission overhead ($M_{r'}/B$) from the sum of the current time and SLO. Then, r' is inserted after the requests with smaller deadline (Line 2–5).

Operational experience. Production clusters frequently employ a mixed deployment of online and offline tasks to improve efficiency. In our scenarios, the disaggregated DLRM serving introduces frequent RDMA network communication. We observe that even with exclusive access to the RNIC, RDMA transfer latency can experience a tenfold increase under intense resource contention. The root cause is that under the container overlay network [72], both RDMA and TCP rely on the overlay network scheme for communication. The TCP traffic from mixed workloads affects the flow table logic at the bottom layer of the network card, impacting RDMA traffic. Our current workaround involves monitoring node resource utilization and online service latency, triggering the eviction of offline tasks when the metrics become abnormal. We consider this as an open question for future research.

Implementation. We extend the native RoCEv2 [24] stack and implement an efficient middleware to fully leverage RDMA communication capabilities in a virtualized environment. The implementation consists of 40k lines of C++ code. Standard protocols [71] running in RNICs act as a black box for upper-level system components, which is not suitable for rapid testing and deployment. Thus, we implement an additional software-level control strategy to mitigate the negative impact of incast congestion. We design specialized meta-message packets for negotiation between senders and receivers to restrict the number of busy connections (Figure 12). This complementary software control mechanism is tuned with underlying congestion control protocols to ensure stable performance. To reduce overhead from registering memory regions for RDMA requests, Prism maintains a pre-allocated memory pool and several maps from buffer addresses to the related memory region objects. A memory allocator similar to slab is adopted to prevent buffer fragmentation.

5 Evaluation

In this section, we conduct extensive experiments to evaluate the performance impact and resource efficiency improvements of Prism. Our results demonstrate the following:

- Prism's disaggregated inference can maintain service performance under *high*-traffic scenarios (§5.2).
- Prism can effectively separate CPU and GPU computations, enhancing GPU efficiency in multi-GPU nodes by 5–9× (§5.3).
- Prism has been deployed in production clusters for over two years. In a daily GPU cluster with a high allocation rate (90%), it can reduce CPU fragmentation by 53% and GPU fragmentation by 27%. Additionally, during seasonal peak traffic, Prism can efficiently borrow training nodes to meet the increased demand, saving over 90% of GPUs (§5.4).

Model	Emb Size (Approximate)	RDMA TX (Per Req)	Dense Features
Model-XS	100 GiB	552.96 KiB	338.67 MiB
Model-S	450 GiB	6.84 MiB	57.20 MiB
Model-M	500 GiB	3.87 MiB	21.46 MiB
Model-L	600 GiB	3.69 MiB	20.79 MiB
Model-XL	700 GiB	9.03 MiB	8.73 GiB

Table 2: Models for evaluation.

5.1 Methodology

Production workloads. We use models from our industrial DLRM system, with test data originating from *real-world* user requests. Table 2 outlines the *high-level* characteristics of these models, including the size of their embedding tables, the communication volume per request transferred via RDMA after disaggregation, and memory space required for storing dense features. The models analyzed span a range of scales and use cases, processing *billions* of daily requests for tasks such as video click-through rate prediction, ad conversion rate prediction, and item ranking.

Machine specifications. The hardware topology of the HN and CN is illustrated in Figure 10. By default, model instances are deployed on HNs. Each HN contains 128 CPU cores, 8 A100 [5] GPUs with 80 GiB GPU memory each, and 4 RNICs with a 200 Gbps. After resource disaggregation using Prism, CN instances are deployed on CNs. Each CN is configured with 128 CPU cores and a single 200 Gbps RNIC. All nodes use Intel(R) Xeon(R) Platinum 8369B CPUs, with 1024 GiB memory, interconnected in a pod.

Baselines. To the best of our knowledge, Prism is the first GPU-disaggregated inference system for DLRMs. Our experiments feature three primary baselines for comparison: (i) *Baseline* refers to our highly optimized production DLRM inference system without resource disaggregation, as a comparison for performance overhead; (ii) *Local Disaggregation* splits the original DLRM instance, but the CN instance and HN instance co-locates on the same HN server; (iii) *Prism (Remote Disaggregation)* disaggregates the DLRM inference service by placing CN instance on the CN server and the HN instance on the HN server.

Metrics. We seek to evaluate the DLRM system's processing capabilities under peak traffic loads. To simulate such conditions, we initialize 30 workers to continuously send requests at a predefined frequency. Our key indicators are categorized into two groups:

Performance-level metrics: (i) *goodput*, defined as the number of requests that DLRM instances can process; (ii) *average latency*; and (iii) *p99 latency*.

Resource efficiency metrics: (iv) *CPU usage*: the overall CPU consumption of the DLRM service and the proportion of CPU usage on GPU nodes; (v) *GPU efficiency*: measured by the number of inference requests that can be processed on

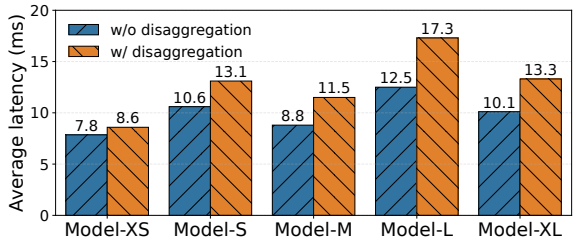

Figure 13: Latency of sequentially executing requests.

a single GPU node; and (vi) *resource fragments*: the amount of unallocated resources that are *expected* to be fragmented because they are too small to meet workload requirements or become stranded from other dimensional resources, quantified using the methodology proposed in [64].

5.2 Prism Performance: End-to-End Results

Overhead of serving a single request. First, we quantify the impact of model disaggregation on inference efficiency in the *worst-case* scenario. We send only *one* request at a time to the DLRM inference system for sequential execution, which indicates *low* resource utilization and throughput. Figure 13 records the average latency of sequentially processing requests in different models, showing a 10–38% increase. In this setup, the performance degradation of inference mainly stems from two aspects: (1) each request processing requires data transmission across the RDMA network, and (2) when executing requests sequentially, only one instance of Prism's CN instance or HN instance is computing at a time, whereas the baseline allows *asynchronous* executions of CPU and GPU operators on the same node.

Performance under varying traffic loads. Figure 14 shows the performance of various baselines under differing levels of requests per second (RPS). While Prism incurs minor overhead from cross-node communication during low RPS inference (e.g., p99 latency of Model-L at 200 RPS), it can *lower latency and increase goodput under higher RPS* compared to other baselines (e.g., p99 latency of Model-L at 800 RPS). Two main factors drive these improvements. First, modern GPUs' first-in-first-out scheduling can result in substantial queue head-of-line blocking [48], where at high RPS, concurrent requests *interleavingly* submit kernels to the GPU will drastically increase the latency. Prism mitigates this by leveraging `FusedGraphOp` to fuse each request's GPU operators, into a single sequential execution rather than interleaving across requests. Second, Prism decreases PCIe volume by converting host-to-device data transfers in DLRM computation to high-bandwidth device-to-device RDMA transfers. *Local disaggregation* also shows performance gains due to the graph optimizations mentioned above, but CPU contention between the CN instance and HN instance results in inferior performance compared to Prism. One special case is Model-XL, which has the largest communication volume (i.e., over 9 MiB) but very short GPU time ($<$ 1 ms, the lowest part of Figure 15). Even under this condition, Prism only suffers at most 6% performance loss. Overall, Prism is capable of maintaining service performance under *high* traffic scenarios in real-world deployments.

Latency breakdown. We perform additional breakdown analysis of elapsed time across stages, divided into CN computation time, data transmission latency via the RDMA network, and HN computation time. We discover that different DLRM inference services have distinct bottlenecks, which can be classified as *CPU-bounded*, *balanced*, or *GPU-bounded*. For example, the increased latency of Model-XS at high RPS is primarily attributed to the HN instance, indicating that the computational capacity (i.e., GPU) of the HN instance becomes the bottleneck. In contrast to the baseline, Prism decouples the resource usage of DLRM inference, allowing for *arbitrary* configuration of the number of CN and HN instances. This *flexibility* enables Prism to better accommodate the diverse resource requirements of different DLRM services (e.g., independently scale out HN instances to alleviate the computational bottleneck, in the case of GPU-bounded services like Model-XS, as shown in Figure 17).

5.3 Prism at Node: Resource Efficiency

Distinct resource separation. Figure 16 compares the CPU usage across different DLRM services before and after resource disaggregation. Prism maintains nearly identical CPU consumption when processing equivalent amounts of goodput, in comparison to the baseline. Notably, Prism effectively separates the computational resources of DLRM, resulting in a substantial reduction of CPU consumption on GPU nodes by 15–84×. These findings suggest that Prism possesses the capability to effectively mitigate GPU fragmentation issues that arise due to insufficient CPU resources.

Better resource efficiency on multi-GPU nodes. We deploy varying numbers of inference instances on a single HN to handle DLRM requests, limiting the service latency to 25 ms, and then compare the total goodput. Figure 17 demonstrates that Prism can deploy more DLRM instances on a single multi-GPU node, increasing inference throughput by 5–9×. Without disaggregation, the baseline can deploy a maximum of two Model-XS inference instances on the HN, fully saturating the CPUs while leaving 6 GPUs completely idle and *stranded*. For Model-XL, due to the memory limitations imposed by its massive embedding tables (i.e., 700 GiB), the baseline can deploy at most one instance. Prism supports flexible configuration of the ratio between CN and HN instances. For CPU-bounded Model-XL, only increasing the number of CN instances from 1 to 4 can yield a 36% improvement. For GPU-bounded Model-XS, if the MIG [8] feature

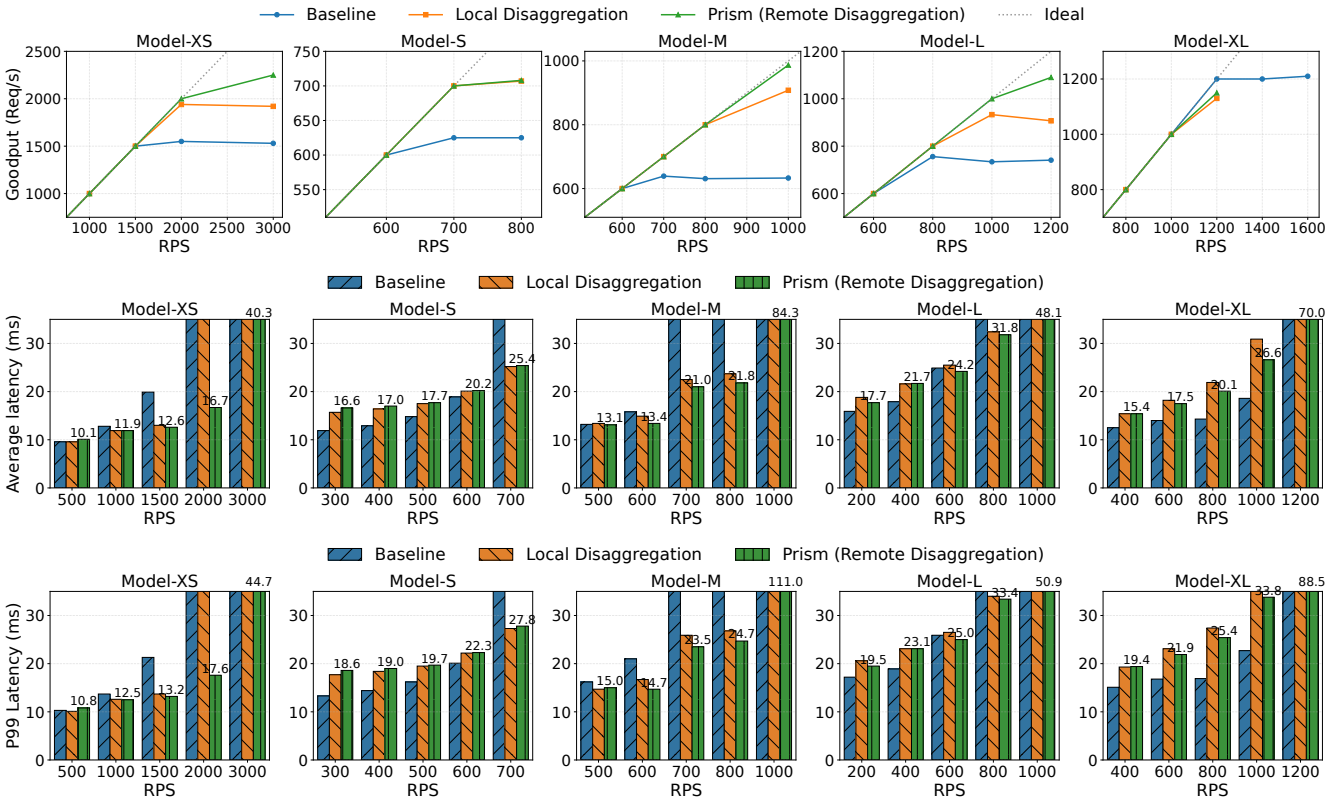

Figure 14: The end-to-end performance under varying traffic loads.

of A100 (i.e., fine-grained GPU allocation) is enabled, up to 24 HN instances can be deployed, boosting throughput to 9× compared to the baseline. This demonstrates that Prism's resource disaggregation allows for more efficient utilization of multi-GPU nodes customized for training workloads.

5.4 Prism at Scale: Production Deployment

Prism has been deployed in our production cluster for over two years, scaling to more than 10k GPUs to date. The system addresses two challenges: (1) resource allocation in GPU clusters with high allocation rates and (2) resource provisioning during seasonal traffic spikes. By leveraging a design that avoids costly infrastructure upgrades, Prism has enabled serving scale to grow continuously throughout this period.

Reduced resource fragmentation in GPU clusters. As discussed in [64], cluster resource fragmentation must consider the distribution of workloads. For tasks with different resource requirements, the cluster resource fragmentation from their perspective varies. Figure 18 compares the changes in resource requirements of DLRM instances before and after our deployment of Prism. Prism reduces the stringent resource requirements of the DLRM inference service. For HN instances that require GPU allocation, their CPU requests are less than 12 cores, and memory requests are below 24 GiB. In contrast, CN instances, which are CPU-intensive and need to load embedding tables, have CPU requests exceeding 48 cores and memory requests greater than 240 GiB. We simulate the deployment of DLRM instances before and after resource disaggregation to cluster H with a high allocation ratio. Figure 19 compares the changes in fragmented cluster resources. As Prism separates the resource requirements of DLRM instances, CN instances can run on nodes where GPUs are exhausted but CPUs remain, while HN instances can run on nodes with insufficient CPUs but available GPUs. Statistical analysis reveals that this approach significantly reduces the cluster's CPU fragments by 53% (18k cores) and GPU fragments by 27% (60 GPUs). These findings suggest that even in clusters with high allocation rates, the disaggregated DLRM service can efficiently utilize fragmented resources to meet deployment requirements.

Efficient resource loans for peak demand. During e-commerce promotional periods, we leverage Prism to borrow a portion of training nodes (equipped with A100 GPUs) to scale out DLRM inference services, meeting the *short-term* yet *high-throughput* traffic peaks. Table 3 outlines the resource requirements of three online services, with each HN instance requiring only one MIG GPU and minimal CPU resources (≤ 4), while the remaining CN instances handle the vast majority of CPU computations. These instances are

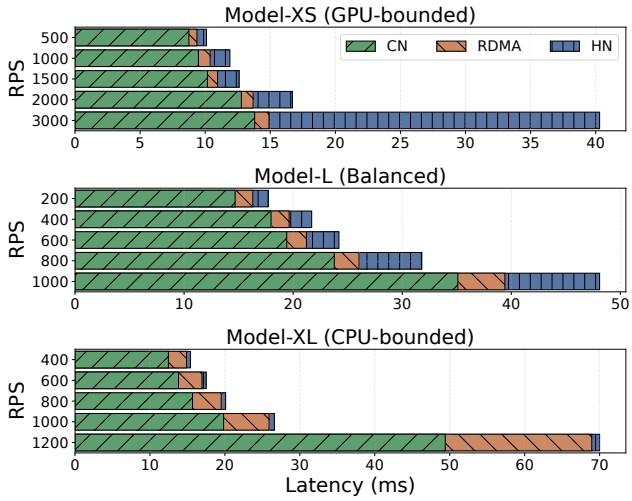

Figure 15: Latency breakdown of disaggregated DLRM inference services, which consists of CN computation time, RDMA transfer latency, and HN computation time. Model-XS, Model-S, and Model-M demonstrate consistent trends.

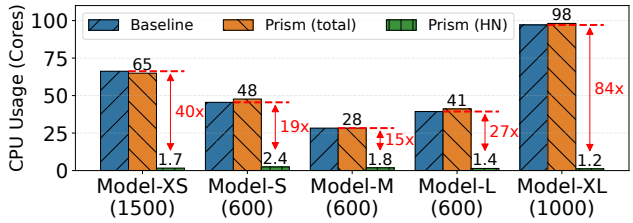

Figure 16: Comparison of CPU utilization. Prism (total) represents the total CPU consumption of the CN instance and HN instance in the disaggregated DLRM inference service, while Prism (HN) denotes the CPU consumed by the HN instance. The x-axis labels include the goodput in parentheses.

distributed across different nodes to ensure high availability. Figure 20 illustrates the QPS and latency of the three services during seasonal promotions, with the peak occurring at the 20th hour. Latency for the online service was not detrimentally impacted—overall latency remained within 25 ms and no request exceeded 35 ms, demonstrating the ability in handling production-level traffic loads. A rough estimation reveals that only 6 A100 nodes are required to satisfy GPU requirements of these services, whereas previously, an A100 node could deploy at most 2 inference instances, requiring up to 70 A100 nodes to meet the same demand. By decoupling resource requirements, Prism enables DLRM services to more efficiently borrow multi-GPU training nodes during promotional periods, saving over 90% of GPUs.

6 Discussion and Related Work

DLRM systems. Existing DLRM systems primarily focus on scaling embedding table capacity for enhanced model accuracy [34,36,46], optimizing embedding lookup operations for accelerated inference [55,59,63,65,66], maximizing resource efficiency during training [60,61], developing embedding table pruning techniques [37], and expediting model parameter updates [54]. Only a few works study DLRM provisioning at the datacenter scale. Hercules [33], developed for monolithic servers, efficiently searches the task scheduling space and dynamically provisions the best-matching heterogeneous resources in the presence of diurnally changing load. To our knowledge, DisaggRec [34] is the only work that advocates resource disaggregation for large-scale DLRM serving. Unlike Prism, DisaggRec is a memory-disaggregated system that decouples the deployment of compute and memory, with the aim of addressing the growing memory demands of large-scale DLRMs. DisaggRec is only a prototype evaluated in an emulated memory-disaggregated infrastructure.

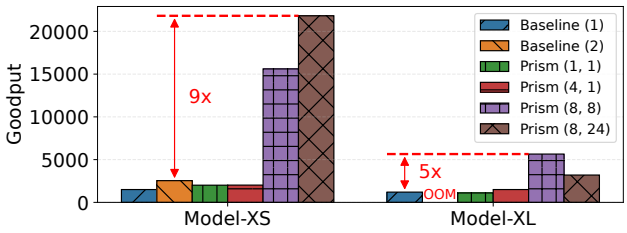

Figure 17: Comparison of HN GPU efficiency, measured by the total goodput. Baseline (count) represents the number of monolithic DLRM instances deployed on the HN, while Prism (CN count, HN count) denotes the number of CN instances and HN instances, respectively.

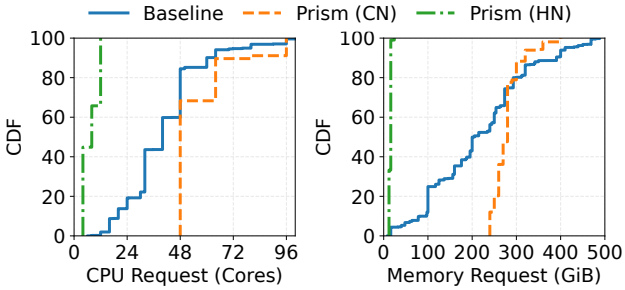

Figure 18: Comparison of resource requirements. Baseline, Prism (CN), and Prism (HN) denote the original monolithic DLRM instances, the disaggregated CN instances, and the disaggregated HN instances respectively. Both the baseline and Prism (HN) instances are allocated one GPU.

Colocation of training and inference workloads. Modern cluster management systems aspire to create a *unified* infrastructure that seamlessly integrate training and inference workloads, optimizing resource multiplexing while minimizing fragmentation. Specifically, Lyra [39] advances this paradigm by leveraging elastic training mechanisms to repurpose low-load inference servers. In this work, Prism reveals fundamen-

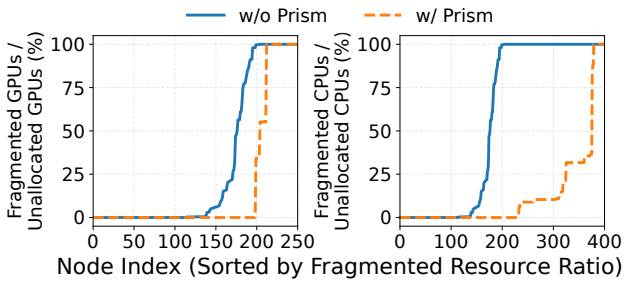

Figure 19: The change in resource fragments of a large-scale GPU cluster *H* before and after resource disaggregation. The original node residual resources are depicted in Figure 3.

Service	Role	# of Instances	CPU	GPU
Product-A	CN	25	48	-
	HN	45	4	MIG 2g.20gb
Product-B	CN	15	48	-
	HN	40	4	MIG 2g.20gb
Product-C	CN	15	48	-
	HN	55	2	MIG 2g.20gb

tal inefficiencies in repurposing training clusters for DLRM inference workloads, eliminating resource mismatches through resource disaggregation.

Resource disaggregation. Resource disaggregation holds tremendous promise in datacenters, with many prototype implementations demonstrating benefits of independent scaling of compute and memory resources, improved reliability, and cost-efficient hardware deployment. Existing works span multiple domains, encompassing API and framework innovations [15, 51, 70], operating system and network architectures [18, 53], and hardware design [25, 29, 38]. Prism specifically targets DLRMs, which are characterized by their substantial memory footprints and intensive CPU usage. By disaggregating CPU and GPU provisioning, Prism optimizes resource utilization in heterogeneous GPU clusters. This approach can potentially generalize to other models exhibiting distinct resource usage patterns, including graph neural networks [52] and large language models with retrieval augmented generation [20].

Model parallelism. The idea of model parallelism has been long introduced [35], yet the partitioning of computation graphs across available devices continues to evolve for different model architectures [17, 31, 44, 45, 56]. Prism focuses on DLRMs, which are distinct in their large embedding tables [36, 37]. Moreover, we aim to optimize the inference rather than the training, thus more concerned with the per-request latency rather than long-term throughput.

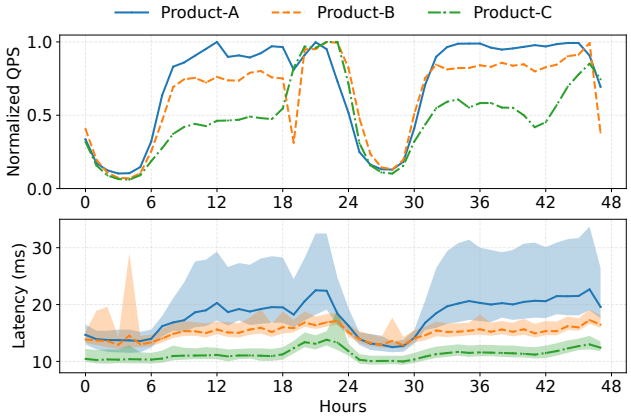

Figure 20: The statistics of three production services (Table 3) during a tremendous traffic promotional period.

Communication optimization with RDMA. RDMA technology has revolutionized datacenter applications across domains, including remote storage systems [10, 19, 43, 62], distributed training frameworks [6, 7, 14], and cluster monitoring solutions [41]. Specifically, previous work [24, 40, 71] attempts to implement high performance and stable RDMA communications from the protocol level. Prism adopts software-level flow control and scheduling strategies, which are more customizable for online services. Prism is complementary to the above RDMA-optimizing techniques.

7 Conclusion

In this work, we propose Prism, the first GPU-disaggregated DLRM serving system to efficiently provision resources at scale. Prism divides DLRMs into CPU- and GPU- intensive subgraph and offloads them to CPU and GPU servers. Prism employs various techniques to minimize the latency overhead, including optimal graph partitioning, topology-aware resource scheduling, and RDMA network optimization. Experimental results demonstrate that Prism effectively separates CPU and GPU computations while maintaining service performance. Prism effectively reduces CPU fragmentation by 53% and GPU fragmentation by 27% in a GPU cluster with a high allocation rate. During seasonal promotional events in e-commerce platforms, Prism can efficiently borrow GPU servers from training clusters to meet peak traffic demands, resulting in up to 90% of GPU savings.

Alibaba Cloud

Abstract

Despite the success of diagnosis systems in traditional cloud computing, these systems are not suitable for pinpointing faults in AI model training cloud scenarios due to the differences in computing paradigms between traditional cloud computing and model training. As one of the largest cloud providers, we present Aegis, a fault diagnosis system specifically designed for AI model training service. We share our experience in the motivation, design, and evolution of Aegis. Keeping easy-to-deploy as the primary principle, Aegis Phase-1 started by enhancing existing general-purpose diagnosis systems. After several months of evolution, Aegis Phase-2 cogitatively customized the collective communication library for sophisticated failure localization in runtime without modifying customer code. Besides the failure localization, we further equipped Aegis with the capabilities on handling performance degradation and failure checking before delivery. Aegis has been deployed in our production training cloud service for one year. Aegis decreases more than 97% of the idle time wasted by diagnosis, 84% of the training task restart count, and 71% of the performance degradation.

1 Introduction

The AI model training has brought about tremendous revolutions to today's cloud services. In a typical AI model training scenario, the customer (i.e., model designer) submits the AI model as a task to the training cluster maintained by a training cloud service provider (e.g., AWS, Azure and Google). The hosts within the training cluster perform model computation, then synchronize intermediate results via collective communication, then perform model computation, and continue. Eventually, these hosts finish a training process (typically lasting weeks) based on the above synchronization way.

Reliability is important. The reliability of the training cluster is crucial to both the training service provider and customers. If a failure occurs during model training, the entire training process should be restarted, resulting in a significant loss of time and money [36, 45, 60]. As the scale of the AI model increases, maintaining the reliability of the training cluster becomes increasingly more important and challenging.

Why maintaining the reliability is challenging? The large-scale AI model training clusters are equipped with tens of thousands of high-tier GPUs (e.g., NVIDIA A100 [13] and H100 [16]) to cooperate through high-speed network connections (including rail-optimized network [1] and NVLINK [17]) to achieve high-throughput training. Nevertheless, the failure rates of these high-performance components (both hardware and network) are much higher than regular ones such as CPU and Clos network used in general cloud computing scenario (see §2.1.1 for more details). Even worse, due to the synchronization nature of model training, the single-point failures resulting from the high-performance GPUs within one host can lead to a cascading failure across all hosts in this training task. The diagnosis systems used in traditional cloud computing [23–26, 28, 29, 31, 32, 34, 35, 37–43, 46–48, 50–55, 57–59, 61, 63, 64], in principle, localize the root causes by tracing back the source-destination path through the sequence of system component calls such as the 5-tuples or devices of given faults; however, in the model training, task failures spread from a single point to the entire cluster, causing the culprit to be hidden among error reports from all hosts. As a result, the diagnosis systems used for traditional cloud computing are not suitable for localizing the root causes in model training cluster.

The state-of-the-art efforts. To fill this gap, some diagnosis systems for the model training scenarios were proposed, such as SuperBench [60] deployed in Microsoft and MegaScale [36] deployed in ByteDance. SuperBench provides a comprehensive benchmark suite for gray failure checking before the cluster deployment. While useful, it is hard to localize the root causes of faults occurred in the model training runtime. On the other hand, MegaScale identifies failures by monitoring CUDA events from "critical code segments" in customer model. This is only suitable for scenarios where the model designer and model training service providers belong to the same party; otherwise, no model designer (i.e., customer)

* Equal Contribution.

is willing to allow the training service provider to monitor or modify their code. Such an assumption is impractical to public model training service providers.

Our approach: Aegis. As one of the largest model training service providers in this world, we decided to build a practical diagnosis system that achieve our key goal: diagnosing root causes of failures in service runtime without modifying customer code. This goal is important to public model training service providers like us, because (1) we need to cover failures during the entire lifecycle, not only the cluster deployment phase and (2) our diagnosis system should be general and transparent for various customers. To this end, we build Aegis. This paper shares our experience in the motivation (§2), design (§3), and evolution (§4) of Aegis.

Driven by our in-production investigation and motivation (detailed in §2), we started the design of Aegis. In the Phase-1 of Aegis (§4.1), we enhanced our existing diagnosis system with the training-output log and a diagnosis procedure fitting in the large-scale model training scenario. This enhancement enabled us to narrow the entire task-level failure down to specific error devices in major failure cases. For more sophisticated cases, we employ offline diagnosis as the backstop.

While Aegis Phase-1 constructs a comprehensive diagnosis system handling various failures in our model training scenario, once the offline diagnosis is involved, all used hosts in this large-scale AI model training task need to be isolated, greatly complicating the scheduling of the training cluster and harming the overall cluster utilization. Therefore, Aegis evolved to Phase-2 (§4.2). Phase-2 focused on diagnosing most failure cases directly at runtime. We conducted a comprehensive investigation of the possible runtime information sources. Adhering to the principle of minimizing customers' perceptions, we chose to customize the Collective Communication Library (or CCL) to acquire runtime status because of the following two reasons. (1) in mainstream training frameworks (e.g., Megatron [49] and DeepSpeed [8]), CCL is integrated as an independent plugin. Customizing CCL would not introduce any code modification in customers' models or training frameworks. (2) CCL "sits at the boundary" of computation and communication, making it a perfect place for generating ideal failure diagnosis information. Through defining appropriate CCL metrics and constructing the corresponding runtime diagnosis system, we improve the runtime diagnosis ratio from 77% to close 100%.

Besides failure diagnosis, significant performance degradation is another crucial problem. Based on our experience, we further develop the basic-metric correlating diagnosis and enhanced procedure-aware diagnosis to discover the root cause of performance degradation (§5).

Other than solving issues during the training procedure, we note that more than 73% of tasks failed at the initialization phase. This phenomenon indicates errors already existed in the cluster before the model training tasks start. To minimize unnecessary retries from customers, we deploy Check Before Delivery (CBD) to conduct essential checks before delivering hosts to customers (§6).

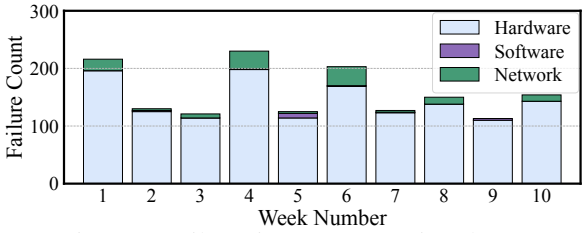

Figure 1: Failures in a representative cluster.

We present the diagnosis efficiency on our training clusters during the evolution of Aegis (§7). For confidential reasons, we use the statistics from our in-house LLM training project as a representation. During the last 16 months, the training scale of our project increased by more than 40×. Impressively, with the deployment of Aegis Phase-1, the GPU idle time caused by failure diagnosis is decreased by 71%. With the deployment of Aegis Phase-2, almost all model training task failures can be diagnosed in runtime. The GPU idle time is further reduced by 91%. For handling performance degradation, with the gradual deployment of the correlation diagnosis and enhanced procedure-aware diagnosis, the degree of performance degradation is decreased by 71%. With the deployment of CBD, the training task restart count is decreased by 84%.

2 Motivation

2.1 Challenges Introduced by Model Training

Large-scale model training is fundamentally different from traditional cloud computing. As shown in Figure 1, we studied the repairing tickets from one of our largest training clusters (containing $O(1K)$ hosts with $O(10K)$ GPUs) in production during the last ten weeks. Each week, 100-230 critical failures occurred in the training cluster, which is orderly higher than that in general cloud computing data centers. If not pinpointed and fixed on time, these failures may contribute to model training task crashes. This subsection presents our findings on why more failures occur and why failure diagnosis is harder in large-scale model training.

2.1.1 Higher hardware failure ratio

Large-scale model training introduces unique challenges, particularly in terms of hardware reliability.

High failure rate of high-tier GPUs. High-tier GPUs (e.g., NVIDIA A100 [13] and H100 [16]), the most fundamental component of the large-scale model training cluster, exhibit a significantly higher failure rate than traditional computing hardware. For instance, our statistical data show that an A100 GPU, on average, fails after approximately 400 days of operation, whereas an H100 GPU has an even shorter mean time to failure of around 200 days. Given a large-scale training task involving thousands of GPUs, this failure rate is orders higher than that of general cloud computing scenarios. As shown in Figure 2, 45.6% of failures are caused by GPU-related reasons (i.e., GPU execution error, GPU driver error, GPU memory error, CUDA error, NVLINK error and GPU ECC error).

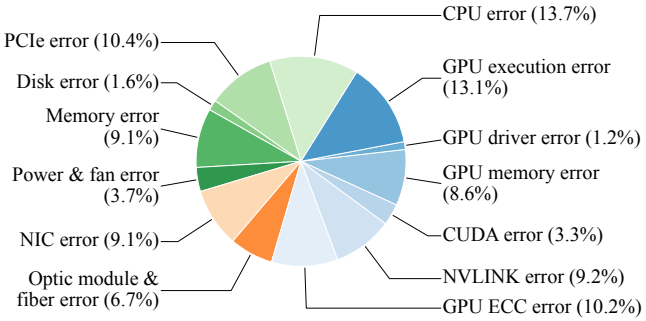

Figure 2: Types of failures encountered in production.

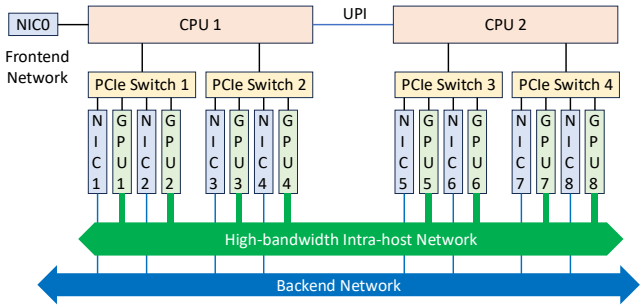

Figure 3: Intra-host network topology.

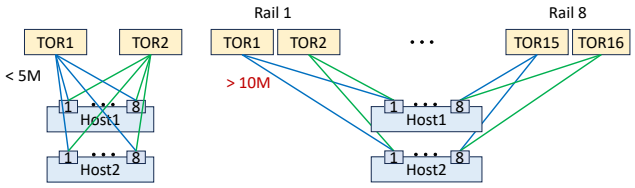
Complex intra-host network topology. As shown in Figure 3, each host in the our training cluster is equipped with eight GPUs and eight NICs, interconnected via PCIe. GPUs in the same host also utilize NVLINK for inter-GPU communication, which, while enhancing performance, introduces more complex forwarding paths and higher failure rates. Our operational experience has revealed 9.2% issues related to NVLINK failures, as well as 10.4% performance anomalies due to PCIe error. These intra-host network problems are very rare in general cloud computing scenarios.

More link failures in large-scale model training cluster. To maximally utilize the high bandwidth provided by the intra-host network, rail-optimized networking [45] is widely deployed in construction training clusters. While this approach improves performance, as shown in Figure 4, compared with the traditional single-ToR topology, the rail-optimized connections require long-distance links. It necessitates using the optic modules and optic fiber to overcome the distance limitations of copper cables. However, optic modules and fiber have a higher failure ratio [18]. Statistics from our production reveal that optic modules and fiber can introduce a $1.2 \sim 10\times$ higher failure ratio compared with DAC, which varies according to different vendors and link speeds. Although we have implemented the dual-ToR design proposed in HPN [45] to mitigate these issues, the inherently higher failure rates still introduce significant operational challenges. While one of the two dual-ToR links fails, the entire training task may not crash, but may encounter significant performance degradation.

2.1.2 Lacking direct root cause indicators

Besides the high failure ratio, the specific workload of large-scale model training differs from general cloud computing



(a) Single-ToR access (b) Rail-optimized access

Figure 4: Different types of host accessing topology.

tasks, further introducing difficulties in diagnosing the root cause of failures. The limited diagnostic information provided by mainstream training frameworks adds additional difficulty to the failure diagnosis. In traditional general cloud computing scenarios, a failure only affects several specific hosts, with clear fault localization indicators (e.g., the specific 5-tuple connection encounters high RPC completion time). In contrast, in the model training, task failures spread from a single point (e.g., a host or a link) to the entire cluster, causing the culprit to be hidden among all the faulty tasks.

In addition, the entire large-scale model training procedure heavily relies on collective communication to cooperate with all GPUs. Usually, the failure is observed throughout the entire training task crash (e.g., most hosts concurrently encounter the same CCL timeout error). While there are many potential root causes, the CCL timeout is often the first signal to identify the occurrence of a failure. As a result, diagnosing the problem typically begins with the network, but the root cause may not be in the network.

2.2 Why Our Existing Systems Do Not Help?

We have three diagnosis tools used in our data center networks for general cloud computing.

Tool 1: Network monitoring and analysis. During the running of training tasks, each NIC and switch continuously generates logs recording their runtime status, especially warning and error messages. Furthermore, a series of statistic-based monitors are deployed in hosts and switches (e.g., RX/TX throughput, Out-of-order number, ECN mark number on each port). This diagnosis system is primarily designed to collect and analyze logs and statistical data from NICs and switches. By matching specific network failure patterns (e.g., critical errors shown in the log and abnormal statistics), it can automatically identify the failure node and isolate it.

Tool 2: RDMA Pingmesh. In the general cloud computing scenario, we have deployed TCP Pingmesh service on a large scale, and we have transformed it into RDMA Pingmesh during the support of high-performance block storage service, which is similar to R-Pingmesh [41]. RDMA Pingmesh can actively probe the network to diagnose connectivity and high latency issues.

Tool 3: Inband network diagnosis. The above two systems are responsible for end-to-end information to diagnose the faulty device in the training cluster. However, in some complex failure scenarios, we also need hop-by-hop statistics,

rather than end-to-end information, to discover the root causes of failures. We build such a system, which can conduct coloring on specific packets and trace their forwarding status among each single switch.

The procedure: Tool1+Tool2+Tool3. The entire diagnosing procedure (combining the above three tools) works as follows. When application monitors report an abnormal event, this abnormal event points to a clear source-destination pair. Our network monitoring and analysis system is triggered to analyze whether critical errors occur among the source-destination pair. If so, devices with critical errors would be isolated. If there is no such clear conclusion, Pingmesh results are used to verify whether abnormal packet loss and high latency occur in the network. If so, the in-band diagnosis system is triggered to color specific traffic that passes through the source-destination path hop-by-hop to determine the location of the failure.

Limitations. This diagnosis system works well in general cloud computing scenarios; however, it is not suitable in the model training scenario due to the following two reasons.

Reason 1: Focusing on the network itself. In general cloud computing scenarios, a failure notification points to a clear source-destination path. Therefore, existing diagnosis systems only need to focus on identifying faults inside the network. However, serving model training in the cloud is quite different. It heavily relies on collective communication to cooperate with all GPU hosts. Any single failure would cause a cascading task crash across all participating hosts. Therefore, a large number of secondary issue errors may overshadow the root cause error. We encounter numerous false positives in the diagnostic results by directly employing existing diagnosis systems in model training production.

Reason 2: Focusing on single request/response. Our traditional diagnosing systems diagnose faults in the request-response way, focusing on the issues of individual connections. In contrast, large-scale model training requires correlating information from multiple devices to accurately diagnose faults, necessitating an automated localization system that is vacant in the previous procedure.

2.3 Limitations of State-of-the-Art Efforts

State-of-the-art general-purpose diagnosis systems [23–26, 28, 29, 31, 32, 34, 35, 37–43, 46–48, 50–55, 57–59, 61–64] move a step towards handling failures beyond the network. Some of them further consider the correlation between different devices to improve the analysis accuracy [29, 30, 33, 35, 44]. However, due to the lack of taking into account model training-specific features such as collective communication, they are unable to cover many failures in the model training scenario. For example, in LLM training, each single collective communication forces dozens or even hundreds of GPUs in synchrony. Simply extending these correlation-analyzing methods to such a large scale forces the comparison among many nodes. According to our experience, it leads to an increase in unacceptable diagnosis latency and accuracy loss. We, therefore, turn to investigate whether there is any diagnosis system specifically designed for the model training scenario. There are two representative diagnosis solutions built for model training clusters and large-scale deployed in production (i.e., SuperBench [60] deployed in Microsoft and MegaScale [36] deployed in ByteDance). Unfortunately, as shown in Figure 5, both cannot perfectly fit the demands in the model training cloud scenario due to the following reasons.

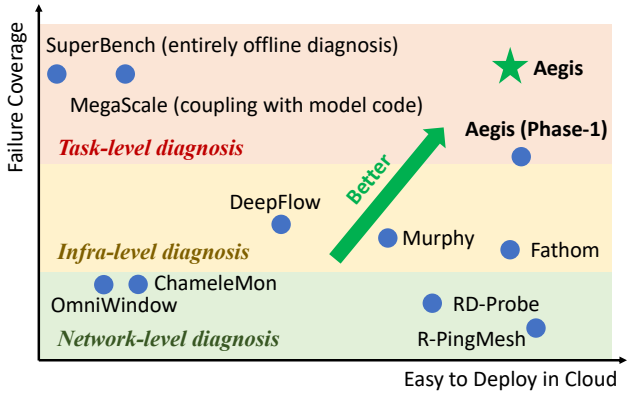


Figure 5: Limitations of state-of-the-art solutions.

Time-consuming offline diagnosis is insufficient. SuperBench constructs a comprehensive benchmark suite, including computation/communication microbenchmarks and typical end-to-end model training benchmarks. By executing this benchmark suite before delivering the training cluster to production, SuperBench can proactively figure out possible issues. We have deployed a similar procedure during each host's online procedure. However, failures may happen during the entire life cycle of the cluster, not only before the online procedure.

It is also impractical to execute SuperBench after any failures. Initializing a single model training benchmark would take tens of minutes, making the entire SuperBench execution lasting hours. Employing this system as the only diagnosis method would introduce a great waste of computation resources and a bad user experience (i.e., prolong waiting time after each failed training).

Deep coupling with customers' code is inappropriate. MegaScale, on the contrary, proposes a fully runtime method to execute failure diagnosis. It monitors the executions of CUDA events in "critical code segments" to diagnose training issues. It is a proper solution for companies that train models for their own use (e.g., ByteDance and Meta). However, it is not suitable for us who offer public AI training services for customers. The reasons are twofold.

First, MegaScale needs a clear definition of "critical code segments". However, as a cloud service provider, we offer training services for various customized models from different customers. Each model may have different architectures and implementations, leading to varying definitions of "critical code segments". Requiring clients to explicitly define

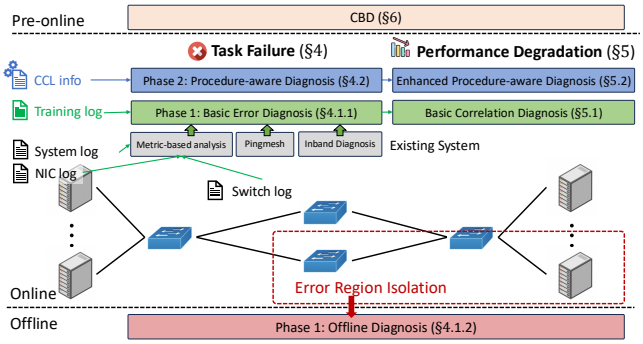

Figure 6: Aegis overview.

the "critical code segments" they use is also impractical, as many model details are highly confidential. Therefore, we need a generic and efficient solution that introduces minimal intrusion on customers.

Second, monitoring CUDA events requires initializing a customized monitor module exactly in the same thread these CUDA events are called. It means this initialization can only be explicitly called in customers' model code. Deploying a new tool that forces modifying customers' model code is hard. The negotiation between our salesman and customers mainly bottlenecks the entire deploying procedure.

3 Aegis Overview

We decided to build a diagnosis system (named Aegis) for the AI model training scenario. Aegis achieves our key goal: diagnosing the culprit of failures in service runtime without modifying customer code. Notice that, in production, when a failure happens, the most urgent issue is timely locating which device is introducing this failure/degradation. Then, we can isolate this device and go on the training. The root cause analysis is conducted offline (i.e., after the isolation), which is another big topic and not covered in Aegis. Figure 6 shows the overview of Aegis. Aegis focuses on two types of abnormalities: training failure and performance degradation. Training failure is the first critical disease we need to cure. Aegis has experienced a two-phase evolution for handling training failure. Considering the limitations of our existing diagnosis system as discussed in §2.2, in Aegis Phase-1, we further involve the error information from the training log and construct a training-specific runtime diagnosis procedure (§4.1.1). We also design a comprehensive offline diagnosis backstop for hardcore cases that cannot be handled in runtime diagnosis (§4.1.2). During the operation, we find that a non-negligible number of failure cases need an offline diagnosis, which leads to unsatisfied GPU utilization. Therefore, we evolve Aegis Phase-2 to get more training-specific information through customizing CCL to conduct the training procedure-aware diagnosis (§4.2). For handling performance degradation, based on previous experience, we design both metric correlation diagnosis (§5.1) and enhanced procedure-aware degradation diagnosis (§5.2). To further improve user experience, we add a new "pre-online" process conducting efficient cluster checking before delivering it to the customer (§6).

4 Task Failure Diagnosis

This section illustrates the evolution of Aegis. We start by enhancing existing diagnosis systems and then move to constructing a better runtime diagnosis system.

4.1 Phase-1: Enhancing Existing Systems

4.1.1 Basic error diagnosis

In most failure cases, there are no clear indicators even to determine the scope of the failure. Therefore, diagnosis begins with identifying whether the current issue originates from the endpoint or the network. At the very beginning of our diagnosis practice, most failures are located through manual diagnosis. Our engineers filter error and warning logs on each host and switch through different sources (e.g., OS dmesg [9], training log, CCL log, NIC driver, switch syslog [5] and customized counters) and analyze the time-sequence relationship between these abnormal reporters with the actual failure. After dealing with hundreds of online failure cases, a series of critical errors are summarized and transformed into our initial automated task failure diagnosing system. Two main challenges are faced and conquered in this procedure.

Not all reported errors are critical. Error logs are widespread during the entire training process. Not all errors deterministically lead to task failures or performance degradation. Considering ECC errors as an example, there are multiple types of ECC errors. Only double-bit ECC errors (e.g., XID 48 Error [21]) and uncorrectable ECC errors (e.g., XID 94/95 Error) are root causes of failures. Other single-bit ECC errors (e.g., XID 92 Error) and correctable ECC errors (e.g., XID 63/64 Error) indicate HBM memory errors, but do not trigger failures. However, widespread errors are reported from different hosts near the task's crash time. If all these hosts were directly isolated, the entire utilization of the training cluster would be greatly damaged.

Our solution first involves identifying critical errors that intrinsically lead to task anomalies, such as GPU missing, PCIe lane drops, or NVLink issues. When such issues are detected, the corresponding host is directly isolated. This method covers only a portion of potential anomalies.

In the early stages of operating LLM training clusters, our engineers devoted much effort to handling online training failures. They summarized other error patterns that certainly lead to task failure. This experience formed the foundation for our critical error diagnosis: $CriticalError()$. Critical errors contain several categories in production: (1) hardware failure (e.g., double-bit ECC error, link down, GPU/NVLink/NIC missing, fan error, and power error) (2) unrecoverable software failure (e.g., GPU/NIC driver error) and (3) unbearable performance degradation (e.g., GPU/host overheat).

Not all critical errors point to a clear location. Besides the clear critical errors, which can directly indicate failure location, many other errors do not point to specific nodes. A

widely encountered example is the crash of network connections (e.g., "connection reset by peer"). These failures can trigger NCCL error handlers, causing the corresponding training thread to exit and leading to cascading thread crashes in other hosts. We also construct a distributed error list to record these errors: *DistError()*.

We enhance our fault diagnosis process with the above experience, as shown in Appendix A (Algorithm 1).

• If a machine encounters critical errors, it is isolated, and the task is restarted.

• If distributed errors appear on only two hosts, it means errors occur on these hosts. They are isolated, and the task is restarted. There is a trade-off behind this process logic. When the potential culprit host set is small enough, it is more efficient to directly isolate all nodes in this list to accelerate the diagnosis procedure. However, the side-effect is that some normal hosts in this set are also isolated, introducing resource wastage. In production, we take the size of this potential culprit host set to 2 to achieve the sweet point.

• For distributed errors across multiple machines, *RootDiag()* analyzes the reported errors to identify if they can be clustered by the source or destination. If GPU G_j is the root cause of the failure, then connections from G_j and connections to G_j crash the first time. Therefore, *RootDiag()* can precisely determine the faulty G_j. If not, it means that the root cause is not on the host-side. Then, network components need to be further checked.

• If errors are distributed without a clear pattern, systemic issues are most likely, such as network or configuration problems. We develop *ConfigCheck()* and *NetDiag()* to conduct further diagnosis. *ConfigCheck()* maintains a checklist and corresponding scripts to identify various causes of configuration errors. *NetDiag()* is constructed by the existing DCN diagnosing system illustrated in §2.2.

• If all the above procedures cannot pinpoint the root cause of the failure, then all hosts used in this training task need to be isolated and conduct offline diagnosis (details in §4.1.2).

Lesson: Exhausting host-side critical failures first is the most efficient way to diagnose. In large-scale model training, host-side issues may be misinterpreted as network issues. In practice, 71% distributed failures turn out to be irrelevant to the network. Therefore, in environments with mixed network-side and host-side faults, solving host-side issues first is important and efficient.

4.1.2 Offline failure diagnosis

After the entire diagnosis procedure, some issues still cannot be directly diagnosed with the available runtime information. To locate the root cause of these failures, we have designed an offline failure localization mechanism. It isolates and diagnoses all suspicious hosts used in the current training task. Unlike SuperBench [60] monopolizes the entire cluster for multiple hours of testing, our offline system diagnoses failures in parallel for targeting hosts. After ensuring each host is problem-free, this host is returned to online service.

Parallelized offline failure localization. To expedite the offline localization process, we design a parallelized approach to maximize efficiency. In the offline localization procedure, all hosts undergo a series of self-checks, including stress testing for CPU, GPU, PCIe, and NVLink. This part is fully parallelized (i.e., each host runs self-checks independently). If an issue is identified during the single-host self-checks, that host is marked as faulty. If no issues are detected in the single-node tests, further multi-host failure diagnosis is required.

The next step is a multi-host failure diagnosis. We select typical models similar in SuperBench [60], and we include more emerging typical models (e.g., MoE models [12] and Multimodal models [4, 20]). The basic idea is that the end-to-end training failure is triggered by a specific combination of computing and communication in the customer's model. Traversing our selected typical models, we can determine which model covers this combination of computing and communication and use it as the reference model in the following multi-host diagnosis. The cluster is then divided into smaller segments, and the reference model is trained on different segments independently, ultimately pinpointing the problematic host. Once a subset of the cluster is confirmed normal, these hosts are promptly returned to the resource pool, minimizing resource wastage.

Topology-aware parallel localization. During parallel localization, the partitioning of different subsets is crucial. Since the network is shared among different hosts, splitting hosts indiscriminately may lead to parallel training tasks competing with the same network links. This can result in two side effects. (1) If the failure occurs within the network (e.g., silent packet loss) and the parallel diagnosing tasks use the same problematic link, both tasks will be affected, making the parallel diagnosing procedure fail to locate the root cause. (2) If the fault is not in the network but on the host, the current running of training tasks may share the same network link and cause congestion, leading to inaccurate diagnosis results.

To handle this issue, hosts are not evenly split into different subsets. We split hosts into two subsets according to their location in the physical network topology. We count the number of hosts in different Pods and ToR groups (in rail-optimized topology, multiple ToRs are used to serve the same host, called a ToR group), respectively. Hosts are split according to whether they belong to the same Pods and ToR groups. As a result, during the parallel diagnosis, traffic from different diagnosing tasks would not interfere with each other in the network.

After training the reference model on two subsets, the subset encountering failure is chosen for further diagnosis. Hosts in the other subset can be returned to online service. With the proceeding of the parallel diagnosis, left hosts would gradually converge to be in the same ToR groups. In this case, the splitting could be arbitrary since any splitting would not lead to network congestion. If both subsets encounter failures, the

root cause exists in both subsets, and then all hosts in these two subsets need to be isolated.

Transforming the missing piece into a new clue. The above procedure can cover the diagnosis of most failure cases. However, there is a missing piece: if the root cause is the misbehavior of Core (Tier-3) switches or Aggregation (Tier-2) switches, this independent parallel diagnosis would miss this root cause of failure (since we delicately minimize traffic passing Core and Aggregation switches).

We indeed encounter this issue in production. There was a failure in a training task occupying 1.5K GPUs. In the offline failure diagnosis, we successfully find a reference model to reproduce the failure. However, when we employ the parallel diagnosis, the failure cannot be reproduced in any subsets of hosts. We are surprised at first since there is a missing piece that the default diagnosis procedure cannot handle. After several times of reproduction and further analysis, we derived insight from this missing piece and concluded that there must be some misbehavior in the Aggregation switches. Through succeeding switch-specific diagnosis, the root cause is clear: silent packet loss happens on one Aggregation switch. But why is this switch error not detected by the $NetDiag()$ in the online diagnosis? We encounter an exceptional kind of silent packet loss, which only drops packets larger than 1KB. As a result, the RDMA Pingmesh system does not throw any error since the size of all probing packets is 64B.

After comprehensive reviews of this failure case, we make several enhancements to our system. (1) We supplement the offline diagnosis to handle this case automatically. (2) We enhance RDMA Pingmesh to cover varied lengths of probes.

4.2 Phase-2: Procedure-aware Diagnosis

Despite significant improvements in failure localization through enhanced legacy systems, we still encounter many cases that need to trigger the offline diagnosis to finally locate the root cause, inevitably leading to considerable computation resource waste. Furthermore, even though most cases can be handled with Aegis Phase-1, we encountered several rare cases where typical models could not reproduce the failures encountered in production. In these cases, to finally solve customers' problems, we had to cooperate deeply with them to reproduce failure cases online and collect more diagnosis information. These failures are caused by systematic reasons, requiring not just basic error information but also training-procedure-specific information to find out the culprit. Therefore, we upgrade our system to diagnose runtime failures using a procedure-aware approach.

4.2.1 What is the ideal solution?

The main difficulty of fully online diagnosis is lacking precise information. Therefore, we enhance our online task monitoring capabilities to provide more valuable runtime information. However, several practical constraints must be considered before implementing such improvements:

High confidentiality. LLM training is a synchronous process, which is also the main reason for the difficulties in failure diagnosis. Accurate localization of such issues requires detailed outputs, and since the root causes vary across different cases, the necessary data for diagnosis also differs. Choosing the right metrics for high-confidence diagnosis is crucial.

Minimal customer modifications. Comprehensive fault localization typically requires extensive metrics collection, which demands tight fusion with customers' code or training frameworks. However, as a model training cloud service provider, extensive modifications to customer code or training framework are impossible in production. The ideal solution is fully transparent to customers.

Low overhead. Adding new information collection and processing should introduce minimal overhead to avoid impacting the main training tasks.

4.2.2 Customizing CCL is the bridge

After comprehensive consideration, we employ a customized CCL as the bridge for enhanced runtime diagnosis. This decision is based on several valuable characteristics of CCL:

First, in mainstream training frameworks (e.g., Megatron and DeepSpeed), collective communication is a modularized component that can be replaced independently. By replacing the CCL, we can collect customized diagnostic information without any change in customers' model codes. Unlike higher layers, which may involve extensive modifications, customizing the CCL offers a more practical solution for diagnostics.

Furthermore, collective communication sits at the boundary of computation and communication. Precise runtime information from this layer can provide clear information about the host-side processing time (computation) and network-side processing time (communication). This information is vital for the localization of faulty devices.

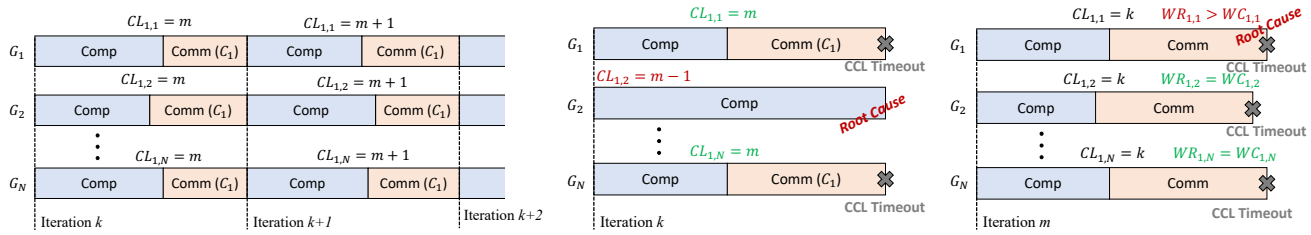
Information collection. During the training, our customized CCL records several statistics of each communication operator (C_i) in each GPU (G_j).

- Collective launch count($CL_{i,j}$) records how many times C_i is launched by G_j.
- Work request count ($WR_{i,j}$) records how many work requests in C_i are launched by G_j.
- Work completion count ($WC_{i,j}$) records how many work requests in C_i are finished by G_j.

We have tried other different metrics in our testbed and found that the information mentioned in our paper is both sufficient and necessary. Keeping collected metrics lightweight and easy to deploy is important.

As shown in Figure 7a, all GPUs alternately execute computation and collective communication in a synchronized way. In normal cases, $CL_{i,j}$ from different G_j keep the synchronized increasing in each iteration. We further present how to localize failures with the above statistics.

Scenario-1: failure in computation. If a failure occurs in the computation phase, as shown in Figure 7b, G_n ($n = 2$ in this case) fail in launching the succeeding C_i ($i = 1$ in this



(a) Normal training iterations. (b) Failure in computation. (c) Failure in communication.

Figure 7: Customizing CCL for failure diagnosis.

case). As a result, all other workers in the same communicator would stall at the C_i and crash owing to CCL timeout. In this case, $CL_{i,n} < CL_{i,j\neq n}$ in the same group. As a result, G_n is pinpointed as the root cause of the failure.

Scenario-2: failure in communication. If the failure is in communication, then the transmission of a specific work request in C_i would fail, causing all GPUs in this group to endure CCL timeout as shown in Figure 7c. More detailed statistics $WR_{i,j}$ and $WC_{i,j}$ are used for further diagnosis. In normal GPUs, $WR_{i,j} = WC_{i,j}$. If $WR_{i,n} < WC_{i,n}$ ($n = 1$ in this case), it means G_n is related to the root cause. We further conduct *NetDiag()* on all sources and destinations related to these abnormal work requests.

After deploying deep runtime diagnosis in production, almost all training failure cases can be pinpointed in runtime (more details in §7).

Limitations. Leveraging information from collective communication is a compromise that is easy to deploy. Actually, just using collective communication information is not enough to find the root cause of failures. However, as aforementioned, collective communication is located at the boundary between computation and communication. This intrinsic characteristic is important for our primary goal: locating the culprit.

As a cloud service provider, our customers may employ various versions of official or self-constructed images with differing CUDA, drivers, and CCL versions. To provide consistent diagnosis ability for all customers, we need to make sure (1) our diagnosis system can seamlessly deploy in different images and model training tasks and (2) solutions deployed in different environments should deliver the same diagnosis information for delivering the consistent diagnosis performance. Therefore, we need to provide our corresponding customized version based on all CCL-released versions. Although the above limitations exist in customizing CCL, it is still easy to deploy compared with other alternatives (e.g., customizing the training framework or modifying customers' model code).

5 Performance Degradation Diagnosis

Besides complete training task failure, some device abnormalities may not crash the entire training but lead to significant performance degradation. These abnormalities should also be diagnosed on time. Since the training task is still running when a performance degradation occurs, we cannot use *OfflineDiag()* as the final fallback solution. Therefore, we design a degradation diagnosis system.

5.1 Basic Correlating Diagnosis

Similar to Phase-1 in §4.1, we first leverage the existing runtime statistics to detect the potential performance degradation.

Key metric selection. The first challenge is to determine precise metrics that can help recognize and diagnose the fault. After solving various cases in production, we notice that most performance degradation is triggered by one single abnormal device, where two categories of metrics can indicate it.

(1) Abnormal operating metrics. These metrics are designed to directly indicate that some components are running at abnormal conditions. For example, the Retran metric denotes how many packets are retransmitted per second. In ordinary cases, this Retran metric should always be zero. The high Retran metric denotes misbehavior in the network.

(2) Performance metrics. These metrics are designed to reflect the execution efficiency of specific components. The abnormal evolution of one component would lead to overall performance degradation. For example, the Actual TensorFLOPS metric denotes how many tensor float-point calculations are completed each second.

We select 20+ metrics according to operating in production including host metrics (e.g., CPU utilization, GPU utilization, GPU temperature, and PCIe utilization) and network metrics (e.g., Bandwidth utilization, Retransmission count, Switch port queue length, and ECN count). Owing to the confidential policy, we cannot release a detailed list of all metrics used. Intuitively, if one metric (especially abnormal operating metrics) is running in a faulty range (e.g., continuously high Retransmission metric), then this value should lead to performance degradation. To filter these clear signals, we set corresponding thresholds for these metrics, respectively.

However, simply using static thresholds cannot fit various training scenarios. Simply setting thresholds for every single metric would lead to numerous misjudgments since resource utilization varies greatly, even in the normal training procedure. Considering that the entire training procedure is well-organized, we, therefore, leverage the synchronizing training characteristics for further correlating diagnosis.

Cross-host correlating diagnosis. The monitored results of the same metric from different hosts should follow the same

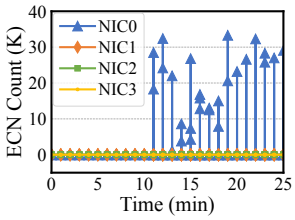


Figure 8: Abnormal ECN metric evolution.

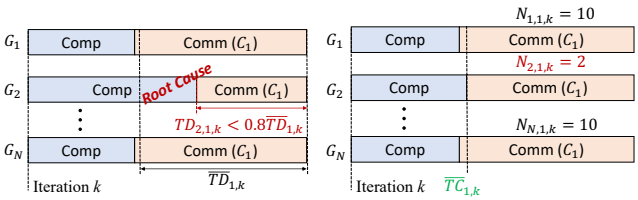

(a) Computation degradation. (b) Communication degradation.

Figure 9: Customizing CCL for performance diagnosis.

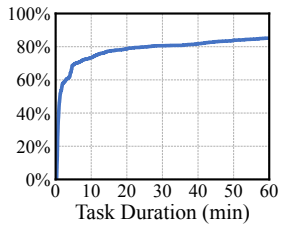

Figure 10: Durations of training tasks in production.

changing pattern among different training iterations. The basic idea is that a small part of nodes causes the entire performance degradation, and performance degradation usually occurs along with abnormal changes in some metrics, which can indicate the root cause. Therefore, we design a Z-Score [22] outlier analyzer for different metrics.

For each selected metric, the outlier analyzer calculates the average value λ and standard deviation δ in the period T. If the metric value from a single host is higher than $\lambda + 2\delta$ for the lasting T, then this host is defined as an outlier. T is set to be ten minutes in production. In practice, the abnormal node usually generates significantly different values compared with others, which makes $\lambda + 2\delta$ a simple and good enough threshold for diagnosis in production.

Actually, we have tried a series of other outlier analysis mechanisms (e.g., LOF [27], Isolation Forest [3] and DBSCAN [7]). They lead to similar precision and recall ratios. Considering that this entire process needs to run in a stream processing way, the calculation cannot be too complex. We finally choose this simple but efficient outlier analysis mechanism. This correlating diagnosis helps us troubleshoot various malfunctioning devices, including decelerating GPU/CPU/PCIe/NIC/link/switch, which covers a large proportion of failures in production.

Case study. We use an actual case met in production to further illustrate how the cross-host correlation diagnosis runs. During our in-house LLM model's training, as shown in Figure 8, the ECN statistic from one NIC increases from zero to 10-30K per second. At the same time, our model training team reports a 26% training iteration time increase. The correlating diagnosis mechanism immediately identifies this abnormal situation, since this abnormal NIC exceeds $\lambda + 2\delta$ of the ECN metric. The root cause is that one of the links connecting to this NIC drops packets silently. It triggers all traffic forward to this NIC through another link, introducing network congestion at the last hop and finally delaying the entire training iteration. Correlating diagnosis immediately pinpoints the root cause of this performance degradation. After isolating the host containing this abnormal NIC and restarting the training task, the training performance returns to normal.

Limitation. This correlating diagnosis can work out the root cause for performance degradation cases in which one or several hosts generate significantly different metrics compared with others. However, this is not always true. It is also common that when performance degradation happens, several metrics change on all hosts, and we are unable to pinpoint the root cause. Therefore, we need to acquire more information and a new mechanism to solve these hard cases.

5.2 Enhancing Procedure-aware Diagnosis

Inspired by the design choice in §4.2, we choose to further customize CCL for more information helping degradation diagnosis. We further record the following statistics of each collective operator (C_i) for each GPU (G_j) in iteration I_k.

- In I_k, the duration of C_i in G_j is $TD_{i,j,k}$.
- In I_k, average duration of C_i is $\overline{TD}_{i,k}$.
- In I_k, the network throughput for the last L ($L = 5$ in practice) work requests of C_i in G_j is $N_{i,j,k}$.
- In I_k, average network throughput of C_i is $\overline{N}_{i,k}$.

Figure 9a represents the computation degradation case, where the unexpectedly long duration of the computation is the culprit of performance degradation. Since the end of each collective operation is synchronized, we can utilize the duration of communication time to deduce the computation time. If the $TD_{i,j,k} < \alpha\overline{TC}_{i,k}$ ($\alpha = 0.8$ in practice), then G_j is the root cause of the computation degradation. Figure 9b represents the communication degradation case, where the long duration of the communication is the culprit of performance degradation. If $N_{i,j,k} > \beta\overline{N}_{i,k}$ ($\beta = 1.5$ in practice), there is a communication degradation. We use a slack threshold here to resist noise caused by possible temporary network congestion. Based on this information, we filter out GPUs group $\mathbb{G}$ directly suffering degradation. $\mathbb{G}$ is further used to determine which source or destination is the root cause of this communication degradation. The principle of this procedure is similar to *RootDiag()* in Algorithm 1 in Appendix A. We omit the details due to limited space.

6 Solving Problems Before Delivery

We analyze the runtime duration of all failed training tasks. As shown in Figure 10, 73% of tasks failed within the first 10 minutes, which is unexpected since the initialization phase of a training task usually takes between 5 to 20 minutes. It indicates that many tasks are failing during the initialization process. It is also in alignment with our experience: many components (both software and hardware) may already endure errors before engaging in the new training task. We have reviewed all failures that occurred during the initialization phase, and there are two main reasons for these failures.

Table 1: CBD task list

Phase	Tasks	Time
Configuration check in parallel	Host configuration check	<1min
	GPU configuration check	
	NIC configuration check	
Single-host test in parallel	GPU kernels test	3min
	NVLink test	
	HBM test	
	PCIe test	
	CPU execution test	
	Dataset/Model/Checkpoint load test	
Multi-hosts test in parallel	Collective communication test	6min
	Comput./Comm. overlap test	

Frequent component updates. Components such as training frameworks, CCL, container networks, NIC drivers, and switches are updated frequently. For example, as released by Meta [19], during the training of LLaMa3, 47 planned updates are executed during a 54-day training snapshot (i.e., 26 times per month). In our model training cloud service, we have a bunch of update requirements for many purposes (including bugfix, safety reinforcements, version unifying and performance optimizations) from many components. To keep the entire service steady, we do not execute updates at such a high frequency. Critical updates, including bugfix and safety reinforcements, are merged to be released weekly. Other updates are released monthly. Even so, updates still trigger many failures in production.

Post-usage failures. If a host encounters a fault after its last use, it will trigger the failure of the new training task during the initialization phase. This issue is especially challenging in cloud environments where hosts are dynamically allocated from a shared resource pool, making failure reproducing much harder. Additionally, once a host is delivered to the customer, the cloud provider cannot run diagnostics on it arbitrarily, making diagnosis much more difficult.

To address these issues, we introduce the Check Before Delivery (CBD) procedure. This check is done right before the resources are handed over to the customers. It brings two main advantages. First, this check process is added at the final stage of resource delivery, so it does not disrupt the existing workflow. Second, by running the validation after the entire environment is set up, we can catch more issues. For example, a connectivity test executed on the physical host will miss connectivity problems caused by incorrect routing configurations in the container network. These issues can only be detected after the container is completely created.

However, CBD has a drawback. Since CBD is called after the environment is fully prepared, it must be in the last phase of delivery. This means CBD needs to be efficient to avoid impacting user experience. Taking these factors into consideration, we designed a set of CBD operations (as outlined in Table 1). We comprehensively select representative tests that cover the main components and organize them to execute in parallel. The entire execution of CBD is less than 10 minutes. If a large number of machines fail in the CBD procedure

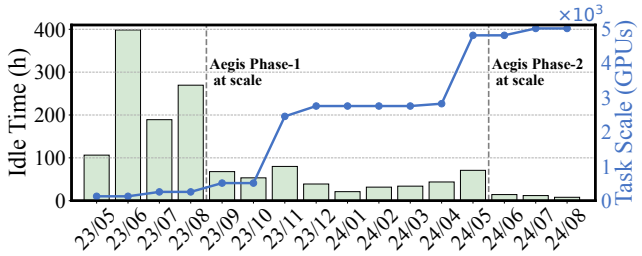

Figure 11: Evolution of idle time in production.

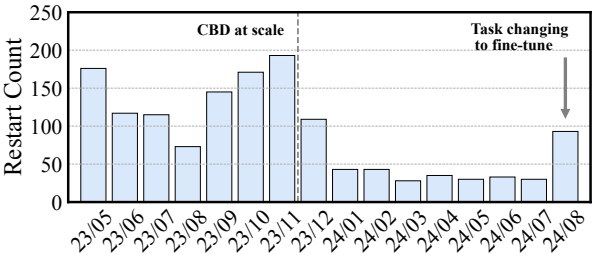

Figure 12: Evolution of restart counts in production.

(reaching a certain threshold), we roll back recent updates to prevent widespread service disruption. There are several different sale modes of the model training service. For the complete PaaS mode, introducing an extra 10 minutes before the startup of each single training task is still unbearable. We also deliver a lightweight CBD version, which only contains parallelized configuration checks and other critical quick local host tests. This lightweight CBD can be completed within 1 minute and can cover most fundamental failures.

With the deployment of CBD, we have intercepted 1-2% problematic hosts before final delivery. If not detected on time, these problematic hosts would lead to training task failures. Considering this significant benefit, we have made CBD a mandatory procedure in delivery.

7 Evaluation: Aegis in Production

The first version of Aegis was online in September 2023, and it immediately became one of the most fundamental components in all succeeding delivery of training services. Aegis has served dozens of large-scale training clusters for more than one year. Due to confidential reasons, we cannot release statistics from our external customers. Therefore, we statistic training task information from our inner model training team, which works to train one of the top-tier LLMs (i.e., large language model) in the world.

7.1 Evolution of Training Stability

As shown in Figure 11, the line records the scale of the training tasks from our inner model training team, which increases by more than 40× during the last 16 months. The bars represent the monthly accumulated idle time of the training tasks owing to the waiting for the failure diagnosis. After Aegis Phase-1 is online, the idle time (time duration where no task running in the training cluster) is decreased by 71% in the next month. This result is impressive, considering that we even doubled the training scale in September 2023. There is

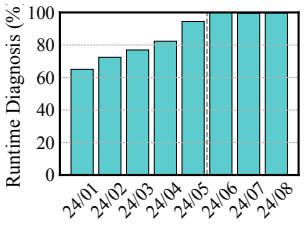

Figure 13: Runtime diagnosis percentage.

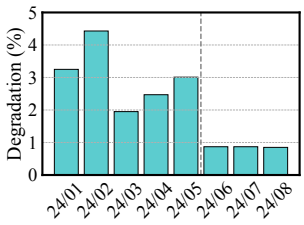

Figure 14: Performance degradation percentage.

an increase of idle time in November 2023, which is owning to a 4× boosting of training scale. The increase in the training scale introduces several unexpected corner case issues, which consume a long time for diagnosis and affect idle time. Aegis Phase-2 is deployed in June 2024, directly leading to 91% save of the training idle time. This improvement mainly comes from the fact that more failures can be solved without involving offline diagnosis.

Figure 12 shows the restart counter of the training task. The increase of the training task scale in November 2023 also triggers more training restart, and a large amount of failures during the initialization phase. We, therefore, speed up the development of CBD and put it into online service in December 2023. It contributes 44.8% decrease in the restart counter in the next month. Through continuously handling more cases and optimizing the checklist, it finally decreased 84.6% of the restart counter. With CBD fully deployed and comprehensively optimized, it discovers around 1-2% problematic hosts before final delivery. Note that the restart number increases in August 2024, the reason is that our model training team switched the task from pre-train to fine-tuning, introducing planned experiments and tests. The root causes of these errors are diverse (e.g., device aging, incorrect configurations, wiring mistakes caused by repairs, complex serving mode switching, etc.). Moreover, since we serve model training requests from multiple tenants, not all tasks are mature and steady-running. Many failures are caused by unoptimized LLM designs or incorrect use of the training infrastructure.

7.2 Runtime Failure Diagnosis

We further answer how many failure cases are diagnosed in runtime (rather than offline) in Figure 13. This metric is important since each offline diagnosis would introduce great damage to the overall GPU utilization and user experience. With the deployment of Aegis Phase-2, the runtime diagnose percentage gradually converges to near 100%. It means that a training task can automatically recover from almost all types of failures without human interference.

7.3 Handling Performance Degradation

To quantify the efficiency of performance degradation diagnosis of Aegis, we deeply cooperate with our model training team to acquire records of iteration time in all training tasks. The iteration time T_k is measured from our model training log. The standard iteration time is calculated as $T_S = 1.2 \times \overline{T_k}$. Performance degradation is calculated as $\frac{\sum_{k:T_k>T_S}(T_k - T_S)}{\sum_{all} T_k}$. The

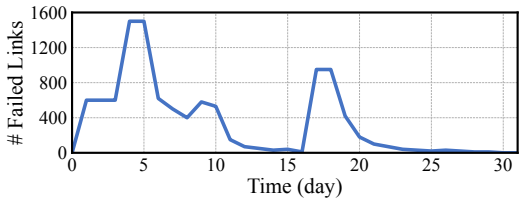

Figure 15: Number of failed links during the batch failure.

statistic results are shown in Figure 14. Performance degradation diagnosis of Aegis is deployed in June 2024. It significantly eliminates performance degradation by 71%.

8 Experience and Lessons

We share key experiences and lessons we learned during the evolution of Aegis as well as the entire reliability guarantee for model training cloud service (additional experience can be found in Appendix B).

Handling batch link failure cases. We have built and delivered dozens of large-scale training clusters. At the delivery of one cluster in them, we encounter an unbearable increase in the link failure ratio ($10-20\times$ higher than the normal link failure ratio). Our investigation revealed that the primary cause was overlapping construction timelines for the data center's building infrastructure and the installation of servers and network wiring. This overlap resulted in significant contamination of optical modules and fibers.

Figure 15 illustrates the change in failure rates over a month. With new machines delivered in batches, the number of failed links increases swiftly due to contaminated links. As cleaning efforts progressed, the failure rate decreased gradually. It takes tens of deep cleaning to completely solve this contamination problem. After identifying this problem, we implemented stricter guidelines for data center construction and delivery to prevent similar issues in the future.

Multiple sale modes and heterogeneous devices in production. Another significant factor affecting the stability of training clusters is the complexity of delivery scenarios. The constant updates to top-tier GPUs (e.g., NVIDIA A100 [13], H100 [16]), NICs (e.g., NVIDIA CX-6 [6], CX-7 [15], BF3 [14]), and switches have led to the deployment of a wide variety combinations of heterogeneous devices in our clusters. This diversity in hardware configurations adds complexity to both the testing and delivery processes, as well as to identifying the root causes of stability issues. Furthermore, to satisfy the diverse needs of our customers, we offer different sales models. For customers focused solely on model optimization, we provide the Platform-as-a-Service (PaaS) sale mode. Therefore, these customers only need to care about constructing novel models and managing their Docker images. On the other hand, for customers who seek further optimization that combines models, training frameworks, and infrastructure, we offer a basic Infrastructure-as-a-Service (IaaS) sale mode. These sale modes involve significant differences in the technology stacks, such as how devices are virtualized and

how the entire cluster is managed. Each mode has its unique set of configurations and delivering procedures, greatly impacting the overall reliability.

Furthermore, in practical operations, we often need to transfer machines originally used in one environment to another, such as relocating servers from one cluster to another with a completely different network architecture or converting a cluster from IaaS to PaaS. These transitions involve numerous configuration changes. Initially, we directly reconfigure all hosts according to the new scenario. However, we encounter several issues where the configurations from the previous setup are not fully compatible with the new one. For example, some modules lack initialization options and only have the overwrite function (e.g., NIC firmware). If the new configurations did not completely overwrite the old ones, residual configurations could remain active, leading to potential issues.

To address these problems, we devote significant effort to thoroughly reviewing and rewriting all configurations to ensure compatibility under different scenarios. By adding a corresponding configuration check in CBD, we ultimately avoid such problems from occurring again.

Traffic pattern evolution triggers the congestion control issue. During the continuous delivery of new training clusters, we encounter a significant issue, where the iteration time increased significantly during the training. Through comprehensive correlation analysis, Aegis identifies the problem but does not find out any abnormal indicators on individual hosts. Further Aegis's runtime analysis based on collective communication information reveals that the performance degradation was due to communication delays caused by many hosts. Despite isolating the abnormal hosts, the training performance can recover, but soon, a similar issue occurs again.

Initially, we suspect that the issue might be related to some faulty switches, since network problems are typically the cause of persistent communication performance issues. However, our thorough investigations show no abnormalities in switch behavior. To resolve this, we conduct extensive offline reproduction and testing. We eventually pinpointed the cause: a bug in the congestion control implementation of NICs. The bug causes an issue where a small number of continuous ECN signals could cause the NIC to enter a preset maximum rate limit. This rate limit is set very low, resulting in significant communication slowdowns.

We report this issue to the NIC vendor, who also confirms this bug. Given that a firmware update to fix the issue would take a considerably long time, we implement two immediate patches in production. (1) We raise the maximum speed limit to alleviate the performance impact. (2) We employ periodic resets of the congestion control state to prevent prolonged performance degradation. We later fix this issue permanently by updating the official bugfix firmware.

Protecting customers' privacy. It is always an important topic for cloud service providers to keep customers' privacy (e.g., training dataset, customized models, training strategies and model checkpoints) well protected. Aegis Phase-1 builds the fault diagnosis ability fully based on existing statistics, introducing no privacy risk. During the design of Aegis Phase-2, to achieve further runtime information for better diagnosis, we investigate and attempt a series of different methods. We have had multiple times of conversations with our product development, solution architect and solution sales teams to figure out the best solution path for Aegis Phase-2. Although for those heavy solutions (e.g., encoding specific statistic functions in customers' models), we can force the deployment of these solutions by re-signing authorization agreements with customers, these solutions would be rejected by most of our customers. After extensive design deliberation, we ultimately opt to enhance CCL.

9 Related Work

Large-scale AI model training diagnosis systems. SuperBench [60] provides a comprehensive benchmark suite for diagnosing issues before deployment, which cannot cover runtime failures. MegaScale [36] monitors CUDA events of "critical code segments" in the model code, which is impractical from the perspective of the cloud service provider. There are some other diagnosis solutions based on infrastructure logs and statistics like monitor_train_log [2] and SageMaker [11], which can only cover a limited range of failures. Dynolog [10] integrates PyTorch profiler to further get code-block level tracing, which however cannot locating root causes in the GPU kernel executions. We have tried this technology roadmap before, but owing to the limited failure coverage, we eventually chose to not deploy them in production.

General abnormality diagnosis systems. In the general cloud computing scenario, various efforts have been devoted to anomaly diagnosis in the host [23–25, 28, 31, 34, 35, 39, 42, 43, 46–48, 50, 52, 55, 57] or in the network [26, 29, 32, 35, 37, 38, 40, 41, 51, 53, 54, 56, 58, 59, 61, 63, 64]. However, as illustrated in §2, without specific optimization focusing model training scenarios, these solutions cannot provide satisfied diagnosing precision for model training specific failure cases.

10 Conclusion

We present the evolution of Aegis, a large-scale model training diagnosis system, in our production. Keeping easy-to-deploy in the cloud as the first principle, Aegis solves training failures and performance degradation cases. Aegis decreases 97% of the idle time wasted by failure diagnosis, 84% of the training task restarts, and 71% of the performance degradation.

A Failure Diagnosis Procedure

Algorithm 1 shows the pseudo-code of the entire Failure Diagnosis Procedure.

B Additional Experience

Dual-ToR really helps, but it migrates failure cases to degradation cases. As aforementioned, we deploy a dual-ToR design in production to conquer the high link failure ratio. This design is very effective. We handle dozens of link-repairing tickets every week, but most of them do not lead to the crash of training tasks. Furthermore, thanks to dual-ToR, we can conduct a hotfix for these faulty links without isolating the host (i.e., the training task can train continuously during the hotfix). We deliver a complete Standard Operating Procedure (SOP) for resident staff in the cluster to conduct the hotfix. They need to check (1) the correctness of both ports' links, (2) the status of both links, and (3) the switch ports'

Algorithm 1 Failure Diagnosis Procedure

```
T //The set containing all hosts used in this training
L_CE = CriticalError(T)//get critical error locations
L_DE = DistError(T)//get distributed error locations
if L_CE.size() > 0 then
    Isolate(L_CE) & Restart the task
else if L_DE.size() <= 2 then
    Isolate(L_DE) & Restart the task
else
    N = RootDiag(L_DE)
    if N! = NULL then
        CheckError(N)
        Isolate(N) & Restart the task
    else//distributed problem
        R_C = ConfigCheck(L_DE)
        R_N = NetDiag(L_DE)
        if R_C||R_N! = NULL then
            Repair(R_C, R_N)
        else
            Isolate L_DE & OfflineDiag(T)
        end if
    end if
end if
```

status before conducting the real link replacement. More than $O(10K)$ link hotfixs are successfully executed.

Although dual-ToR can significantly decrease the possibility of training crashes caused by link failure, it transfers these failure cases into performance degradation cases (since the available network bandwidth is halved). As a result, we devote more effort to handling performance-related issues. As the training does not crash, actually customers can independently determine whether to proactively terminate the current training right after a new checkpoint and restart it, greatly improving the overall user experience.

Reboot or repair? As illustrated in Figure 2, most stability issues ultimately trace back to problems with the fault in hosts. Once a faulty host is isolated, a critical next step is determining whether it can be fixed by reboot or repair. Some issues can be fixed with a reboot, but others necessitate sending the host for repair, which can take several weeks or even months. The primary challenge is that error reports alone cannot definitively indicate whether a problem can be resolved by reboot. For example, an ECC Error could be caused by an unexpected bit flip, which might be fixed by a reboot. On the other hand, an ECC Error could indicate a hardware fault in the HBM, which must be repaired by sending the host back to the vendor.

Given the lack of an efficient method to determine whether the host needs reboot or repair, we have developed a SOP for it. After isolating the faulty host, we first perform a reboot and then conduct a series of hardware stress tests. Unlike CBD, since the host is already isolated, we need a comprehensive (rather than fast) test to make sure the host is back to normal. We first check the current installation settings. If any irregularities are found, the machine is sent to execute the complete re-installation. If all settings are correct, the host further undergoes a thorough computing power, CPU, GPU, Memory, PCIe, NVLink and network check. If all checks pass, the host is returned to the online cluster pool. Otherwise, the host is sent for repair.

Despite the above rigorous tests, we still occasionally encounter corner cases where a host that passes all tests still exhibits faulty issues. To address this, we have implemented an additional backstop: if a host passes the reboot tests three times, but continues to cause failures online, it is mandatory to send for repair. We also engage with our vendors to understand the root cause and update our test cases accordingly. Accurately and efficiently determining whether a host requires repair remains an open issue. Our current approach is practical for production but still leaves room for further refinement and improvement.

PAPAYA Federated Analytics Stack: Engineering Privacy, Scalability and Practicality

Abstract

Cross-device *Federated Analytics* (FA) is a distributed computation paradigm designed to answer analytics queries about and derive insights from data held locally on users' devices. On-device computations combined with other privacy and security measures ensure that only minimal data is transmitted off-device, achieving a high standard of data protection. Despite FA's broad relevance, the applicability of existing FA systems is limited by compromised accuracy; lack of flexibility for data analytics; and an inability to scale effectively. In this paper, we describe our approach to combine privacy, scalability, and practicality to build and deploy a system that overcomes these limitations. The PAPAYA FA system leverages trusted execution environments (TEEs) and optimizes the use of on-device computing resources to facilitate federated data processing across large fleets of devices, while ensuring robust, defensible, and verifiable privacy safeguards. We focus on federated analytics (statistics and monitoring), in contrast to systems for Federated Learning (ML workloads), and we flag the key differences.

1 Introduction

The scale of distributed systems that allow users to transact and interact have grown massively over the past two decades, prompted by the widespread availability of powerful mobile devices: primarily, smartphones, but also tablets, smart watches, and other wearables. These systems are typically mediated by a centralized organization, such as Google, Apple, Meta, Bytedance, or other players broadly in the "high tech" arena. Providing a positive user experience in such systems relies on their operators monitoring a variety of metrics, and gathering data to inform ML workflows such as recommender systems. Consequently, it is necessary to instrument the system for data collection and analysis of user activities and preferences. We refer to this process as *analytics*.

Increasingly, there are strong motivations to ensure high levels of privacy for analytics. Internally, companies recognize the high expectations of users that their data will be used responsibly, and will be protected from threats. Externally, a range of laws and regulations govern how organizations must manage data safely, including GDPR[1], ePD[2], and CCPA[3]. These mean that analytics systems must have strong protections on how user data is stored and processed. Meanwhile, we design the system to operate effectively, so that monitoring queries can be evaluated accurately and unobtrusively.

In response to these needs, the model of federated computation, and specifically federated analytics (FA), has recently risen to prominence [5]. This model embodies the notion that data gathered by client devices should remain on those devices, and only minimal summary information should be sent from devices to a server, which can compute and release aggregate results. Beyond this data minimization paradigm, additional protections can be instantiated, to ensure: deidentification (the identity of the client is dissociated from the messages they send); security (data is encrypted to prevent it being observed by unauthorised parties while in transit or at rest); and privacy (the results of a query do not disclose information about any individual participant).

Putting this philosophy into practice requires significant levels of systems and algorithm engineering. Careful design choices are needed to ensure that components can cope with the scale of millions to billions of active participants. Components must interact reliably, so that the security and privacy guarantees compose constructively, and do not allow leakage or expose vulnerabilities. The system must also be flexible enough to allow complex queries to be evaluated over subsets of users, whose ongoing active participation is not guaranteed.

1.1 Our Contributions

Variations of federated analytics technology are utilized across the industry, such as by Google for identifying popular items and producing geographic heatmaps [2, 19, 45] and by Apple for autocorrect and user experience purposes [1, 38].

[1] https://gdpr-info.eu/
[2] https://www.edps.europa.eu/data-protection/our-work/
[3] https://oag.ca.gov/privacy/ccpa

However, the first generation of FA systems faced challenges that tend to limit their wider applicability. Some systems suffer from low accuracy due to overly restrictive models of privacy, making them less reliable for deriving valuable insights. Others lack the flexibility that analysts need to obtain the information necessary for making data-driven decisions. Moreover, several early FA solutions do not scale effectively, preventing them from reaching many millions of devices.

In this paper, we present the Federated Analytics stack at Meta that integrates privacy, scale, and practicality in a cohesive architecture. The FA stack enables efficient computation across three zones: (1) Device, (2) Trusted Environment, and (3) Untrusted Orchestrator. We first provide an overview of the challenges and then our approach to solve them.

Practicality and Accessibility to Analysts. Previous FA systems have struggled with limited expressivity, slow query deployment (time from query creation to result), and requiring deep expertise in federated paradigms—barriers to wider adoption. Our approach addresses these challenges as follows:

- **Expressive and Flexible Computational Model.** We provide a powerful yet intuitive model combining local (device-level) data transformations with a minimal set of private cross-device aggregation primitives. Analysts can configure federated computations using familiar SQL queries to define local operations, select cross-device aggregation methods, and specify privacy parameters. This balance of expressivity and simplicity meets most analytical needs without requiring deep technical knowledge. See section 3.2.
- **Ad-Hoc Query Support and Fast Iteration.** A rapid iteration cycle is crucial for an effective analytics platform. With active query management, periodic device synchronization with the server, and batched computations, our system allows analysts to go from query creation to results within a day. This quick turnaround facilitates agile data exploration and decision-making.

Scalability and Resource Consumption. Our system must tackle two aspects: (1) device population—the total number of devices answering a query, which can vary from thousands to billions, and (2) query volume—the number of active queries within the FA system. Additionally, the processing must be stateful, fault tolerant, and mindful of resource usage on constrained devices. See Sections 3.6 and 3.7.

- **One-shot Algorithms.** Unlike Federated Learning, the system is optimized for only one or a very few (constant) rounds of data collection. We express these algorithms with a flexible primitive, namely Secure Sum and thresholding. Furthermore the algorithms are robust to devices dropping out or being unavailable. They also avoid any inter-device dependence, and require that client information can be encapsulated in a single message. We give a discussion of FA algorithms for quantiles in Appendix A.
- **Batch Processing.** To reduce resource use, PAPAYA batches computations on each device. Each device retrieves all relevant queries, executes them and makes one report back, effectively amortising the cost across metrics. See Section 3.6
- **Predictable Query Load.** We randomize the sync and reporting schedules of individual devices to distribute data submission over a defined period, controlled by a system parameter, ensuring a manageable and predictable Query Per Second (QPS) to the TEEs. This is in Section 5.1

It's important to highlight that *one-shot algorithms* with batched processing were critical to minimise the computational and communication cost on resource constrained devices and maximise inclusion of all device types.

Privacy and Security (Section 4). Federated systems inherently offer a baseline of privacy through data minimization, i.e., keeping raw user data on the device, but our stack aims to provide a higher privacy standard through well-defined mathematical guarantees. Given the diversity of differential privacy models, varying trust levels among actors, and evolving data analysis needs, privacy management becomes complex. We address this by centering privacy guarantees around the user's device. Each user's device takes responsibility to ensure that their data is handled properly during its processing and the outputs meet the expected privacy standard.

- **Simple Data Handling Off-device.** TEEs provide a secure environment where the device can verify the behaviour; i.e., how data is handled. We have explicitly designed the TEE code to be simple and use-case agnostic, to ensure a reliable, verifiable, and auditable implementation. Concretely, the only role of this environment is to perform Secure Sum across devices, threshold and apply differentially private noise. With SQL data transformation on device and post processing of the anonymized aggregate on untrusted servers we show that this Secure Sum and threshold functionality is sufficient to support a broadly applicable analytics platform.
- **Device Autonomy and Control.** Each device independently decides which queries to execute and when. It ensures, via remote attestation, that data processing is conducted off-device on a trusted TEE, running authenticated code. This mechanism guarantees that user data is only processed under secure and verified conditions
- **Support for Different Privacy Modes.** Different privacy models, such as local and distributed differential privacy, offer varying trade-offs between privacy and utility. Recognizing there is no one-size-fits-all solution, our stack supports both. For each query, the analyst can choose between on-device or TEE-based noise addition

and configure privacy parameters accordingly. Devices validate these parameters before accepting a query, ensuring that only those queries meeting the user-defined privacy standards are processed.

Production-Grade System and Evaluation (Section 5). Building on standard concepts in Federated Analytics, we developed a cohesive architecture that addresses the limitations discussed above, with a focus on resource efficiency and fault tolerance (Section 3.7). We successfully implemented this architecture at production scale. Beyond system design, we present empirical results from real-world experiments involving a population of nearly 100 million Android devices. These experiments carefully ensure system and data heterogeneity, measuring key performance metrics such as the time required to iterate over devices and data, and the effects of variables like time of day and device usage patterns. The large-scale experiments demonstrate the system's ability to handle challenges such as unpredictable device availability, diverse network conditions, and maintaining a predictable Query Per Second (QPS) rate to the TEEs. To the best of our knowledge, this is the first large-scale evaluation of a production FA system of this magnitude.

Similarities and Differences with Federated Learning. Both FA and FL instantiate the federated model of computation to protect client data. However, they differ significantly in their workloads, each posing distinct challenges to the system. Thus our FA system has fundamental differences in protocol, execution, scalability and hence is implemented separately. Specifically, FL systems are optimized for ML model training, which entails a fairly homogeneous set of tasks around sending a (large) model to clients, and obtaining (large) updates back from clients in the form of gradient updates. This process is repeated many times across small batches of clients (hundreds to thousands). By contrast, the FA system is meant for general purpose analytics on all device types. It optimizes for computations with fewer rounds of interaction, smaller messages from client to server, and participation from more clients (as many as billions). While we can use the FA system to run FL workloads, it would not be a good fit, and vice-versa.

Example use-cases. The system is used for a range of applications in production. Some indicative scenarios include: counting daily and monthly active users of different products, while ensuring that duplicates are not counted repeatedly [24]; identifying popular content (heavy hitters) within different geographic regions; producing heatmaps of density of activity at differing levels of granularity [2]; tracking the tail of response time distributions to ensure that SLAs are met and to raise warnings (see Appendix A); efficient collection of quality statistics (means, counts and variances) on system health metrics that impact user experience [11]; gathering accuracy and calibration metrics on the performance of deployed federated learning systems; populating dashboards for adoption of new features in applications; and reporting results of federated experiments (A/B testing) on different user interface designs.

2 Background: Secure Computation in TEEs

No matter the approach, federated analytics requires client devices to report some information about their data. Therefore, in order to provide robust security and privacy guarantees, it is necessary to rely on *secure computation*. The goal of secure computation is to evaluate functions on distributed inputs while disclosing only the result of the computation and revealing as little information about the inputs as possible. There are two feasible approaches for secure computation that are resilient against a curious or adversarial server and which are suited for a federated workload: secure multiparty computation (MPC) [13] and trusted execution environments (TEEs) [36]. While fully homomorphic encryption (FHE) is often suggested as a third alternative, existing FHE techniques are not flexible or performant enough to operate at scale.

MPC involves the use of techniques like secret sharing to instantiate partially homomorphic encryption across multiple co-operating servers [7]. Meanwhile, TEEs rely on hardware security to ensure that the TEE operates as described and does not leak any information to an external observer. TEEs provide several features for establishing trust that a unit of code has been executed faithfully and privately:

- **Confidentiality**: The state of the code's execution remains secret, unless it explicitly publishes a message.
- **Integrity**: The code's execution cannot be affected by any party, except by the code explicitly receiving a legal input.
- **Measurement/Attestation**: The TEE can prove to a remote party what code (binary) is executing and what its starting state was, ensuring confidentiality and integrity.

Our focus in this paper is on the trust that clients place on the FA system, and in ensuring that raw information does not leak to the analyst or other clients or even the orchestrator. We therefore focus on the security and privacy attached to client messages, and providing verification back to clients that their data is handled correctly. Handling clients who try to subvert the protocol by manipulating their responses to "poison" the results is not in scope for this work—separate mitigations are in place to ensure that clients are only running authorized binaries. TEEs enable us to derive anonymized, aggregated insights from distributed datasets while protecting the data of individual clients. Via attestation, clients obtain proof of confidentiality and integrity before data ever leaves their devices.

Enforcing Security through Remote Attestation. In our deployment, we use Intel SGX hardware to provide TEE functionality in the form of *secure enclaves*, similar to the Papaya FL system and others [18, 27, 38]. One needs to be mindful

about the possible attacks on SGX and apply appropriate mitigations [20]. With client attestation and hosting on public cloud one can limit the attack vectors. While TEEs provide confidentiality and integrity guarantees, these guarantees are valuable only if a client device can obtain proof that it is sending its data to a valid TEE running a known, trusted binary before the data leaves the device. It is possible to do this by using *remote attestation* as follows:

1. Before protocol execution, the TEE code is made available for audit along with the hash of the trusted binary. Ideally, the code is fully open-sourced to allow public scrutiny.

2. The TEE generates an *attestation quote* (AQ). This quote is used to cryptographically verify the initial state of the TEE, the hash of the binary running inside the TEE, the hash of public parameters used to initialize the TEE at runtime, and a Diffie-Hellman (DH) key exchange context used to establish a shared secret with the TEE. Under standard operating assumptions, it is not feasible to forge an AQ.

3. Upon receiving an AQ the client checks (a) the hash of the running trusted binary is the same as the one published with source code, (b) the public parameters used to initialize the TEE at runtime are valid, and (c) the DH key exchange context was actually generated by the TEE. The client aborts if any of these conditions can't be verified.

4. The client uses the DH key exchange context to establish a shared secret with the TEE, and sends its data encrypted.

Via this protocol, each client ensures it is talking to a legitimate TEE running trusted code with acceptable parameters.

3 System Design

Within a global-scale distributed system, we identify multiple types of participating entities. The system is operated for the benefit of many users (ranging in scale from millions to billions). Each user makes use of *client devices* (*clients* for short) to interact with the system. Each user can operate multiple devices, and one device can be shared among multiple users (switching between accounts). For simplicity, we focus on the case where each user uses a primary client device to access the system. The client devices communicate with a number of system servers which deliver the service on behalf of the system operator. Again, we simplify this to focus on client device interactions with a single device-facing server, which in turn will interact with various *backend servers* on the operator side. In order to offer additional privacy guarantees, the system engages additional *trusted aggregators* outside the direct control of the system operator to perform aggregation of client messages. These may be sourced from, e.g., a cloud service provider. Within this setting, trusted *analysts* seek to find the answer to various queries about client performance, such as measuring client latency and user engagement with new features. We seek a solution where client devices retain control over data generated by user actions, sharing only the minimum information necessary to support monitoring queries. This paradigm is *federated analytics*, a.k.a. *FA* [5].

The PAPAYA FA system (Figure 1) comprises three applications: an end-user application that runs on client devices, a TEE-based trusted secure aggregator that can run on a system server or a cloud server, and a server application that runs on a data center server and orchestrates the complete protocol.

3.1 System Overview

We introduce the major components of the federated system. We describe how an analyst can derive aggregated insights from a distributed dataset in a secure, privacy-preserving way:

1. The analyst authors a *federated query*. This has two parts: a SQL-like query that runs on user devices and specifies what data should be uploaded to the server for aggregation; and a server specification that describes how it should aggregate client data and which privacy techniques to use.

2. The analyst publishes the federated query to the *untrusted orchestrating server* (UO), which allocates resources for aggregation and makes the query visible to user devices.

3. The *client runtime* on each user device downloads the federated query spec and retrieves/transforms the relevant data from the on-device data store (see Section 3.4).

4. The client runtime uses a secure channel to upload data to the *trusted secure aggregator* (TSA) running in a TEE.

5. The TSA uses the federated query spec to aggregate the data across user devices before releasing an anonymized, aggregated result to the orchestrating server.

6. The UO uploads the anonymized, aggregated result to a database for consumption by the analyst.

We now present each of the above components in more detail.

3.2 Federated Query

First, we introduce some terminology: *Dimensions* are discrete data attributes representing "group by" columns, in the sense that a federated query will group by the specified dimensions before aggregating within each unique set of dimension values. For example, if a query includes `city` as a dimension, then data points with `city="Paris"` will be aggregated separately from data points with `city="New York"`. *Metrics*

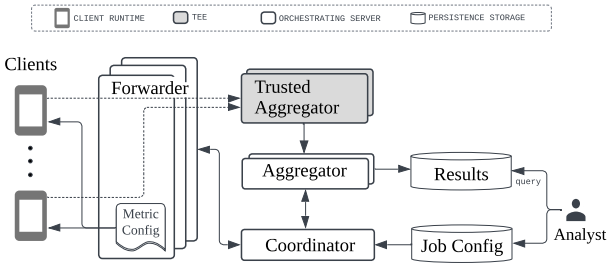

Figure 1: Overall system architecture

```
query:
  onDeviceQuery: "SELECT ...", // SQL to run on device
  dimensionCols: ["city", "day"] // grouping columns
  metricCols: // aggregations (e.g., count, mean, ...)
    mean: ["timeSpent"]
privacy:
  centralDP:
    epsilon: ...
  kAnonThreshold: ...
output: ... // where to persist the anonymized result
```

Figure 2: Example configuration for federated query

are quantitative measurements aggregated across clients after grouping by the dimensions of interest, e.g., total time spent on an app across all users.

For example, suppose an analyst wants to compute average time spent by city and by day of the week. The query is split into two parts:

1. *Data transformation on device*. This is typically defined by a SQL query which runs on the client device. In our example, this local query would retrieve all relevant data on device, group by the dimensions `city` and `day`, and then sum the total time spent for each city-day pair.

2. *Private aggregation across devices*. This defines how to aggregate the reports from different devices under the chosen privacy-preserving regime. In our example, this will tell the trusted secure aggregator to take the average `timeSpent` across devices for each city-day pair, and to apply privacy perturbations before publishing the result.

The schemata of on-device tables are present on server and accessible to analysts. The analyst can configure their query such as in Figure 2. The query result is a table in the data center with one column for each dimension and one column for the metric. In our example, there would be columns for `city`, `day`, and mean `timeSpent`. Each row would contain a unique city-day pair and the average time spent associated with that pair.

With the above framing, the most common analytical queries can be realized with only a handful of secure aggregation protocols—such as `COUNT`, `SUM`, `MEAN`, and `QUANTILE`—in combination with on-device local transformation and downstream post-processing to capture use case-specific needs.

3.3 Untrusted Orchestrating Server

Once the analyst has defined their federated query, it is handed off to the untrusted orchestrating server (UO) to begin execution. The UO has the following responsibilities:

- Provide centralized coordination to ensure queries progress with enough clients active in the face of hardware failures;
- Send active federated queries to clients;
- Facilitate communication between clients and TSAs; and
- Publish query results to persistent storage.

The UO has several sub-components:

- A fleet of *aggregators*. Each federated query is assigned to a single aggregator at a time. The assigned aggregator is responsible for allocating a TSA for the query, requesting periodic results from the TSA, publishing query results to persistent storage and reporting query progress. Each aggregator may be responsible for multiple queries.
- A central *coordinator*, which monitors the state of each federated query, assigns each query to an aggregator and builds the list of active queries to broadcast to clients.
- A *forwarder* layer, which handles incoming client requests and forwards them to the relevant backend components.

After a federated query is registered with the UO, it becomes visible to clients, which retrieve query instructions from the forwarder layer using the client runtime.

3.4 Client Runtime

The client application runs on end-user devices and so needs to be lean, performant and also mindful of the resources consumed by the process. The client runtime (Figure 3) provides:

- A *local store* that securely persists data on the device. It manages data lifetime and scope, and provides the ability to run simple analytic functions over the data.
- An *engine* to execute the client protocol, described below.
- A *scheduler* to monitor the resources consumed and invoke the engine if the device is idle and cumulative resources consumed by the runtime are below a set threshold.

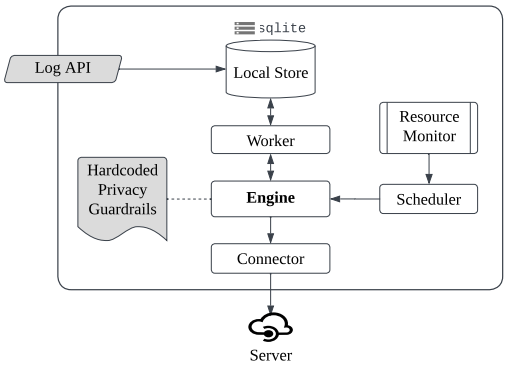

Figure 3: Core components of the Client runtime

The client protocol is split into selection and execution phases:

Selection Phase. Each client periodically fetches the list of active federated queries by polling the UO (subject to a self-enforced daily limit on total resources consumed). Each query configuration in the list has the instructions the client needs to execute locally for each query. Each query configuration may also contain extra information the client uses to decide whether or not it can execute the query. For example, it may include privacy-related parameters to be used for aggregation on the server side, and the client can reject a query if these parameters do not meet locally enforced guardrails (e.g., by capping the number of queries per day, or barring access to certain features). The query configuration could also include a client subsampling rate, where the client uses its own randomness to reject the query with some probability; this can be leveraged to establish stronger privacy guarantees [38]. Last, the client inspects its local state to see if it has any new data to report for each query. After these steps, the client has a list of queries to execute.

Execution Phase. The goal of the execution phase is for the client to calculate the required outputs for each query from the selection phase, then share the outputs with the TSA assigned to each query. The client splits the set of queries into batches. For each task in a batch, the client retrieves and transforms the relevant data; validates the TSA and establishes an encrypted channel via remote attestation; then encrypts its data and sends the encrypted reports to the server, which forwards them to the target TSAs.

3.5 Trusted Secure Aggregator

The TSA is the component of our system that handles the concrete aggregation logic to combine data from different clients. One TSA corresponds to one federated query, though there can be multiple independent TSA instances on the same physical host. The TSA runs inside a TEE and uses remote attestation to establish trust and shared secrets with clients. Clients encrypt their data before sending it to the TSA, so it is the *only* component of our backend that sees plaintext data from individual client reports. Once enough time has passed and enough client devices have reported, the TSA releases an aggregated anonymized result to the UO.

Secure Sum and Thresholding (SST). Many analytical queries can be realized with only a handful of private aggregation protocols such as `COUNT`, `SUM`, `MEAN` and `QUANTILE` (Section 3.2). To further streamline this, our system implements each aggregation primitive via private sparse histograms. Here, *histogram* refers to taking a set of key-value pairs from distributed client devices and outputting a map from keys (or "buckets") to two quantities: the sum of values for the key across all clients with that key, and the count of clients that reported a value for the key. Histograms are one of the most used queries within FA, and many FA queries rely on histograms as a building block, including prefix queries, range queries, heavy hitters, and quantiles. Specifically, these queries use histograms over data with different bucket granularities to build a picture of the data distribution. Histograms allow us to address privacy and scalability with a single aggregation primitive. The TSA running in a TEE allows us to build histograms while maintaining strong privacy and security guarantees via a *Secure Sum and thresholding (SST)* process (Figure 4). This process, which can run from minutes to days, goes as follows:

1. At the start of federated query execution, a TSA is initialized with an empty histogram.
2. Each client validates the TSA and shares encrypted key-value pairs (essentially a "mini" histogram) with the TSA if validation succeeds, using remote attestation (Section 2).
3. The TSA decrypts each client's key-value pairs and immediately aggregates them into the histogram before discarding the individual client data.
4. Once enough clients have reported and enough time has passed (see Section 5.1), the TSA anonymizes the histogram by applying privacy noise to both the sum value and client count value for each bucket. It filters out any buckets with a noisy client count below a threshold specified by the analyst—i.e., if too few clients report a value for some bucket, that bucket will not be released from the TSA (see Section 4.2).
5. The anonymized histogram is released to the UO.

3.6 Handling Scale

For scalability, we employ strategies that address both the volume of devices and the number of queries, while enabling random and unbiased device sampling.

Single-Query Scalability. Employing one-shot algorithms built on Secure Sum and thresholding, each device submits data only once per query, reducing traffic and processing load. To mitigate the "thundering herd" problem, where multiple

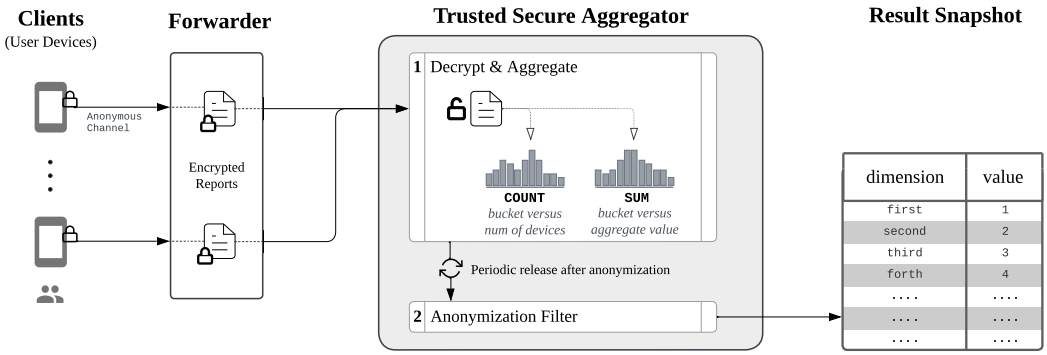

Figure 4: Secure Sum and Thresholding (SST)

devices attempt to connect simultaneously, we randomize the reporting schedules of individual clients. This distributes the data submission over a defined period, controlled by a system parameter, ensuring a manageable and predictable QPS to the TEEs (see Section 5 and Figure 6). The server immediately aggregates incoming reports, using memory proportional to the histogram's dimensions and simplifying the processing involved. Our experiments show a single server is sufficient for one query, but this can be expanded to a tree-level aggregation scheme to distribute the workload.

Multi-Query Scalability. To handle multiple queries, our system batches computations on each device and shards by query on the server. Devices receive all relevant metrics at once, execute their computations, and report back collectively. This setup amortizes process initiation costs and server communication, scaling with query volume.

3.7 Handling Failures

There are multiple potential failure modes, which we classify into two clusters: faulty clients, and faulty servers. For simplicity, we consider faulty connections and clients together, since clients often have unreliable connections that are subject to interruptions. To circumvent this, we break the device work into batches of size ~ 10. This size was empirically determined and can be fine tuned on the respective platform to make sure interruptions are infrequent. If interruptions do happen, we retry during the next period. The client computation is idempotent and will occur again until a successful acknowledgement (`ACK`) for that metric has been received from the server.

This leaves failures that occur on the server side, especially the aggregator and TSA, as they are stateful. Each aggregator-TSA pair stores periodic snapshots of query progress (every few minutes) that would allow a different aggregator-TSA pair to recover intermediate results and resume query execution in case of failure. The coordinator component of the UO can detect fatal query execution errors and will reassign and restart a query on a new aggregator when this occurs. If the coordinator itself fails, a new coordinator instance is started, recovering the previous state from persistent storage.

An important issue here is the privacy of the intermediate aggregation state with partial query results. If the partial results meet the privacy requirements as defined in the query, they can be released and stored in plaintext. Alternatively, the intermediate results can be stored in an encrypted form that is only accessible by another TEE running the same binary as the TEE that generated the results. This is achieved by maintaining a separate group of TEEs responsible for generating, storing and replicating encryption keys. Maintaining robust privacy guarantees is possible with careful bookkeeping and replication logic [28]. Encrypted aggregation state becomes unrecoverable when the associated encryption key is lost, which occurs if and only if a majority of the TEEs with that key fail. This is not a significant obstacle in practice. Because we replicate encryption keys rather than actual data, it is relatively inexpensive to increase the number of replication nodes. As intermediate aggregation state is cumulative, we only need the latest encrypted data. Increasing the frequency of encrypted snapshot generation further reduces the impact of data loss.

A final consideration for the robustness comes from the federated algorithms themselves. In Appendix A, we require that the algorithms do not need participation from all clients, expecting that drop outs will occur as a matter of course. Additionally, if a client is malicious and tries to 'poison' its output the effects are negligible due to (1) its contribution is bounded per report on the TEE prior to aggregation, (2) the typical large scale of operation.

4 Privacy and Security

Secure Aggregation provides a baseline of data protection by insisting that clients do not share raw information, and only aggregated statistics are revealed. We now discuss how data is further protected as it is handled by the FA stack via authentication, access control, and explicit privacy noise addition.

4.1 Secure Data Handling

Storage. Our FA system protects data at rest by design by storing the data on the user's device. The device application manages data scope and lifetime, with encryption and access controls applied to protect data from potential adversaries. Data retention time is configurable with max lifetime (typically 30 days) hard-coded in the application as a guardrail.

Communication. Protecting data during transit is a well-studied problem, and we rely on the standard Transport Layer Security (TLS) protocol to secure network communications. To further minimize leakage of data, communications happen via anonymous authenticated channels, making use of the Anonymous Credentials Service (ACS) library [26, 44]. Thus, the platform is unaware of the identity of the client.

Processing. Secure processing is nuanced due to intricate interactions. Each user's device takes responsibility to ensure that their data is handled properly during its processing. All data from one user is either handled on their device or in an environment where their device can verify the data handling.

Device control over computation. A first component of privacy is admission control. Each device determines which computations to run and when, based on eligibility criteria like previous FA participation, geographic region, hardware type, software version, user features, available data, privacy guardrails, and local randomness. In this way, client devices have total control over their participation in the FA process.

Validation before sharing. Because additional data processing occurs on the TSA server, it is not sufficient that the device controls its own computation. The device must also ensure that the server will handle its data properly and privately. In order for the device to make a fully informed decision about whether to provide data without trusting the UO, the device can use remote attestation as described in Section 2. With this protocol, before sharing any data, the client validates that its data will be processed by a legitimate TEE running a known binary. We have explicitly designed the TEE code to be simple and use case-agnostic, ensuring a reliable, verifiable, and auditable implementation. Thus, prior to any communication, clients obtain proof that their data will be handled as expected.

4.2 Private Handling of Outputs

The previous section discussed how the system provides protections for the data while it is processed in order to compute aggregate statistics. However, aggregating statistics alone is not necessarily sufficient to preserve a strong notion of privacy, as some statistics can still inform on the state of the client. We enforce additional measures in order to meet the higher bar of differential privacy.

Definition 1 ([17]) *Approximate differential privacy (DP) is parameterized by* (ε, δ) *and requires that we define a randomized mechanism* M *such that, for pairs of inputs* X*,* X' *that are neighboring (differing in the presence of a single piece of information) and for any possible output set* O*,* $\Pr[M(X) \in O] \leq \exp(\varepsilon)\Pr[M(X') \in O] + \delta$.

Many randomized DP mechanisms have been defined for different applications; here, we focus on obtaining privacy for a histogram of values, where adding zero-mean Gaussian noise to each count gives (ε, δ)-DP [17].

After adding noise, we apply k-anonymity, where any counts below k are removed from reports. While k-anonymity on its own has been deprecated as a formal privacy tool, this additional step provides an intuitive notion of privacy to our histograms for both users and decision makers—in contrast with the formal DP guarantee, which requires some statistical sophistication to appreciate. Moreover, when histogram dimensions are not known *a priori*, this thresholding step is critical to the DP guarantee [43].

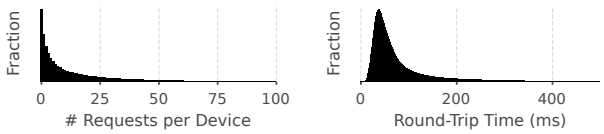
We briefly show DP models which vary in how the notion of neighboring inputs is defined and at what granularity the definition is enforced: centrally or by each client individually.

Central DP at the Enclave. Applying DP via the central aggregator (TEE) is the most straightforward way to obtain DP. The TEE can compute the exact histogram, in the form of a `SUM` or `COUNT` aggregation, then add noise to each value in the bucket of the histogram to achieve differential privacy.

Local DP. Local differential privacy takes the standard DP definition, but applies it to every message from every device. For `COUNT`-queries we can represent the user's input as a 1-hot vector and randomly flip the bits, or pick a value to report from an appropriate probability distribution. The enclave or server aggregates the reports from all devices, and performs a statistical de-biasing step to obtain the estimated histogram.

Distributed Privacy Noise. In the distributed DP model, each client adds a small amount of noise, so that after aggregation the noise is sufficient to give the desired DP guarantee. Each client builds a "mini histogram" with the full set of buckets, records its values, and draws random noise to add. The noisy mini histograms are sent to the TSA, which sums them and checks that enough have been received to achieve the central noise requirements. It then performs k-anonymity enforcement and releases the final result. We use the "sample-and-threshold" approach to distributed noise addition, where the uncertainty is introduced due to client randomly deciding whether or not to participate in the data collection [5].

Periodic Data Release. An important consideration in anonymizing the histogram is when results should be released. Client devices have intermittent connectivity and availability; there can be a delay on the order of days before enough participate in FA query to report results with confidence. This poses a challenge to our system, as analysts want results as soon as possible. We balance the desire to give up-to-date results against the privacy cost of making multiple disclosures. The TSA sends partial results to the orchestrating server every few hours. To uphold the privacy guarantee, we limit the num-



(a) Daily values stored per device (b) Round Trip Times (RTT)

(a) Three query runs (b) Coverage by RTT

Figure 6: Coverage of the device population over time: *(a)* for different query execution times, *(b)* by device latency

ber of times the TEE releases partial results. The overall DP privacy parameters (ε, δ) set by the query configuration are budgeted across all releases, using "composition" results [17].

5 Empirical Study

We perform our experimental study using queries in our production deployment of the PAPAYA FA stack. Queries are issued on various system health metrics to ensure smooth running of different systems. Here, we focus on queries of network activity: round trip times (RTT) per network request and request volume. These queries give insights into system and device heterogeneity. They are used to track system performance and are an important canary for regression issues.

Formally, each device i records a set of n_i round trip times $x_{i1}, \ldots, x_{in_i}$, which are aggregated on-device into a local RTT histogram $u_i = (u_{i1}, \ldots, u_{iB})$, where u_{ik} denotes the number of RTT values from device i assigned to bucket k. We compute a federated histogram $v = \sum_i u_i$, making use of the trusted secure aggregator (TSA, Section 3.5). To objectively measure performance, the data points x_{ij} are also stored in a central database (for evaluation purposes only), from which we compute a ground-truth histogram $w = (w_1, \ldots, w_B)$, where w_k denotes the total number of data points in bucket k across all devices. For the device activity histogram, each device has a single data point of interest, n_i (as defined above). So the local histogram produced is a one-hot vector $u_i \in \{0,1\}^B$, i.e., $u_i[j] = 1$ encodes n_i is in bucket j out of B. The rest of the federated histogram collection proceeds as in the RTT case.

Each device has a periodic job to poll the server, compute the local histogram u_i, and report to the TSA. This job has a 10-second timeout, runs in the background, and is run at most twice per day to minimize the burden placed on client devices. Each device also adds individual randomness on when to initiate reporting, to smooth out traffic load.

Queries run on a population of nearly 100 million Android phones that report the relevant data to Intel SGX devices operated by a secure cloud service provider, under the guidance of the UO. Data are gathered at both daily and hourly granularities. The number of data points in the hourly reports is proportionately lower than in daily reports.

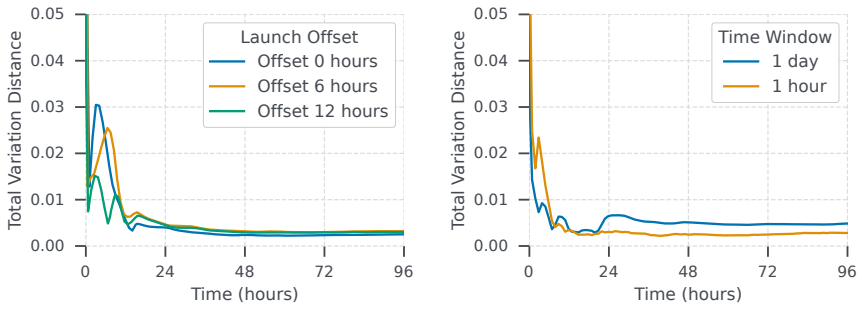
Figure 5 shows the distribution of device data, highlighting two different aspects of heterogeneity. Figure 5a shows that usage patterns differ widely across devices, leading to varying dataset sizes on each device. While the most common case is for clients to have just a single sampled value to report, it is not unusual for them to have tens, with a few having in excess of 100 values to report. Figure 5b shows the differences in network RTT. The mode is around 50 ms RTT, but the distribution stretches out to half a second or more. This reflects variation in device resources and capabilities.

5.1 Collection Speed and Scalability

To begin, we evaluate how long it takes for a task to reach all devices and iterate over the data in its entirety. It is important to note that in practice a random sample of a fraction of the devices or data is considered sufficient to answer most metrics. However, in order to build a thorough understanding of our system, we evaluate the time needed to access all data and devices. We measure wall-clock time from the launch of the query and compute *coverage*, the number of data points processed by the FA task divided by the number of ground-truth points in the database. There are many variables that can impact the collection speed, including time of day (device usage and connectivity patterns vary throughout the day), job restrictions (configuration indicating when a device should not report, based on conditions like network metering, battery status, cumulative quotas, etc.), and other device characteristics (e.g., capabilities, frequency of use, connection quality).

Figure 6 shows how quickly our system accesses the population over different query executions. These queries request the round trip time (RTT) values from devices. Figure 6a shows three executions of the same query launched at six-hour intervals. Encouragingly, results are not much influenced by time of day, and so are similar across all runs.

In fact, the behavior we see in Figure 6 is most strongly influenced by our choice of system parameters: We observe a linear growth in coverage up to around 85% over the initial 16 hours after issuing the query. This reflects that clients check into the server at random, with a uniform delay of 14-16 hours. Coupled with random offsets, this means that active



(a) TVD: different offsets

(b) TVD: Different queries

Figure 7: Accuracy over time: *(a)* for different query execution times, *(b)* for two different queries

client reports are spread uniformly through the initial 16 hour period after the query is issued. This accounts for a majority of clients. The remaining 15% of less active clients check in more gradually, hitting 90% in 24 hours and reaching over 96% coverage after 96 hours, i.e., 4 days from when the query is issued. We should not expect to attain 100% coverage, as a small minority of devices may go fully offline, have local storage reset, or otherwise be unable to report in. For faster collection, we could narrow the check-in window from 16 hours to a lower value. This would speed up the time to reach 85% coverage, but we expect that the "long tail" of less active clients would still require up to a week to check in, due to their sporadic availability.

Figure 6b tests whether the speed of coverage is correlated with network connection quality, by measuring coverage from a single query based on subsets of the histogram corresponding to different ranges of RTT values. The correlations observed are very small, with the coverage rate for low and high latencies following remarkably similar curves. On close inspection, there is a small effect: low latencies have higher coverage than high latencies. This is easiest to see at 16 hours—as time passes, this gap shrinks further.

Through our experiments, we observed that the majority of resource consumption on devices is driven by process initiation and communication with the server, while the actual computation of metrics is comparatively insignificant. This aligns with our hypothesis and design, as unlike Federated Learning, we only execute lightweight SQL queries on the device. Our batched processing setup effectively amortizes these initiation and communication costs, enabling the system to handle many concurrent queries (around 100) efficiently.

5.2 Analysis of Accuracy

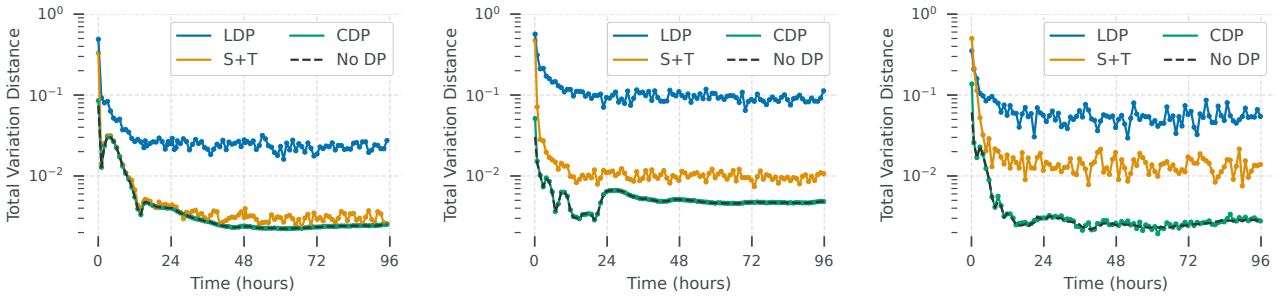
Next we evaluate the accuracy of a metric computed in the federated setting against the same metric computed from the ground-truth dataset. As explained in Section 3.2, all metrics can be computed through data manipulation on the device followed by a handful of aggregation primitives. Since each aggregation primitive is built via the histogram operator using the Secure Sum and Threshold primitive (Section 3.5), measuring the accuracy of a histogram can be used as a proxy for measuring accuracy of any standard metric.

Letting $n_v = \sum_k v_k$ denote the number of data points in the histogram v, the normalized histogram $\bar{v} = \frac{1}{n_v} v$ reflects the relative frequencies per bucket. To plot error between federated histogram v and the ground-truth w, we use total variation distance (TVD) between their normalized versions, $d_{\mathrm{TV}}(\bar{v},\bar{w}) = \frac{1}{2}\|\bar{v}-\bar{w}\|_1 = \max_{S\subseteq\{1,\ldots,B\}} \left|\sum_{k\in S}(\bar{v}_k - \bar{w}_k)\right|$. This straightforward measurement of error reflects the bucket-wise absolute differences between the frequencies observed in $\bar{v}$ vs. $\bar{w}$ for any subset of histogram buckets.

Figure 7 shows the total variation distance across several queries as a function of the time since query launch. In Figure 7a, histograms of round trip time (RTT) are created with $B = 51$ buckets: 0-10 ms, 10-20 ms, ..., 490-500 ms, 500+ ms. These are created with the same time offsets as in Figure 6. In Figure 7b, histograms of device request counts are created at the daily and hourly grain, using $B = 50$ and $B = 15$ buckets (respectively), corresponding to sampled counts of 1, 2, ..., $B-1$, B+. In both cases, we see that it is possible to achieve a very accurate representation: the final TVD is negligible, meaning that the distribution obtained via federated reporting is nearly identical to the ground truth. This is obtained quickly: within 12 hours, an accurate result is found, corresponding to when half of clients have checked in (per Figure 6). Even within a few hours, the result is pretty accurate.

5.3 Analysis of Privacy Mechanisms

To better guide how different privacy guarantees may affect query accuracy, we study how adding differentially private noise impacts the accuracy of histograms. In Section 4.2, we described ways to provide a differential privacy guarantee, based on how and where noise is added in the system: centrally at the secure enclave (central DP, *CDP*), by each client locally (local DP, *LDP*), or in a distributed fashion (sample-and-threshold, *S+T*). We compare generating his-



(a) RTT histogram accuracy (b) Daily event count histogram accuracy (c) Hourly event count histogram accuracy

Figure 8: Experiments on histogram generation with different models of privacy noise addition

tograms in our system under these three different models of privacy via TVD to the ground truth. Each data release from the CDP and S+T privacy mechanisms satisfies (ε, δ)-DP (Definition 1), and each LDP release satisfies $(\varepsilon, 0)$-DP, all with $\varepsilon = 1, \delta = 10^{-8}$.

Recall that against the ground truth, the steady-state total variation distance (Section 5.2) is considerably below $10^{-2} = 0.01$ (Figure 7). Figure 8 shows that there is a clear difference in behavior based on the scale of the input population and the privacy model. When building the histogram of round trip times (Figure 8a), we see that local differential privacy (LDP) achieves an order of magnitude more noise than other methods, and this gap does not decay over time. Nevertheless, this error is in the region of 0.02, which is tolerable for most of our applications. The gap between privacy mechanisms is replicated across other tests (Figures 8b, 8c), where the error for CDP and S+T is much lower than LDP—for CDP, the result is essentially indistinguishable from the un-noised data collected. Results in Figures 8b and 8c consider the accuracy of reporting histograms on the amount of activity recorded on a daily and hourly basis (respectively). Note that the hourly activity counts are proportionately lower than the daily ones. Here, the hourly activity was 34 times lower than the daily activity, as the measurements correspond to a quieter than average period. Hence, the impact of privacy noise introduces more variation for the hourly event counts. This is particularly notable for S+T, where thresholding the sampled data leads to more signal loss. Meanwhile, error introduced by CDP noise addition remains almost imperceptible on these plots.

Thus, for histogram generation, privacy can be achieved with minimal impact on accuracy in FA. The three privacy techniques shown are arguably incomparable, since they exercise different trust models. But even our "weakest" model, CDP, is stronger than simply gathering the data on a regular server, since we use secure TEEs to perform the aggregation and noise addition. Furthermore, the local model of privacy, as previously deployed at scale [1, 19], has the biggest impact on accuracy. So, where permissible, we advocate for central or distributed privacy noise within FA systems.

Additional experiments on the impact of privacy noise of the accuracy for the quantiles (CDF) query are presented and discussed in Appendix A.

6 Related Work

Instrumenting large scale deployments of distributed clients has been studied widely in the distributed systems and networking communities. However, building systems with data privacy as a main goal has enjoyed less focus until recently.

The notion of federated computation has emerged as a distributed paradigm that emphasizes the privacy of the participants [5]. Systems implementing federated *learning* (FL) have been described by Google [8], Apple [31], LinkedIn [41], Snap [32], Meta [27] and others in the big tech arena. FL is primarily concerned with the training of machine learning models, with examples held by the clients used as the training set. Typically, FL workflows have access to a very large number of clients (millions or billions), but engage only a few thousand in each round. In each round, a batch of clients suggest improvements to the current model. This process is repeated over a large number of rounds, often several thousands in total [23]. The duration can thus be days to weeks, allowing for clients that may be slow to respond or only intermittently available. Here, we focus on analytics tasks that are qualitatively different in nature. Rather than concentrate on a single computation task (model training), we seek a system with greater flexibility for processing a range of possible queries. These queries are typically processed in few rounds: ideally, a single round or two. However, we seek to engage many more clients in each round (at least tens of thousands, often millions), and so the latency to complete a round is higher, due to greater variability in client availability and dropouts.

This approach to FA was promoted by Google [33], with an emphasis on gathering information on frequency distributions. The antecedents of this model can be seen in Google's prior RAPPOR system [19] and Apple's differential privacy deployment [1]. Both these systems use local differential privacy to mask client inputs, building on the classical technique

of randomized response [42]. Clients are prompted to provide (perturbed) information on browsing and typing behavior (e.g., frequently visited webpages, new words), in order to improve autocomplete suggestions and detect malware. This information is gathered regularly and perturbed based on a sparse vector encoding with random noise. These first systems demonstrated the utility of private information gathering. However, the level of noise due to local DP is high, requiring a very large population of clients and a loose setting of privacy parameters to get actionable information [39].

Subsequent developments have sought to broaden the range of statistics that can be collected, and to provide stronger privacy and security protections. Work on secure aggregation [4, 7] highlights the power of a primitive that computes the sum of inputs from a large number of clients without revealing any intermediate values. Google's described solution uses interactions between clients to recover from other clients dropping out during the protocol, via cryptographic techniques (threshold secret sharing) and a single coordinating server. Other approaches to implement secure aggregation achieve a similar functionality but remove client-client communications by instead having two or more independent aggregating servers. PRIO, implemented by Mozilla, performs aggregation of inputs from clients based on secret sharing, along with simple zero-knowledge proofs to check that client inputs are well-formed [9, 12, 25]. Apple's sampling-based system adopts this model, where two servers (*leader* and *helper*, as in [21]) interact to perform the aggregation [38]. Systems such as Honeycrisp and Orchard use additively homomorphic cryptography to aggregate client reports across multiple servers [34, 35]. For our implementation, we adopt TEEs for aggregation, to simplify key management and scaling issues, and to be able to handle the thresholding primitive.

Most effort in FA has been directed towards learning frequency distributions of (discrete) values held by clients, such as commonly visited web sites. Since rare values are likely to be privacy-revealing (e.g., URLs that encode identifying information), we seek popular values, or "heavy hitters." Google researchers show that sampling a random (secret) subset of clients can achieve differential privacy [45]. PRIO also targets towards secure computation of heavy hitters, where DP noise can be introduced by the aggregating servers [12, 29]. Other approaches are via distributed noise addition, where each client adds small random noise [2], or via shuffling client responses to disassociate the message from the sender, which has a similar statistical effect [6, 38]. Explicitly suppressing responses with low frequencies captures the intuitive privacy definition of k-anonymity [14].

7 Discussion and Concluding Remarks

We have laid out our experience and insights in building a state-of-the-art large scale FA system. The chief takeaways that we draw from our experience are: (1) It is indeed possible to achieve large scale, secure federated analytics. At this scale, failures are inevitable, and so it was important for us to design with these in mind (e.g, incorporating snapshotting and recovery). (2) Security is increasingly available as a commodity, thanks to availability of secure hardware. Designing for simplicity ensured that security was auditable and efficient for us. (3) A wide range of tasks are served by the Secure Sum and threshold operation, including finding popular values, capturing distributions, and gathering feature usage statistics. (4) We obtained privacy in addition to security by designing in noise addition (differential privacy), and at scale this made minimal impact on accuracy.

Key design choices that could be revisited in future are:

Privacy Models and TEEs. The FA system accommodates various privacy models (central, local and distributed DP). The use of TEEs is of particular importance in allowing complex central DP algorithms, and the secure aggregation for local and distributed DP. Current TEE hardware comes with some tradeoffs, which will alter as new generations are released. Our threat model treats data poisoning efforts as negligible, but protections against malicious clients could be hardened.

Privacy Budgeting. DP parameter ε captures the degree of privacy, which is weakened as more queries are answered. Our pragmatic approach is to focus on per-query privacy impact, and seek to ensure that analysts do not posed repeated queries to the same data. In future we may use stronger constraints, and more sophisticated privacy accounting tools [15, 28].

Longitudinal Issues. Currently, we allow clients to respond to one batch of queries per day, pertaining to data collected over the previous 24 hours. We will loosen these constraints in future versions as we allow more fine-grain responses.

Other considerations. When we try to batch queries together for efficiency, we can combine responses while ensuring that the results do not expose too much private information. For analytics, the main demand is for aggregation queries, future plans are to expand to more types of queries and data. As we extend the deployment of our FA stack to more use cases, we will face new types of queries, and have to decide whether to answer these via custom code, or extend the capability of our system to provide more "built-in" support for common query patterns. A leading concern is how to simplify the deployment of queries by non-expert analysts, and in particular how to provide useful debugging and cross-checking information, while maintaining the high levels of privacy guarantees.

Markov and Akash Bharadwaj.

A Federated Algorithms: Quantiles

The federated model opens itself to a number of design techniques to answer a wide range of queries. Simple queries, such as sums and counts, are straightforward to implement within FA, while more complex queries require more nuanced solutions. Examples include finding the "heavy hitters" (frequent items) from a large domain [45], estimating U-statistics across pairs of observations [3], finding the mean of scalar and vector values [40], measuring classifier accuracy and AUC [10], and making heat maps of data distributions [2].

For FA algorithms, there is a strong preference for techniques that require only one or a very few (constant) rounds of data collection. This is distinct from Federated Learning, where it is common to iterate towards a solution over hundreds or thousands of short-lived rounds. It is also highly desirable to express the algorithms using well-supported tooling, specifically the SST primitive. We favor algorithms that are robust to clients drop outs and unavailability, via sampling and ensuring that client information is encapsulated in a single message.

To illustrate the design space and considerations of building support for a non-trivial query into a federated analytics system, we study an example query in depth: to find the quantiles of a (distributed) data distribution. Finding quantiles (or percentiles) is one of the most requested queries for the FA stack. We have made several implementations to handle different trust and privacy models, and thus refined our understanding and optimized the approach that we advocate. Our first efforts used multiple rounds of interaction, which slowed down the process, and led to synchronization issues. Subsequently, we focused on approaches using few rounds.

Given a (multi)set of readings, the quantile query seeks the point p such that a q fraction of readings are below it. For instance, the median asks for the 0.5-quantile, where half the readings are below and half are above. We also often seek the 90%-ile, 95%-ile and the 99%-ile corresponding to the 0.9-, 0.95- and 0.99-quantiles. There is noise in the reported answer as we use approximate algorithms and introduce noise for (differential) privacy reasons. Outside of FA, there are algorithms to build compact summaries for the quantiles problem, particularly when processing the inputs as a single stream of data. These include the q-digest [37], t-digest [16], dd-sketch [30] and Greenwald-Khanna (GK) summary [22]. However, these do not all immediately map to the federated setting, nor do they provide a privacy guarantee.

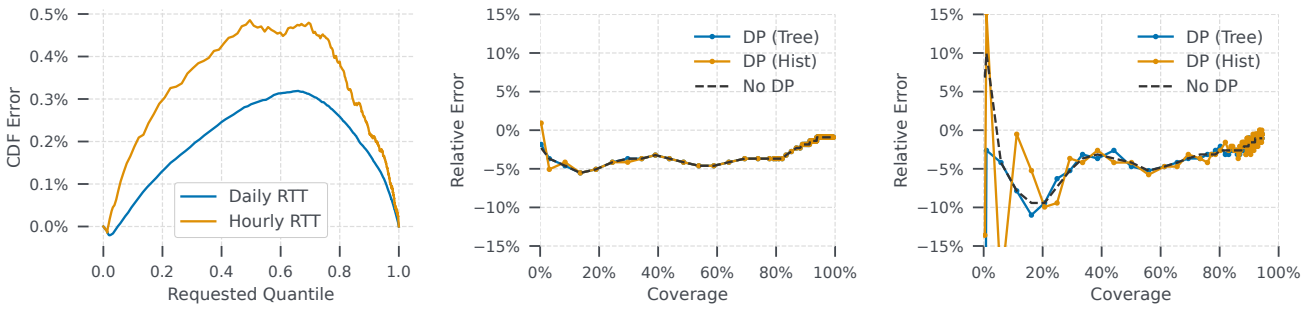
The simplest approach to answering a fixed quantile query in the federated setting is to perform a binary search over multiple rounds. We start with a range $[\texttt{low}, \texttt{high}]$ that all the data falls in, and issue a federated counting query to find what fraction of examples fall in this range. This process is repeated for ranges $[\texttt{low}, p]$, adjusting p higher and lower based on the result of the previous rounds, until we find an answer for which the count is close enough to the target q (as a fraction of the number of participating clients). Typically, 8-12 rounds suffice, provided the initial range is fairly tight around the true data. However, this can be slow to complete.

The key to reducing the number of rounds is to think of the multi-round algorithm as looking up values in a collection of histograms of progressively finer granularity. The first round looks up the two values in a two bucket histogram, where the buckets correspond to the left and right halves of the value domain, respectively. Depending on what answer is obtained, the second round looks up two values in a four bucket histogram (corresponding to dividing the domain into four equal pieces), and so on. Importantly, although the set of buckets to inspect depends on what we find in the previous round, the choice of bucket boundaries is not data dependent. Hence, we can build out the complete set of histograms in a single round of FA, and use the output of this query to answer all-quantiles queries. We refer to this as the hierarchical, or *tree*, approach to quantile estimation.

To put this into practice we need some prior knowledge of a range that all values fall into (or a first round of FA to gather this knowledge), in order to specify the histograms. We must determine the number of histograms to build, based on the granularity of the finest histogram. Building histograms out to a depth of 12 (giving 2^{12} buckets at the finest level of detail) gives a good level of accuracy in practice, while remaining relatively quite compact. In some cases, rather than the full hierarchy, it suffices to collect data at the finest level and treat the resulting (noisy) histogram as if it gave the exact distribution. We refer to this as the flat, or *hist*, approach.

A.1 Experiments on Quantile Data Collection

We implement and apply these quantile algorithms in order to evaluate the impact of our design choices on query accuracy and scalability. Figure 9a shows the error in estimating the cumulative distribution function (CDF) of the number of data points per device, based on histograms of $B = 2048$ buckets representing sampled counts of $1, 2, \ldots, 2047, 2048+$. That is, for each potential quantile query (e.g., the median, being the 0.5-quantile), we identify which true quantile the reported value corresponds to, using knowledge of the ground truth distribution. We plot this for both daily and hourly round-trip times, using data collected after 48 hours from initiating the query. The pattern for both is similar: the error is zero at either extreme, since the measure can be satisfied by reporting an arbitrarily small value for the 0.0-quantile, and an arbitrarily large value for the 1.0-quantile. We gain more information when studying quantiles that are closer to the middle of the distribution. After 48 hours of data collection, the maximum error is 0.32% for the daily measurements, and 0.49% for the hourly data—this is the Kolmogorov-Smirnov test statistic for measuring similarity of distributions. In both cases, it is much less than 1%, indicating close agreement. The error is higher in the hourly case, due to fewer observations.



(a) CDF approximation error for RTT

(b) DP error for daily 90%-ile daily RTT

(c) DP error for 90%-ile hourly RTT

Figure 9: CDF error after 48 hours *(left)* and relative error in DP estimation of 90th percentile RTT *(center, right)*

Figures 9b, 9c show our results for estimating the 90th percentile (i.e., 0.9-quantile), under different privacy approaches. Per Appendix A, we add noise either to a flat histogram, *DP (hist)*, or to a hierarchy of histograms, *DP (tree)*. In both cases, we follow a central DP model, adding Gaussian noise to the histograms to achieve an (ε, δ)-DP guarantee for $\varepsilon = 1, \delta = 10^{-8}$. We compare the accuracy of these quantile estimates against a federated quantile estimate without any privacy noise addition (*No DP*). Here, we measure the relative error: we compute the ratio of reported value to the ground truth value of the 90th percentile.

Unsurprisingly, when only a few clients have reported, there is a lot of uncertainty in the value of the target quantile, particularly for the hourly data (Figure 9c). However, once more than about a quarter of clients have submitted their input, we can find a reliable estimate of the quantile, up to a few percentage points in variation. For these experiments, where we have many clients each reporting a single contribution to the histogram, the impact of DP noise is marginal: the greater uncertainty comes from the sampling effect of partial client participation. The tree histogram method adheres closer to the no-DP case than the simple flat histogram. Our practical experience is that the tree approach is preferred when larger histograms are needed to represent the input. We conclude that we can obtain very accurate answers to quantile queries while enjoying FA's strong security and privacy properties.

Abstract

Layer 7 network functions (NFs) are a critical piece of modern network infrastructure. As a result, the scalability and reliability of these NFs are important but challenging because of the complexity of layer 7 NFs. This paper presents HA/TCP, a framework that enables migration and failover of layer 7 NFs. HA/TCP uses a novel replication mechanism to synchronize the state between replicas with low overhead, enabling seamless migration and failover of TCP connections. HA/TCP encapsulates the implementation details into our replicated socket interface to allow developers to easily add high availability to their layer 7 NFs such as WAN accelerators, load balancers, and proxies. Our benchmarks show that HA/TCP provides reliability for a 100 Gbps NF with as little as 0.2% decrease in client throughput. HA/TCP transparently migrates a connection between replicas in 38 µs, including the network latency. We provide reliability to a SOCKS proxy and a WAN accelerator with less than 2% decrease in throughput and a modest increase in CPU usage.

1 Introduction

Middleboxes are ubiquitous in modern networks. Providers often deploy middleboxes or network functions through network function virtualization (NFV) to simplify their management and deployment by freeing them from physical appliances. Layer 7 NFs are a growing area in industry and academia that includes caching proxies [3, 30], TLS termination [40], TCP splicers [14, 36, 37], and WAN accelerators/optimizers [44, 48]. These NFs provide complex network services that process and transform traffic in non-trivial ways at critical points in the network. For example, Cloudflare uses layer 7 proxies to improve performance and security for web services. As a central point for incoming traffic, every outage translates to a financial loss and a reputational loss for both customers and service providers [19, 52].

Layer 7 NFs compound the well known reliability and scalability concerns of users of layer 2–3 NFs [45]. Many layer 7 NFs perform transformations, e.g., traffic encapsulation and TLS termination, that prevent using fail-to-wire to temporarily bypass the NF to avoid service outages. Disruptions of these NFs are problematic as connections are terminated inside the NF [36], making failures visible to end nodes.

To support migration and failover, these NFs must migrate all states including, the TCP stack and any data currently being processed by the NF. Layer 7 NFs are unique because they read-modify-write many state variables throughout their software stack (e.g., TCP, TLS, and NF state) multiple times during traffic processing. State changes must be replicated immediately to allow a replica to take over connections seamlessly when failures occur.

Prior approaches to NF reliability, including those of S6 [47], Stateless-NF [31], and FTC [21], cannot be applied to layer 7 NFs. These prior systems commonly assume that layer 2–3 NFs modify at most a few state variables. Most of these systems store the state remotely for migration and failover, and it is practical because most NFs only access or modify 1–2 state variables per flow or per packet. Layer 7 NFs have complex state that is accessed multiple times throughout the packet processing pipeline, necessitating multiple remote accesses to the state that is more costly than existing systems are designed to handle.

This paper introduces HA/TCP, the first framework to support the migration and failover of TCP-based layer 7 NFs for reliability and multi-node scalability. HA/TCP actively replicates traffic from primary to replica to support seamless failover and migration. We build a high performance IP-based protocol for low overhead traffic replication between primary and replica. HA/TCP introduces *replicated sockets*, a compatible socket API that hides the complexity of replication and eliminates the non-determinism between primary and replica. Replicated sockets simplify reliable NF development because we observed that most NF state derives from the TCP flow.

HA/TCP is highly optimized for modern high speed networks. Our benchmarks show that HA/TCP can saturate a 100 Gbps link while providing reliability. We made many critical optimizations, including eliminating all deep and shallow

copies of packets inside the critical path, relying on TCP itself to correct network errors between the primary and replica, supporting receive side scaling (RSS) and process concurrency, and supporting TCP options important to NF performance. Together these optimizations improve the performance of HA/TCP by more than 10×.

HA/TCP is built on a production grade TCP stack based on FreeBSD 13.1 and runs under DPDK using F-Stack. Our system consists of a TCP/IP stack extension to replicate the connection state, the replicated sockets API that eliminates non-determinism in sockets, and the IP Clustering system negotiates with network switches for load balancing. HA/TCP uses the common address redundancy protocol (CARP [9]) for failure detection and leader election. We implement many optimizations for high throughput and low latency. To evaluate HA/TCP, we built three layer 7 NFs including a WAN accelerator, a SOCKS proxy and a distributed load balancer. Each NF supports HA/TCP in less than 100 lines of code.

Our system makes the following contributions:

- HA/TCP is the first system to provide reliability and scalability for TCP-based layer 7 NFs. We introduce the *replicated sockets* interface that simplifies the development of reliable NFs.
- HA/TCP migrates TCP connections 2.4× faster than Prism [24] and 1.7× faster than Capybara [12] when including network latency.
- The implementation of several systems in addition to HA/TCP including: the first open-source WAN accelerator, our distributed load balancer, and our novel IP clustering system that works with commodity switches.
- Our experience building and optimizing HA/TCP for 100 Gbps networks.

Our evaluation results show that HA/TCP saturates 100 Gbps with just four connections. HA/TCP adds on average 11 µs to the round-trip time and reduces client throughput by as little as 0.2%. Our NF benchmark shows HA/TCP migrates transparently in 38 µs, which is faster than the state-of-the-art TCP migration systems. HA/TCP scales linearly across multiple nodes. The load-balancing benchmark shows HA/TCP evenly distributes load among nodes.

2 Background

The reliability and scalability challenges of layer 7 NFs are unique because their complexity far exceeds other types of NFs. Layer 7 NFs contain a complete TCP stack that terminates connections. A few recent works, Microboxes [36] and mOS [29], introduce frameworks that provide a custom TCP stack with better APIs for developing layer 7 NFs. Neither system provides reliability or multi-node scalability. Our work is complementary and can be used with either system.

Types of Layer 7 NFs. For our purposes, we classify layer 7 NFs into two categories: *pass-through* and *endpointing* NFs. Pass-through NFs, such as an Intrusion Detection System (IDS), are transparent to network connections as they only monitor traffic. They only read the packets that flow through connections and reconstruct the TCP state of each connection locally, but do not alter the packet contents.

Endpointing NFs, such as a TCP splicer, SOCKS proxy and WAN accelerator, terminate the TCP connection. The NF splices the traffic from one connection to another while optionally transforming the payload.

Endpointing NFs contain a complete TCP stack and the NF application. The TCP stack provides full TCP packet processing for the NF application. The TCP connections on either end of the NF terminate at the NF. The NF application works directly on the data that it reads from the TCP stack and sends over another connection.

The failure of pass-through NFs does not affect the connections that they are monitoring. This is because they tap each connection and reconstruct a copy of the minimal TCP state for monitoring purposes. Pass-through NFs use fail-to-wire to allow traffic to continue to flow after a failure.

However, if an endpointing NF fails, all connections through the NF break, because endpointing NFs terminate all TCP connections. A TCP connection is stateful, and the NF relies on having the correct state of both the TCP stack and the NF application. The connections to nodes on either end of the NF cannot be re-established without the NF state, which is lost during a failure.

The Need of Seamless Failover. Prior works have cited that vendors are reluctant to reset network connections because of user visible disruptions [45]. FTMB [45] shows that a number of popular applications come with defaults that cause user visible disruptions and suffer poor recovery times in the range of minutes. A recent Microsoft study stated that NF failures accounted for 42% of severe incidents, and that some failures lasted over a day [41].

NFs such as WAN accelerators are often deployed to efficiently make use of a company's network infrastructure to connect all of their remote sites together. Often they are deployed using a hub and spoke model [13, 43] which means a few NFs in the primary data centers can disrupt traffic nationally or globally for these companies.

There is no equivalent to fail-to-wire for endpointing NFs, because these NFs transform traffic. For example, a WAN accelerator may compress, encrypt and encapsulate a TCP flow over UDP to traverse the internet. Sending the traffic without traversing the NF may leave the destination unable to process the incoming connection that is incompatible, or the intermediate network is unable to forward the traffic.

Existing Replication Frameworks. Existing NF state management systems [20, 21, 31, 32, 42, 47] address the major problems of scalability and reliability for layer 2–3 NFs. These systems either replicate the state among NF instances or store the state on another node. These NFs can scale elastically by migrating flows and seamlessly handling failures.

Existing layer 2–3 NF frameworks show that their state is relatively simple, consisting of a few state variables [21, 31, 47]. These frameworks use this fact to efficiently replicate state updates by coalescing or piggybacking state updates into a smaller set of packets.

The state in layer 2–3 NFs does not update frequently. StatelessNF [31] summarized the states and the access patterns for common layer 2–3 NFs. For most NFs, such as load balancers, firewalls and NATs, the states are updated at the beginning or the ending of the connection, and the state is only read during steady state processing. Other NFs may read and write the state simultaneously, but at most once per packet.

The Problem with State Replication. Existing state replication systems are ill suited for layer 7 NFs for two reasons. First, the TCP NFs have a large complex state. TCP NFs terminate the TCP connection which necessitates replicating a non-trivial state. These NFs terminate both endpoints of the TCP connection to rewrite the TCP traffic. Both the NF application state and TCP stack state are part of the NF state that must be made reliable. Furthermore, all packets inside the NF application are thus part of the state. The resulting state update of a single packet is larger than the packet itself.

Second, the states are updated multiple times throughout the NF pipeline, and attempting to batch state updates leads to correctness or performance issues. All packet data, including the payloads, is part of the NF state. When sending the data in TCP, the TCP stack holds the data in the socket buffer until it receives the acknowledgment from the peer. However, the acknowledgment packet only indicates that the peer TCP stack has processed the packet, but the application may not have started processing. If the peer, say an endpoint NF, fails before the NF application finishes the processing, even if the NF gets failed over, the sender will never retransmit the previously sent packet.

Delaying the TCP acknowledgment until the NF application completes processing and updates its state is problematic. While simplifying replication, it introduces a performance problem for TCP, because the acknowledgment will be delayed. The delay increases the perceived round-trip time (RTT), which increases the TCP window size and the memory requirements of all nodes. More importantly, any variability in the RTT reduces the TCP window depending on the congestion control algorithm. The result is that the end nodes perceive worse network conditions, which hurts performance.

Prior TCP Failover Systems. Unfortunately, prior approaches to TCP failover [2, 49, 50] are not transparent, do not support common TCP extensions, and suffer from high overheads. These systems change the TCP protocol and require nodes to participate in migration or failover events. Several systems use another machine (i.e., a NF) to store traffic to ensure the replica node can resume communications after a failure [4, 16]. Their NF is a single point of failure that must be made reliable, yet they still incur overheads of 30% or more. These systems are unmaintained for over 20 years.

Our Approach. Our approach is to use active replication inside the network stack. We intercept incoming packets just before the TCP stack, transmit them to the replica, and resume TCP processing once the replica has acknowledged reception. Naïvely implementing this approach results in low performance. One of the main challenges of HA/TCP is how to achieve good performance.

One benefit of our approach is that we simplify the development requirement for providing high-availability for NFs by introducing *replicated sockets*. Rather than replicate the NF application state, we maintain output determinism through our replicated socket interface, which means the output from the network stack is identical on all nodes. NF applications need to ensure that they do not generate any externally visible non-determinism. This is similar to the programming discipline that game engines [11] use.

Providing output determinism does not preclude applications internally diverging, for example, the WAN accelerator may take a cache hit on the primary and a miss on the replica because of timing differences. NFs with unavoidable internal non-determinism must ensure that the output remains identical. In this example, the replica that misses, would fetch the value from its peer, resulting in identical output. Alternatively, one could use record/replay [38, 45] to synchronize state.

3 Design

TCP NFs using HA/TCP are deployed similarly to other NFs. In an NFV environment, we use an SDN controller (e.g., ONOS [7]) to manage the deployment of NF instances and coordinate traffic steering. The SDN controller coordinates with the network function's controller, which uses our novel IP Clustering system to manage the network function and traffic routing. Our main contribution is a TCP stack extension that supports the migration and failover of individual flows between NFs.

HA/TCP has three main goals:

1. **Transparent to Remote Nodes:** We cannot make protocol changes that require modifying existing TCP stacks in client nodes.

2. **Low Overhead:** While network reliability is important, users are not willing to sacrifice performance. The end-to-end impact on throughput and latency must be low to make HA/TCP practical.

3. **Fast Failover and Migration:** Failover and migrations must complete quickly to avoid user visible disruptions.

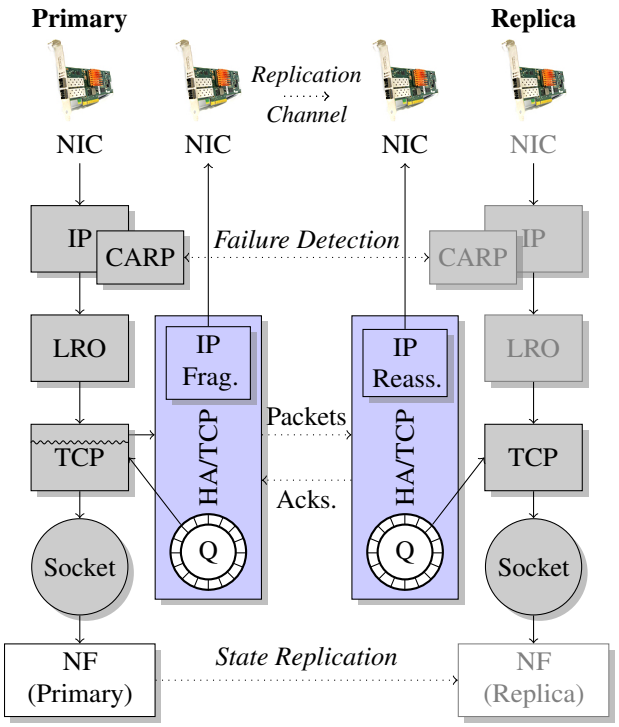

Figure 1: HA/TCP system architecture.

NFs using the HA/TCP framework, support migration and failover using our *replicated socket* interface. Our replicated socket provides a socket object that behaves identically on both primary and replica. In the rest of the design, we explain the operation of our replicated sockets, which we use to create reliable NFs. The most difficult challenge is to replicate the TCP stack to ensure that it behaves identically on both the primary and replica. In § 3.8 we discuss our extensions to CARP and our IP clustering protocol that provides additional functionality to the NFs.

3.1 Overview

Figure 1 shows the HA/TCP system architecture. HA/TCP intercepts and queues incoming packets from the TCP stack after *large receive offload* (LRO) and checksum validation. HA/TCP sends the TCP traffic and non-deterministic state (e.g., congestion control variables) over the replication channel. Both primary and replica have copies of the same incoming packet in their respective HA/TCP queue. After the replica acknowledges receiving the packet, both sides dequeue the packet and begin TCP processing. If the primary fails, CARP notifies HA/TCP to fail over the connection.

To achieve the full duplex throughput of our primary network interface, we dedicate a network interface for the replication channel between nodes. We use dual ported network interface cards (NICs), which are marginally more expensive than a single ported NICs. Our design uses active replication to a single replica. When a node fails, a new replica is deployed through NFV. Alternatively, HA/TCP supports multiple active replicas, see § 3.8.

Our performance goal is to support 100 Gbps network cards which requires examining many performance issues throughout the network stack. We can classify our optimizations into four categories: First, reducing overhead by processing larger packets. Second, eliminating memory allocations and copies throughout our code. Third, hiding replication latency. Fourth, supporting RSS for multithreaded application scalability.

HA/TCP creates listening and connected sockets that behave identically on the primary and replica, including all TCP states. The NF only needs to ensure that it identically transforms the data on the primary and replica.

Applications use `setsockopt` and `getsockopt` to enable and configure HA/TCP. A typical workflow is to enable HA/TCP on a listening socket, and any accepted connections will inherit the configuration. The listening socket may accept spoofed connections where the NF uses `getsockname` and `getpeername` to retrieve the endpoint addresses.

When the primary fails, the connection seamlessly fails over to the replica. The replica takes over the client connection and becomes the new primary. The new primary exchanges the traffic directly over the local NIC rather than the replication channel. In addition, HA/TCP provides the ability to migrate sockets to other nodes as needed.

3.2 Replicated Sockets

HA/TCP's replicated socket interface extends network sockets to provide a socket object that behaves identically on the primary and replica. Both listening and connected sockets are replicated between nodes. A common workflow for our NFs is to enable HA/TCP on a listening socket, which each accepted socket inherits.

Connected Sockets: After enabling HA/TCP, the primary continues to process traffic until a replica joins. Once a replica joins, the primary temporarily pauses the traffic and synchronizes all TCP state with the replica. Once complete, the primary resumes the client traffic.

HA/TCP Replication Channel: HA/TCP exchanges state and packet data over the replication channel, which is an IP protocol that encapsulates these packets with a small header. Our system implements and registers an IP protocol with the network stack that allows us to process packets in-line. For example, on the replica we decapsulate packets and forward them to the usual TCP input processing path as if they were received from the client directly.

The IP protocol is simpler and more efficient than using layer 4 protocols such as UDP or TCP for replication. The IP layer does not look up control blocks, update the internal state, acquire any locks nor apply congestion control, which lowers overhead and simplifies our design. Furthermore, modern NICs support IP checksum offloading.

The IP layer offers several other benefits over layer 2 protocols such as Ethernet. The IP layer provides IP fragmentation and reassembly to exchange large packets in MTU sized chunks. IP protocols are routable and can traverse many network devices including over metropolitan area networks.

As a performance optimization (see § 3.5), we do not handle packet loss in our replication channel. Instead, we rely on the clients to time out and retransmit to the primary and replica. Without an acknowledgment from the replica, the primary will not acknowledge the TCP packet and thus the client will retransmit the packets.

In an earlier design, we used a TCP connection for the replication channel, which led to performance issues from high CPU usage and the TCP meltdown problem [27]. This doubles most of the network stack overhead as every incoming packet traverses the primary's NIC driver through the TCP stack and out the replication interface's NIC driver to the replica. Similarly, the replica processes TCP twice before forwarding data to the application.

TCP meltdown is a problem that occurs when running TCP over TCP. It arises because HA/TCP holds packets on the primary until the replica acknowledges reception. If a packet is held longer than the client's retransmission timeout, the client treats this as packet loss and retransmits the packet. For example, the replication channel may delay delivery because of congestion control, which triggers a cascade of retransmissions by the client that exacerbates the issue.

Avoiding IP Reassembly Collisions: The challenge of using IP for the replication channel is that IP fragmentation suffers from reassembly collisions [26]. The IP layer breaks up larger packets into MTU sized chunks. At high throughput, packets may be incorrectly reassembled because of collisions with the fragment identifier. HA/TCP discards incorrectly assembled packets, which results in the client observing packet loss. The packet loss causes client retransmissions, which reduces application performance.

IP reassembly uses the 16-bit *IP identification* field and the 13-bit *IP offset* field to identify fragments belonging to the same packet and reassemble them into the original packet. Packets that are retransmitted because of loss or timeouts pollute the IP reassembly queue with old fragments. Usually, this is handled by clearing the IP reassembly buffer every 30 seconds. At high throughput, this is insufficient and we see periodic collisions.

To solve this we added an IP option containing a 32-bit unique ID and 32-bit timestamp to eliminate collisions. Each replicated TCP connection is assigned its own unique ID to avoid collisions between different connections.

Listening Sockets: HA/TCP replicates listening sockets to the replica. Upon establishing the replication channel on the replica, all states in the socket object and TCP stack are synchronized. The replica then copies and applies all states to the corresponding object.

HA/TCP ensures that new connections are created identically on both primary and replica. When a new connection arrives, the primary forwards the 3-way handshake packets to the replica.

First, the SYN packet, the primary's initial sequence number, and a time offset for TCP timestamps are forwarded to the replica. This packet is processed normally by the TCP input path except that it uses the initial sequence number from the primary.

Second, after receiving an acknowledgment from the replica, the primary generates and sends a SYN-ACK packet back to the client.

Third, the primary replicates the ACK message from the client and the initial window size. We replicate the initial congestion window size in case TCP fast open or the host cache provides initial values. The replica processes the TCP ACK normally.

HA/TCP inherits the replication configuration for newly accepted sockets. Before returning from `accept`, HA/TCP initializes and activates replication on the newly created socket, before the application uses the socket.

3.3 Steady State Processing on Primary

In normal operation, packet processing on the primary undergoes five steps.

First, HA/TCP intercepts incoming packets inside of the TCP input path. After the TCP input performs the checksum validation and looks up the TCP control block, which filters out any corrupt packets or packets not belonging to established connections, HA/TCP intercepts the packet.

Second, HA/TCP places the original packets in a queue. The packet mbufs and the TCP control block are stored to allow the resumption of the TCP processing without repeating the work completed in the first step.

Some time-based state is modified by buffering. The round trip time increases by the additional latency of waiting for the replica's acknowledgment. For some congestion control algorithms, we need the replica to respond with near constant latency otherwise the algorithm may believe there is congestion in the network. To avoid accidental duplicate packet detections, we deliver packets in order so the packet timestamps [8] are monotonic (see § 3.7).

Third, HA/TCP duplicates and transmits the packet to each replica. The duplication is necessary because when the packet is sent through the replication channel, the network stack frees the packet mbufs. As an optimization, we merge packet duplication with IP fragmentation to reduce overhead (see § 3.5). HA/TCP prepends a small header containing the packet size and, critically, any congestion control updates including window size changes (see § 3.4). The packets are then transmitted over the replication channel to the replica nodes.

Fourth, HA/TCP waits for an acknowledgment from the replica. While waiting for the replica to reply, HA/TCP continues to process incoming packets from the client.

Fifth, HA/TCP releases the queued packet to the TCP stack once the replica acknowledges the packet. The packet resumes processing in the TCP stack, where it left off in the first step.

3.4 Steady State Processing on Replica

The replica socket replicates the state and traffic from the primary. HA/TCP simulates the interface and TCP behaviors until a failover or migration event occurs. Critically, for good performance, the replica acknowledges packets back to the primary in constant time to avoid triggering client retransmissions and congestion control. In normal operation, packet processing on the replica also undergoes five steps.

First, HA/TCP receives a packet from the replication channel and parses the HA/TCP header. If the packet contains a replicated packet, HA/TCP removes the header and acknowledges back to the primary. All processing in this step occurs on the NIC thread associated with the replication channel. By acknowledging immediately, we eliminate any timing jitter from queuing or TCP processing. Otherwise, TCP congestion control may reduce the window because of timing variance.

After the replica acknowledges the packet, the primary may send a TCP acknowledgment to the client. The replica is required to keep all packets it has acknowledged regardless of whether the TCP stack is ready to process them. HA/TCP uses a queue to store any packets that are not ready to be processed by the TCP stack. For example, the client may acknowledge a packet from the primary that the replica has yet to transmit. In this case, the acknowledgment number is in the future and the TCP stack would discard it.

Second, HA/TCP enqueues the packet until it is ready to be processed by the replica TCP stack. The queue masks performance differences between primary and replica. When a replicated packet arrives, HA/TCP checks if the acknowledgment number is within the maximum sequence number sent, and only delivers the packet when this condition is met.

The queue length trades off tolerance for the performance differences between nodes and the failover time. Large queues better mask performance variability and tail latency in the replica application. However, the large queue increases the switchover time during the failover process because the queue must be drained before the replica assumes the role of primary. The queue size can be tuned for a specific workload and we limit the queue size to the receive socket buffer size.

HA/TCP monitors the queuing level on the replica and throttles the incoming traffic if the replica queue is saturated. The replica acknowledgment contains the queue size that the primary uses to check whether the replica is keeping up. When the replica falls behind and the queue fills up, which should not happen in a properly configured environment, the primary throttles to avoid overflowing the replica queue.

Third, HA/TCP checks the packet header to determine if any time-based state must be synchronized. The RTT estimates and window sizes are synchronized between nodes as needed to prevent inadvertently rejecting packets.

Fourth, HA/TCP iterates through all packets queued for delivery. If the condition mentioned in the second step is met, HA/TCP delivers the packet to the TCP stack; otherwise it moves to the next packet in the queue. For example, if packet loss occurs between the primary and client, the packets at the front of the queue will not match the TCP state. Without iterating through the queue, the retransmitted packets at the tail will block further processing.

Fifth, for outgoing traffic, HA/TCP inspects and discards the packets after all TCP processing is complete. Although HA/TCP frees the packet, the content of this packet resides in the socket buffer until the replica receives the TCP acknowledgment from the client. The packet can be retransmitted from the socket buffer. HA/TCP also attempts to deliver packets from the queue, after the TCP output code path transmits a packet. This delivers any packets that did not previously meet the condition (from the second step).

3.5 Performance Optimizations

HA/TCP is optimized for high performance network interfaces. In this section, we discuss each optimization and show the performance breakdowns. Table 1 shows the performance as we enable optimizations one at a time.

HA/TCP has three major data processing paths.

1. INPUT: The input path includes enqueuing the packets and transmitting them through the replication channel.

2. DELIVERY: Receives the replica acknowledgments and releases packets to the TCP stack.

3. REPLICA: The input path on the replica.

In HA/TCP, the INPUT path contains most of the high overhead operations. The DELIVERY path and REPLICA paths are similar to the baseline TCP network path. The total system overhead from HA/TCP consists of all three paths from all nodes. The overhead of each path is shown to make the effect of the optimization clear.

Recall from § 3.2, our early design uses TCP as the transport for our replication channel. Columns 2–4 in Table 1 use the TCP-based replication channel, while the remaining columns use the IP-based replication channel.

Use TCP LRO to Reduce Overhead. HA/TCP is optimized for the standard MTU of 1500 bytes to support user facing services in the cloud or data centers. In our experience, the FreeBSD TCP stack consumes CPU proportional to the packets per second (PPS). Thus, reducing the number of packets reduces the processing cost. LRO merges multiple TCP packets into a single packet earlier in the network stack to eliminate the cost of processing many TCP headers. For large flows, LRO can combine packets into 64 KiB packets.

		Unreplicated	No Opt.	w/LRO	w/LRO+NoCopy	IP+LRO	w/NoCopy+ReAsm
	Throughput	93.60 Gbps	8.60 Gbps	53.39 Gbps	73.13 Gbps	54.23 Gbps	90.50 Gbps
	Pkt/s	7.80 Mpps	0.72 Mpps	4.45 Mpps	6.09 Mpps	4.52 Mpps	7.54 Mpps
Primary	CPU INPUT	79 %	94 %	91 %	94 %	90 %	89 %
Primary	CPU DELIVERY	-	53 %	66 %	63 %	28 %	28 %
Primary	CPU APP	61 %	35 %	52 %	59 %	54 %	71 %
Repl.	CPU REPLICA	-	67 %	39 %	52 %	43 %	71 %
Repl.	CPU APP	-	47 %	42 %	56 %	38 %	60 %

Table 1: Shows HA/TCP with optimizations turned on/off. The first column shows the performance without replication. Columns two through four uses our TCP-based replication channel, and the last two columns uses our IP-based replication channel.

Without any optimization, the INPUT path is the performance bottleneck with two sources of overhead.[1] First, the INPUT path spends 9.7% of CPU time processing the incoming packets. This is roughly 0.72 M PPS with the default MTU of 1500 bytes. Without optimizations, CPU overhead scales linearly with the packets per second.

Second, the INPUT path consumes 5.3% of CPU time duplicating network packets using `m_dup`. The CPU time scales with the number of packets and the size of the payload, because `m_dup` deep copies the packet headers and data.

Enabling LRO chains consecutive packets into larger packets of up to 64 KiB in size through mbuf chaining, i.e., without deep copies. LRO trades off the processing overhead of identifying consecutive packets in a stream with the per-packet processing costs throughout the TCP stack. Furthermore, LRO piggybacks on interrupt coalescing to chain packets that are delivered in the same interrupt without increasing latency. Potentially LRO can use hardware offloads, but in the NICs we tested this performed worse.

The average packet traversing the network stack with LRO is 61400 bytes in size, resulting in a 40× reduction in effective PPS. While HA/TCP saves the per-packet CPU processing and packet duplication overheads with LRO, LRO itself adds overhead. However, the performance gain more than offsets the cost of LRO. LRO improves HA/TCP throughput by 6.2×. In our measurements, LRO slightly decreased latency because of the substantial increase in throughput.

Avoid Deep Copies of mbufs on the Primary. Our replication protocol prepends its headers to the packet for transmission. HA/TCP duplicates every incoming packet to retain an unmodified copy for the local TCP stack.

Even after enabling LRO, the INPUT path remains the performance bottleneck. The deep copying of mbufs using `m_dup` consumes 12% of CPU. To address this, we use `m_copypacket` to perform a shallow copy. The function duplicates mbuf headers and reference counts the payload. Shallow copying reduces memory copies and cuts the number of allocation/deallocations in half. Switching to `m_copypacket` improves throughput and reduces CPU usage.

Use IP-based Protocol for the Replication Channel. In § 3.2, we mentioned HA/TCP uses an IP-based protocol for the replication channel. Compared to a TCP-based transport, the IP protocol is simpler and more efficient.

With the optimizations we mentioned above, we use our original TCP-based replication channel. We found that the INPUT path consumes 8% of the CPU time on TCP encapsulation and processing. Our TCP-based replication channel reduces the client throughput by 28% to 73 Gbps as compared to an unreplicated setup. Furthermore, TCP over TCP suffers from TCP meltdown problem (see § 3.2).

Next, we implement an IP-based replication protocol. We compare the IP-based and TCP-based protocols with LRO enabled. This rules out effects from other dependent optimizations (see next section).

The IP-based protocol simplifies the locking design. Sending and receiving traffic in the TCP-based replication channel goes through the TCP stack, which locks the TCP control block. In addition, reading or writing the socket buffer for the replication channel requires an additional lock. By switching to an IP-based protocol, we eliminate these locks; moreover, this simplifies the design and avoids lock ranking problems that may lead to deadlocks.

Both versions are bottlenecked on the INPUT path because of the packet duplication function. With the IP-based protocol, the throughput only increases marginally. Turning on the shallow copying optimization significantly improves the performance but it requires the next optimization.

Create Replica Copies with IP Fragmentation. Our IP-based replication protocol depends on IP fragmentation to split large packets into smaller MTU sized packets, which replaces TSO (TCP segmentation offloading) in our TCP-based protocol. IP fragmentation is required as LRO merges small packets up to 64 KiB in size and this size far exceeds the jumbo MTU size of the replication channel.

Our next major source of overhead arises from the deep packet copies caused by IP fragmentation. When transferring

[1] Adaptive polling is disabled in our configuration. The CPU spends 5–10% on CPU scheduling and waiting for interrupts. We confirmed by monitoring the interrupt rate and using CPU profiling.

the replicated packet through the replication channel, IP fragmentation breaks the packet to fit the MTU of the replication channel. The IP fragmentation process calls the packet duplication function, which allocates and copies the mbuf. The MTU between the primary and the client is by default 1500 bytes, while the replication channel uses a 9k MTU. LRO merges small packets into a 64 KiB packet, and subsequently these large packets are broken into 9k jumbo packets.

To optimize IP fragmentation, HA/TCP unifies packet duplication and IP fragmentation. The unified IP fragmentation path only copies the packet once to simultaneously fragment the large packet into the replication channel and retain a reference to the original mbuf chain for retries and delivery to the TCP stack. Merging these two functions with shallow copying reduces the overhead. Combining these functions improves client throughput by 67% over the LRO optimization alone.

3.6 Additional Optimizations

We also added a few optimizations that we do not include in our performance breakdown. These optimizations reduce CPU usage on non-bottlenecked paths, avoid unpredictable behavior or support performance features of TCP/IP.

Allow Client to Repair Packet Loss. We expect packet loss to be more common between the client and the primary than over the replication channel. We rely on the client to retransmit any lost packets. Recall that the primary only processes the packet after receiving the acknowledgment from the replica. Any packet loss on the client-primary connection or replication channel causes the primary to not acknowledge the packet, resulting in a client retransmission. Packet loss in a data center, or even across a metro area network, is rare when compared to the wide area network, and thus having the client retransmit packets negligibly impacts performance.

Eliminate Delayed Processing on the Replica. We disable Naggle's algorithm and TCP delayed acknowledgments on the replica to reduce buffering. Both optimizations delay and batch network packets to reduce the overhead in the network stack. However, the delay results in more packet buffering and slows down the TCP state updates. The falling behind TCP state on replica leads to more buffering in the queue, and thus affects the performance of failover and migration.

Support Receive Side Scaling. RSS is a NIC feature that load balances traffic across CPU cores for performance. Connections are routed to a specific core based on a hash of the 5-tuple. Unfortunately, IP protocols are hashed based on their 3-tuple of IPs and protocol numbers resulting in a miss match between flows and application threads. We use Intel Flow Director [15] or Mellanox Flow Steering to maintain a one-to-one match between cores on the primary and replica. We use a range of IP protocol numbers so that the flow rules can forward the replication channel traffic to the correct core.

3.7 Challenges with TCP options

HA/TCP supports modern TCP options. Failing to support these features leads to performance or correctness issues.

Concurrent Listening Ports (`SO_REUSEPORT`). Multi-process or multi-threaded applications often create multiple listening sockets on the same port with `SO_REUSEPORT(_LB)`. To ensure deterministic behavior we establish a one-to-one mapping of listening sockets on the primary and replica.

SYN Cache. HA/TCP handles randomness from the TCP handshake. When the primary receives the SYN packet, the SYN cache generates random states for security purposes. These random states are sent to the replica along with the SYN packet. After the replica acknowledges the replication of this SYN packet, the primary delivers the packet again to the SYN cache for the client to respond. However, the primary needs to reapply the same random states to make sure the SYN cache generates the identical states.

Syncookie and TCP Fast Open (TFO). The syncookie and TFO use a cryptographic secret and a MAC function to allow the client to store cached values from the server. To ensure both TCP options function correctly, we synchronize these two secrets between the primary and replica.

SACK on the Replica. HA/TCP guarantees the state of SACK is identical on the primary and replica after a failover or migration. The replica delivers queued packets only when the acknowledgment number refers to packets that have already been "sent" by the replica (§ 3.4). During the migration, HA/TCP drains all remaining packets into the TCP stack, and missing packets will result in the same SACK state.

Synchronizing Clocks for PAWS. TCP PAWS [8] uses TCP timestamps to detect retransmitted packets and discards the packet. To support PAWS, HA/TCP tracks the time difference between primary and replica (`ts_offset`) and delivers the packet with an updated TCP timestamp adjusted by the time difference. The PAWS check is completed on the primary and for valid packets, the timestamp offset will ensure that the PAWS check will pass on the replica. We periodically synchronize the clocks to avoid drift.

Congestion Control Algorithms. We tested HA/TCP with both loss-based and RTT-based congestion control algorithms and found no significant performance differences. For loss-based algorithms, such as NewReno [22], DCTCP [6], and H-TCP [35], HA/TCP does not alter the retransmission mechanism in TCP, nor the congestion detection that the algorithms rely on. For RTT-based congestion control algorithms, such as HD [10] and CHD [25] that monitor network latency and latency variance to detect congestion, both of which are relatively stable. HA/TCP, and in particular the IP replication channel, is optimized to reduce the processing overhead, which results in a low and constant increase in latency (§ 5.4).

3.8 Load Balancing, Failover and Migration

HA/TCP uses the Common Address Redundancy Protocol (CARP) [9] protocol (based on VRRP [39]) to detect node failures and perform leader election, and our novel IP Clustering system to share a single IP address across nodes for scalability. We also discuss migration and having multiple replicas at the end of this section.

Failover (CARP). Each CARP node sends a periodic multicast advertisement. If three consecutive advertisements are not received from the primary, CARP declares the primary as failed. CARP then promotes a replica to be the new primary, and transmits an ARP announcement to notify the switch of the migration of the IP and MAC address to the new port.

In this paper, we set the advertisement interval to 100 ms, which results in a 300 ms detection and recovery time that is less than most application and TCP timeouts. Identifying the proper trade-off between detection time and false positives is beyond the scope of this paper.

HA/TCP fails over with minimal disruption. During steady state, HA/TCP replicates the incoming traffic to all replicas. Although replicas may lag behind the primary, our measurements show that the delay is only in the tens of milliseconds. The CARP failure detection time masks this lag and allows the replica to drain the queue before the failover.

IP Clustering. HA/TCP's IP clustering allows multiple nodes to share the same IP address for scalability. Our IP clustering system uses the link aggregation control protocol (LACP) to negotiate load balancing with the switch [1]. LACP allows one node to have multiple network interfaces to a switch, but we developed a distributed version of LACP that allows multiple nodes to share the same IP and MAC address.

Our distributed LACP protocol communicates between nodes in a cluster to load balance traffic between the switch and the nodes. The challenge is that HA/TCP's distributed LACP needs to synchronize the LACP state and ARP state between nodes continually. All the nodes must present themselves to the switch as a single node with several state fields being synchronized. ARP messages from the switch are only routed to a single node, leaving other nodes unaware of the ARP traffic. We use the replication interface to synchronize the LACP state and the ARP entries among all nodes.

Currently, IP clustering is supported without replication, because it requires additional application orchestration to manage the placement of per-connection primary-replica pairs. With complete orchestration, our IP clustering system will subsume CARP's functionality.

Migration. Migrations are driven by the primary, which stops processing the client traffic, sends a migrate command to the new primary, and demotes itself to a replica. The new primary sends the promotion message to the replica, i.e., the previous primary, to confirm the migration completion. Once complete, the replica updates its state and the new primary begins processing traffic.

Implementation	Count
HA/TCP Kernel Code	10K SLOC
HA/TCP IP Clustering	1.4K SLOC
SOCKS Proxy	3.3K SLOC
WAN Accelerator	8.7K SLOC
Distributed Load-balancer	1.2K SLOC
Latency Prober	1.9K SLOC
Multi-protocol Load Generator	1.9K SLOC

Table 2: Approximate source lines of code (SLOC) for HA/TCP and our NF applications.

Multiple Replicas. HA/TCP supports multiple replicas. Given the resource requirements of active replication between the primary and replica, it is recommended to use NFV to deploy a new replica if a node goes down. This eliminates the resource consumption of having another full replica, and the extra demands on the primary to keep them synchronized.

HA/TCP supports multiple active replicas with unicast connections for the replication channel. The primary requires additional dedicated network interfaces if it wants to serve the full available bandwidth of its primary interface. Alternatively, multicast can be used to eliminate the need for additional network interfaces with low latency and low packet loss, but it has not been implemented.

4 Implementation

HA/TCP is implemented in the FreeBSD 13.1 network stack. This is a popular operating system for network appliances and the basis of F-Stack, a TCP/IP stack for DPDK. Table 2 shows the breakdown of lines of code for HA/TCP and the NFs. The HA/TCP implementation consists of 8.8K source lines of code (SLOC) that extend the TCP stack, 100 SLOC in CARP, and 1.6K SLOC in the socket API. The IP Clustering system consists of 1.4K SLOC. The SOCKS proxy, WAN accelerator and load balancer consist of 13.2K SLOC. In addition, the SOCKS proxy and multiprotocol client conform to RFC1928 [34], RFC7230 [17] and RFC7231 [18].

5 Evaluation

We evaluate HA/TCP with micro-benchmarks and three TCP NF applications. The micro-benchmarks measure the scalability, migration/failover time, replication overhead, and latency of HA/TCP. For the three TCP NF applications we show the throughput and CPU usage.

In all benchmarks, the throughput is measured from the client application. HA/TCP replicates and forwards the traffic to the replica, and thus generates traffic in the replication channel equal to the client traffic. The replication channel uses

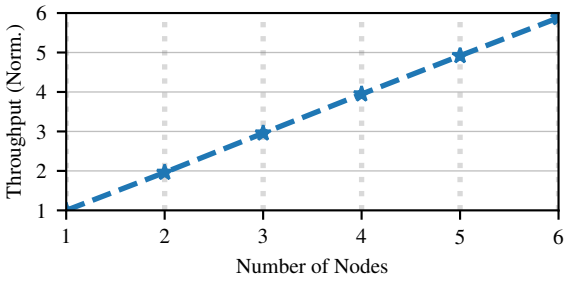

Figure 2: HA/TCP scales linearly with number of nodes while sharing a single IP and MAC address. HA/TCP load balances connections through our IP Clustering system. The throughput with 6 nodes is 2% lower than ideal.

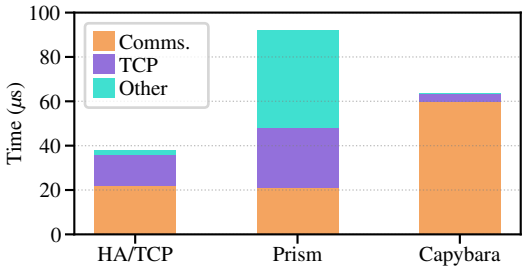

Figure 3: Migration time breakdown including network latency. HA/TCP takes 16 µs to complete the migration process, while the network latency adds the remaining 22 µs. HA/TCP is faster than the state-of-the-art systems.

a dedicated network interface to support the full bandwidth of the primary interface for client traffic.

We measure the CPU usage in the INPUT, DELIVERY and REPLICA paths (see § 3.5), along with the application CPU usage including both user and kernel time. We present a breakdown of the CPU usage for the baseline, primary and replica. The total CPU overhead is the percentage increase in CPU from both the primary and replica.

To minimize variance in our measurements, we pinned each context to a separate CPU and presented the total CPU usage. We used multiple tools to monitor system performance and hardware performance counters to breakdown the CPU usage. This is the same process we used during development.

All measurements were done on a local area network with low latency between all clients, primary and replica nodes. This represents the worst-case, as the latency between the client and primary is the same as the latency between the primary and replica. Over wide area networks, the extra latency induced by replication is negligible when compared to WAN latencies. In all benchmarks we used a single replica.

The primary and replica ran on two dual socket Intel Xeon Gold 6342 processor machines. All servers and clients use a dual-ported 100 Gbps Mellanox ConnectX-6 Ethernet NICs connected to a 100 Gbps Mellanox switch. The MTU between client and primary is set to the standard 1500 bytes, while the MTU between nodes is 9000 bytes. The TCP stack uses the New Reno congestion control algorithm. For failover tests, we set the advertisement interval (`adv_base`) to 100 ms to allow CARP to detect failures on average in 300 ms (§ 3.8).

5.1 Scalability

Figure 2 shows the scalability of HA/TCP's IP clustering. Our IP clustering allows NFs to share a single IP address across any number of nodes. The scalability is only limited by the switch's ability to load balance traffic. In this benchmark, we had the clients send traffic to six Intel Xeon Silver 4116 nodes each with a 25 Gbps interface. We use these nodes because we have a limited number of nodes with 100 Gbps NICs.

5.2 Migration and Failover

Figure 3 shows the breakdown of the migration time for HA/TCP, Prism [24] and Capybara [12]. To provide a fair comparison, we breakdown the migration time for the TCP/IP state, and omit system specific features such as application level migration that not all systems support. For each system, we breakdown the migration into three main costs: *Comms.* that includes any synchronization between nodes, *TCP* that includes the serialization and reconfiguration costs, and *Other* that contains other system specific costs.

Migrations are initiated by the source. The migrate message is sent through the replication channel to the destination in 22 µs. The communication latency dominates the total migration time. Afterwards, HA/TCP updates the TCP control block with the new IP address in 5 µs. The control block is stored in a hash table indexed by the connection's 5-tuple. HA/TCP removes and re-inserts the control block into the hash table using the new 5-tuple value. After updating the control block, HA/TCP flushes any buffered packets in 3 µs. Finally, HA/TCP re-enables the TCP processing in 2 µs.

Prism takes 92 µs if we consider only TCP operations. Prism serializes and reconfigures TCP in 27 µs. Prism takes 21 µs to communicate once to exchange the TCP state. The *Other* in Prism includes the traffic blocking and rule rewriting, which takes 44 µs to complete.

Capybara transfers the TCP state in 3.7 µs, which is much faster than HA/TCP and Prism because it uses a library OS with a custom TCP stack. HA/TCP and Prism are based on commercially used networking stacks (FreeBSD and Linux), which are substantially more complex to reconfigure. While Capybara's state transfer is fast, it communicates over the network three times. Capybara completes the migration in 64 µs including the three round trips over the network.

The failover process is identical to the migration process except that it is triggered by CARP. The failover time depends on the CARP detection time. As mentioned in § 3.8, we configured CARP to detect failures on average in 300 ms. HA/TCP finishes the migration 13 µs after failure detection.

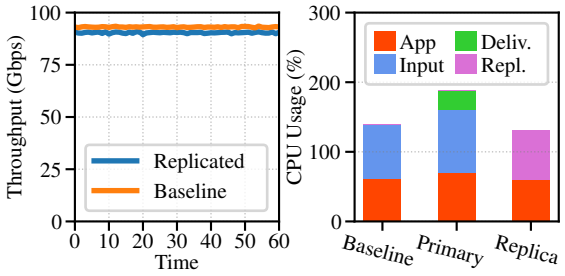

Figure 4: Replication overheads for iPerf3 with the receive-bound traffic configuration. The increase in latency results in a decrease of 3.4% in throughput.

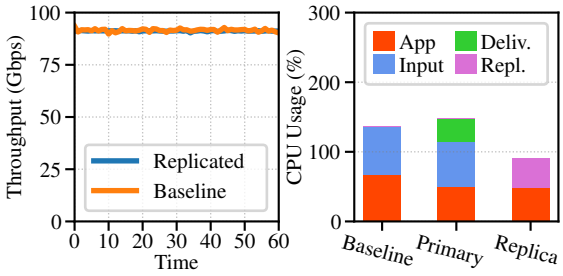

Figure 5: Replication overheads for iPerf3 with the transmit-bound traffic configuration. The throughput and CPU overheads are low because HA/TCP is mainly doing bookkeeping and replicating acknowledgments.

5.3 Replication Overhead

We ran iPerf3 in transmit-bound and receive-bound configurations to measure the overhead of the transmit and receive paths. The transmit-bound configuration has the client send data to the server, while the receive-bound configuration has the server send the data to the client.

Figures 4 and 5 show the results for the receive-bound and transmit-bound configurations. The replication channel adds 116 bytes of metadata to every packet. For iPerf3, LRO reconstructs mostly 64 KiB packets that are fragmented by our IP fragmentation code. The replication channel header should result in a 0.2% decrease in peak throughput if the workload is saturating the 100 Gbps link.

The receive-bound configuration reduces throughput by 3.4%, because of the higher input path processing costs and the additional latency of waiting for the acknowledgment from the replica, before completing TCP processing. In our measurements, we found that the input path is the bottleneck with over 90% of a single core used per connection.

The transmit-bound configuration reduces throughput by 0.3%, because the primary mostly performs bookkeeping to track which outgoing packets are ready to be sent to the client. Application CPU usage is lower than the baseline, because the longer latency taken for application acknowledgments results in more buffering in the outgoing socket buffer. The increase in latency causes the application to block more often. In response, the application increases the amount of data sent in subsequent calls, which amortizes the system call overhead.

HA/TCP uses additional memory for replication. During the steady state, both the primary and replica hold the replicated packet in the packet queue until the conditions are met. The memory overhead is small because HA/TCP reduces memory consumption through shallow copying.

In our setup, under the maximum throughput of 100 Gbps the RTT of the replication channel acknowledgments was approximately 70 µs resulting in a peak memory usage of 875 KiB. The peak memory usage on the primary is derived from the bandwidth delay product of the replication channel. We expect the replica to use a similar amount of memory.

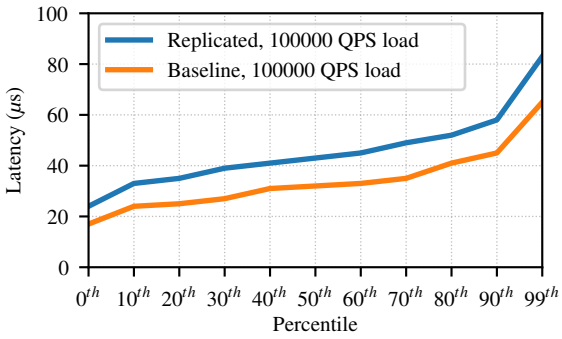

Figure 6: Latency overheads for replication. The client probes the latency by sending requests at 1000 QPS while the server is serving a 100k QPS workload. The latency increase reflects the delay in replicating packets to the replica. We achieve consistent low latency by avoiding the latency of waiting for TCP processing on the replica.

5.4 Latency Overhead

We evaluated the latency response using a distributed workload simulator for key-value stores [56]. In this benchmark, two clients connect to the server simultaneously. One client generates 100k queries per second (QPS) while another client measures the server response time by issuing 1k QPS. The results are an average of ten runs for each configuration.

Figure 6 shows the application latency with and without replication. The latency increases 11 µs on average.

The latency is lower than twice the RTT because the RTT in the replication channel is lower than the RTT between the client and the primary. We achieve this low replication channel RTT by having the replica send acknowledgments inline in the network stack, and our optimizations, including using our IP-based replication protocol, which reduce the CPU usage. Furthermore, the replica buffer hides processing delays to avoid increasing tail latency.

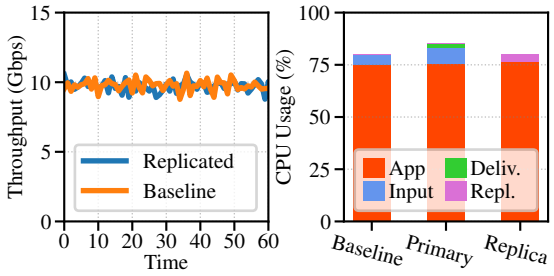

Figure 7: Replication overheads for the WAN accelerator. This workload is CPU and latency bound.

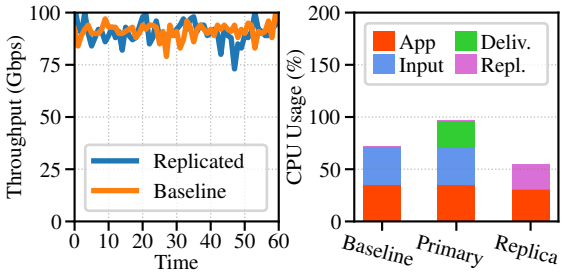

Figure 8: Replication overhead for the SOCKS proxy that shows a decrease in throughput of 2%. This workload is transmit-bound with small incoming requests and large responses. The higher variance in throughput comes from the replica's queuing mechanism delaying a substantial amount of response traffic from the server.

5.5 WAN Accelerator

The WAN accelerator is our most complex NF. WAN accelerators often serve as permanent VPNs connecting two or more data centers, but with the addition of compressing and deduplicating traffic to increase the effective bandwidth. They also aggregate traffic and send them through fewer connections between instances.

We found no open-source WAN accelerators and developed our own that will be available for others to use. WAN accelerators have very high CPU requirements because of the compression and deduplication, but commercial ones also provide protocol specific optimizations that require more CPU. Our accelerator can support 9.7 Gbps, which is faster than commercially available accelerators [48].

The WAN accelerator is configured to deduplicate and compress traffic before encapsulating and sending the traffic to the remote accelerator. This benchmark is unique because we replicate both sides of the WAN accelerator. During the test, the client creates eight long-live connections and issues requests to fetch a 10 MiB size file from the HTTP server through the accelerator. The accelerator uses eight cores for traffic deduplication and eight cores for traffic compression.

Throughput Overheads. Figure 7 shows the throughput. We apply HA/TCP to both the connection between accelerator peers and the connection between the accelerator and the server. We measured no statistically significant change in client throughput. In this benchmark, the application is not throughput bound or CPU bound, therefore we expect no change in client throughput.

CPU Overheads. The application is CPU and latency bound when passing data through the WAN accelerator's deduplication and compression pipeline on the side closest to the server. HA/TCP consumes 6.4% more CPU on the primary compared to the baseline CPU usage. Including the total replica's CPU usage, the replication consumes 106% more CPU across both the primary and the replica.

Failover. We tested failover using a multi-path setup with three appliances. There is a primary and replica on each site. This setup bridges two networks and allows for per-connection load-balancing. CARP's failure detection accounts for most of the failover time, and HA/TCP fails over all connections to the replica in 132 µs after failure detection.

5.6 SOCKS Proxy

A SOCKS proxy is an NF that forwards multiple protocols through a server to restrict Internet access from inside a secure network. It is often used to block phishing and other undesirable sites. We built an event-driven SOCKS proxy that conforms to the SOCKS5 protocol as defined in RFC1928 [34].

We used our multi-protocol load generator with 16 connections to fetch a 1 MiB file from the HTTP server through the SOCKS proxy. The long-lived connection option is enabled on the server and client. The connections between the SOCKS proxy server and clients are replicated for the benchmark.

Throughput Overheads. Figure 8 shows the client throughput with HA/TCP enabled. Replication reduces throughput by 2%. The throughput is bounded by the remote server response latency.

CPU Overheads. Figure 8 shows the CPU usage in the application and the input path does not change significantly from the baseline. HA/TCP consumes 29% CPU more on primary compared to the baseline. Including the total replica's CPU usage, the replication consumes 102% more CPU in total across both the primary and the replica.

Failover. Each buffered client request generates a 1 MiB response from the server. Even a modest amount of queuing on the replica leads to a large failover time. As part of the steady state processing on the replica, the queue is drained concurrently with failure detection. The replica is behind the primary by roughly 44 requests. The failover completes in 84 ms after failure detection.

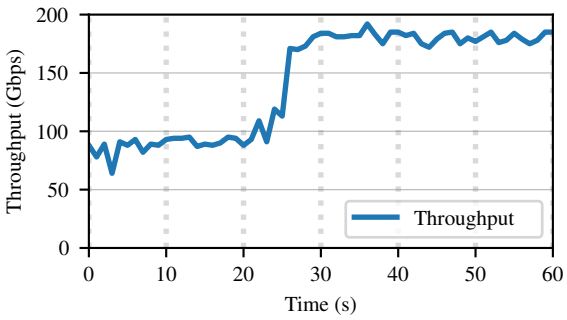

Figure 9: Connection level load-balancing. The load-balancer is deployed on two nodes. Two clients initially connect to a single server, and then load balancing is enabled to migrate half the connections to the second node.

5.7 Load Balancer

HA/TCP allows transparent connection-level load balancing among nodes. We implemented a distributed load-balancer that uses HA/TCP to balance connections for an HTTP service. The load-balancer works across multiple nodes to direct traffic to an HTTP server instance.

In this experiment, we run the load balancer on two servers and migrate half the connections while leaving the other connections alone. We used two identical servers with 100 Gbps NICs and two clients also with 100 Gbps NICs. Initially we create 64 connections to one server, and we enable the load balancing operation at around 22 s. HA/TCP then migrates 32 connections to the second server.

Figure 9 shows the aggregate throughput of all servers. One server is processing 90.6 Gbps and after the migration both are processing an aggregate of 181.2 Gbps.

6 Related Work

In addition to the works described in the background, there are other works on migration and replication of transport protocols. Most of these approaches deviate substantially from our criteria for HA/TCP.

Record-and-replay Based TCP Failover. FT-TCP [53,54] replicates TCP using record and replay. During a connection's lifetime, FT-TCP records all client network traffic and system calls on the server. When a failure occurs, the replica replays the recorded traffic and the system calls to reconstruct the primary's state. This approach suffers from high overheads and a slower failover.

Application Specific TCP Failover. Snoeren et al. [49] proposed an approach that supports TCP failover and migration. This approach uses a non-transparent state replication extension to facilitate the migration. The migration process is based on a proposed TCP migration extension [5], which requires the client to respond to a new *MigrateSYN* packet. However, this proposal has since been abandoned.

Surton et al. [51] introduced a middleware system TCPR that masks TCP failures from the border gateway protocol (BGP). TCPR implements a protocol specific *graceful recovery* technique, which avoids the cost of replaying the entire session for long lived connections, to recover the BGP session state quickly and resume communications. This proposal does not include the transparent failover and the migration features present in HA/TCP.

Other Protocols. QUIC [28, 33] is a transport protocol initially made to improve performance for HTTPS traffic. The protocol is based on UDP and allows multiple streams per connection. QUIC replaces the IP-Port tuple with a connection-ID to allow for connection migration. QUIC requires client application support. Our techniques from HA/TCP can be applied to support the failover of QUIC NFs.

Trickles [46] is a TCP-like transport protocol that is stateless on the server. The server-side protocol state and the application state are moved to the client and sent along with the user payload every time. This allows the server to migrate because all states are stored on the client. Trickles requires kernel and application changes on both servers and clients. Moreover, the state information that is included with every request, is prohibitively expensive for small packet workloads.

Zandy et al. [55] proposed a reliable network connection library. The library addresses issues for mobile clients. The library is not transparent since it requires integration on both server and client applications. In addition, the library only supports server side connection migration using an external checkpointing mechanism.

Other NF FT Techniques. FTvNF [23] combines replay of state access, similar to FTMB [45], with in-chain replication, similar to FTC [21], to provide low overhead reliability. None of these systems provide support for TCP NFs.

7 Conclusion

We present HA/TCP, a scalable framework that enables migration and failover for TCP NFs. HA/TCP provides a replicated socket interface to simplify the implementation of migration and high availability in NFs. HA/TCP fails over in milliseconds after detecting the failure. The migration is faster than the state-of-the-art systems. HA/TCP can also be used to extend these benefits to server applications.

Our code is available at https://github.com/rcslab/hatcp/

Abstract

Application networks facilitate RPC communication between the microservices of cloud applications. They are built today using service meshes which employ low-level specifications and have high overhead—it is difficult to express even simple application-specific functionality (e.g., access control based on RPC fields) and RPC latency can more than double. We develop AppNet, a framework for building expressive and high-performance application networks. Developers specify rich application network functions (ANFs) in a high-level language with generalized match-action rules. We compile the specifications to high-performance code after optimizing *where* (e.g., client, server) and *how* (e.g., RPC library, proxy) each function runs. The optimization uses symbolic abstraction and execution to judge if different runtime configurations of possibly stateful functions are semantically equivalent for arbitrary RPC streams. Our experiments show that AppNet can express common ANFs in only 7-28 lines of code. Its optimizations lower RPC processing latency by up to 82%.

1 Introduction

Modern cloud applications are composed of a collection of microservices instead of monolithic binaries [10, 50, 56]. This architecture speeds up software development because each microservice can use the language and libraries best suited to its task. It also improves scaling because each service can be scaled (via replicas) independently.

However, when applications are disaggregated, many simple function calls become remote procedure calls (RPCs) over the network. To secure and manage this communication, developers build *application networks*, also known as service meshes, using chains of application network functions (ANFs) that implement authentication, fault tolerance, logging, load balancing, etc. Enabled by RPC traffic processing platforms (e.g., Envoy proxy [19], RPC library plugins [18]) and by controllers such as Istio [39], application networks are ubiquitous today. Nearly all cloud application developers use them [7].

In theory, it should be easy to build performant application networks that are specialized to application needs. After all, an application network is meant to support known application(s) and functionality, in contrast to the Internet which is meant to support arbitrary applications. But the current reality is that implementing even simple application-specific functionality, such as access control or routing based on RPC fields, is challenging [1, 70, 76], and application networks can increase RPC latency as well as CPU usage by 2-7x [3, 5, 6, 66, 76, 86].

These shortcomings stem from the low-level programming model of current application networks. Developers can either write custom ANFs in general-purpose languages such as C++ and Rust or use generic HTTP modules. Implementing application-specific functionality is difficult either way. Custom ANFs are difficult to write because high-level abstractions do not exist, and a separate ANF must be written for each RPC processing platform. That is why HTTP modules, used after wrapping RPC traffic in HTTP, are more popular. But using them requires modifying the microservice code to expose relevant RPC information as HTTP headers [25, 70, 76]. Such modifications are onerous, especially when the microservice code is authored by third parties (a common case).

Low-level programming of application networks also hurts performance. There are different locations, including the client, the server, or another remote host [13], and different platforms where ANFs can be run. Different options offer different trade-offs [70, 76]—e.g., RPC libraries have low overhead but cannot be used with untrusted microservice code; and rate limiting total requests to a microservice is better done at the server-side to eliminate the coordination overhead among clients. Today, developers must explicitly configure the order, location, and platform for each ANF. However, it is difficult to manually determine high-performance configurations because performance depends on the interactions between various ANFs and on the (dynamically varying) number of client and server replicas. Since the semantics of ANFs are unknown to current network controllers, they must execute exactly what the user provides, even if semantically-equivalent configurations with significantly better performance exist.

*Now with UIUC.
†Now with Peking University.

Our goal is to enable expressive, easy-to-build, and high-performance application networks. We explore an approach based on high-level programming, inspired by works that achieve a similar goal for layer-3/4 networks [43,44,65,68,80] and switch forwarding [46,47,54,74]. We develop AppNet, a framework for building application networks which has (1) a high-level language to specify ANFs, (2) a compiler that generates an optimized configuration across multiple platforms, and (3) a controller that instantiates the configuration.

With AppNet, developers specify network functionality as a chain of *elements*, where each element expresses some type of RPC processing (e.g., load balancing). Our language offers a generalized match-action primitive where matches can be performed on RPC fields, state, or results of built-in functions (e.g., *random*) and actions can be reading or writing RPC fields and state. This primitive is expressive enough for RPC processing (unlike others we tried, such as SQL dataflow [9]) and yet can be compiled to high-performance code for multiple platforms. AppNet also provides primitives for managing shared state between multiple instances of the same element and shared state with the control plane. These primitives make it trivial to express functionality such as global rate limiting that may require coordination across element instances.

Based on element specifications, the AppNet compiler outputs runnable modules for various platforms. The mapping between elements and runnable modules is not one-to-one and is optimized for performance. A module may contain multiple elements to reduce overhead, the element order may be altered (e.g., moving elements that drop RPCs upstream reduces work for downstream elements), elements may be migrated based on state synchronization costs, or elements may be co-located in selected locations to completely bypass the (expensive) invocation of some platforms.

It is critical that the output of the compiler be semantically equivalent to the user's specification. Determining equivalence is challenging because elements are stateful (thus, processing an RPC impacts subsequent RPCs) and RPCs can be dropped or reordered (which can impact downstream state). AppNet uses a form of symbolic abstraction and symbolic execution [59] to determine when two chains of elements, each a possible runtime configuration, are equivalent for arbitrary streams of RPCs. It abstracts each element as symbolic transfer functions that capture its side effects (e.g., RPC field modifications and state updates). It then uses symbolic execution over these functions to compute the processing semantics of a chain, including changes to the element state and auxiliary outputs such as logs. The outputs of this execution help determine whether two chains are equivalent.

As part of its compilation, AppNet allows users to opt for weak consistency and improve performance. It can weaken consistency in two ways: *state consistency*, which controls the consistency of shared state among element instances, and *observation consistency*, which controls whether auxiliary outputs such as logs record the same information. Weak consistency may not always be appropriate, but applications that can tolerate them can experience higher performance. Such modulation of network behavior based on application characteristics is a unique opportunity for application networks.

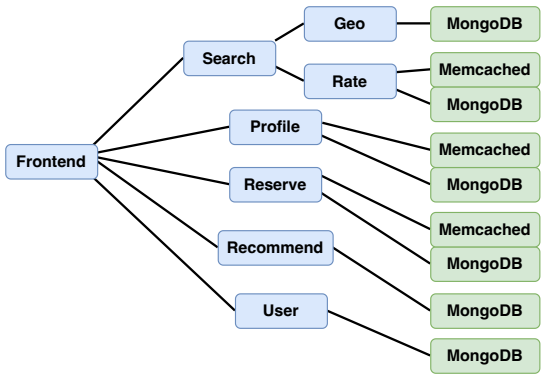

Figure 1: Hotel Reservation application's microservices [53].

Our current implementation of AppNet [16] supports three popular RPC processing platforms: EnvoyNative [31], EnvoyWasm [40] (respectively, C++ and WebAssembly-based execution environments in Envoy), and gRPC interceptors [29]. The Envoy platforms support deployment as a proxy located with the client or server ("sidecar") or as a remote proxy.

We evaluate AppNet by implementing 14 ANFs and studying a range of chain specifications. We find that 12 common ANFs need only 7–28 lines of code, and 2 more complex ANFs which integrate load balancing and routing—Meta's ServiceRouter [70] and Google's Prequal [82]—need only 62 and 88 lines. AppNet's compiler optimizations lower RPC processing latency by up to 82% and CPU usage by up to 75%, compared to unoptimized chain configurations.

Our results show that it is possible to build application networks that are both expressive and performant. Decoupling network specification from the running implementation opens up new capabilities too. One such capability, which AppNet already supports, is consistently upgrading the network when specifications change or microservices scale. The upgrade ensures that no RPC ever experiences a mix of old and new network policies, which can lead to performance anomalies and policy violations [4,69]. We are exploring others, including offloading RPC processing to kernel or hardware and serializing RPCs based on fields accessed in the network.

2 Background

Microservices are the dominant paradigm for modern cloud applications. Figure 1 shows a typical microservices-based application. Intended to enable hotel reservations, its functionality is split across eight types of microservices. Clients contact (a replica of) the Frontend service, which then communicates with a middle-tier service depending on the query. The middle-tier services handle tasks such as searching for hotels, completing hotel bookings, updating user profiles, and provid-

Function	Description
Fault Injection [23]	Randomly drop an RPC
Cache [22]	Generic cache for RPC responses
Rate Limiting [24]	Control the rate of RPC requests
Load Balancing [26]	Load balance across service replicas
Logging [20]	Record the RPC content to disk
Mutation [30]	Modify the RPC content
Application Firewall [15]	Rejects an RPC based on pattern matching
Metrics [28]	Monitor the RPC latency and success rate
Admission Control [45]	Drop RPC requests based on success rates
Encryption [12]	Encrypt certain RPC fields
Bandwidth Limit [21]	Control the amount of data to the service
Circuit Breaking [32]	Limit the impact of undesirable network peculiarities

Table 1: Common ANFs for microservices.

ing recommendations. They may contact other microservices and storage infrastructure. Production settings can have anywhere from 1 to 100s of replicas of each microservice [10,56], communicating via remote procedure calls (RPCs).

To manage communication between microservices, developers build application networks with rich functionality. Table 1 lists 12 common ANFs which we identified by surveying popular platforms to build application networks [11,14,30,31,39].

As Figure 2 shows, ANFs can be run in different locations and using different platforms. Common platforms include: (1) RPC library [18,70], which is embedded directly into the client or server microservice's code to manage communication without external proxies, (2) sidecar [19,35], a proxy co-located with the client and server that intercepts all traffic, and (3) remote proxy [13,76], a standalone proxy that handles traffic between services. Simple RPC processing may be located in the kernel (using eBPF) as well [17]. We will extend our work to this platform in the future.

ANFs are implemented in a platform-specific manner, and developers typically invoke them via *service mesh* controllers [35,39]. The controllers configure the target platform and also configure RPC traffic interception and redirection. Regardless of whether ANFs run inside an RPC library, a proxy, or both, developers must manually decide their execution order, platform, and placement.

This decision is complex and significantly impacts performance. As an example, consider the communication between two replicas of Search and one of Geo (Figure 3). The developer wants to run Logging, Load Balancing, Rate Limiting, and Application Firewall ANFs from Table 1 between the microservices. Rate Limiting uses a stateful token bucket to control the RPC request rate to a Geo replica. Figure 3a shows a possible configuration provided by the developer.

However, factoring in the properties of the platforms and ANFs' semantics, configurations with better performance exist. We could move Rate Limiting to the server side, which eliminates the need for synchronizing state between multiple ANF instances because the state depends on server replica, and we could move Logging to the RPC library because that platform has lower overhead. Figure 3b shows an optimized configuration for the chain.

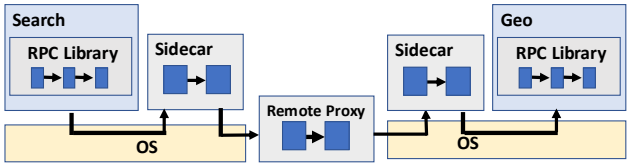

Figure 2: RPC processing between Search (client) and Geo microservices. Dark blue rectangles are ANFs.

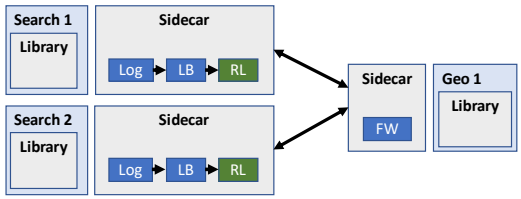
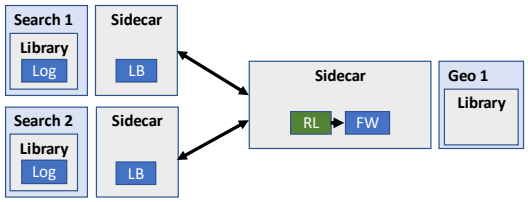


(a) User-provided configuration



(b) Optimized, semantic-preserving configuration

Figure 3: Two possible configurations for an application network. 'Log' is Logging, 'LB' is Load Balancing, 'FW' is Application Firewall, and 'RL' is Rate Limiting (stateful).

Not all performance-enhancing configurations preserve the semantics of the input chain. Identifying optimized configurations that preserve semantics requires careful reasoning about semantics and state dependencies. For example, reordering Application Firewall and Rate Limiting and moving the Application Firewall to the client side can improve performance by preventing RPCs that would eventually be dropped from traversing the network. Yet, this reordering would violate the input semantics, as Rate Limiting's internal state could be affected depending on whether Application Firewall drops a packet before or after it.

The current architecture of application networks—with low-level, platform-specific ANFs whose ordering, location, and platform are manually determined—has evolved organically, and it has the limitations mentioned earlier: difficult-to-express application-specific functionality and poor performance. We ask what a principled design for a framework

to build application networks might look like and if it can effectively address these limitations.

3 AppNet Overview

AppNet provides high-level programming abstractions for application networks. The abstractions simplify the specification of desired network functionality and enable optimizations that help realize the functionality with low overhead. This section overviews the abstractions, the optimizing compiler, and the runtime controller.

3.1 Programming abstractions

Like high-level languages for layer-3/4 networks [43], the AppNet language focuses on the data plane, which has complex, performance-sensitive processing. Some ANFs have a control plane as well. For load balancing, the data plane forwards the RPCs to different replicas, and the control plane maintains the list of active replicas. AppNet provides shared state abstractions that enable the control plane to communicate easily with the data plane, but it does not provide high-level abstractions for control plane logic.

With AppNet, users specify network functionality between a pair of microservices using chains of *elements*, where each element encodes an ANF. Key aspects of the specification language are:

Generalized match-action rules RPC processing is specified as match-action rules that operate over RPC fields (not arbitrary low-level code for standard protocols), state, and built-in functions. RPC fields (both metadata and payload) are represented as key-value pairs, which the elements can easily read/write without worrying about (de)serialization. The state is also represented as key-value pairs.

Match-action rules are natural for RPC processing, and they give the compiler visibility into which RPC fields are accessed and what the state depends on. At first glance, the match-action paradigm may seem limiting for layer-7 processing, but we have found it to be rich enough to encode a wide range of ANFs. This encoding is made possible by allowing richer match expressions and actions than switch languages like P4 [46]. Match expressions go beyond static table lookups and can use a suite of operators and built-in functions, and actions can read/write state multiple times.

Shared-state management Shared state, between multiple instances of the same ANF (e.g., for global rate limiting) or between control and data planes, is common in application networks. Developers manage this state manually today, which is onerous. AppNet abstracts away this state management and provides APIs to read-write state. This abstraction lets us reduce synchronization costs by placing elements and state based on what the state depends on. If the state depends on server replica, we prefer placing the element on the server side so there will be only one reader-writer to this shard of the state; and if we can do that, we can locate the shard on the server as well. Shared state management also lets us trade off consistency and performance, as we discuss next.

Performance-consistency tradeoff AppNet lets users trade consistency for performance in two ways. First, they can opt for weak (eventual) consistency for shared state. This trade-off is well-known for distributed systems [49,85]. Users can also specify weak observation consistency. Two network configurations have strong observation consistency when all outputs—the microservices themselves and auxiliary outputs like logs—get the same content in both configurations. Weak observation consistency permits the auxiliary output channels, but not microservices, to get different content, e.g., logs will differ when logging occurs before versus after an ANF that modifies the RPC's *geo-region* field. Applications that can tolerate weak observation consistency can get higher performance because it creates more optimization opportunities.

Location & platform agnostic elements, paired elements AppNet does not require users to specify an element's location or platform explicitly (though they can pin if they want). This under-specification enables the compiler to determine the location and platform based on performance. Thus, while AppNet uses element chains as a specification primitive like application networks today, a key difference is that AppNet chains specify processing semantics, not execution order.

AppNet also lets users define pairs of elements that must be used in concert (e.g., compression/decompression). For paired elements, AppNet ensures that one element is allocated to the client side and the other to the server side, and conflicting elements are not placed between them. This primitive simplifies specification and prevents errors such as forgetting the decompression element or placing compression between encryption and decryption [1].

3.2 Compiler

The AppNet compiler takes in the network specifications and RPC definitions (e.g., Protobuf [37]) used by the application code. Using RPC definitions during compilation frees the developer from having to write RPC (de-)serialization code, helps validate the specifications (e.g., RPC field names), and ensures that the generated code is up-to-date with RPC definitions. After parsing and sanity-checking the specifications, the compiler tags each state variable with what it depends on (e.g., client-replica, server-replica, global, etc.) based on what the state is indexed on. This information is used for optimizing element and state placement.

The compiler outputs modules that can run on one or more platforms (e.g., RPC library, sidecar). The heart of this process is computing a performant runtime configuration that is semantically equivalent to the user input. In the output configuration, elements may be reordered and combined into one module. The challenge in this computation is that elements can be stateful, which means that we must analyze equivalence for arbitrary streams of RPCs, not individual RPCs;

state updates caused by an RPC impact all subsequent RPCs. The analysis must also account for RPCs getting dropped or reordered—a stateful element that is upstream of a rate limiter, which drops RPCs, will see a different RPC stream than when it is moved downstream, leading to different state updates. Statefulness and the possibility of dropped/reordered streams make it hard for us to reuse equivalence analysis developed in domains such as stateless packet forwarding [43] or instruction reordering [77].

AppNet solves this challenge by first symbolically abstracting elements. The abstraction captures all of an element's side-effects and dependencies using transfer functions, without capturing the exact processing logic. For the rate limiter, it will capture that it may drop an RPC, that its internal state is updated when an RPC appears, and that this update does not depend on the RPC content. AppNet then uses symbolic execution over chains of element-level transfer functions to determine end-to-end transfer functions of a chain, including output RPCs, state updates, and what is sent to auxiliary outputs such as logs. Two chains are deemed equivalent if their end-to-end transfer functions are equivalent.

3.3 Controller

The AppNet controller maintains an up-to-date, global view of all service replica locations by integrating with cluster managers such as Kubernetes [33]. It orchestrates the deployment of runnable modules generated by the compiler, ensuring they are deployed to the appropriate replicas and platforms. It also ensures that configuration updates are consistent.

4 AppNet design

We now describe the AppNet language and compiler in detail. Appendix A describes code generation and consistent updates.

4.1 Specification language

Figure 4 shows the core of the AppNet grammar, without type annotations and syntactic features that enhance usability. Figure 5 show an example specification. At the highest level, RPC processing between two microservices is described using four sub-chains of elements: two for those that must run on the client or server sides, one for those that can run anywhere, and one for paired elements (e.g., encrypt/decrypt). For paired elements, the first element is run on the client side and the second on the server side. It is not mandatory to have an element in any of these sub-chains. Users can include all elements in the "any" sub-chain. The implied processing order for elements is client, pair(client), any, pair(server), server; the compiler may re-order the elements, but it will preserve this semantics. Users can optionally specify weak observation consistency. Figure 5a shows the AppNet chain specification for the example in Figure 3, where only the "client" and "any" chain are specified.

An AppNet element specification has four sections. The `state` section declares variables that hold local or shared state

$$
\begin{aligned}
\mathit{Chain} ::= & \left[\begin{array}{l} \textbf{client}: \mathit{Element}^* \\ \textbf{any}: \mathit{Element}^* \\ \textbf{server}: \mathit{Element}^* \\ \textbf{pair}: (\mathit{Element}, \mathit{Element})^* \\ [\textbf{weak}] \end{array}\right. \\

$$

Figure 4: AppNet specification language.

among all running instances of the element (serving different microservice replicas). Shared state declarations optionally accompany desired consistency and aggregation methods. By default, all reads and writes to shared state are synchronous. If users specify weak consistency, AppNet maintains a local copy and syncs this copy in the background (thus providing eventual consistency). During the sync, the default semantics is last-writer-wins, but users can specify custom aggregations (akin to CRDTs [73]). Sum (useful for counters) is a supported aggregator currently, and we will add more as needed.

The `init` section initializes the state variables. Initialization may use user input. The `req` and `resp` sections have match-action-based processing for RPC requests and responses. AppNet invokes these methods with a map that represents the content of the RPC payload and metadata (which includes RPC sender, destination, and method type). Users can match on any valid expression (Exp), and they can specify multiple actions for each case. Actions either update state or send a message. The message content can be the RPC (with its content represented by Var) or an Error. Messages can be sent downstream (`down`) to the next element or, if it is the last element in the chain, to the microservice; they can also be

init():

req(rpc):
    key = get(rpc, 'dst')
    has_token = get(bucket, key, lambda(token):
        match token > 0:
            true =>
                token = token - 1
                return true
            false =>
                return false
    )

    match has_token:
        true =>
            send(rpc, down)
        false =>
            send(err('rate limited'), up)

resp(rpc):
    send(rpc, up)
```

(b) The element specification for rate limiting.

Figure 5: Example AppNet specifications.

sent upstream (`up`) to the previous element, which is used for sending back errors or cached responses. AppNet checks at runtime if transmitted content can be cast into the expected RPC. In addition to the `up` and `down` channels, users can declare (in `state` section) and use auxiliary channels (e.g., for logging to disk).

To access state, AppNet provides `get` and `set` functions, enabling the compiler to infer state dependencies and determine whether operations should be local or remote. The `get` function can accept an optional lambda for computations, with updates to shared state being atomic. When a lambda is provided, the original return value of the `get` function is passed as an argument to the lambda. AppNet also supports various computations on RPC fields and states using built-in functions, including mathematical operators, random number generators, and utilities for encryption and compression.

Figure 5b shows the AppNet specification for an element that limits the rate of RPCs to each server replica using a token bucket. The `state` section defines a shared state variable called bucket that tracks available tokens. This element assumes that the control plane (not shown) refreshes the token bucket periodically by writing to this shared state. During request processing (Lines 6-21), the element checks if a token is available in the specified key of the bucket (state variables are key-value maps). The third argument of the `get` function specifies the logic that the data store should execute during the `get` operation. If a token is available, it is decremented.

4.2 Optimization

The AppNet compiler finds a high-performance configuration (location, platform, and execution order of each element) that respects users' constraints and is semantically equivalent to the input specification. We face a few challenges in computing such a configuration. First, there is a large space of possible configurations. For a chain of n elements with k placement options (location/platform combination) for each, there are $O(n! \cdot n^k)$ possible configurations. Second, we need to know which configurations are semantically equivalent to the user input, which is difficult for reasons mentioned in § 3.2. Third, multiple competing concerns (e.g., network traffic, CPU usage, latency, synchronization cost) make performance estimation difficult. For instance, positioning elements that drop RPCs early in the chain can reduce CPU usage and network traffic, but it can increase synchronization costs by preventing the consolidation of stateful elements.

AppNet addresses these challenges using a multi-start simulated annealing framework because it works well with large, intractable search space. Starting from an initial configuration with all elements randomly mapped to locations and platforms, the algorithm iteratively applies semantic-preserving mutations to the current solution and evaluates the new solution using a cost function. It decides whether to adopt the new solution based on the cost difference and a probability function. Finally, it periodically resets the temperature to avoid getting trapped in local optima.

We describe the cost function below, which is a key determiner of the final output. Appendix E provides more details on mutation strategies, termination conditions, and evaluation results on the optimality and scalability of the framework.

Cost function. Our cost function is a heuristic that combines six preferences. In priority order, they are: (1) Prefer platforms with lower processing costs (e.g., RPC library). (2) Prefer chains where all elements are located on a single platform, as this enables bypassing other platforms (e.g., server-side sidecar), significantly reducing processing overhead. (3) Prefer placements that align with state dependency to avoid synchronization cost. So, elements sharing a state indexed on a client replica should be located on the client side. (4) Prefer co-locating elements that require strong state synchronization (because dependencies are not aligned). Co-location facilitates the consolidation of state synchronization messages, reducing synchronization costs. (5) Same preference, but for elements with weak state consistency. (6) Prefer placing elements that may drop RPCs earlier because it reduces work for downstream elements.

We combine these preferences into a cost function in three steps. First, we compute element-level costs, which are represented as tuples with three components: the estimated frac-

tion of RPCs reaching the element, a binary value indicating whether the element requires strong state synchronization, and a binary value for weak state synchronization. The fraction of RPCs reaching an element is determined by the expected drop rates of upstream elements, set to 0 for elements that do not drop RPCs and a configurable value for those that might drop them. The default value is 0.05, but it can be provided by the developer or informed via runtime telemetry.

Second, we divide the input chains into sub-chains based on location and platform, and compute the cost of each sub-chain by aggregating the element-level cost tuples into a new tuple (with the same three components). The first component of the tuple sums the RPC fractions, reflecting the total processing cost. The second and third components apply a boolean *or*, indicating that synchronization costs are paid once per platform, regardless of how many elements require synchronization.

Finally, we aggregate sub-chain costs into the final chain-level cost. We convert the sub-chain cost tuples into scalar values by treating the binary components as 0/1 and computing a weighted sum of the three values using weights (0.5, 2, 1) for the three dimensions. We then add the baseline platform processing cost of S_p if there are any elements in the sub-chain for platform p. The chain-level cost is the sum of these five sub-chain-level costs. We use $S_p = 2$ for the out-of-process proxy (either sidecar or remote proxy) and $S_p = 0.1$ for the RPC library. We have found our results to be robust to exact values as long as the ordering between parameters is maintained. In the future, we plan to inform these parameters based on runtime profiling of different overheads [86].

4.3 Equivalence checking

There are three steps for deciding if two chains being considered during the optimization are equivalent: (1) symbolically abstracting what each element does; (2) symbolic execution of the chains based on the abstract elements; (3) comparing the outputs of this execution for two chains. We provide an overview of these steps below. Appendix B has the details and a proof of correctness.

Symbolic abstraction of elements This analysis creates an abstract representation of an element that captures the side effects of the element based on its dependencies. The side effects include modifications to the RPC, updates to the internal state, and writes to auxiliary output channels. The representation does not capture the actual processing.

The abstract representation is a transfer function whose parameters include the incoming RPC and the pre-state (prior to RPC processing). We model RPCs using their metadata and payload fields plus two special fields called *drops* and *reorders*. These fields capture whether the RPC could have been dropped or reordered.

Figure 6 (left) shows the transfer functions for three elements inside the green boxes. It assumes that incoming RPCs have two fields *dst* (for destination address) and *user* (for caller's identity) and the special field *drops* (we elide the special field *reorder* for simplicity). Logger logs the incoming RPC to an auxiliary output channel *out*, and so its transfer function appends the incoming RPC to the channel. Load Balancer is a round-robin load balancer that determines the destination using a state variable *idx* that indexes into a list of replicas and is incremented (with wrap around) after each RPC. Load Balancer has two transfer functions. One updates *RPC.dst* based on *idx*—$\mathbf{LB_R}$ is an opaque function that captures this dependency. The other updates *idx* based on an opaque function of *idx* and the *RPC.drops* field because if the RPC were dropped *idx* will not be updated. The transfer function of Firewall updates *RPC.drops* based on *RPC.user*.

We derive these transfer functions using static analysis on the element specification. For each RPC field and state variable modified by the element, a transfer function is generated that replaces the corresponding value with an opaque function representing the internal logic of the element, together with all symbols that the element reads, which serve as the dependencies for the write. For each element that may drop RPCs, a transfer function is generated that puts a new symbol representing the potential dropping event into the RPC special field. Reordering is handled in a similar way.

Symbolic execution of chains Symbolic execution of a chain produces a chain-level transfer function for the output RPC and for auxiliary channel outputs and state updates for all elements. This analysis essentially combined the element-level transfer functions.

Figure 6 (left) shows the end result of an RPC passing through that example chain. The auxiliary channel *out* outputs the exact RPC that came in; the internal state *idx* of the load balancer is updated by the opaque function $\mathbf{LB_S}$ whose parameters are the value of *idx* prior to RPC's arrival and the empty set for *RPC.drops* field (because the update will be different based on whether the RPC was dropped); and the final RPC has field values that depend on two opaque functions ($\mathbf{LB_R}$ and **FW**).

Comparing two chains Comparing two chains means comparing all of the chain-level transfer functions (result of symbolic execution). When the transfer functions have opaque functions, they are deemed equal iff their parameters are (recursively) equal; thus, this is basically a syntactic check. For strong observation consistency, we look for all transfer functions being equal. For weak observation consistency, we ignore the transfer functions for auxiliary channel outputs.

Figure 6 shows the results of this comparison when the chain on the left is compared against two other options with different element ordering. Option 1 is deemed weakly equivalent because the two transfer functions differ only for the auxiliary output of Logger. These transfer functions differ because the Logging element will record RPCs with a different *dst* field value once it is placed downstream of the Load Balancer. Option 2 is deemed not equivalent even though it

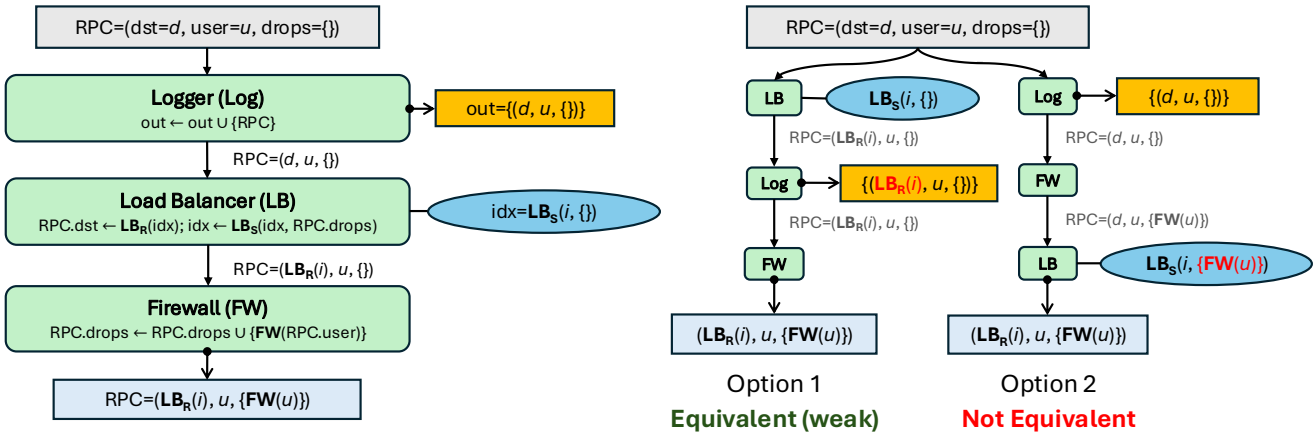

Figure 6: Equivalence-checking example. The transfer functions of the elements are inside the rounded green boxes. The rectangular boxes are channel outputs, and the oval ones are state updates determined by symbolic execution. Equivalence with strong semantics checks all outputs and state updates, and equivalence with weak semantics ignores yellow boxes (auxiliary outputs). The symbols marked red are those different from the original ones.

has identical transfer functions for Logger output and the final output RPC. The problem is that the transfer function for the state update for Load Balancer changes when it is placed downstream of the Firewall. This difference is surfacing the subtlety that Load Balancer will send subsequent RPCs to different destinations because the behavior of its round-robin logic is impacted by dropped RPCs.

5 Implementation

We implemented the AppNet compiler using 16K lines of Python and the controller using 3.1K lines of Go that integrates with Istio [39] and Kubernetes [33]. Developers use a custom Kubernetes resource [34] to provide AppNet specifications. The controller watches for changes to this resource and the application deployment (e.g., a new replica is launched) and updates the data plane platform appropriately.

AppNet currently supports three RPC processing platforms: (1) gRPC, a popular RPC library, for which we produce modules in Go that can be deployed as gRPC interceptors [29]; (2) EnvoyNative, for which we produce modules that C++ Envoy filters [31]; and (3) EnvoyWasm, a WebAssembly-based execution environment provided by Envoy [40], for which we produce modules in Rust that are later compiled to WebAssembly using the Rust compiler.

The overhead of these platforms increases in the listed order and the platforms differ in other ways as well (which makes the choice of the right platform a complex one). The gRPC modules run within the client or server address space, and so this platform cannot be used to run elements for which microservice code cannot be trusted. gRPC and EnvoyWasm allow dynamically updating running modules (without downtime); EnvoyNative does not. EnvoyNative and EnvoyWasm can be co-located with the client or server (as a sidecar proxy) or run in a remote proxy [13]; gRPC cannot be executed via a remote proxy.

AppNet assumes that its target platform provides access to RPC headers and payloads in plaintext (i.e., without mTLS). gRPC interceptors are always executed before mTLS is applied, and Envoy (in both sidecar and remote deployments) can be configured to terminate the mTLS connection [8]. In scenarios where end-to-end mTLS is required, AppNet will limit its target platforms to gRPC interceptors to ensure compliance with encryption requirements.

To synchronize shared state with strong consistency, we adopted the approach used by Envoy's global rate limiter [27] and StatelessNF [57]. Specifically, we use Redis [38] and route every state access through it. The synchronization for weak state consistency uses the same approach, but the synchronization is moved to the background.

Compiler benchmarks Finding the optimal runtime configuration takes 1.4s for 5-element chains that we use in § 6.2. Generating modules for gRPC interceptors and EnvoyWasm takes a few seconds, but it takes 1-2 minutes for EnvoyNative because that involves compiling the Envoy codebase.

6 Evaluation

Our evaluation aims to answer the following: (1) Can AppNet easily express common ANFs? (2) Can it reduce the overhead of application networks? (3) Does that reduction improve application performance?

6.1 Expressiveness

To evaluate the expressiveness of AppNet, we implement the 12 common ANFs in Table 1 which we identified based on a survey of common ANFs. As examples of more complex functionality, we also implement routing and load balanc-

	Shared state	LoC (AppNet)

ServiceRouter [70]	✓	62
Prequal [82]	✓	88

Table 2: ANFs implemented in AppNet.

ing in Meta's ServiceRouter [70] and Google's Prequal [82]. Appendix F details these implementations.

We are able to express all 14 ANFs in AppNet. As a proxy for ease of use, Table 2 shows the lines of code (LoC) of each. The 12 common ANFs need only 7-28 lines, and ServiceRouter and Prequal need only 62 and 88 lines. Some elements have a control plane component (e.g., for maintaining the replica list for load balancing). These lines do not include those components. We find it encouraging that so few lines are needed to express the data plane of ANFs.

For comparison, we also implement the same ANFs in the native languages of the platforms (Go for gRPC, C++ for EnvoyNative, Rust for EnvoyWasm). These ANFs need 5-60x more lines than AppNet elements. C++ modules are the worst, needing 4x more lines than Go and Rust modules.

High-level languages can hurt performance if the generated code is not as efficient as hand-optimized code. We find that the processing time and CPU usage of AppNet elements is only 1-4% higher than similar filters [31] bundled with Envoy. See Appendix D for details.

The value of AppNet specifications lies not only in their compactness but also in enabling optimizations that lower overhead. We evaluate this next.

6.2 RPC Processing Overhead

To assess how well AppNet reduces the RPC processing overhead, we need a corpus of network specifications used in practice. But such a dataset does not exist to our knowledge, so we create a wide array of network specifications randomly and benchmark the range of overhead reduction. This method helps understand specification characteristics that lead to higher or lower overhead.

We create a dataset by randomly picking elements in the chain from the 12 common ANFs in Table 2. We study chains of sizes 3 and 5 and randomly assign each element to a subchain (client, server, or any). We also randomly assign platform constraints, which include "do not run in an RPC library" and "requires dynamic upgrades." The first constraint disallows gRPC, and the second constraint disallows EnvoyNative. Modulo these location and platform constraints, AppNet is free to optimize the chain as it sees fit.

Experimental setup We consider three metrics: (1) Service Time is the time to complete an RPC request when the service has a minimal load (at most one outstanding request); (2) Tail Latency is the 90th percentile latency with moderate load (30-40% CPU utilization); and (3) CPU Usage is the number of virtual cores used for processing RPCs.

We use Echo Server as the application which has a frontend microservice that sends an echo request and a backend microservice that responds with an echo response. This simple application helps us microbenchmark RPC processing overhead. We study more complex applications later. All applications in this paper use Go and gRPC, and all experiments use five replicas per microservice. The results are qualitatively similar for different replica counts.

We quantify AppNet's overhead reduction by comparing against two baselines: (1) *NoOpt* randomly assigns elements while honoring explicit location or platform constraints, (2) *LocalOpt* favors platforms with lower processing costs (first gRPC, then EnvoyNative, then EnvoyWasm) and prioritizes placements that align with state dependencies (e.g., placing elements that depend on client replicas on the client side). NoOpt captures what may happen when developers do not attempt any performance optimization, and LocalOpt captures what an informed developer might do—optimize for individual elements—excludes chain-wide optimizations that are difficult to do manually. Both baselines maintain the element ordering of the input specification and make placement decisions for elements in order. Thus, choices available for an element depend on the choices made for upstream elements.

We use Cloudlab [51] machines with two 16-core Intel Xeon Gold 6142 CPUs (2.6 GHz) and 384GB RAM, Ubuntu 20.04 (Linux kernel v5.4.0), Kubernetes v1.28.13, and Envoy 1.30.5. We disable TurboBoost, CPU C-states, and dynamic CPU frequency scaling to reduce measurement variance. We use wrk [41] and wrk2 [42] for load generation as well as high-precision measurement of latency. The remote proxy is shared by all replicas of the client and server microservices.

6.2.1 Overhead reduction

Figure 7 compares the performance of LocalOpt and AppNet with strong and weak consistency against NoOpt. It plots the reduction in the three metrics for 30 randomly selected 5-element chains. The absolute metrics of NoOpt (not shown in the graph) are 0.8–2.0 ms for service time, 2.5–12.1 ms for tail latency, and 10.9–28.6 virtual cores for CPU usage. These numbers exclude the processing time and CPU usage of the Echo Server application itself.

Both LocalOpt and AppNet show improvements across all three metrics. LocalOpt achieves a median reduction of 25% in service time, 27% in tail latency, and 22% in CPU usage.

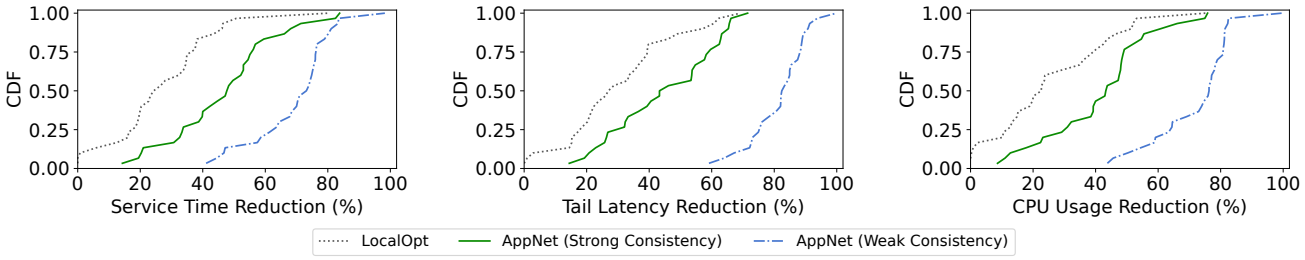

Figure 7: Reduction in RPC processing overhead compared to NoOpt. There are 5 elements in each chain.

AppNet, even when enforcing strong consistency, performs substantially better, with median reductions of 47% in service time, 44% in tail latency, and 42% in CPU usage. With weak consistency, AppNet further reduces overhead. Median reduction is 74-83%.

The degree of overhead reduction varies significantly across chains, influenced by which elements are present and location, platform constraints. By looking at the underlying data, we draw the following conclusions: the presence and placement of shared state elements within the chosen chain determine the potential for reducing synchronization overhead. The greatest reductions occur when multiple shared state elements are present and can be co-located and combined. Chains that allow more flexible element placement tend to yield higher gains. In contrast, chains with strict placement constraints limit the ability to group elements on one side and bypass a platform (e.g., a sidecar) on the other. Noticeable gains are also observed when elements that drop RPCs are positioned early in the chain, enabling them to execute sooner. AppNet's optimization algorithm is able to sift through these opportunities and find performant configurations. In contrast, LocalOpt uses a simplistic approach—selecting platforms based on processing costs and aligning state dependencies—and misses cross-element and cross-platform optimization opportunities.

6.2.2 Impact of available optimization opportunities

To shed light on overhead reduction as a function of available optimization opportunities, we now consider deployment environments that are limited to a single platform (but still multiple locations) or have shorter chains. These experiments are interesting also because some organization may not employ multiple platforms. The optimization opportunities that AppNet can tap in each platform differ. RPC libraries, which can only be used with fully trusted applications, are always in the path and have low overhead. So, they only benefit from reordering and moving elements between clients and servers (e.g., based on state synchronization costs). EnvoyNative has additional benefits when it can be completely bypassed (by moving all elements to one location). EnvoyWasm, which is used when dynamic upgrades are preferred, additionally benefits from consolidating multiple elements into one module because that reduces the number of invocations of the WebAssembly VM.

Figure 8 plots the overhead reduction for all three single-platform environment and the all-platforms environment. The experimental methodology is similar to the last section except that there are no constraints related to application trust and dynamic upgrades. In addition to 5-element chains, it plots 3-element chains which offer fewer optimization opportunities.

For 5-element chains, the median overhead reduction is 3–48% for the median, p10 is 0–24%, and p90 is 27–76%. The extent of the reduction varies across platforms due to the distinct characteristics of each as noted above. Even when reordering and client-vs-server placement are the only optimization opportunities (as in gRPC), we see a noticeable overhead reduction, especially for tail latency and CPU usage. AppNet significantly reduces overhead even for 3-element chains,though the reduction tends to be lower than for 5-element chains.

The reduction is generally higher as optimization opportunities increase. It is highest for the all-platforms environment because that also opens up the opportunity of using the platform with the least overhead when permitted by user policies. Due to implementation-level differences (Go vs. Rust), the state synchronization cost in gRPC is higher than in Envoy, which explains why, in some cases, gRPC optimizations are greater than those of Envoy.

LocalOpt often provides little to no benefit for single-platform environments. Here, it primarily aligns state dependencies, which helps only when an element is unconstrained and NoOpt (randomly) picks suboptimal placement. Such occurrences are rare.

6.2.3 Impact of weak state and observation consistency

Figure 9 shows the impact of using weak state consistency and weak observation consistency separately. It plots the reduction in overhead relative to strong consistency for both. For each curve, the set of chains is limited to those where that consistency type is relevant, i.e., there is at least one shared state variable for state consistency and at least one auxiliary output for observation consistency.

We see that weak state consistency leads to substantial reductions across a variety of chains, with median reduction

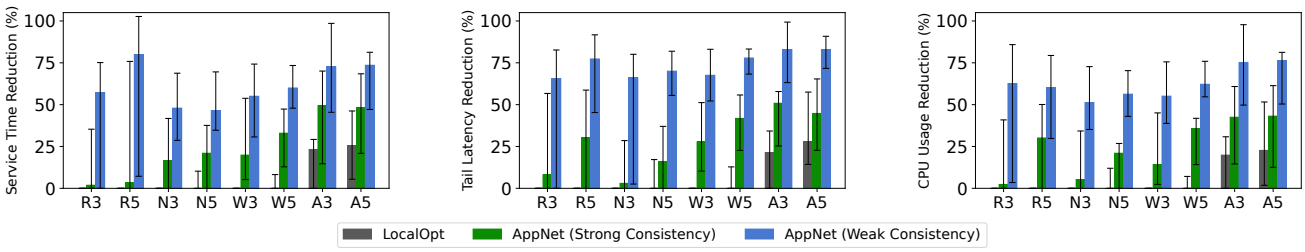

Figure 8: Reduction in RPC processing overhead compared to NoOpt. In the bar labels, the letter denotes available platforms (R = gRPC, N = EnvoyNative, W = EnvoyWasm, and A = all platforms), and the number denotes the chain length. The bar height denotes the median reduction and the error bars denote the 10th and 90th percentiles.

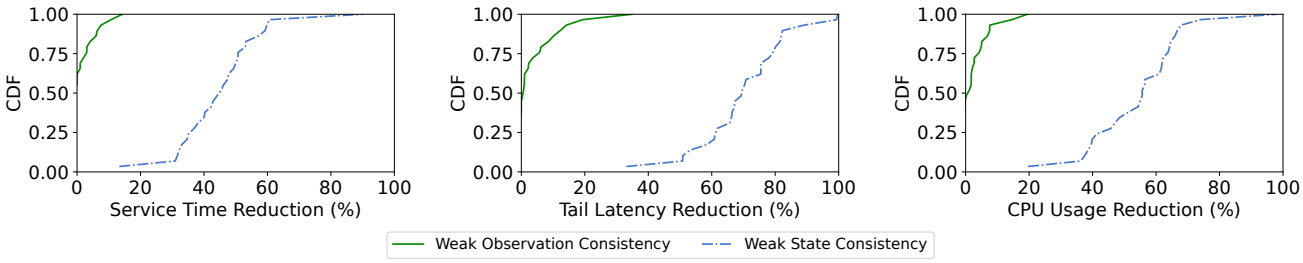

Figure 9: RPC processing overhead reduction with the two types of weak consistency relative to strong consistency.

ranging from 45% to 69%. This reduction stems from making state synchronization a background task. The degree of reduction depends on the number of shared-state elements included and whether they can be consolidated based on their placement constraints.

The overhead reduction from weak observation consistency is lower. A primary source of gain from weak observation consistency is moving a dropping element upstream, which reduces downstream work. But when the drop rate is low, as in our experiments, the gain is small. The gain will be higher in scenarios with higher drop rates (e.g., a rate limiter under heavy load). Despite low drop rates, we see a reduction in service time, tail latency, and CPU usage in 38-55% of the cases. Much of this reduction stems from weak observation enabling AppNet to reorder and consolidate more elements.

6.3 Application performance

We now evaluate the extent to which the reduction in RPC processing overhead in AppNet translates to end-to-end improvement in application-level performance. This section studies the Hotel Reservation application [53] (Figure 1), and Appendix C studies the Online Boutique application [36]. We use Hotel Reservation's search query, which retrieves available hotels based on location and check-in/check-out dates and involves calls to the Frontend, Search, Rates, Geo, Profile, Reserve microservices, and their associated MongoDB and Memcached storage systems. For each communication edge between microservices, we generate 5-element chains randomly (as in § 6.2.1). We measure end-to-end latency and total CPU.

Figure 10 shows the reduction in latency and CPU compared to NoOpt. The baseline metrics (not shown) are 7.2–14.1 ms for service time, 35.6–92.4 ms for tail latency, and 136.4-219.3 virtual cores for CPU usage.

LocalOpt demonstrates moderate performance gains across all metrics and chain configurations, with median reductions of 14% in service time and 11% in both tail latency and CPU usage. AppNet achieves more substantial improvements: with strong consistency, median reductions are 35% for service time, 29% for tail latency, and 26% for CPU usage. Weak consistency improves these numbers to 49%, 41%, and 42%, respectively.

Our results show that reducing RPC processing overhead leads to substantial improvements in end-to-end application performance. This is because this overhead is a substantial contributor toward application latency and CPU usage [5, 66, 71, 86]. Lowering this overhead directly helps applications by alleviating the tax of the microservices architecture.

7 Related Work

AppNet draws on four themes of prior work.

High-level network programming We draw heavily from the large body of work of high-level network programming, which has been explored in several contexts. Early work such as Click [60] focused on packet-processing in software switches. We borrow from this domain the idea of expressing

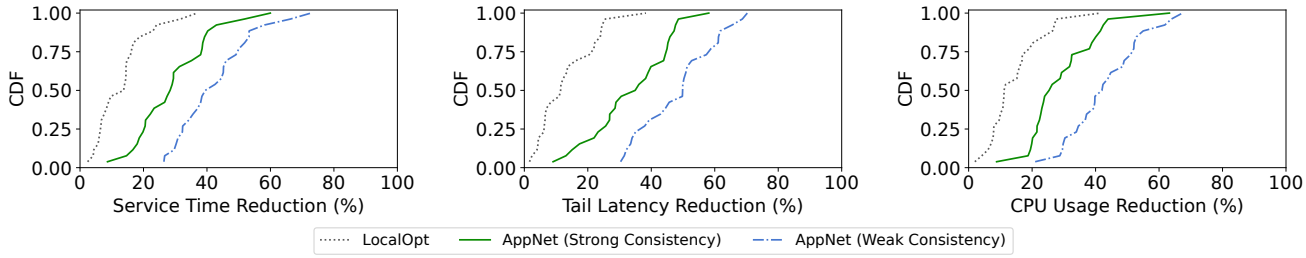

Figure 10: Performance improvement of Hotel Reservation compared to the NoOpt.

network functionality as a chain of elements. A key difference between AppNet and these systems is that AppNet includes abstractions for processing *inside* an element, which allows it to optimize the chain end-to-end.

A second wave focused on network-wide packet forwarding, catalyzed by software-defined networking (SDN) [43, 52, 68], where the focus was on layer-3/4 packet forwarding with capabilities like determining next hops and filtering. In contrast, AppNet targets rich, stateful functions and a setting where the network can scale dynamically.

The advent of programmable switches engendered work on high-level programming for them [46, 54, 75]. We borrow the match-action primitive from this work. Our match-action rules are richer, corresponding to the need for rich, layer-7 processing and aided by not being bound by hardware constraints. AppNet abstractions include shared state handling and optimizations across elements in a chain.

A parallel line of work focuses on NFs (network functions) in middleboxes. NetBricks [63] improves performance by composing multiple functions using a safe runtime, so they do not have to use separate VMs. It does not provide abstractions for individual functions, which allow us to safely combine multiple functions. Rubik [62] provides a language for efficient, low-level packet handling (e.g., assembling IP fragments and reconstructing TCP streams). AppNet abstractions focus on the RPC layer.

Reducing the overhead of application networks. There is broad awareness in the industry about the overhead of application networks [2, 5]. Several projects [13, 17] target this challenge by changing the software design of service meshes. Meta built ServiceRouter [70] to lower application networking overhead for specific functions, such as routing requests based on applications' sharding keys, and Alibaba built Canal Mesh [76] to address the overhead of sidecars by moving processing to a remote proxy. Unlike AppNet, none of these works focus on high-level programming to support diverse applications, deployment modes, and capabilities.

NF Optimizations. Optimizing NF chains for performance and resource efficiency has been an active area of research [48, 58, 64, 72, 78]. OpenBox [48] reduces redundancy in NF chains by eliminating overlapping logic across functions. Metron [58] builds on this by offloading parts of the merged logic to programmable switches. NFP [78] and Maestro [64] leverage parallelization to accelerate both inter- and intra-NF processing. In general, these systems focus on processing lower-level protocols and raw network packets, which have goals distinct from those of AppNet. Additionally, traditional NFs typically operate within dedicated middleboxes, while AppNet targets RPC processing tasks that can run in diverse environments, including RPC libraries, sidecar proxies, or middlebox-style remote proxies.

State management in NFs Works on scaling NFs show that managing state is a central challenge. Split/Merge [67], S6 [81], StatelessNF [57], SwiSh [84] manage different types of state based on its properties, and OpenNF [55] develops techniques to (approximately) infer properties of state in existing NFs. While these works do not focus on high-level message processing abstractions, they have influenced our design—our primitives enable a compiler to automatically infer important properties of state, and our state handling (placement and partitioning) draws on lessons from them.

8 Conclusions

AppNet enables expressive and high-performance application networks by decoupling the specification of ANF from its implementation. Its specification language is easy to use—common ANFs can be expressed in only 7–28 lines of code. It generates high-performance implementations based on an approach that reasons about estimated performance and semantic equivalence of possible implementations. Our experiments show that this approach lowers RPC processing latency and CPU usage by, respectively, 82% and 75%.

A Additional AppNet Design

A.1 Code generation

The AppNet compiler takes in the optimized runtime configuration and produces platform-specific software modules as well as deployment scripts. To handle requests for strongly consistent state, it translates these accesses into blocking network calls to external storage. In contrast, reads from weakly consistent state are performed locally, and writes are applied asynchronously. The compiler further reduces overhead by consolidating co-located elements, effectively removing boundaries introduced by virtualization or sandbox approaches [61, 63]. This consolidation applies to both the processing logic and state synchronization messages.

The generated deployment scripts configure traffic flow for each communication edge (microservices pair) such that sidecars are bypassed when the runtime configuration does not place any element there. (Today, all traffic of a microservice is intercepted by the sidecar, which imposes unnecessary overhead for RPC traffic that does not require processing.)

A.2 Consistent Updates

Application networks evolve frequently due to policy and workload changes (scaling). Service meshes today provide atomic updates for individual ANF, but ensuring consistency across a communication edge with multiple ANFs is left to developers. This approach is vulnerable to application downtime or policy violations [4]. For example, when migrating an application firewall, the developer may first detach the module on one side and then attach it on the other, potentially causing policy violations.

AppNet ensures consistent configuration updates such that RPCs traversing a communication edge are processed entirely by the old configuration or the new, and never a blend of the two. It uses a two-phase update approach [69, 83]. Each RPC is tagged with a version number, and configurations are updated to process only RPCs with the corresponding version. To transition from one configuration to the next, AppNet controller first installs the new configuration, guarded by the next version number. Once that is done, it enables the new configuration by stamping new RPCs with the next version number. Finally, once all RPCs with the old version number have completed, the old configuration is removed.

The header to support consistent upgrades adds 23 bytes to RPCs.

B Equivalence Checking Formalization

This appendix describes equivalence checking of AppNet in more detail. Table 3 lists all types of symbols with their explanations.

Symbolic abstraction of an element We symbolically abstract an element as a set of transfer functions in two steps. In the first step, we convert the element into a tuple of properties (`rf`, `wf`, `rs`, `ws`, `drop`, `reorder`, `channel`), where

- `rf`(read fields), `wf`(write fields), `rs`(read states), `ws`(write states) are sets of RPC field/state names that the element reads/modifies.
- `drop`, `reorder` are boolean values indicating whether the element is likely to drop RPCs or reorder input RPC stream. An element may reorder the RPC stream if it does concurrent processes or delays RPCs by differing amounts.
- `channel` is a set of auxiliary output channels in the element. Elements such as Logging and Metrics will send RPC records to these channels.

All of these properties are obtained by analyzing the (post-parsing) IR of AppNet specifications.

The second step converts these properties into transfer functions. Algorithm 1 illustrates this process. **wf**, **ws**, **ord** and **dr** in the transfer functions are opaque function symbols representing the dependencies of field modification, state modification, reordering decision, and dropping decision, respectively. The meaning of symbol subscripts are explained in Table 3.

Algorithm 1 Symbolic Abstraction Algorithm

Input: *AppNet specification of an element*
Output: *A set of transfer functions for the element*

Function `SymbolicAbstraction`(e)**:**
  (`rf`, `wf`, `rs`, `ws`, `drop`, `reorder`, `channel`) ← get_property_tuple(e)
  $TFs \leftarrow \{\}$ # TFs is a set for collecting transfer functions
  $rv \leftarrow \{\tilde{r}.f : f \in \texttt{rf}\} \cup \{\tilde{s}.v : v \in \texttt{rs}\}$
  foreach $f \in$ `wf` **do**
    TFs.add($\tilde{r}.f \leftarrow \mathbf{wf}_{(\mathbf{i},\mathbf{f})}(rv)$)
  end
  foreach $v \in$ `ws` **do**
    TFs.add($\tilde{s}.v \leftarrow \mathbf{ws}_{(\mathbf{i},\mathbf{v})}(rv \cup \tilde{r}.drops \cup \tilde{r}.reorders)$)
  end
  foreach $ch \in$ `channel` **do**
    TFs.add($ch \leftarrow ch \cup \{\tilde{r}\}$)
  end
  if `reorder` = **true then**
    TFs.add($\tilde{r}.reorders \leftarrow \tilde{r}.reorders \cup \{\mathbf{ord}_{\mathbf{i}}(rv)\}$)
  end
  if `drop` = **true then**
    TFs.add($\tilde{r}.drops \leftarrow \tilde{r}.drops \cup \{\mathbf{dr}_{\mathbf{i}}(rv)\}$)
  end
  return TFs

Symbolic execution of a chain of elements Algorithm 2 shows the process of sequentially iterating over the chain and concatenating element-level transfer functions to obtain chain-level transfer functions. $\mathbf{F}_{\mathbf{f_x}}$ and $\mathbf{S}_{\mathbf{v_x}}$ are primitive symbols representing the initial values of RPC fields and state variables.

Comparing two chains Algorithm 3 shows how we compare two chains under desired consistency level. For weak consistency, we require the transfer functions of output RPC and final states to be identical. For strong consistency, we also compare the transfer functions of auxiliary channels.

Correctness Proof Two chains are equivalent if and only if for any input RPC stream, the contents of output RPCs, the outputs of auxiliary channels, and all RPC-related behaviors such as dropping, are identical. The only differences permitted are those that could occur between two copies of the same chain, such as the differences caused by randomness. In our formalization, we assume that all opaque functions additionally take an implicit seed that makes the function deterministic, and the same seed is used for both chains under comparison to eliminate randomness. We also assume that the RPC stream is not reordered (e.g., during network transmission—by explicitly including the network as a reordering element, we can remove this assumption) unless it

Type	Explanation	Examples
Properties	obtained from AppNet specifications, used for symbolic abstraction	`rf` (read fields, a set of field names), `ws` (write states, a set of state variable names), `channel`
Primitive Symbols	symbols representing initial values of fields and states	$\mathbf{F_f}$ (the initial value of $RPC.f$), $\mathbf{S_v}$ (the initial value of state variable v)
Function Symbols	symbols representing the opaque internal logic of elements, the parameters of which are symbolic values that it depends on	$\mathbf{wf_{(i,f)}}(S)$ (the logic of the i_{th} element writing to $RPC.f$, where S is a set of symbols the element reads)
Dictionary	A dictionary maps field name/variable name to its value symbol. If $a : b \in \tilde{s}$, then $\tilde{s}.a \triangleq b$.	$\tilde{r} = \{f_1 : \mathbf{F_{f_1}}, \cdots, f_n : \mathbf{F_{f_n}}, drops : \{\}, reorders : \{\}\}$.

Table 3: Symbol Explanation and Examples

Algorithm 2 Symbolic Execution Algorithm

Input: *a chain configuration $c = (e_1, \cdots, e_n)$, i.e., a list of AppNet specifications*
Output: *chain-level transfer functions of output RPC, states and auxiliary channels*

Function `SymbolicExecution`*(c)*:
  chainTFs $\leftarrow \{$
  $\tilde{r} \leftarrow (f_1 : \mathbf{F_{f_1}}, \cdots, f_n : \mathbf{F_{f_n}}, drops : \{\}, reorders : \{\})$,
  $\tilde{s} \leftarrow (v_1 : \mathbf{S_{v_1}}, \cdots, v_m : \mathbf{S_{v_m}})$
  $\}$
  foreach $e_i \in c$ **do**
    TFs $\leftarrow$ `SymbolicAbstraction`(e_i)
    chainTFs $\leftarrow$ concatenate(*chainTFs*, *TFs*)
  end
  rpcTFs, stateTFs, channelTFs $\leftarrow$ split(ChainTFs)
  return *rpcTFs, stateTFs, channelTFs*

Algorithm 3 Equivalence Checking

Input: *Two chain configurations c_1, c_2 and desired consistency level L*
Output: *A boolean indicating whether c_1 and c_2 are equivalent under L*

$rpc_1, state_1, channel_1 \leftarrow$ `SymbolicExecution`(c_1)
$rpc_2, state_2, channel_2 \leftarrow$ `SymbolicExecution`(c_2)
if *L = 'weak'* **then**
  return $rpc_1 = rpc_2$ **and** $state_1 = state_2$
else
  return $rpc_1 = rpc_2$ **and** $state_1 = state_2$ **and** $channel_1 = channel_2$
end

meets elements with property $reorder =$ **true**.

We need to prove that for two chains, if the algorithm produces the same transfer functions, then the two configurations are equivalent. The proof below focuses on weak consistency, i.e., analyzing the output RPC and states; strong consistency just additionally checks the auxiliary channels, which follows a similar approach.

We start by showing that if two symbolic transfer functions are identical, then the concrete value or dropping/reordering decisions they represent are equivalent. We prove the statement by structural induction.

- Base case: primitive symbols include $\mathbf{F_{f_1}}, \cdots, \mathbf{F_{f_n}}$ and $\mathbf{S_{v_1}}, \cdots, \mathbf{S_{v_m}}$, which represent initial values of RPC fields and state variables. Identical primitive symbols indicate that they represent the exact same concrete initial value, which are equivalent.
- Inductive case: our symbolic execution system has two kinds of compound symbol structures:
  - $\mathbf{wf/dr/ord_{(i,f)}}(\{\tilde{r}.f : f \in rf\} \cup \{\tilde{s}.v : v \in rs\})$: these three symbols represent the modified field value that the i_{th} element writes into the RPC, the dropping decision, and the reordering decision, respectively. Considering that the essence of RPC processing inside an ANF is a black-box function that maps input RPCs and states to output RPCs and RPC-related operations, if all inner symbols in the parenthesis are identical, which means all the RPC fields and states the element reads are equivalent, then the modified fields or dropping/reordering decisions are also equivalent.
  - $\mathbf{ws_{(i,v)}}(\{\tilde{r}.f : f \in rf\} \cup \{\tilde{s}.v : v \in rs\} \cup RPC.drops \cup RPC.reorders)$: this symbol represents the modified value of state variables. State updates are different from RPC processing in that not only RPC contents and previous state values matter, but also whether an RPC arrives at the element and the order of RPC stream will influence the result. Therefore, our algorithm additionally includes the set of previous dropping/reordering decisions into the parentheses, and if all inner symbols are identical, then the modified state value should also be equivalent.

Therefore, if the transfer functions of output RPC are identical, then equivalence of single input RPC could be guaranteed.

The next step is to show why it is correct to apply analysis

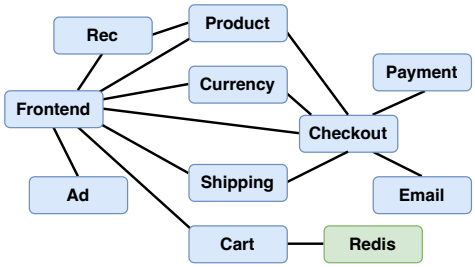

Figure 11: Online Boutique Microservice [36].

on single input RPC to stateful chains that receive a stream of RPCs. Let's consider two scenarios:

- The chain is stateless, i.e., there is no stateful element inside the chain. In this case, RPCs will not interfere with each other, and therefore reasoning about a stream of input RPCs is equivalent to reasoning about each RPC independently.

- The chain contains stateful elements. Considering that (1) The reordering events symbols inside the transfer functions of states are identical, which guarantees that stateful elements see RPCs in the same order in two configurations, and (2) The transfer functions of states, in a whole, are identical, which means given the same pre-states, the n_{th} RPC will produce the same post-states which serve as the pre-states of the $(n+1)_{th}$ RPC, we can inductively conclude that all RPCs in the stream will result in identical symbolic output RPCs.

Therefore, we can conclude that if the algorithm produces identical symbolic output RPC, dropping events and modified states, two chain configurations are equivalent.

C Additional Application Benchmark

In this section, we demonstrate AppNet's ability to reduce RPC processing overhead using the Online Boutique application [36]. It consists of 11 microservices that communicate via gRPC (Figure 11). Since it is implemented in multiple languages (Python, C#, Java, Node.js and Go) and AppNet supports only the Go version of gRPC, we port all services to Go. Our experimental methodology follows the same approach as in § 6.3.

Figure 12 presents the results, showing the performance improvements of the LocalOpt and AppNet relative to the "Fully Pinned" baseline. The baseline metrics (not shown) across all chain configurations range from 14.1–19.2 milliseconds for service time, 90.1–162.2 milliseconds for tail latency, and 106.4–163.8 virtual cores for CPU usage.

Consistent with the results from the Hotel Reservation benchmark, the LocalOpt achieves moderate performance gains across all metrics and chain configurations, with median reductions of 8% in service time and tail latency and 9% in CPU usage. In contrast, AppNet delivers greater improvements: under strong consistency, median reductions reach 22% for service time, 20% for tail latency, and 24% for CPU usage. When weak consistency is applied, these gains increase further to 36%, 37%, and 44%, respectively.

The overall improvements achieved by both the LocalOpt and AppNet are smaller in the Online Boutique application compared to the Hotel Reservation benchmark. This is primarily due to the larger baseline application latency and CPU usage, which reduce the relative impact of RPC processing optimizations. Nevertheless, AppNet still provide substantial performance benefits, demonstrating its effectiveness across different application workloads.

D Abstraction Tax

Systems based on high-level languages sometimes pay a performance tax when the generated code is not as efficient as hand-written code. We quantify this tax for AppNet by running our generated modules against two sets of handwritten modules. Each module is run in isolation (i.e., not as part of a chain), and we measure the same three metrics.

The first set of handwritten modules is Envoy's built-in filters. Envoy has a set of built-in filters written in C++ that users can configure to use with Envoy. Versions of all 12 filters in Table 2 are available except for encryption. Figure 13a shows how our generated EnvoyNative modules compare to these filters. We see that the tax is low. The median increase in latency and CPU is 1-4%, with the worst-case overhead being 3-7%.

The second set of handwritten modules are gRPC interceptors and Envoy WebAssembly filters that we wrote (because we were not able to find usable third-party implementations. Figure 13b presents the results. We see a similar tax to what we saw for Envoy built-in filters.

We investigated the sources of this tax and found that significant contributors include coarse-grained locking of shared state and the data structures used to maintain metadata for matching RPC messages across processing functions. We speculate that this can be reduced with a more careful analysis of the processing logic. Nevertheless, as demonstrated earlier, this low tax is more than compensated for by the optimizations enabled by AppNet's abstractions.

E Details of Optimization Algorithm

As the number of elements in the chain increases, the search space for potential optimal configurations soon becomes large and intractable. One of the possible approaches is to formulate the optimization into an integer programming (IP) problem and invoke a solver to generate solutions. However, solver-based methods are not scalable enough and struggle to incorporate validity checks as IP constraints. To address these challenges, AppNet leverages a multi-start simulated annealing (MSA) algorithm [79] to efficiently find high-quality solutions for long chains. Specifically, during each cooling

process, we iteratively consider valid (i.e., semantics preserving) mutations of the current solution and decide whether to adopt the new configuration according to some probabilities related to the cost difference and dropping temperature. Algorithm 4 shows our strategy of configuration mutation. To further mitigate the risk of local optima, we repeatedly restart the cooling process by resetting the temperature. The algorithm terminates when there's no improvement in cost over the last 15 cooling processes or the time budget runs out. Our final optimization algorithm combines MSA with brute-force searching: for chains with fewer than 10 elements, we exhaustively enumerate all possible combinations of configurations to guarantee optimality; for longer chains, we apply the MSA heuristics to achieve near-optimal solutions efficiently.

To evaluate the efficiency and solution quality of our approach, we compare multi-start simulated annealing against brute-force searching by randomly generating 100 specifications for each chain size ranging from 3 to 12 and recording the solving time and final cost. Figure 14a shows the speed

Algorithm 4 Solution Mutator in Simulated Annealing

Input: *The current solution*
Output: *A new valid solution mutated from the original one*

Function `SolMutation(s)`**:**
  repeat
    $s' \leftarrow s$
    switch $coin \leftarrow random(0,1)$ **do**
      case $0 \leq coin < 0.4$:
        change the position of one element in s'
      case $0.4 \leq coin < 0.8$:
        swap the positions of two elements in s'
      case $0.8 \leq coin \leq 1$:
        change the platform of one element in s'
    end
  until $PassValidityCheck(s')$;
  return s'

comparison. Brute-force searching becomes computationally prohibitive due to its factorial complexity, whereas MSA is 473x faster for 12-element chains and remains practical even when the chain size increases to 100. Figure 14b presents the CDF of the cost of multi-start simulated annealing relative to brute-force searching. MSA successfully identifies the optimal configuration in more than 98% of cases when the chain size is no more than 12, and the worst-case cost increase is lower than 1.5%.

F Details of ServiceRouter and Prequal Implementation

In this section, we describe the implementation details of ServiceRouter and Prequal in AppNet.

ServiceRouter [70] is Meta's global service mesh system. We implement the routing and load balancing as described in the paper. Specifically, it routes RPCs based on their key (for sharded services) and uses adaptive load estimation along with the power of two choices to balance load across service replicas. The AppNet implementation consists of a control plane component, a client-side element, and a server-side element. The control plane component maintains the shard information for each service and maintains an up-to-date global knowledge about the load of each service replica. The client-side

element maintains two states: a shard map and a load map, which store the mapping between request keys and shard replicas, and replicas to their current load, respectively. For each request, the client-side element first checks the freshness of its local states, queries the control plane if they are stale, and applies the power-of-two choices on the corresponding shard replicas. Upon receiving a response, the client-side element updates the load map using the piggybacked load information embedded in the response. The server-side element monitors load locally by maintaining a counter. This counter is incremented when a request is received and decremented when the application sends a response. The current load value is embedded as an RPC header in outgoing responses

Prequal [82] is a load balancer used by YouTube and other production systems at Google. It selects server replicas based on estimated latency and active in-flight requests. The AppNet implementation of Prequal also comprises three main components: a control plane, a client-side element, and a server-side element. The control plane actively probes and stores the load of each replica along with its request latency for various load levels. The client maintains a local cache of the control plane's state. For each request, it applies the power-of-N choices to sample a subset of replicas and retrieves their load information from either the local cache or the control plane, depending on the cache's freshness. It then uses the hot-cold lexicographic rule, as described in the paper, to select the replica for routing the request. The server-side component monitors the current load and maintains a mapping between load levels and the latencies of requests processed at each load point.

State-Compute Replication: Parallelizing High-Speed Stateful Packet Processing

Abstract

With the slowdown of Moore's law, CPU-oriented packet processing in software will be significantly outpaced by emerging line speeds of network interface cards (NICs). Single-core packet-processing throughput has saturated.

We consider the problem of high-speed packet processing with multiple CPU cores. The key challenge is state—memory that multiple packets must read and update. The prevailing method to scale throughput with multiple cores involves state sharding, processing all packets that update the same state, e.g., flow, at the same core. However, given the skewed nature of realistic flow size distributions, this method is untenable, since total throughput is limited by single-core performance.

This paper introduces *state-compute replication*, a principle to scale the throughput of a single stateful flow across multiple cores using replication. Our design leverages a *packet history sequencer* running on a NIC or top-of-the-rack switch to enable multiple cores to update state without explicit synchronization. Our experiments with realistic data center and wide-area Internet traces show that state-compute replication can scale total packet-processing throughput linearly with cores, independent of flow size distributions, across a range of realistic packet-processing programs.

1 Introduction

Designing software to handle high packet-processing loads is crucial in networked systems. For example, software load balancers, CDN nodes, DDoS mitigators, and many other middleboxes depend on it. Yet, with the slowdown of Moore's law, software packet processing has struggled to keep up with line speeds of network interface cards (NICs), with emerging speeds of 200 Gbit/s and beyond [20]. Consequently, there have been significant efforts to speed up packet processing through better network stack design, removing user-kernel crossings, running software at lower layers of the stack (*e.g.,* NIC device driver), and designing better host interconnects.

We consider the problem of scaling software packet processing by using multiple cores on a server. The key challenge is that many packet-processing applications are *stateful*, maintaining and updating regions of memory across many packets. If multiple cores contend to access the same memory regions, there is significant memory contention and cache bouncing, resulting in poor performance. Hence, the classic approach to multicore scaling is to process packets touching distinct states, *i.e.,* flows, on different cores, hence removing memory contention and synchronization. For example, a load balancer that maintains a separate backend server for each 5-tuple may send all packets of a given 5-tuple to a fixed core, but process different 5-tuples on different cores, hence scaling performance with multiple cores. Many prior efforts have implemented and optimized such sharding-oriented solutions [35,46,54,63,68].

However, we believe that the existing approaches to multicore scaling have run their course (§2). Realistic traffic workloads have heavy-tailed flow size distributions and are highly skewed. With sharding, large "elephant flows" must be processed by one CPU core, reducing overall performance due to the low throughput of a single CPU core. With emerging 200 Gbit/s—1 Tbit/s NICs, a single packet processing core may be too slow to keep up even with a single elephant flow. Additionally, with the growing scales of volumetric resource exhaustion attacks, packet processors must gracefully handle attacks where adversaries force packets into a single flow [43].

This paper introduces a scaling principle, *state-compute replication (SCR)*, that improves the software packet-processing throughput for a *single, stateful flow* with additional cores, while avoiding shared memory and contention. Figure 1 shows how SCR scales the throughput of a single TCP connection for a TCP connection state tracker [40] with more cores, when other scaling techniques fail. A connection tracker may change its internal state with each packet.

SCR applies to any packet processing program that may be abstracted as a deterministic finite state machine. Intuitively, as long as each core can reconstruct the flow state by processing *all* the packets of the flow, multiple cores can successfully process a single stateful flow with zero cross-core synchronization. However, naively processing every packet with every CPU core cannot improve throughput with more

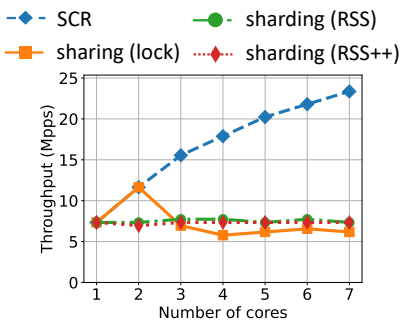

Figure 1: Scaling the throughput of a TCP connection state tracker for a *single TCP connection* across multiple cores. Sharing state across cores degrades performance beyond 2 cores due to contention. Sharding state (using RSS and RSS++ [35]) cannot improve throughput beyond a single CPU core (§2). In contrast, State-Compute Replication (§3) provides linear scale-up in throughput with cores.

cores. We need to meet two additional requirements. First, in systems where CPU usage is dominated by per-packet work, we must preserve the total number of packets moving through the system. Second, we must divide up *dispatch*—the CPU software labor of presenting the packets to the packet-processing program—across multiple cores (§3.1). This leads to the scaling principle below (more formal version in §3.1):
State-Compute Replication (informal). In a system bound by per-packet CPU work and software dispatch, *replicating* the state and the computation of a stateful flow across cores increases throughput *linearly* with cores, so long as we preserve the total number of packets traversing the system.

To meet the requirements for high performance in SCR, we design a *packet history sequencer* (§3.2), an entity which sees every packet and sprays packets across cores in a round-robin fashion, while piggybacking the relevant information from packets missed by a core on the next packet sent to that core. The sequencer must maintain a small bounded history of packet headers relevant to the packet-processing program. A high-speed packet-processing pipeline, running either on a programmable NIC or a top-of-the-rack switch, may serve as a sequencer. We present sequencer designs for two hardware platforms (§3.3), a Tofino switch, and a Verilog RTL module we synthesized into the NetFPGA-PLUS reference pipeline.

We evaluated the scaling efficacy of SCR using a suite of realistic programs and traffic (§4). SCR is the only technique we are aware of that monotonically scales the total processing throughput with additional cores regardless of the skewness in the arriving flow size distribution. However, no technique can continue scaling indefinitely. In §3.1 and §4, we demonstrate the limits of SCR scaling, along with the significant performance benefits to be enjoyed before hitting these limits. Additionally, we show the resource usage for our sequencer's RTL design, which meets timing at 340 MHz. We believe this design is simple and cheap enough to be added as an on-chip accelerator to a future NIC.

All our software is publicly available [31]. This work does not raise any ethical concerns.

2 Background and Motivation

2.1 High Speed Packet Processing

This paper considers packet-processing programs that must work at heavy network loads with quick turnarounds for packets. We are specifically interested in applications implementing a "hairpin" traffic flow: receiving a packet, processing it as quickly as possible, and transmitting the packet right out, at the highest possible rate. Such programs exhibit compute and working set sizes that are smaller in comparison to full-fledged applications (running in user space) or transport protocols (TCP stacks) running at endpoints.

Examples of the kinds of applications we consider include (i) middlebox workloads (network functions), such as firewalls, connection trackers, and intrusion detection/prevention systems; and (ii) high-volume compute-light applications such as key-value stores, telemetry systems, and stream-based logging systems, which process many requests with a small amount of computation per request [51]. A key characteristic of such applications is their need for high packet-processing rate (which is more important than byte-processing rate) and the fact that their performance is primarily bottlenecked by CPU usage [44, 69, 73].

The performance of such applications is mission-critical in many production systems. Even small performance improvements matter in Internet services with large server fleets and heavy traffic. As a specific example, Meta's Katran layer-4 load balancer [8] and CloudFlare's DDoS protection solution [44] process every packet sent to those respective services, and must withstand not only the high rate of request traffic destined to those services but also large denial-of-service attacks. More generally, the academic community has undertaken significant efforts for performance optimization of network functions, including optimization of the software frameworks [46], designing language-based high-performance isolation [61], and developing custom hardware offload solutions [64].

In this paper, we consider applications developed within high-speed packet processing software frameworks. Given the slowdown of Moore's law and the end of Dennard scaling, the software packet-processing performance of single CPU cores has saturated. Even expert developers must work meticulously hard to improve per-core throughput by small margins (like 10%) [37, 50, 52, 67]. The community has pursued various efforts to improve performance, such as re-architecting the software stack to make efficiency gains [21, 56, 69], introducing stateless hardware offloads working in conjunction with the software stack [19, 29], full-stack hardware offloads [30, 34], and kernel extensions [2]. This paper considers software frameworks that modify the device driver to enable programmable and custom functionality to be incorporated by developers at high performance with minimal intervention from the existing kernel software stack [50].

Specifically, we study performance and evaluate our tech-

niques in the context of kernel extensions implemented using the eXpress Data Path (XDP/eBPF [50]) within the Linux kernel. In §3, we will discuss how our observations and principles apply more generally to other high-speed software packet-processing frameworks, including those written with user-space libraries like DPDK [21].

2.2 Parallelizing Stateful Packet Processing

This paper considers the problem of parallelizing high-speed packet processing programs across multiple cores. The key challenge is handling *state*: memory that must be updated in a sequential order upon processing each packet to produce a correct result. Consider the example of the connection tracker [40], a program which identifies the TCP connection state (*e.g.,* SYN sent, SYN/ACK sent, *etc.*) using packets observed from both directions of a TCP connection. Each packet in the connection may modify the internal connection state maintained by the program. There are two main techniques used to parallelize such programs across cores.

Shared state parallelism. One could conceive a parallel implementation that (arbitrarily) splits packets across multiple cores, with explicit synchronization or retry logic guarding access to the shared memory, *i.e.,* the TCP connection state, to ensure a correct result.

Shared-state parallelism works well when the contention to shared memory is low. Specifically, shared-memory scaling could work well when (i) packets of a single flow arrive slowly enough, *e.g.,* if there are a large number of connections with a roughly-equal packet arrival rate, or (ii) when there are efficient implementations available for synchronization or atomic updates in software [47] or hardware [18, 25]. However, neither of these conditions are generally applicable. Many flow size distributions encountered in practical networks are highly skewed [36, 75] or exhibit highly bursty behavior [70], resulting in significant memory contention if packets from the heavier flows are spread across cores. Further, the state update operation in many programs, including the TCP connection tracker, are too complex to be implemented directly on atomic hardware, since the latter only supports individual arithmetic and logic operations (like fetch-add-write). Our evaluation results (§4) show that the performance of shared-state multicore processing plummets with more cores under realistic flow size distributions.

Sharded (shared-nothing) parallelism. Today, the predominant technique to scale stateful packet processing across multiple cores is to process packets that update the same memory at the same core, sharding the overall state of the program across cores. Sharding is achieved through techniques like Receive Side Scaling (RSS [4]), available on modern NICs, to direct packets from the same flow to the same core, and using shared-nothing data structures on each core.

However, sharding suffers from a few disadvantages. First, it is not always possible to avoid coordination through sharding. There may be parts of the program state that are shared across all packets, such as a list of free external ports in a Network Address Translation (NAT) application. On the practical side, the RSS implementations on today's NICs partition packets across cores using a limited number of combinations of packet header fields. For example, a NIC may be configured to steer packets with a fixed combination of source and destination IP addresses (but not a fixed source IP address) to a fixed CPU core. Further, the granularity at which the application wants to shard its state—for example, a key-value cache may seek to shard state by the key requested in the payload—could be infeasible to implement with the packet header sets supported by the RSS capabilities of the NIC [63].

Second, sharding state may create load imbalance across cores if some flows are heavier or more bursty than others, creating hotspots on single CPU cores. Skewed flow size distributions [36], bursty flow transmission patterns [70], and denial of service attacks [43] create conditions ripe for such imbalance. The research community has investigated solutions to balance the packet processing load by migrating flow shards across CPU cores [35, 63]. However, the efficacy of re-balancing is limited by the granularity at which flows can be migrated across cores. As we show in our evaluation (§4), the throughput of the heaviest and most bursty flows is still limited by a single CPU core, which in turn limits the total achieved throughput. Another alternative is to evenly spray incoming packets across cores [41, 71], assuming that only a small number of packets in each flow need to update the flow's state. If a core receives a packet that must update the flow state, the packet is redirected to a designated core that performs all writes to the state for that flow. However, the assumption that state is mostly read-only is not universal, *e.g.,* a TCP connection tracker may update state potentially on every packet. Further, packet reordering at the designated core can lead to incorrect results [35].

2.3 Goals

Given the drawbacks of existing approaches for multi-core scaling discussed above (§2.2), we seek a scaling technique that achieves the following goals:

1. *Generic stateful programming.* The technique must produce correct results for general stateful updates, eschewing solutions that only work for "simple" updates (*i.e.,* fitting hardware atomics) or only update state for a small number of packets per flow.
2. *Skew independence.* The scaling technique should improve performance independent of the incoming flow size distribution or how the flows access the state in the program.
3. *Monotonic performance gain.* Performance should improve, not degrade or collapse, with additional cores.

3 State-Compute Replication (SCR)

In §3.1, we present scaling principles for multi-core stateful packet processing, to meet the goals in §2.3. In §3.2 through §3.4, we show how to operationalize these principles.

3.1 Scaling Principles

To simplify the discussion, suppose the packet-processing program is *deterministic*, *i.e.,* in every execution, it produces the same output state and packet given a fixed input state and packet (we relax this assumption in §3.4).

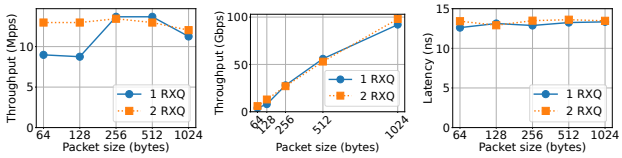
Principle #1 (Replication for correctness). Sending every packet reliably to every core, and *replicating* the state and computation on every core, produces the correct output state and packet on every core *with no explicit cross-core synchronization,* regardless of how the state is accessed by packets.

This principle asks us to treat each core as one replica of a replicated state machine running the deterministic packet-processing program. Each core processes packets in the same order, without missing any packets. With each incoming packet, each core updates a private copy of its state, which is equal to the private copy on every other core. There is no need to synchronize explicitly. Further, replication provides the benefit that the workload across cores is even regardless of how the state is accessed by packets, *i.e.,* skew-independent.

One way to apply this principle naively is to broadcast every packet received *externally* on the machine to every core: with k cores, for each external packet, the system will process k *internal* packets, due to k-fold packet duplication. However, artificially increasing the number of packets processed by the system will significantly hurt performance. In CPU-bound packet processing, smaller packets typically require the same computation that larger packets do. That is, the total amount of work performed by the system is proportional to the packets-per-second offered, rather than the bits-per-second [50, 69].

So how should one use replication for multi-core scaling? Understanding the dominant components of the per-packet CPU work in high-speed packet-processing frameworks offers insight. There are two parts to the CPU processing for each packet after the packet reaches the core where it will be ultimately processed: (i) *dispatch*, the CPU/software labor of presenting the packet to the user-developed packet-processing program, and signaling the packet(s) emitted by the program for transmission by the NIC; and (ii) the *program computation* running within the user-developed program itself. Dispatch often dominates the per-packet CPU work [50].

While these observations are known in the context of high-speed packet processing, we also benchmarked a simple application on our own test machine to validate them. Consider Figure 2, where we show the throughput (packets/second (a), bits/second (b)), and latency (c) of a simple packet forwarder written in the XDP framework running on a single CPU core. Our testbed setup is described in much more detail later (§4),



(a) Packets/second (b) Bits/second (c) Latency (ns)

Figure 2: The nature of CPU work in high-speed packet processing: Consider the throughput of a simple packet forwarding application (packets/second (a), bits/second (b)) running on a single CPU core clocked at 3.6 GHz, as the size of the incoming packets varies. The average latency to execute the XDP program is also shown in nanoseconds (c). CPU usage is tied to the number of packets (not bits) processed per second. Further, significant time elapses in *dispatch:* CPU work to present the input packet to and retrieve the output packet from the program computation.

but we briefly note here that our device-under-test is an Intel Ice Lake CPU configured to run at a fixed frequency of 3.6 GHz and attached to a 100 Gbit/s NIC. At each packet size below 1024 bytes, the CPU core is fully utilized (at 1024 bytes the bottleneck is the NIC bandwidth). The achieved packets/second is stable across all packet sizes which are CPU bound (see the *2 RXQ* curve). With a processing latency of roughly 14 nanoseconds at all packet sizes (measured only for the XDP forwarding program), back-to-back packet processing should "ideally" process $(14 * 10^{-9})^{-1} \approx 71$ million packets/second. However, the achieved best-case throughput ($\approx$ 14 million packets/second) is much smaller—implying that significant CPU work is expended in presenting the input packets to and extracting the output packets from the forwarder and setting up the NIC to transmit and receive those packets. This is not merely a feature of the framework we used (XDP); the DPDK framework has similar dispatch characteristics [50].

Our key insight is that it is possible to replicate program computation without replicating dispatch, enabling multi-core performance scaling. This leads us to the next principle:

Principle #2 (State-Compute Replication). Piggybacking a *bounded recent packet history* on each packet sent to a core allows us to use replication (#1) while equalizing the external and internal packets-per-second CPU work in the system.

Principle #2 states that replication (principle #1) is possible without increasing the total internal packet rate or per-packet CPU work done by the system. Suppose it is possible to spray the incoming packets across cores in a round-robin fashion. If there are k cores, each core receives every k^{th} packet. Then:

1. It is unnecessary for each core to have the most up-to-the-packet private state at all times. For correctness, it is sufficient if a core has a state that is "fresh enough" to make a decision on the current packet that it is processing.
2. With each new packet, suppose the core that receives it also sees (as metadata on that packet) all the $k-1$ packets from the last time it processed a packet, *i.e., a recent packet history*. The core can simply "catch up" on the computations required to obtain the most up-to-the-packet value

for its private state.

3. If packets are sprayed round-robin across cores, the number of historic packets needed to ensure that the most updated state is available to process the current packet is equal to the number of cores. Further, just those packet bits required to update the shared state are necessary from each historic packet, allowing us to pack multiple packets' worth of history into a single packet received at a core.

As a simple model, suppose a system has k cores, and each core can dispatch a single packet in d cycles and runs a packet-processing program that computes over a single packet in c cycles. For each piggybacked packet, the total processing time is $d + (k \times c)$. When dispatch time dominates compute time ($d \gg c$), with k cores, the total rate at which externally-arriving packets can be processed is $k \times \frac{1}{d+(k\times c)} \approx k/d$. Hence, it is possible to scale the packet-processing rate linearly with the number of cores k. In Appendix A, we show that a model like this indeed accurately predicts the empirical throughput achieved with a given number of cores.

Intuitively, doing some extra "lightweight" program computation per packet enables scaling the "heavyweight" dispatch computation with more cores, while maintaining correctness.

Principle #3 (Scaling limits). Principle #2 provides a linear scale-up in the packets-per-second throughput with more cores, so long as dispatch dominates the per-packet work.

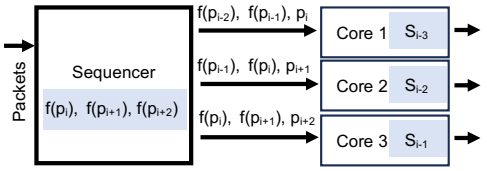
The scaling benefits of principle #2 taper off beyond a point. Dispatch can be overtaken as the primary contributor to per-packet CPU work, for example, when (i) the compute time $k \times c$ for each piggybacked packet becomes sizable; (ii) the per-packet compute time c itself increases due to overheads in the system, *e.g.,* larger memory access time when a core's copy of the state spills into a larger memory; or (iii) other components such as the NIC or PCIe become the bottleneck rather than the CPU. When this happens, the approximation in our simple linear model ($d \gg c$) no longer holds, and the system's packet rate no longer scales linearly with cores.

3.2 Operationalizing SCR

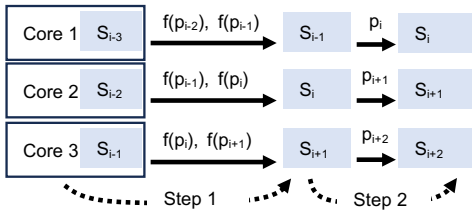
Operationalizing the scaling principles discussed above (§3.1) conceptually requires two pieces.

A reliable packet history sequencer (§3.3). We require an additional entity in the system, which we call a *sequencer,* to (i) steer packets across cores in round-robin fashion, (ii) maintain the most recent packet history across all packets arriving at the machine, and (iii) piggyback the history on each packet sent to the cores. After the packet is processed by a CPU core, its piggybacked history can be stripped off on the return path either at the core itself or at the sequencer. The size of the packet history depends only on the number of cores and metadata size (§3.1) and is independent of the number of active flows.

The NIC hardware or the top-of-the-rack switch are natural



(a) The sequencer stores relevant fields from the packet history, and piggybacks the history on packets sprayed round-robin across cores.



(b) Each core fast-forwards its private state and then handles its packet.

Figure 3: An example illustrating the scaling principles. p_i is the i^{th} packet received by the sequencer, $f(p_j)$ are relevant fields from p_j, and S_i is the state after processing packets $p_1, \ldots, p_i$ in order.

points to introduce the sequencer functionality, since they observe all the packets flowing into and out of the machine. Today's existing fixed-function NICs do not implement the functionality necessary to construct and piggyback a reliable packet history. However, we have identified two possible instantiations that could, in the near future, achieve this: (i) emerging NICs, *e.g.,* with programmable pipelines [1, 3, 27], implementing the full functionality of the reliable sequencer; or (ii) a combination of a NIC implementing round-robin packet steering [4, 7] and a programmable top-of-the-rack switch pipeline [17, 23, 38] for maintaining and piggybacking the packet history. We believe that either of these instantiations may be realistic and applicable given the context: for example, high-speed programmable NICs are already common in some large production systems [45], as are programmable switch pipelines [60]. We will show two possible hardware designs in §3.3. Hereafter, for brevity, we refer to both of these designs as simply sequencers.

An SCR-aware packet-processing program. The packet-processing program must be developed to replicate the program state and keep private copies per core. Further, the program must process the packet history first before computing over the current packet. In Appendix C, we show an example that demonstrates how to transform a single-threaded program to its SCR-aware variant. We believe that these program transformations can be automated in the future.

An example showing scaling principles in action. Consider Figure 3, where a sequencer and three cores are used to run a packet-processing program. As shown in Figure 3a, the sequencer sprays packets (*i.e.,* $p_i, p_{i+1}, \ldots$) in a round-robin fashion across $k = 3$ cores (*i.e.,* $core_1, core_2, core_3$). Further, the sequencer stores the recent packet history consisting of the packet fields from the last k packets which are relevant to evolving the flow state. We denote the relevant part of a

packet p_i by $f(p_i)$. For example, in a TCP connection tracking program, this includes the TCP 4-tuple, the TCP flags, and sequence and ACK numbers. Note that this packet history is updated only by the sequencer and is never written to by the cores. In the example in Figure 3a, the packet history supplied to $core_1$ processing packet p_i is $f(p_{i-2}), f(p_{i-1})$. As shown in Figure 3b, each core updates its local private state, first fast-forwarding the state by running the program through the packet history $f(p_{i-2}), f(p_{i-1})$, and then processing the packet p_i sprayed to it.

If the packet-processing program is deterministic (§3.1), an SCR-aware program is guaranteed to produce the correct output state and packet if every CPU core is guaranteed to (losslessly) receive the packets sent to it by the sequencer. We show how to handle non-determinism and packet loss in §3.4.

3.3 Packet History Sequencer

The primary goal of the sequencer is to maintain and propagate recent packet history to CPU cores to help replicate the computation with the correct program state (§3.2). We assume the NIC is already capable of spraying packets across CPU cores [4, 7], and hence do not discuss that functionality further. We describe the rest of the sequencer's functions in terms of the following: (i) designing a packet format that modifies existing packets to piggyback history from the sequencer to the CPU cores; (ii) designing a hardware data structure that maintains a recent bounded packet history at the sequencer, and enables reading out the history into metadata on the packet. The packet fields that are maintained in the sequencer history depend on the specific fields used by the packet-processing application. The number of historic packets that must be tracked depends on the degree of parallelism that is sought, *e.g.,* the number of available CPU cores over which scaling is implemented.

We have implemented sequencing hardware data structures on two platforms, the Tofino programmable switch pipeline [23] and a Verilog module that we integrated into the NetFPGA-PLUS project [12].

3.3.1 Packet format

The key question answered in this subsection is: given a packet, what is the best place to put the packet history on it? While this may initially appear to be just an engineering detail, the packet format has important implications to the design of hardware data structures on the sequencer and the SCR-aware program.

As shown in Figure 4a, we choose to place the packet history close to the beginning of the packet, before the entirety of the original packet. Relative to placing the packet history between headers of the original packet, this placement simplifies the hardware logic that writes the history into the packet, as the write must always occur at a fixed address (0) in the packet buffer. Further, for reasons explained in §3.3.2, we include a pointer to the metadata of the packet that arrived the earliest among the ones in the piggybacked history. The earliest packet does not always correspond to the first piece of metadata when reading the bytes of the packet in order.

Keeping all the bytes of the original packet together in one place also simplifies developing an SCR-aware packet-processing program. The packet parsing logic of the original program can remain unmodified if the program starts parsing from the location in the modified packet buffer which contains all the bytes of the original packet in order.

Finally, we also prefix an additional Ethernet header to the packet in instantiations of the sequencer which run outside of the NIC, *i.e.,* a top-of-the-rack switch. Adding this header helps the NIC process the packet correctly: without it, the packet appears to have an ill-formatted Ethernet MAC header at the NIC. Our setup also uses this Ethernet header to force RSS on the NIC [4] to spray packets across CPU cores (our testbed NIC (§4.1) supports hashing on L2 headers). This additional Ethernet header is not needed in a sequencer instantiation running on the NIC.

3.3.2 Hardware data structures for packet history

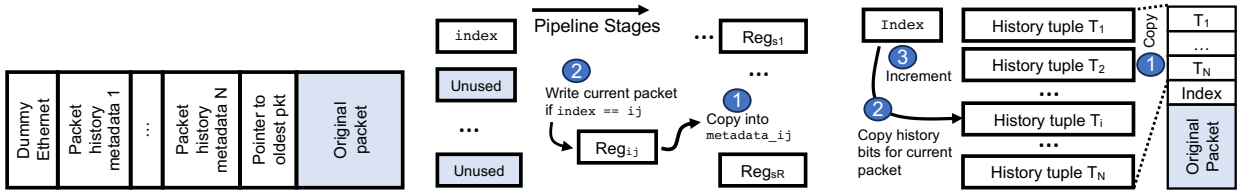
We show how to design data structures to maintain and update a recent packet history on two high-speed platforms, a Tofino programmable switch pipeline [23] and a Verilog module integrated into the NetFPGA-PLUS platform [12]. These designs are specific to the platform where they are implemented, and hence we describe them independently.

A key unifying principle between the two designs is that although the items in the maintained packet history change after each packet, we only update a small part of the data structure for each packet. Conceptually, a ring buffer data structure is appropriate to maintain such histories. Hence, in both designs, we use an *index pointer* to refer to the current data item that must be updated, which corresponds to the head pointer of the abstract ring buffer where data is written.

Tofino. We use Tofino registers [26], which are stateful memories to hold data on the switch, to record the bits of each historic packet relevant to the computation in the packet-processing program. We use the Tofino parser to extract these bits, which restricts our design only to support historic fields up to 4 Kilobits deep in the packet [38].

Suppose the pipeline has s match-action table stages, R registers per stage, and b bits per register. For simplicity in this description, we assume there is exactly one packet field of size b bits used in the computation in the packet-processing program. Our data structure can maintain a maximum of $(s-1) \times R \times b$ bits of recent packet history, *i.e.,* history for $(s-1) \times R$ packets, as shown in Figure 4b. We have successfully compiled the design to the Tofino ASIC.

First, we use a single register in the first stage to store the index pointer. The pointer refers to the specific register in the



(a) Packet format (b) Tofino sequencer (c) RTL sequencer

Figure 4: Hardware data structures. (a) Packets modified to propagate history from the sequencer to CPU cores. The sequencer prefixes the packet history to the original packet, which allows for a simpler implementation in hardware (§3.3) and simpler transformations to make a packet-processing program SCR-aware (Appendix C). In instantiations where the sequencer is partly implemented on a top-of-the-rack switch (§3.2), we further prefix a dummy Ethernet header to ensure that the NIC can process the packet correctly. (b) The data structure used to maintain and propagate packet history on the Tofino programmable switch pipeline (§3.3.2). Inset shows the specific actions performed on each Tofino register. (c) The data structure used to maintain and propagate packet history in our Verilog module on NetFPGA-PLUS (§3.3.2).

subsequent stages that must be updated with a header field from the current packet. The index pointer is incremented by 1 for each packet, and wraps back to 0 when it reaches the maximum number of packets required in the history. The pointer is also carried on a metadata field on the packet through the remaining pipeline stages.

Next, register ALUs in subsequent stages are programmed to read out the values stored in them into pre-designated metadata fields on the packet. If the index pointer points to this register, an additional action occurs: rewrite the stored contents of the register by the pre-designated history fields from the current packet.

Finally, all the metadata fields, consisting of the packet history fields and the index pointer, are deparsed and serialized into the packet in the format shown in Figure 4a. We also add an additional Ethernet header to ensure that the server NIC can receive the packets correctly (§3.3.1).

Recent work explored the design of ring buffers to store packet histories in the context of debugging [53], reading out the histories from the control plane when a debugging action is triggered. A key difference in our design is that reading out histories into the packet is a data plane operation, occurring on every packet.

NetFPGA. To show the possibility of developing high-speed fixed-function hardware for sequencing, we also present a sequencer design developed in Verilog in Figure 4c.

Suppose we wish to maintain a history of N packets, each packet contributing b bits of information. A simple design, for small values of N and b (we used $N = 16$ and $b = 112$), uses a memory which has N rows, each containing a tuple of b bits. We also maintain a register containing the index pointer (p bits), initialized to zero. At the beginning, the memory is initialized with all zeroes. When a packet arrives, it is parsed to extract the bits relevant to the packet history. Then the entire memory is read and put in front of the packet (moving the packet contents by a fixed size known beforehand, $N \times b + p$ bits). The information relevant to the packet history from the current packet is put into the memory row pointed to by the index pointer, and the index pointer is incremented (modulo the memory size). We have integrated this design into the NetFPGA-PLUS platform.

3.4 Discussion

In this section, we discuss how to generalize SCR to handle non-determinism, packet loss, and multiple packet-processing programs.

Handling Packet Loss. Packets can be lost either prior to the sequencer, after the sequencer but prior to processing at a CPU core, or after processing at a core. Among these, we only care about the second kind of packet loss, since this is the only one that is problematic specifically for SCR, introducing the possibility that flow states on the CPU cores might become inconsistent with each other.

We expect that SCR will be deployed in scenarios where the event of packet loss between the sequencer and CPU cores is rare. First, we do not anticipate any packet loss in an instantiation where the sequencer is running entirely on a NIC, since the host interconnect between the NIC and CPU cores uses credit-based flow control and is lossless by design [32, 59]. In an instantiation where the sequencer is running on a top-of-the-rack switch, it is possible to run link-level flow control mechanisms like PFC [6] (as some large production networks do [48]) to prevent packet loss between the switch and server cores. We discuss below how SCR can handle rare packet drop and corruption events while maintaining consistency among the states on CPU cores.

How should a CPU core that has lost a packet arriving from the sequencer synchronize itself to the correct flow state? There are two design options: the core can either explicitly read the full flow state from a more up-to-date core, or it can read the packet history from either the sequencer or a log written by a more up-to-date core, and then use the history to catch up its private state (akin to Figure 3). Since we operate in a regime where packet losses are rare, but the full set of flow states is large, we prefer to synchronize the packet history rather than the state. Further, to simplify the overall design, we avoid explicit coordination between the cores and the sequencer, synchronizing the history among the cores only.

Our objective is *atomicity:* any packet is either processed by all the cores or none of the cores. If a packet is sent by the sequencer to *any* core (in original or as part of the packet history), it should be processed in the correct order by *all* the cores. To achieve this, we (i) have the sequencer attach an incrementing sequence number to each packet released by it; (ii) use a per-core, lockless, single-writer multiple-reader log, into which each core writes the history contained in each packet it receives (including the relevant data for the original packet); and (iii) introduce an algorithm to catch up the flow state on each core upon detection of loss.

The algorithm proceeds as follows (more information is available in Algorithm 1 in Appendix B). Each CPU core c maintains a per-core log with one entry for each sequence number i. In a system with N cores, the history metadata of the packet with sequence i (say $history[i]$) will appear in packets with sequence numbers i through $i+N-1$; conversely, a packet with sequence number j contains $history[minseq], \cdots, history[j]$ where $minseq \triangleq max(1, j-N+1)$.

For core c and sequence number i, $log[c][i]$ takes on one of three possible values:

$$\begin{cases} history[i] & \text{if history for sequence } i \text{ was received at } c \\ NOT_INIT & \text{if the highest sequence received at } c \text{ is } j < i \\ LOST & \text{if } c \text{ has received sequence } j > i, \\ & \text{but sequence } i \text{ was not received at } c \end{cases}$$

At the beginning, for all cores c and sequence numbers i, $log[c][i]$ is set to NOT_INIT, to denote that each log entry is uninitialized at every core. When a (fixed) core c receives a packet with sequence number j, it first detects packet loss by comparing the max sequence number it has seen so far (say $max[c]$) with the earliest sequence number in the new packet it receives ($minseq$), assuming no reordering between the sequencer and the core. Then, c processes every sequence number k such that $max[c] < k \leq j$, in order of increasing k, as follows:

1. if $k < minseq$, *i.e.,* sequence k was lost between the sequencer and core c, the core updates $log[c][k] \leftarrow LOST$. For such packets, core c will read from the logs of other cores $c' \neq c$ in a loop, until c discovers either that (i) $history[k]$ is written in $log[c'][k]$, in which case c catches up its private state by reading this history; or (ii) $log[c'][k] = LOST$ on all cores $c' \neq c$, concluding that sequence k was never originally received on any core, and does not need to be recovered for atomicity;
2. if $minseq \leq k \leq j$, *i.e.,* sequence k is successfully received at core c (as part of the current packet), core c updates $log[c][k] \leftarrow history[k]$ available in the packet, and then proceeds with regular processing as in §3.2.

In Appendix B, we formally prove that, under some mild assumptions, this algorithm always terminates in a state that is eventually consistent across all CPU cores. Despite cores possibly waiting on one another, there will be no deadlocks. While the treatment above uses an infinitely large log, practically, our log implementation is a circular buffer with a fixed size (it is unnecessary to garbage-collect the log). The buffer must be sized large enough to recover from packet losses and transient speed mismatches across CPU cores, both of which are expected to be small in practical deployments.

Handling programs that depend on timestamps. The use of timestamps measured locally at each CPU core (*e.g.,* to implement a token bucket rate limiter) may result in the results of computations at different CPU cores diverging from each other. To handle this, we avoid measuring time locally at each CPU core, and instead have the sequencer attach a timestamp for each packet to the packet history. Modern NICs and programmable switches support high-resolution hardware timestamping over packets [13, 26].

Handling programs involving randomization. For SCR to produce a consistent state across cores, it is necessary that the state computations on all CPU cores agree on the result even if the computations involve random numbers. None of our current benchmark programs involve randomization. For those programs that do, we recommend to fix the seed of the pseudorandom number generator to the same value across different CPU cores.

Handling chained packet-processing programs. SCR can handle multiple packet-processing programs run sequentially (for example, for service function chaining [49]) by piggybacking the union of the historical packet fields for all the programs on each packet from the sequencer to the core. In addition to the program changes typically needed for SCR parallelism (Appendix C), the programs must also be rewritten to handle packets that include additional fields of history for the co-resident programs. We believe this can be accomplished by the design of a suitable automatic compiler. We leave the design of such compilers to future work.

4 Evaluation

We seek to answer two main questions through the experiment setup described in §4.1.
(1) Does state-compute replication provide better multi-core scaling than existing techniques (§4.2)?
(2) How practical is sequencer hardware (§4.3)?

4.1 Experiment Setup

Machines and configurations. Our experiment setup consists of two server machines connected back-to-back over a 100 Gbit/s Nvidia/Mellanox ConnectX-5 NIC on each machine. Our servers run Intel Ice Lake processors (Xeon Gold 6334) with 16 physical cores (32 hyperthreads) and 256 GB DDR4 physical memory spread over two NUMA nodes. The system bus is PCIe 4.0 16x. We run Ubuntu 22 with Linux kernel v6.5.

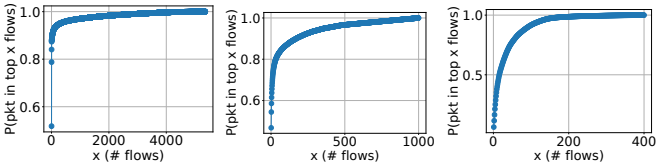
Program	State		Metadata size	RSS hash	Packet traces	Atomic HW	Lines of code
	Key	Value	(bytes/packet)	fields	evaluated	vs. Locks	(shard/RSS)
DDoS mitigator	source IP	count	4	src & dst IP	CAIDA, Univ DC	Atomic HW	168
Heavy hitter monitor	5-tuple	flow size	18	5-tuple	CAIDA, Univ DC	Atomic HW	141
TCP connection state tracking	5-tuple	TCP state, timestamp, seq #	30	5-tuple	Hyperscalar DC	Locks	1029
Token bucket policer	5-tuple	last packet timestamp, # tokens	18	5-tuple	CAIDA, UnivDC	Locks	169
Port-knocking firewall	source IP	knocking state (*e.g.,* `OPEN`)	8	src & dst IP	CAIDA, UnivDC	Locks	123

Table 1: The packet-processing programs we evaluated.

One machine serves as a packet replayer/generator, running a DPDK burst-replay program which can transmit packets from a traffic trace. We have tested that the traffic generator can replay large traces (1 million packets) at speeds of $\sim$ 120 million packets/second (Mpps), for sufficiently small packets (so that the NIC bandwidth is not saturated first). The traffic generator can be directed to transmit packets at a fixed transmission (TX) rate and measure the corresponding received (RX) packet rate. Our second server is the Device Under Test (DUT), which runs on identical hardware and operating system as the first server. We implement standard configurations to benchmark high-speed packet processing [50]: hyperthreading is disabled; the processor C-states, DVFS, and TurboBoost are disabled; dynamic IRQ balancing is disabled; and the clock frequency is set to a fixed 3.6 GHz. We enable PCIe descriptor compression and use 256 PCIe descriptors. Receive-side scaling (RSS [4]) is configured according to the baselines/programs, see Table 1. We use a single receive queue (RXQ) per core unless specified otherwise. On our setup, we have checked that the per-core packet-forwarding throughput is comparable to prior work benchmarking the XDP framework [50]. However, the absolute numbers are lower than the multi-core throughput reported in recent literature using DPDK. We believe this may be due to the differences in the packet-processing framework (XDP vs. DPDK).

The definition of throughput. We use the standard *maximum loss-free forwarding rate* (MLFFR [5]) methodology to benchmark packet-processing throughput. Our threshold for packet loss is in fact larger than zero (we count $< 4\%$ loss as "loss-free"), since, at high speeds we have observed that the software typically always incurs a small amount of bursty packet loss. We use binary search to expedite the search for the MLFFR, stopping the search when the bounds of the search interval are separated by less than 0.4 Mpps. Experimentally, we observe that MLFFR is a stable throughput metric: we get highly repeatable results across multiple runs. We only report throughput from a single run of the MLFFR binary search.

Traces. We are interested in understanding whether SCR provides better multi-core scaling than existing techniques on realistic traffic workloads. We have set up and used three traces for throughput comparison: a university data center trace [36], a wide-area Internet backbone trace from CAIDA [11], and a synthetic trace with flows whose sizes and inter-arrivals were sampled from a hyperscalar's data center flow characteristics [33]. These traces are highly dynamic, with flow states being created and destroyed throughout—an aspect that we believe is crucial to handle in real deployment environments (*i.e.,* the programs are not simply processing a stable set of active flows). Further, we ensure that all TCP flows that begin in the trace also end, by setting TCP SYN and FIN flags for the first and last packets (respectively) of each flow in the trace. This allows the trace to be replayed multiple times with the correct program semantics. The flow size distributions of the traces are shown in Figure 5.



(a) University DC (b) Internet backbone (c) Hyperscalar DC

Figure 5: Flow size distributions of the packet traces we used. We used real packet traces captured at (a) university data center [36] and (b) wide-area Internet backbone by CAIDA [11]. We also synthesized (c) a packet trace with real TCP flows whose sizes are drawn from Microsoft's data center flow size distribution [33].

The eBPF framework limits our implementations in terms of the number of concurrent flows that our stateful data structures can include. This is not a limitation of the techniques, but an artifact of the current packet-processing framework we use (eBPF/XDP). To account for this limitation, specifically for the CAIDA trace, we have sampled flows from the trace's empirical flow size distribution to faithfully reflect the underlying distribution, without over-running the limit on the number of concurrent flows that any of our baseline programs may hold across the lifetime of the experiment.

Baselines. We compare state-compute replication against (i) state sharing, an approach that uses either hardware atomic instructions (when the stateful update is simple enough) or eBPF spinlocks [10] (when it is not) to share state across CPU cores; (ii) state sharding using classic RSS; and (iii) sharding using RSS++ [35, 63], the state-of-the-art flow sharding technique to balance CPU load. RSS++ solves an optimization problem that takes as input the incoming load imposed by flow shards, and migrates shards to minimize a linear combination of load imbalance across CPU cores and the number of cross-core shard transfers needed. Both SCR and state sharing spray packets evenly across CPU cores. The packets sent to

each core for the sharding techniques depends on the configuration of RSS, which varies across the programs we evaluated (see below and Table 1). Running RSS++ over eBPF/XDP requires patching the NIC driver [9] to expose the RX hash on packets to XDP programs. Unless specified otherwise, we run SCR without loss recovery (§3.4) as we believe this is the most representative scenario in which SCR will be deployed. We evaluate loss recovery separately (§4.2).

Programs. We tested five packet-processing programs developed in eBPF/XDP, including (i) a heavy hitter monitor, (ii) DDoS mitigator, (iii) TCP connection state tracker, (iv) port-knocking firewall, and (v) a token bucket policer. Table 1 summarizes these programs. Each program maintains state across packets in the form of a key-value dictionary, whose size and contents are listed in the table. We developed a cuckoo hash table to implement the functionality of this dictionary with a single BPF helper call [15]. The packet fields in the key determine how RSS must be configured: packets having the same key fields must be sent to the same CPU core. However, today's NICs do not allow RSS to steer packets on arbitrary sets of packet fields [63]. We pre-process the trace to ensure that RSS hashing indeed shards the flow state correctly. For example, on the NIC in our testbed, the source (`srcip`) and destination (`dstip`) IP addresses may be used together, but not separately, as the RSS key to hash a packet to a core. For a program that maintains flow state at the granularity of `dstip`, an RSS key (`srcip, dstip`) could steer two packets with the same `dstip` but different `srcip` to different CPU cores, violating sharding at the granularity of `dstip`. To prevent this, and to evaluate our sharding baselines fairly, we pre-process our traces (*e.g.,* modifying packets such that every `srcip, dstip` combination in the trace hashes to a core that only depends on `dstip`) to ensure that RSS hashing indeed shards the flow state correctly. For the connection tracker, since both directions of the connection must go to the same CPU core, we use the keyed hash function prescribed by symmetric RSS [74].

4.2 Multi-Core Throughput Scaling

In this section, we compare the MLFFR throughput (§4.1) of several packet-processing programs (Table 1) scaled across multiple cores using four techniques: SCR (§3), state sharing with packets sprayed evenly across all cores, sharding using RSS, and sharing using RSS++ (§2). Since the TCP connection tracking program requires packets from the two directions of the connection to be aligned, we evaluated it on a synthetic but realistic hyperscalar data center trace (§4.1). For the rest of the programs, we report results from real university data center and Internet backbone traces.

We have ensured that these experiments reflect a fair comparison of CPU packet-processing efficacy. First, we truncated the packets in the traces to a size smaller than the full MTU, to stress CPU performance with a high packets/second (Mpps) workload (§3.1). Further, we fix the packet sizes used across all baselines for a given program. We used a fixed packet size of 256 bytes for the connection tracker and 192 bytes for the others. The packet size limits the number of items of history metadata that can be piggybacked on each packet. Since the metadata size changes by the program (Table 1), the maximum number of cores we can support for a fixed packet size also varies by program (we support 7 cores for the token bucket, heavy hitter detector, and connection tracker, and 14 for the DDoS mitigation and port-knocking firewall).

Throughput results. Figure 6 and Figure 7 show the throughput as we increase the number of packet-processing cores. SCR is the only multi-core scaling technique that can monotonically scale the throughput of all the stateful packet-processing programs we evaluated across multiple cores, regardless of the flow size distribution (§2.3). The throughput for SCR increases linearly across cores in all of the configurations we tested. Somewhat surprisingly, SCR provides even better absolute performance than hardware atomic instructions in the case of the heavy hitter and DDoS mitigation programs. However, the performance of lock-based sharing falls off catastrophically with 3 or more cores.

The throughput of sharding using RSS depends on how the RSS hash function steers flows to cores. On our experimental setup, RSS can split flows evenly across CPU cores. However, RSS neither splits individual heavy flows, nor does it intelligently distribute heavy flows across CPU cores to balance the load. When the packet rates of individual heavy flows in the workload are within the processing capabilities of a single CPU core, RSS++ [35] can improve upon RSS by spreading the heavy flows across CPU cores. By measuring and adapting to the workload on each CPU core, RSS++ can scale throughput effectively with additional CPU cores, as has been shown in prior work [35, 63]. However, when the workload includes heavy flows whose (individual) packet rates exceed the processing capability of a single CPU core, and the number of such flows is smaller than the number of available CPU cores, simply spreading out the heavy flows across cores is insufficient to improve throughput with additional cores. This is the situation with the real packet workloads we tested (§4.1). Such situations also arise under attacks that force sharded packets to be handled on the same CPU core [43, 62]. It becomes necessary to process individual heavy flows using multiple cores, which is what SCR does.

Our results also show that RSS++ is not always better than RSS. Re-balancing load by migrating a flow shard across cores requires bouncing the cache line(s) containing the flow states across cores, an action that can degrade performance if done too frequently. On the other hand, rebalancing too infrequently may fail to mitigate skew across cores, since the per-shard load used to make CPU-balancing decisions may become stale relative to the current load.

Why does SCR scale better than other techniques? Figure 8 shows detailed performance metrics measured from Intel's

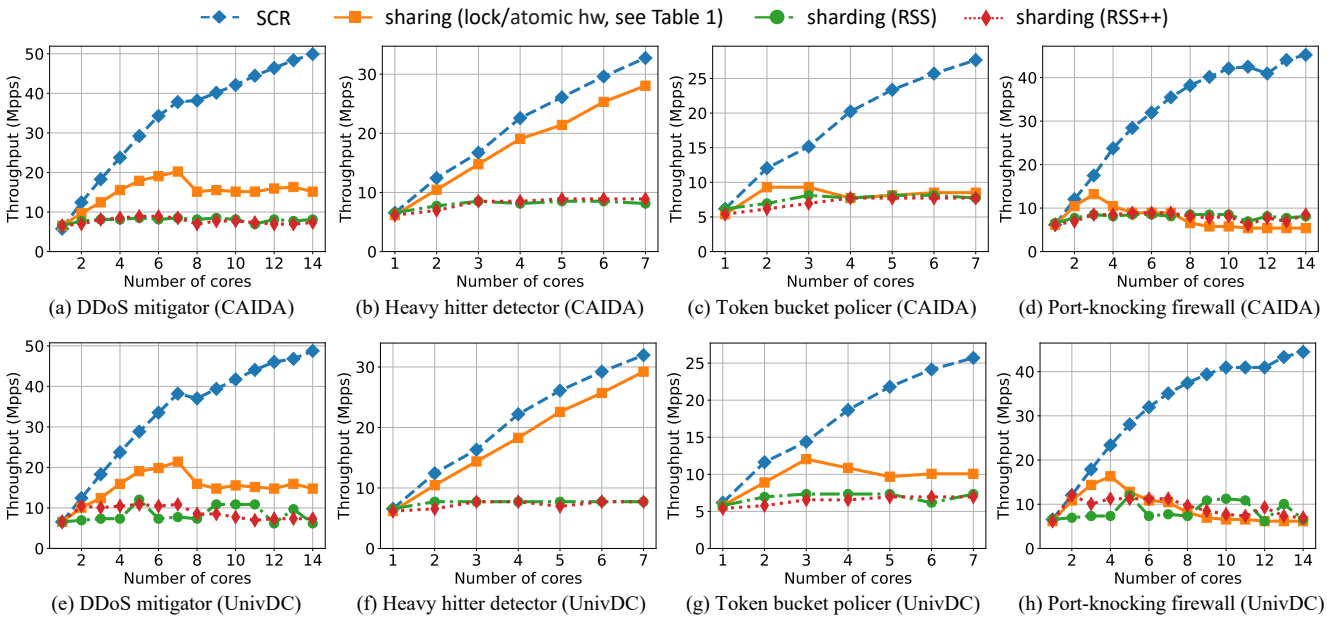


Figure 6: Throughput (millions of packets per second) of four stateful packet-processing programs implemented using state-compute replication (§3), shared state, and sharding (§2). Packet traffic is replayed from real data center and Internet backbone traces (§4.1).

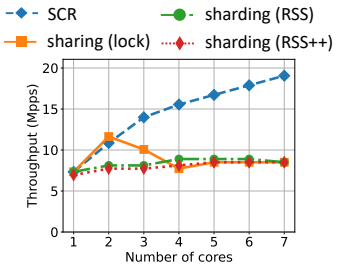

Figure 7: Throughput of TCP connection tracking parallelized using four techniques, SCR (§3), shared state, sharding with RSS, and sharding with RSS++ [35], on a hyperscalar data center trace (§4.1).

performance counter monitor (PCM [24]) and BPF profiling [14]. We measure the L2 cache hit ratios, instructions retired per cycle (IPC), and the program's computation latency (only the XDP portion, excluding the dispatch functionality in the driver), as the load offered to the system increases, when our token bucket policer is run across different numbers of cores (2, 4, or 7). The numbers show the averages for these metrics across the cores running the program. Error bars for IPC show the min and max values across cores. IPC is a meaningful metric to evaluate "CPU goodput" for eBPF/XDP programs: unlike high-speed packet processing frameworks like DPDK which poll the NIC and exhibit persistently high IPC [42], eBPF/XDP drivers adapt CPU usage to load through a mix of polling and interrupts.

Lock-based sharing in general suffers from lower L2 cache hit ratios ((a)–(c)) and higher latencies ((g)–(i)) due to lock and cache line contention across cores—a trend that holds as the offered load increases and also with additional cores

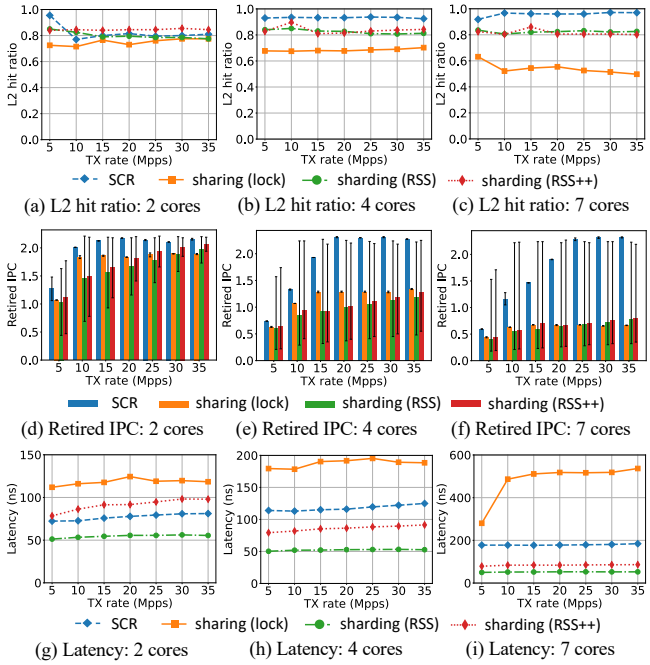

Figure 8: Hardware performance metrics drawn from Intel PCM while executing the token bucket program. As the offered load increases, we show the program's compute latency (measured purely for the XDP portion), the L2 hit ratio, and the number of instructions retired per CPU clock cycle (IPC), when the program is scaled to 2, 4, or 7 cores. Packet traffic is from a university data center (§4.1).

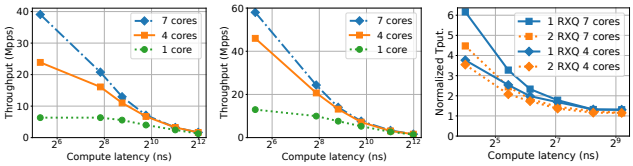


(a) Packets/sec (1 RXQ) (b) Packets/sec (2 RXQ) (c) Normalized to 1 core

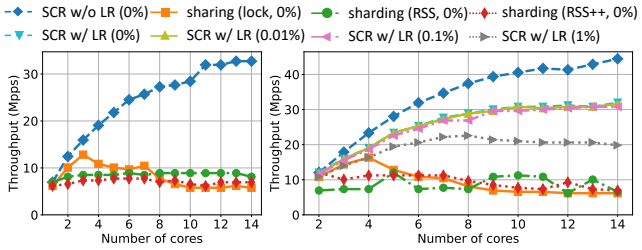
Figure 9: The throughput scaling of a stateless program using SCR, as the compute latency of the program varies but the dispatch latency remains constant ((a) and (b) in packets/second, and (c) normalized against single-core throughput at the same compute latency). As discussed in §3.1, the more the dispatch time dominates compute time, the more effective the multi-core scaling from SCR.

at the same offered load. As we might expect, IPC increases with the offered load ((d)–(f)), since the cores get busier with packet processing. While the sharding approaches (RSS and RSS++) effectively use the CPU with a high average IPC for 2 cores, their average IPC values drop significantly with additional cores, with large variation across cores (see error bars). This indicates a severe imbalance of useful CPU work across cores: Flow-affinity-based sharding approaches are unable to balance packet-processing load across cores, leaving some cores idle and others heavily used.

In contrast to sharing and sharding approaches, SCR has a consistently high IPC with more cores and higher offered loads. SCR has higher packet-processing latency ((g)–(i)) than RSS-sharding since it needs to process the history for each packet. RSS++ sometimes incurs higher compute latency than SCR due to its need to monitor per-shard load, which requires additional memory operations. SCR's more effective usage of the CPU cores results in better throughput scaling than RSS and RSS++ (Figure 6 (g)).

Limits to SCR scaling. SCR suffers from two kinds of scaling limitations. First, as discussed in §3.1, as the compute latency increases in comparison to the dispatch latency, the effectiveness of SCR's multi-core scaling reduces. This is because more time is spent "catching up" state, incurring significant duplicated work across CPU cores. We evaluate how the throughput of a stateless program varies as the compute latency of this program increases, shown both in packets/second (Figure 9a, Figure 9b) and normalized to the single-core throughput for that compute latency (Figure 9c). With a small compute latency (left of the graph), using N cores provides $\approx N\times$ throughput relative to a single core, but this relative benefit diminishes with increasing compute latency. Latency profiles of our benchmarks show compute latencies smaller than 70 nanoseconds (Table 4, Appendix A).

Second, SCR's attachment of histories to packets incurs non-negligible byte/second overheads. Adding to the number of bytes per packet increases L3 cache pressure due to higher DDIO cache occupancy [22] and incurs additional PCIe transactions and bandwidth [59]. Further, when packet histories are appended outside the NIC (*e.g.,* top-of-the-rack switch),



(a) Adding packet history externally (b) Impact of loss recovery

Figure 10: (a) The throughput of a token bucket policer on the university data center trace (§4.1), while truncating all packets in the trace to 64 bytes, with only SCR adding metadata to packets before feeding them to the NIC. (b) The throughput of a port-knocking firewall on the university data center trace. SCR is run with and without loss recovery (§3.4) at multiple packet loss rates.

Rows	LUT			Flip-flops	
	Usage	Logic	%	Usage	%
16	1045	646	0.060	2369	0.069
32	1852	1444	0.107	3158	0.091
64	2637	2229	0.153	4707	0.136
128	3390	2982	0.196	7786	0.226

Table 2: Sequencer resource usage after synthesis into the NetFPGA-PLUS reference switch and meeting timing at 340 MHz.

SCR may saturate the NIC earlier than other approaches. We compare SCR against the shared and sharded approaches, when SCR alone adds history metadata before packets are fed into the NIC while the packets for the latter approaches are truncated to 64 bytes. Figure 10 (a) shows the throughput of the token bucket program with the university data center trace. After 11 cores, the CPU is no longer the bottleneck for SCR. This prevents SCR from scaling to a higher packets/second throughput. Yet, SCR saturates at a throughput much higher than the other techniques.

Overheads of SCR's loss recovery handling. We evaluate how SCR's loss recovery algorithm impacts throughput with and without packet loss. Figure 10 (b) compares a version of SCR without incorporating the loss recovery algorithm, against a version that incorporates loss recovery at different artificially-injected random packet loss rates (0%, 0.01%, 0.1% and 1%). We also show the performance of existing scaling techniques (shared state, RSS, RSS++). The mere inclusion of the loss recovery algorithm impacts performance due to the additional logging operations. Moreover, SCR's throughput degrades with higher loss rate due to recovery-related synchronization (§3.4). However, SCR still outperforms and outscales existing multi-core scaling techniques.

4.3 Practicality of Sequencer Hardware

We integrated our Verilog module implementing the sequencer (§3.3.2) into the NetFPGA-PLUS [12] reference

Resource	Avg%	Resource	Avg%
Exact match crossbars	23.31%	SRAM	9.69%
VLIW instructions	9.11%	TCAM	0.00%
Stateful ALUs	93.75%	Map RAM	15.62%
Logical tables	23.96%	Gateway	23.44%

Table 3: Resource usage (average % across stages) of a Tofino implementation of the sequencer that uses as many stateful ALUs as possible to store packet history, amounting to 44 32-bit fields.

switch, which is clocked at a maximum frequency of 340 MHz with a 1024-bit wide data bus, providing a bandwidth of 348 Gbit/s. We use the Alveo U250 board, which contains 1728000 lookup tables (LUTs) and 3456000 flip-flops.

We synthesized our sequencer design with different numbers of memory rows (§3.3.2), corresponding to the size of the packet history (in number of packets). Each row is 112 bits long, enough to maintain a TCP 4-tuple and an additional 16-bit value (*e.g.,* a counter, timestamp, *etc.*) for each historic packet. Table 2 shows the resource usage. If each packet history metadata in the program is smaller than a row (112 bits), parallelizing across N cores requires N rows. For such programs, our design can meet timing (340 MHz) while scaling to 128 cores. The LUT and flip-flop hardware usage is negligible compared to the FPGA capacity at all row counts measured. We believe that our sequencer design may be simple and cheap enough to be added as an on-chip accelerator to a future NIC.

We have also implemented a stateful-register-based design of the sequencer on the Tofino programmable switch (§3.3.2). The resource usage of this design is shown in Table 3. Our implementation was designed to use as many stateful registers and ALUs as possible (our design uses 93% on average across stages) to hold the largest number of bits of packet history. Our design holds 44 32-bit fields, sufficient to parallelize (Table 1) the DDoS mitigator over 44 cores, the port-knocking firewall over 22 cores, the heavy hitter and token bucket over 9 cores, or the connection tracker over 5 cores. The small number of stateful ALUs on the platform, as well as the limit on the number of bits that can be read out from stateful memory into packet fields, restrict the Tofino sequencer from scaling to a larger number of CPU cores.

5 Related Work

Frameworks for network function performance. The problem of scaling out packet processing is prominent in network function virtualization (NFV), with frameworks such as split/merge [68], openNF [46], and Metron [54] enabling elastic scaling. There have also been efforts to parallelize network functions automatically [63] and designing data structures to minimize cross-core contention [47]. These efforts are flow-oriented, managing and distributing state at flow granularity. In contrast, SCR scales packet processing for a single flow.

General techniques for software parallelism. Among the canonical frameworks to implement software parallelism [57], our scaling principles are most reminiscent of Single Program Multiple Data (SPMD) parallelism, with the program being identical on each core but the data being distinct. The sequencer in SCR makes the data distinct for each core.

Parallelizing finite state machines. A natural model of stateful packet processing programs is as finite state automata (the state space is the set of flow states) making transitions on events (packets). There have been significant efforts taken to parallelize FSM execution using speculation [65, 66] and data parallelism [58]. In contrast, SCR exploits replication.

Parallel network software stacks. There has been recent interest in abstractions and implementations that take advantage of parallelism in network stacks, for TCP [55, 72] and for end-to-end data transfers to/from user space [39]. SCR takes a complementary approach, using replication rather than decomposing the program into smaller parallelizable computations.

6 Conclusion

It is now more crucial than ever to investigate techniques to scale packet processing using multiple cores. This paper presented state-compute replication (SCR), a principle that enables scaling the throughput of stateful packet-processing programs monotonically across cores by leveraging a packet history sequencer, even under realistic skewed packet traffic.

Acknowledgments

Table 4: The throughput model parameters (in nanoseconds) for packet-processing applications we evaluated.

Appendixes

The appendixes include supporting material that has not been peer-reviewed.

A Predicting Throughput

This section provides a model that predicts the throughput of SCR (§3.2) for any number of cores, given latency measurements made with one and two cores at low load. We also check the agreement between the empirically-measured throughput and our model.

Suppose a system has k cores, where each core can dispatch a single packet in d cycles, and run a packet-processing program that computes over a single packet in $c = c_1 + (k-1) \times c_2$ cycles, where c_1 is the time required to process the current packet and c_2 the time for a state update using one item of packet history. The time c_2 is smaller than c_1, as the state transition is a fragment of the computation extracted from the program which processes one packet in entirety. For each piggybacked packet, the total processing time is $d + c_1 + (k-1) \times c_2$. We define $t \triangleq d + c_1$, the time to process one packet including the dispatch and the program computation. When t dominates the state-computation time (*i.e.,* $t \gg c_2$), with k cores, the total rate at which externally-arriving packets can be processed is $k \times \frac{1}{t+(k-1)\times c_2} \approx k/t$. Table 4 lists the parameters we measured for packet-processing applications we evaluated. It shows that $t \approx 3.6 - 9.9 \times c_2$. Hence, it is possible to scale the packet-processing rate linearly with the number of cores k.

We applied the parameters in Table 4 to the throughput model and compared the predicted throughput to the actual throughput. Figure 11 shows that they match well.

B Loss Recovery Algorithm

This section provides the detailed pseudocode and a proof of correctness of the packet loss recovery algorithm outlined in §3.4.

Before we start the correctness proof of loss recovery algorithm, we define the following notations.

1. sp: an SCR packet. sp_i: the i^{th} SCR packet sent from the sequencer to a core (please refer to §3.3.1 for more details).

Algorithm 1 SCR loss recovery

Input: the received SCR pkt (sp), current core (c)

```
1:  Initialize:
        max[c] ← 0, ∀i : log[c][i] ← NOT_INIT
2:  function scr_loss_recovery(sp, c)
3:      maxseq ← sp.seq_num
4:      minseq ← max(1, maxseq − N + 1)
5:      for i ← max[c] + 1 to maxseq do
6:          if i < minseq then
7:              log[c][i] ← LOST
8:              handle_loss_recovery(i, c)
9:          else
10:             history ← get history of i from sp
11:             log[c][i] ← history
12:         end if
13:     end for
14:     max[c] ← maxseq
15: end function

16: function handle_loss_recovery(i, c)
17:     C_others ← C \ {c}
18:     C_lost ← ∅
19:     while true do
20:         for each c′ ∈ C_others do
21:             if log[c′][i] is NOT_INIT then
22:                 continue
23:             else if log[c′][i] is LOST then
24:                 C_lost ← C_lost ∪ {c′}
25:                 if C_lost = C_others then return
26:                 end if
27:             else
28:                 history ← log[c′][i]
29:                 update state using history
30:                 return
31:             end if
32:         end for
33:     end while
34: end function
```

(d) Port-knocking firewall (e) TCP connection tracking

Figure 11: Predicted and actual throughput (§4.1) in millions of packets per second (Mpps) of five stateful packet-processing programs implemented using SCR (§3). The workloads of (a)-(d) and (e) are from a university data center and a hyperscalar data center (§4.1) separately.

2. p: a regular packet. p_i: the i^{th} regular packet received by the sequencer (in original or as part of the packet history, please refer to §3.3.1 for more details).
3. C: the collection of all cores.

We want to prove that no core will be deadlocked by loss recovery, *i.e.,* every core will *start processing* (execute line 6) and *finish processing* (finish executing line 6-12) every regular packet, under the assumptions that (1) each core will receive at least one SCR packet after packet loss, (2) we have infinite memory, and (3) packet number monotonically increases.

Theorem 1. *For any regular packet p_i, if every core has received p_j ($j \geq i$), every core will finish processing p_i.*

Proof. We will first prove that any core will process p_1 to p_i in order. The order of packets to process follows the order at line 5 (from $max[c]+1$ to $maxseq$), *i.e.,*, after a core finishes processing p_k, it will start processing p_{k+1}. Each core will be triggered to process all packets including p_1 to p_i, since each core has received p_j ($j \geq i$),

Given the order of packets to process, we now prove all cores can finish processing p_i. If $i = 1$, all cores will start processing p_1 (line 6) and then finish processing p_1 (Lemma 1). If $i > 1$, according to the order of a single core processing packets and Lemma 1, we get the induction hypothesis that if all cores have started processing p_k, all cores will finish processing p_k and start processing p_{k+1}. Using induction hypothesis for i times, all cores will start and then finish processing p_i. □

Lemma 1. *For any regular packet p_i, if all cores have started processing p_i, then all cores will finish processing p_i.*

Proof. For any core c, no matter p_i is lost or received, c will finish processing it.

If p_i is received by c, after c updates $history[i]$ in its log (line 10-11), c finishes processing p_i.

If p_i is lost at c (detected at line 6), c will wait for other cores to update p_i in their logs until c gets $history[i]$ or confirm p_i is lost at all the other cores (line 19-33). c will not be deadlocked in waiting, since p_i will be updated to $history[i]$ or *LOST* in the logs of all cores which have started processing p_i (if line 6 is executed for p_i, line 7 or line 11 will be executed). □

In a practical implementation, logs are finite and sequence numbers wrap around. We handle these concerns with a sufficiently large log and a sequence space. Our current implementation uses the values 1,024 and 842,185 for the aforementioned two quantities (respectively).

C SCR-Aware Multi-Core Programming

Consider a packet-processing program developed assuming single-threaded execution on a single CPU core. The question we tackle in this subsection is: how should the program be changed to take advantage of multi-core scaling with state-compute replication? We walk through the process of adapting a program written in the eBPF/XDP framework [50], but we believe it is conceptually similar to adapt programs written in other frameworks such as DPDK.

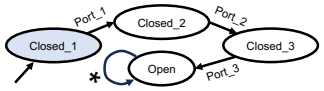

Figure 12: A state machine for a simple port-knocking firewall.

We describe the program transformations necessary for SCR through a running example. Suppose we have a port-knocking firewall [28] with the state machine shown in Figure 12. The program runs a copy of this state machine per source IP address. If a source transmits IPv4/TCP packets with the correct sequence of TCP destination ports, then all further communication is permitted from that source. All other packets are dropped. Any transition not shown in the figure leads to the default `CLOSED_1` state, and only the `OPEN` state permits packets to traverse the firewall successfully. A simplified XDP implementation of this single-threaded firewall is shown below.

```
/* Definition of program state */
struct map states {
  /* assume we define a dictionary with keys
     as source IP addresses and values as firewall
     states among CLOSED_{1, 2, 3} and OPEN. */
}

/* State transition function. See Figure 12  */
int get_new_state(int curr_state, int dport) {
  /* A function that implements the state machine for
     the port knocking firewall. */
  if (curr_state == CLOSED_1 && dport == PORT_1)
    return CLOSED_2;
```

```
  if (curr_state == CLOSED_2 && dport == PORT_2)
    return CLOSED_3;
  if (curr_state == CLOSED_3 && dport == PORT_3)
    return OPEN;
  if (curr_state == OPEN)
    return OPEN;
  return CLOSED_1;
}

/* The main function */
int simple_port_knocking(...) {
  /* Assume the packet is laid out as a byte array
     starting at the address pkt_start. Suppose the
     packet is long enough to include headers up to
     layer 4. First, parse IPv4/TCP pkts. */
  struct ethhdr* eth = pkt_start; // parse Ethernet
  int l3proto = eth->proto; // layer-3 protocol
  int off = sizeof(struct ethhdr);
  struct iphdr* iph = pkt_start + off;
  int l4proto = iph->protocol; // layer-4 protocol
  if (l3proto != IPv4 || l4proto != TCP)
      return XDP_DROP; // drop non IPv4/TCP pkts
  int srcip = iph->src; // source IP addr
  off += sizeof(struct iphdr);
  struct tcphdr* tcp = pkt_start + off;
  int dport = tcp->dport; // TCP dst port

  /* Extract & update firewall state for this src. */
  int state = map_lookup(states, srcip);
  int new_state = get_new_state(state, dport);
  map_update(states, srcip, new_state);

  /* Final packet verdict */
  if (new_state == OPEN)
      return XDP_TX; // allow traversal
  return XDP_DROP; // drop everything else
}
```

The program's state is a key-value dictionary mapping source IP addresses to an automaton state described in Figure 12. The function `get_new_state` implements the state transitions. The main function, `simple_port_knocking` first parses the input packet, dropping all packets other than IPv4/TCP packets. Then the program fetches the recorded state corresponding to the source IP on the packet, and performs the state transition corresponding to the TCP destination port. If the final state is `OPEN`, all subsequent packets of that source IP may traverse the firewall to the other side. All other packets are dropped.

To enable this program to use state-compute replication across cores, this program should be transformed in the following ways. We believe that these transformations may be automated by developing suitable compiler passes, but we have not yet developed such a compiler.

(1) *Define per-core state data structures and per-packet metadata structures.* First, the program's state must be replicated across cores. To achieve this, we must define per-core state data structures that are identical to the global state data structures, except that they are not shared among CPU cores. Packet-processing frameworks provide APIs to define such per-core data structures [16].

Additionally, we must define a per-packet metadata structure that includes any part of the packet that is used by the program—through either control or data flow—to update the state corresponding to that packet. For the port-knocking firewall, the per-packet metadata should include the `l3proto`, `l4proto`, `srcip`, and `dport`.

The data structures that maintain packet history on the sequencer correspond to this per-packet metadata (§3.3).

(2) Fast-forward the state machine using the packet history. The SCR-aware program must prepend a loop to "catch up" the state machine for each packet missed by the CPU core where the current packet is being processed. By leveraging the recent history piggybacked on each packet, at the end of this loop, the CPU core has the most up-to-the-packet state.

```
/* Assume the pointer 'data' locates where the
   per-pkt metadata begins in the byte array of
   the packet (Figure 4a ). Suppose 'index'
   is the offset of the earliest packet §3.3.2 ,
   and NUM_META is the number of packets in the
   piggybacked history.
*/
int l3proto, l4proto, srcip, dport, i, j;
for (j = 0; j < NUM_META; j++) {
  i = (index + j) % NUM_META; // ring buffer
  struct meta *pkt = data + i * sizeof(meta);
  l3proto = pkt->l3proto;
  l4proto = pkt->l4proto;
  srcip   = pkt->srcip;
  dport   = pkt->dport;
  if (l3proto != IPv4 || l4proto != TCP)
     continue; // no state txns or pkt verdicts
  /* Update state for this srcip and dport: */
  /* map_lookup; get_new_state; map_update. */
  /* Note: No pkt verdicts for historic pkts. */
}
pkt_start = data + NUM_META * sizeof(struct meta)
              + sizeof(index);
```

A few salient points about the code fragment above. First, the semantics of the ring buffer of packet history (§3.3) are implemented by looping over the packet history metadata starting at offset `index` rather than at offset 0. The decision to implement the ring buffer semantics in software makes the hardware significantly easier to design, since only a small part of the hardware data structure needs to be updated for each packet (§3.3.2). Second, the loop must implement appropriate control flow before the state update to ensure that only packets that should indeed update the flow state do. Note that the metadata includes parts of the packet that are not only the data dependencies for the state transition (`srcip, dport`) but also the control dependencies (`l3proto, l4proto`). Third, no packet verdicts are given out for packets in the history: we want the program to return a judgment for the "current"

packet, not the historic packets used merely to fast-forward the state machines. Finally, the code fragment conveniently adjusts `pkt_start` to the position in the packet buffer (Figure 4a) corresponding to where the "original" packet begins. The rest of the original program—unmodified—may process this packet to completion and assign a verdict.

What is excluded in our code transformations is also crucial. This program avoids locking and explicit synchronization, despite the fact that it runs on many cores, even if there is global state maintained across all packets.

With these transformations, in principle, a packet-processing program is able to scale its performance using state-compute replication across multiple cores.

MTP: Transport for In-Network Computing

Abstract

In-network computing (INC) is being increasingly adopted to accelerate applications by offloading part of the applications' computation to network devices. Such application-specific (L7) offloads have several attributes that the transport protocol must work with—they may mutate, intercept, reorder and delay application messages that span multiple packets. At the same time the transport must also work with the buffering and computation constraints of network devices hosting the L7 offloads. Existing transports and alternative approaches fall short in these regards. Therefore, we present MTP, the first transport to natively support INC. MTP is built around two major components: 1) a novel message-oriented reliability protocol and 2) a resource-specific congestion control framework. We implement a full-fledged prototype of MTP based on DPDK. We show the efficacy of MTP in a testbed with a real INC application as well as with comprehensive microbenchmarks and large-scale simulations.

1 Introduction

Datacenters today are experiencing ever-increasing demand for computing with the emerging of large-scale distributed applications and intensive workloads such as ML/AI and VR/AR. These applications run heavy computational logic and rely on infrastructure services (e.g., for caching and load-balancing) that themselves impose non-trivial computational needs. In-network computing (INC) has emerged as a promising approach to meet the resulting compute demand by leveraging specialized in-network hardware for offloading. With INC, application-specific and infrastructure processing functions—which we together refer to as L7 functions—can be run atop network devices. This can provide vastly improved application throughput and latency compared to approaches that rely on conventional server architectures [65].

We have seen a blossoming of ideas for offloaded L7 functions (or "L7 offloads"). Examples include key-value caches [35, 46, 75], file and storage systems [41, 48, 59], machine learning (ML) tasks [45, 55, 69], transaction and database systems [32, 34, 70], consensus [47], as well as load balancing [17, 81]. Alongside, we have seen a growing number of devices and platforms that can support INC, including programmable switches [1–3, 12, 40, 78, 79], and SmartNICs [10, 53, 54, 64]. While the growing number of showcases for INC is promising, we argue that there are fundamental problems that need to be addressed before INC can be utilized in a systematic and effective manner to accelerate datacenter computation. This paper focuses on one such problem, namely the design of an INC-compatible transport protocol.

Despite the wide diversity of INC possibilities and platforms, we argue that all of them need in common a transport protocol with two properties:

(1) The transport's basic functions—reliability and congestion control—should work in the face of key attributes of INC, namely that the L7 offloads can induce mutation, intercept, reordering and arbitrary delays upon application messages. For example, an HTTP load balancer can insert cookies to an HTTP request [17], and an in-network aggregator can delay producing the result until the straggler provides the input [78]. We detail all such attributes in §2.1.

(2) The transport should not impose additional transport-specific resource needs on INC hardware (e.g., needing significant buffering or state maintenance). Switches and SmartNICs that host INC have limited memory and compute power.

Most datacenters today use either TCP variants or RDMA as their transport [29, 72, 82], and new experimental transports have emerged, such as the receiver-driven Homa protocol [61]. Unfortunately, none of these transport protocols can accommodate the attributes of INC. When used alongside INC, they result in either broken reliability semantics, poor and ineffective congestion control, or both (§2.2). Alternative approaches either have prohibitive compute and memory overheads or are ad-hoc, eschewing reliability and/or congestion control while only supporting a subset of the INC attributes (§2.3), and hence are not widely applicable.

This paper presents MTP (Message Transport Protocol), the first INC-compatible transport protocol. It makes key design choices that elevate L7 offloads—how they function and how

they are used in datacenter networks—to first-class entities from a transport perspective. MTP works on *messages* as this aligns with the processing semantics of L7 offloads—all key decisions in MTP, be they for loss detection/recovery, congestion control or path selection, operate at the message granularity. To handle message mutation, intercept and reordering, MTP decouples key transport actions, e.g., loss detection and recovery, from the packet or byte sequence numbers (§4).

MTP recognizes and operates on *pathlets*, groups of offloads that share fate. For example, a pathlet can be either a single instance of an offload or multiple replicas of an offload that a NIC load balances across. MTP elicits *per-pathlet feedback* both for MTP's reliability protocol to set appropriate timeouts when messages are delayed by pathlets rather than dropped (§5) and for congestion control to take per-message decisions on when to transmit and which pathlets to use. This controls the load on pathlets, avoiding the overloaded ones and causing load imbalance (§6).

Additionally, using MTP has low overheads: pathlets need not maintain MTP-specific state and can easily leverage MTP primitives by generating appropriate ACK packets (§4–6). The endpoint-maintained state is constant and proportional to (an upper-bounded) number of in-flight messages and pathlets in use (Appendix B). The MTP header is only 20 B plus optionally a 5 B pathlet congestion feedback (Appendix A), and the ACK primitives have low bandwidth and endpoint processing overheads (§8.2.3).

To evaluate MTP, we implement a full-fledged MTP prototype based on DPDK [23] and perform end-to-end benchmarks by running on top of MTP NetCache [35], a real-world INC application. We show that MTP improves the throughput by over 15% (§8.1). We conduct comprehensive microbenchmarks (§8.2) showing MTP's effective loss recovery and congestion control in the face of INC. We also simulate MTP's operation at large scales (§8.3) and find that MTP achieves 65% less tail latency and can sustain 10–20% higher loads compared to TCP under heavy message reordering.

2 Motivation

In this section, we argue that a novel transport for INC is warranted. For that, we capture the essential message operations that INC performs (§2.1), describe how existing transports are not compatible with these operations (§2.2), discuss how the ways in which INC is made to work with transports today are not widely applicable (§2.3), and extract the requirements of a novel transport (§2.4).

2.1 On-Path Message Processing

INC enables applications to offload portions of their (L7) logic to NICs or switches. Traditional offloads, such as network address translation and transmit segmentation offload, have dedicated network- or transport-level logic and process the corresponding protocol headers in packets. In contrast, L7 offloads process application-level (L7) messages, which are the payloads that span one or more network packets. L7 offloads have more diverse functions. Examples include various key-value caches [35, 46, 49], intrusion detection/prevention [80], L7 load balancing [17, 81], transaction and database acceleration [32, 34, 70], as well as in-network aggregation (INA) for machine learning jobs [45, 55, 69, 78].

These offloads are "on-path": located on the communication path between end hosts, and multiple offloads that perform different processing (e.g., load balancing and intrusion detection) or different parts of the same processing (e.g., two levels of INA [45]) can form a "chain" on the path.

However, the operations that these offloads perform on L7 messages can often interact poorly with the underlying transport, potentially causing low performance and even breaking the transport protocol. We summarize the operations below and discuss their impact on transport in the next section.

Mutation. An offload can change the L7 message payload. At times this can result in changes in the message size and the number of packets that the message spans. For example, an HTTP load balancer [17] can inject cookies into HTTP responses, which makes the response messages longer. The in-network aggregator of SwitchML [69] replaces the per-worker gradients in the RDMA message with aggregated gradients.

Intercept. In some scenarios, an offload can explicitly drop a message so that it does not reach the transport's receiving endpoint. Some RPC load balancers, for example, can proactively drop the requests that will anyway violate the service-level objectives [42].

Reordering. An offload can reorder messages between the same sender and receiver for two reasons. First, the offload explicitly does so as part of its logic. Transaction triaging, for example, reorders messages to batch similar transactions, which improves server performance [34]. Second, many hardware architectures support running replicated instances of the same offload logic in parallel to improve performance [53, 54, 78]. Messages that take different amounts of processing time at various instances can finish in a different order.

Delaying. An offload can impose delays on a message in various cases, and such delays can be long and unpredictable. (1) Complex INC logic or wimpy hardware: FPGA-based intrusion detection, for instance, can incur a tail processing delay of ∼4x median for infrequent slow-path processing [80]. Some wimpy SmartNICs can even incur ∼80μs tail delay (∼2x average) on packet steering [54]. These delays are of the same order of magnitude as the network fabric delay (10s of μs [43]). Such offloads themselves are often bottlenecks and when experiencing high load may incur increased queuing delay. (2) In some cases, the processing of a message cannot complete if another message is delayed. E.g., in INA, gradients cannot be completely aggregated if a straggler worker delays its part, and mitigating a straggler can take 10s of ms, which is much higher than the usual aggregation [78] and network fabric delay.

2.2 Today's Transports Are Incompatible

We discuss three transports, i.e., TCP (including its variants such as QUIC [44]), RDMA [29, 82], and Homa [61]. All of them provide reliability and congestion control, which are essential transport-layer functions. TCP variants and RDMA are arguably the most widely adopted transports in production datacenters. Homa is an emerging receiver-driven transport providing message transfer semantics with efforts to deploy it in production [31, 63]. Unfortunately, these transports are largely incompatible with INC operations which can have a fundamental impact on the correctness and efficacy of the transports' reliability and congestion control.

The TCP variants and RDMA do not work in the face of mutation, intercept, or reordering. Consider these transports' reliable delivery: they both use a per-connection continuous byte/packet sequence number space, and all the bytes/packets transmitted by the sender must be acknowledged by the receiver. When an offload mutates a multi-packet message in a way that changes its length or intercepts it, the byte and/or packet counts that reach and are ACK'd by the receiver also change. In that case, the sender cannot correctly decide if a missing byte/packet needs retransmission, and can be confused if ACK'd bytes/packets are more than what it has transmitted. Also, reordering can cause severe out-of-order packet arrivals resulting in discontinuous received sequence, which both protocols can interpret as loss and trigger wasteful retransmission as well as reduction in congestion window.

Homa cannot properly perform loss recovery with mutation. Homa's receiver detects missing bytes with a timeout and asks the sender to retransmit the missing part. However, if the message is mutated to a different length, the range of bytes in the mutated message that the receiver asks for is likely not the same bytes in the original message. Note that Homa could work with intercept and reordering because the transmission of each message is independently controlled, and there is no cross-message state such as a sequence number that can be disrupted by dropping or reordering messages.

Finally, delaying can also disrupt congestion control in fundamental ways in all three protocols. TCP and RDMA rely on some end-to-end measurements such as ECN [8, 82] and RTT [43, 60] to quickly and accurately detect congestion. These measurements traverse the forward path and are eventually reflected back to the sender by the receiver. When messages can be delayed at an offload for unpredictably long, the measurement might not arrive at the sender in a timely manner, which prevents the sender from quickly reacting to congestion. To achieve line rate and low queuing, Homa's receiver tries to keep 1 BDP (bandwidth-delay product) of credits in flight. However, this assumes that both network RTT and bandwidth is known and constant. With INC, message mutation that causes changes in length, below-line rate bottleneck offloads and unpredictable delays can make it extremely difficult to accurately control the outstanding credits.

2.3 How INC Works With Transports Today

Some existing INC works have made simplifying assumptions or workarounds so that transports can correctly function with a specific offload. However, such approaches have important limitations.

One approach to be compatible with INC operations is for an offload to "terminate" the transport, running both the receiver- and sender-side protocol logic [28]. However, transport stacks need significant hardware resources on the offload for transport processing and message buffering. The hardware limitations of some INC platforms like switches preclude running transports altogether [55, 69], while the limitations of others like SmartNICs may limit scalablity and require careful parallel decomposition and many cores for performance [71].

Furthermore, the simplifying assumptions made by prior work are also usually unrealistic. For example, prior work has assumed that an RPC's length never exceeds one MTU (maximum transmission unit) and hence can always be carried by just one packet [35,46,49,53,64]. Other work has assumed that a new connection can be established for each RPC [81]. However, these don't generally hold: A significant proportion of RPCs in datacenters are indeed larger than the MTU [8,61], and RPCs typically reuse connections because connection establishment incurs overhead [4].

Some works have proposed workarounds, which usually cover only the subset of message operations required by the specific offload and are not generalizable. As a result, these solutions require case-by-case human efforts to apply to other use cases. For example, NetReduce [55] accommodates mutation in a way that is transparent to TCP and RDMA, but the message size must not change. As such, this approach is not compatible with an HTTP load balancer that adds cookies. Additionally, this approach does not support intercept or reordering. SwitchML [69] and ATP [45] build their own transport functions such as reliable delivery based on UDP, but neither work in the face of intercept. The transaction triaging offload [34] supports intercept and reordering but does not work amidst mutation of the message (transaction) body.

Others have relied on specific hardware architectures. The HTTP load balancer [17], for example, accommodates mutation that changes the message length based on NICs that have general-purpose cores. However, it must maintain per-connection state that correctly maps between the altered and original byte sequences, and it must buffer the mutated messages for retransmission. Maintaining such per-connection state can be expensive in hardware, and buffering payload might not be supported by some hardware architectures.

2.4 Design Requirements

We argue for a novel transport that is widely applicable to INC. Such a transport must meet these requirements:

- Provide correct reliable delivery in all scenarios where the packets or bytes are altered in the network as a result

of message mutation, intercept, or reordering;

- Provide effective congestion control for all potential bottlenecks in the network, including the network fabric and slow offloads, despite the delaying of messages.
- Support all kinds of INC hardware without assuming that special transport-specific state or buffering can be maintained by the offload.

We present MTP (Message Transport Protocol), the first transport designed for INC, satisfying all of these requirements.

3 Pathlets

Before describing MTP, we provide a brief overview of pathlets, which is a key building block. Then, we discuss the infrastructure support needed to allow MTP to leverage pathlets and our assumptions on how pathlets work.

3.1 Pathlets and Grouping

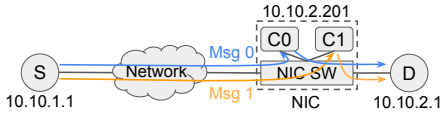
We observe that on the path of a message, between the transport sender and receiver, there can be multiple offloads, potentially with different types of computation. For example, an L7 load balancer [17, 81] can be followed by intrusion detection [80], if the requests can come from untrusted senders. In a two-level INA deployment, a message can go through two aggregators on different switches [45].

We refer to each such offload instance on the path as a pathlet [1]. Pathlets that perform the same computation are said to have the same pathlet type. An ordered chain of pathlet types defines the computation that the message goes through in the network.

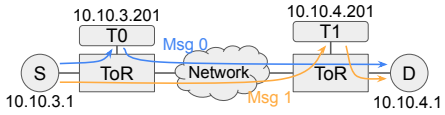
Instances of a pathlet type can be arranged in two forms. First, as shown in Figure 1b, offload instances can be at different network locations; in this case, as we describe below, MTP allows a sender to select which specific pathlet instance to use. Second, as shown in Figure 1a, the instances are co-located on the same NIC or switch, and an on-NIC/switch scheduler locally balances their loads [53]. Thus, these should not be viewed as individual pathlets as the scheduler hides internal load imbalance or partial failure. MTP groups the latter such instances together and views them as one pathlet.[2]

3.2 Pathlet Discovery and Routing

For the MTP transport to work with pathlets, the network must provide two services: (1) Pathlet discovery: The datacenter network (DCN) should determine the chain of pathlet types to be used for messages towards a given receiver, and provide for each type the specific pathlet instances for the transport to use. (2) Pathlet routing: The network should route the packets of a message to the transport-selected pathlets in the same order. We now describe how these services can be provided in an MTP-enabled DCN.



(a) Locally load-balanced offloads C0 and C1.



(b) Non-locally deployed offloads T0 and T1.

Figure 1: **Possible deployment models for offload instances that perform the same computation.**

Discovery. We assume that the applications that leverage INC capabilities follow the client-server model. When a client attempts to reach a service, it first queries for the server(s) with a service discovery protocol (SDP), such as [5, 6]. The SDP provides, in addition to server addresses, a list of pathlet types that client messages should go through toward the service. The client then queries a pathlet registry for the available instances of each pathlet type and the address of each instance. The replied pathlet information for the service is cached in the client host hypervisor or OS for fast retrieval.

This pathlet registry is similar to a service registry that would back a SDP today. It can be scaled up with standard sharding techniques that are used for service registries, such as employing a distributed key-value store [68, 76].

Routing. To reach the pathlets, we employ a form of source routing. When a client connects to a service, it configures MTP with the server and pathlet addresses that it queries from the SDP. When sending messages, MTP encodes the list of pathlet addresses it selects in the packet header, and the network forwards the packets through the hops with given addresses in order, and eventually to the server. This can be achieved with IPv6 segment routing [22] on commodity off-the-shelf network devices. We assume that each pathlet has an IPv6 address.

3.3 Pathlet Processing

We observe that there can be two ways in which the pathlet gathers data to process: 1) *full buffering*, where the pathlet buffers messages in full, and the processing can only be done when the whole message has arrived at the pathlet; and 2) *streaming*, where the pathlet starts processing with partial messages, and can receive and transmit packets of the message while processing. Full buffering can utilize *cut-through* forwarding, so the biggest difference between streaming and full buffering is in the buffering requirements.

We design MTP to cater for full buffering, which we argue is the most common case, for two reasons. First, applica-

[1] While inspired by prior art on "pathlet routing" [26] where a pathlet is a link or set of links, we use the term "pathlet" differently.

[2] A datacenter operator can conservatively decide to have just one instance for each pathlet type as default. However, if the operator chooses to expose multiple pathlets, MTP can offer improved performance.

tions can often break down large data into packet-sized messages for offload processing. For example, SwitchML [69] and ATP [45] encapsulate partial gradients in single-packet messages to fit in the programmable switch, each message with an L7 header as application context. Also, for many applications in datacenters, messages are small, with over 90% messages each fitting in one Ethernet jumbo frame, and many offloads also assume single-packet messages [35, 46, 51, 81].

Second, it is usually an application requirement or choice to process larger messages in whole, in which case the pathlet should already have the capability to achieve full buffering of multi-packet messages. For instance, NetReduce [55] works with large messages that contain ML gradients by relying on the transport to chunk the message, and the FPGA-based aggregator can reassemble the message based on transport sequence numbers.

We note that some applications employ limited-capability offload hardware, such as Tofino [3], where it is hard to perform processing that involves maintaining cross-packet (message) state. MTP is still applicable: such offloads can leverage MTP's reliability and congestion control primitives by simply generating appropriate ACK packets (detailed later) upon receiving a "single-packet message".

We discuss how MTP can be used as a building block to support streaming applications in §9.

4 Overview

We now present MTP, starting with an overview of its architectural components and a basic end-to-end workflow.

4.1 MTP Architecture

MTP consists of two major components: (1) a message-oriented reliability protocol that natively accommodates message mutation, intercept and reordering; and (2) a multi-pathlet congestion control framework that enables congestion control algorithms to operate effectively in the face of pathlets causing long and unpredictable delays. Neither component requires additional state at pathlets. As such, MTP meets all of the requirements in §2.4.

To design such a reliability protocol, we make a key observation about why existing transports fall short (§2.2): The receiver cannot tell whether a missing place in the received packet or byte sequence is because of loss or intercept/reordering; nor can it, in case of mutation, provide the before-mutation sequence number for the sender to retransmit. Our design choice is therefore to rely on the sender to detect losses with *per-message retransmission timeouts (RTOs)*: The receiver, upon the arrival of all packets of the message, sends an end-to-end (E2E) ACK, which disarms the timer. Otherwise the timer triggers retransmission of the whole message. We discuss the challenges that come with this design in §5.1.

To enable effective congestion control (CC) under long and unpredictable delay caused by INC, our framework provides two primitives. (1) Per-pathlet early congestion feedback: A pathlet has the choice of communicating its own congestion state, as well as reflecting any congestion signal along the path (such as ECN for link congestion), directly back to the sender in the form of a *dedicated packet*, that does not incur additional delay from the offload processing. (2) Per-message pathlet decision: If multiple same-type pathlets are available, the congestion control can *decide the instance to use on a per-message basis*. This allows quickly steering messages away from the congestion point. We show how these primitives can be leveraged to build effective congestion control in §6.

4.2 Basic Workflow

We now walk through an example (Figure 2) of end-to-end MTP message delivery with in-network mutation.

MTP is connection-based. Each connection endpoint is bound to an IP address and a port. A flow is defined by the 5-tuple as in TCP. We focus on transport operations over an established connection. MTP's connection establishment is achieved with a three-way handshake similar to TCP.

Before sending the first message, the sender queries the service and pathlet discovery protocols for pathlets, and CC remembers these pathlets. To send a message, the application posts to the MTP stack a message descriptor, which carries metadata such as the length and location of the message body. The MTP stack assigns a message number to the descriptor, which increments in the order of descriptors polled, and stores the descriptor in the connection state. CC then selects the pathlets to use for this and subsequent messages and stores the pathlet addresses in the descriptor.

Once CC determines that this message is admissible into the network because there is sufficient room in the congestion window, the MTP stack divides the message body into segments each up to the MSS (maximum segment size, 4096 bytes in this example). A message smaller than the MSS is sent in one segment of the message length. Each segment is identified by a segment number unique within the message. Then MTP encapsulates the pathlet addresses and segments into packets and transmits them.

Upon receiving the segment, pathlet A *immediately* generates a congestion feedback that potentially includes its own congestion signal and link congestion signal such as ECN. We explain how the feedback values are decided in §6. Pathlet A then performs message mutation that increases the message size by 8 bytes so that the message now consists of two segments.

When receiving the first arrived segment of a message, the receiver creates in its connection state a message descriptor that keeps track of the received segments of a message with a bit mask of the received segment numbers. To enable the receiver to determine when all segments are received, every segment packet carries the message length, which divided by MSS gives the number of segments in the message. Once all segments have arrived, the receiver sends an ACK for the

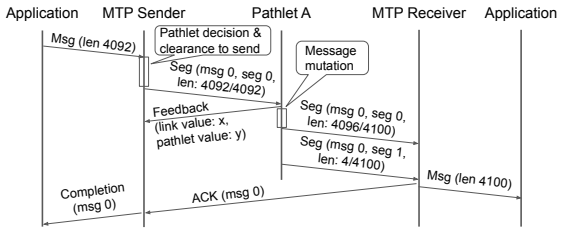


Figure 2: **The MTP basic workflow with mutation.**

(now mutated) message to the sender host. The MTP stack then provides the message to the receiver application and notifies the sender application of completion.

This example shows how MTP works with mutation. Note that the receiver is "passive": It only sends out the E2E ACK for fully received messages and does not check the continuity or order of arrived message numbers. Also, the receiver does not act on out-of-order arrived packets within a message, and can create the message descriptor based on any segment packet of a message that arrives first. Therefore, no special accommodation is needed for reordered messages and even reordered packets, which can be a result from fine-grained network load balancing [20]. However, such a passive receiver design makes it challenging to provide an exactly-once guarantee, which we discuss in §5.2.

By design, MTP does not guarantee in-order message delivery, since this is known to cause head-of-line blocking between messages, which hurts latency-sensitive applications [74]. Applications that require ordering can achieve this by adding their own ordering mechanism [74].

In MTP, a pathlet is expected to output at most one message for each incoming message. The pathlet can intercept a message by sending an E2E ACK to the sender as if the message was delivered to the receiver. Otherwise, the pathlet must forward the message towards the next pathlet or receiver. Any additional payload generated should be added to a message in the form of mutation. We leave the support for branching pathlets in MTP, i.e., multicast, to future work.

5 Reliability

In this section, we discuss the challenges to MTP's reliability protocol that arise from the design choices that we have made, and how we address them.

5.1 Delays and RTOs in MTP

We have previously made the design choice to rely on the sender to detect losses with per-message RTO. In a legacy DCN, relying on a constant RTO for loss detection is acceptable because the network fabric delay is bounded and the RTT is predictable, and the operator can configure a short RTO [9, 61]. However, as discussed in §2.1, an offload can incur a long and unpredictable delay that can be much higher than the fabric delay. Setting a long RTO for the worst-case scenario hurts the quickness of loss recovery, whereas a short RTO causes spurious retransmissions (§8.2.1).

To resolve this, our idea is to distinguish whether the message is in the network or in a pathlet that can incur long or unpredictable delays. With this knowledge, the sender can apply *different RTOs* that fit the respective cases. MTP achieves this with two dedicated types of ACKs as follows.

Pathlet ACKs. A pathlet can leverage two types of ACKs to notify the sender of the arrival and departure of a message, allowing the sender to apply different RTOs. When the pathlet receives all message segments, it sends a pathlet receive ACK, or *PRX ACK*, to the sender to indicate that the whole message is buffered. Until further notice, the sender assumes that the message is being processed, and does not retransmit until the long RTO (*"pathlet RTO"*) is triggered. When the pathlet finishes message processing and sends all the segments out, it sends a pathlet transmit ACK, or *PTX ACK*, to the sender, indicating that the message has left the pathlet. Upon PTX ACK, the sender restarts the short RTO timer for timely retransmission for fabric drops.

Loss of PRX and PTX ACKs does not impact correctness, since the sender always maintains one RTO timer and will retransmit upon timeout until eventually getting the E2E ACK for the message. We prioritize PTX and PRX ACKs, as well as the E2E ACK in the network so that they are rarely dropped.

Configuring the RTOs. With the pathlet ACKs, the fabric RTO can be set to the fabric RTT between the furthest hosts in the network under heavy congestion (i.e., a few hundred μs [43]), plus the message serialization delay, to prevent false positives, because such delay is nearly the worst case between the sender/any pathlet and the next pathlet/receiver. For generally underutilized networks or latency-sensitive messages, the fabric RTO can be set shorter but this risks spurious retransmissions under sudden congestion.

The pathlet RTO should be set to cover the processing delay and the buffering time under pathlet congestion, which is known to the pathlet owner and distributed with the SDP (§3.2), plus the message serialization delay. In practice, though, assuming the message is seldom lost once buffered by a pathlet, the pathlet RTO can be set loosely.

5.2 Exactly-Once Guarantee

Most applications are programmed under the assumption that the transport delivers a message to the receiving application exactly once, and it is important that MTP provides the same semantics. However, MTP's receiver design (§4.2) so far does not guarantee this. Suppose a message is successfully delivered to the receiving application, the MTP receiver removes the message descriptor from the connection state, and the E2E ACK is then dropped; the sender times out and retransmits the whole message. When the duplicate message arrives, the MTP receiver cannot realize that the message is duplicated, and will deliver it to the application again.

Challenge. For the receiver to detect and drop duplicate messages, it must track some state about the delivered messages.

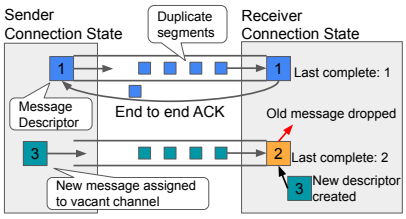

Figure 3: **Workflow of virtual channels.**

The approach must only occupy constant space so as not to exacerbate the connection state scalability issue in datacenters [37].

A strawman is to leverage a fixed-sized window with the lower bound representing the highest message number below which all messages are received and use a bitmap to represent message numbers received within the window. However, when messages can be heavily reordered like in an INC-enabled DCN, a slow-arriving head-of-line (HoL) message can block the window's stepping forward, preventing messages beyond the window from being processed.

Virtual Channels. We devise a scheme called virtual channels[3] to track the delivered messages, which uses constant per-connection state, and is tolerant to reordering. A virtual channel (Figure 3) essentially represents the correspondence between the sender-side state of a message and its receiver-side counterpart. Each inflight message uses a separate virtual channel, and each connection maintains a fixed number of virtual channels (the figure shows 2).

This scheme prevents the delivery of duplicate messages to the application. Each virtual channel maintains the last message number fully received. Suppose the E2E ACK from the receiver is lost, the sender retransmits the message (upper channel in the figure). Note that the message remains in the channel upon RTO. The receiver checks the message number specified in the packets against the last message number. If they are the same, or the just-received segments bear a smaller message number, then the just-received segments are duplicates of the last fully received message. The receiver drops them and retransmits the E2E ACK. On receiving the E2E ACK the sender removes the message state from the channel, which then becomes vacant.

When a new message comes from the application, the sender assigns it to a vacant virtual channel (lower channel in the figure). The virtual channel starts transmitting segments when CC provides the pathlets to use and clearance to send. When the receiver obtains the first arrived segment of the new message, it finds that a new message has arrived because the packet bears a greater message number than its last message number for this virtual channel, then it removes the state of the last message and creates the state of the new message.

This scheme can tolerate high degrees of reordering because each virtual channel independently performs message transfer, and the connection makes progress as long as one channel does. The number of virtual channels determines the maximum number of inflight messages and is communicated during connection establishment. Generally, this number should be set to allow at least one BDP of messages in flight to sustain the line rate. For example, with 4KB messages and a network of 40μs RTT (including the usual processing time of offloads) and 100Gbps line rate, $\sim$122 virtual channels should achieve the line rate.

[3]We use this term differently from existing works where it refers to the multiplexing of the physical interconnect in a computer [18, 39].

6 Congestion Control

MTP provides for congestion control algorithms (CCAs) a framework that consists of two mechanisms, per-pathlet early congestion feedback and per-message pathlet selection (§4.1). We now demonstrate how one can build an effective congestion control solution for INC-enabled DCNs combining these mechanisms with existing ideas for congestion control [8, 43, 67, 77].

6.1 Using MTP's Congestion Feedback

To leverage MTP's per-pathlet congestion feedback, it is important to unify the semantics in which different pathlets express their congestion conditions: Unlike network links, pathlets have vastly different implementation details and performance characteristics, based on which programmers may tend to expose distinct congestion information for each pathlet; however, doing so would require many different CCAs to interpret all the feedback, which is impractical. Also, mixing different CCAs for different pathlets on a path may cause interference among the CCAs.

To this end, we observe that in an INC-enabled DCN, each offload must maintain some sort of logical buffer or queue to temporarily store the pending workload for work conservation, and the buildup of the buffer or queue indicates offload congestion. Therefore, we can use 8 bits to map the pathlet queue or buffer occupancy to 256 quantiles. This is extending the existing idea of 2-bit queuing encoding [77]. The 8-bit encoding is then communicated to the sender with MTP's dedicated congestion feedback packet.

We then employ the Swift CCA to act on the pathlet feedbacks, inspired by how it has been used for endpoint congestion [14]. Swift [43] is a datacenter CCA that is highly effective, achieving very low loss rates at high loads, and deployed in production. It naturally fits because it reacts on RTT measurements, which are multi-bit indirect proxies of the queuing condition that MTP now directly provides, and because it is the state-of-the-art CCA based on multi-bit feedback. Our adapted algorithm essentially adjusts the congestion window (`cwnd`) based on the buffer occupancy feedback to maintain the occupancy at a moderate target level to achieve work conservation without overflowing, which is detailed in Appendix C with parameters we adopt in evaluation.

MTP maintains per-pathlet `cwnd`s and updates them in-

dependently to avoid conflicting feedbacks from different pathlets. It also uses a separate `cwnd` for link congestion. The receiver or next pathlet that provides feedback immediately reflects a marked CE bit to the sender in feedback packets. A message is only "cleared to be sent" when all pathlet `cwnds` and the link `cwnd` have sufficient room.

6.2 Proactive Pathlet Switching

So far we have assumed that all messages of a flow use the same sequence of pathlets. However, recall that the network can provide alternative instances of the same pathlet type (§3). It has been shown that mapping a flow to a fixed set of network resources, though the resources might be randomly chosen with approaches like ECMP, can result in hotspots [67], where many flows are mapped to the same resource, leaving alternative resources underutilized. In an INC-enabled DCN, pathlets are also resources that can become hotspots.

Therefore, it is important to enhance the CCA with the capability to resolve hotspots, which may further improve resource utilization. To that end, we complement our CCA with a mechanism called *proactive pathlet switching (PPS)*. The idea, inspired by PLB [67], is simple: When congestion at a pathlet cannot be quickly resolved by the CCA, which implies that the resource is likely a hotspot, the flow should be steered to use an alternative pathlet. Specifically, PPS monitors the congestion state of pathlets: If congestion causes the CCA to fail to decrease the buffer occupancy reflected in the multi-bit feedback of a pathlet below a threshold for some time, then PPS randomly chooses a pathlet from all the same-type pathlets provided by the DCN for future messages (Line 14 in Algorithm 1 in Appendix C). This is enabled by per-message pathlet selection.

7 Implementation

Our implementation has two types of components: an MTP stack that runs on end-hosts, and wrappers for making L7 offlaods MTP-compatible.

MTP Stack: We used DPDK [23] to implement an MTP stack prototype for testbed experiments. The prototype adopts a queue pair (QP)-based API (resembling RDMA's verbs [57]) for applications to communicate with the MTP stack. The MTP stack prototype is a process, similar to the Snap userspace networking system [56]. However, this is not fundamental, and the MTP stack could also be implemented as a library, in the kernel, or offloaded to the NIC.

Different from RDMA, the MTP stack prototype is a process, which, unlike the NIC, cannot access arbitrary memory in the application. Therefore, when creating the QP, the MTP stack also creates two shared memory regions, one for outgoing (TX) message bodies and one for incoming (RX), and the application maps the shared message body region to its address space. These memory regions are asynchronously accessed by both the application and MTP. To receive a message, the MTP stack must allocate space from the RX region to accommodate the message body; meanwhile, the occupied space of a message can only be freed by the application when it finishes using the received content, and vice versa for sending a message. The freeing of message space is not necessarily in the same order as allocation due to, for example, the reordering of messages. We implement a lock-free memory allocator to efficiently support this.

We encapsulate the MTP API into a shared library called `libmtp`, and implement a message generator that works with this library for evaluating MTP. The MTP stack, `libmtp`, and the message generator add up to ∼6K lines of C/C++ code.

Wrapper and Reference Offload: To allow commodity off-the-shelf L7 offloads to work with MTP, we implement our own MTP-compatible reference message processing wrappers, for complex L7 offloads or "middleboxes". The wrapper is implemented over DPDK with the ability to generate PTX and PRX ACKs, as well as providing early congestion feedback. We assume that routing packets from/to the middlebox is handled by separate switching logic in the INC hardware.

One key challenge is in efficiently utilizing the middlebox's buffer: With the assumption of full buffering, the middlebox cannot start processing a message until all segments have arrived. When one segment is dropped, the received segments occupy the buffer until retransmission comes. During this time other messages that would have been received in full might be dropped due to the lack of space. Our insight here is that a partially received message can be removed if the missing segments don't arrive within a short timeout. This is based on the protocol design that MTP messages are always sent in full and one can expect that the gap between packets of a message is predictable, only subject to serialization and fabric queuing delays. In our experiments, we conservatively set the receive timeout to 100μs.

To aid in our experiments, we embellish the middlebox wrapper with NetCache (§8.1) and a reference L7 offload. The reference offload emulates configurable processing time and buffer size. It reassembles message segments received from the wrapper, adds processing delay, segments the processed message and sends the segments out through the wrapper. This reference middlebox (wrapper and the reference offload) takes 600 lines of C code.

8 Evaluation

We first perform an end-to-end evaluation with NetCache [35] an existing INC application, showing that MTP improves its performance (§8.1). Then in §8.2, we carry out microbenchmarks on testbed to evaluate the two major design aspects of MTP that accommodate pathlet *delaying*: the pathlet ACK-based dual-RTO design for the reliability protocol, as well as MTP's congestion control that consists of pathlet feedback and proactive pathlet switching. We also study the overheads of pathlet ACKs. After that, we use large-scale simulation in

§8.3 to evaluate MTP's support for message reordering (at DCN scale), mutation, and intercept compared to alternatives.

8.1 Application Benchmarks

We adopt NetCache [35], a programmable switch-based key-value cache offload for this experiment. We run the NetCache client on one node in our testbed and run the NetCache backend server on another node. Each node has a Intel Xeon 1.8GHz 16-core CPU and 64GB DRAM. The two nodes are interconnected with 25Gbps Ethernet via a Tofino-based switch which runs the cache offload. We focus on read operations . As per our workflow, the vanilla client (which is also our baseline) encapsulates each read request RPC into a UDP packet toward the cache offload. For cache hits, the cache directly appends the value to the packet and sends it back to the client, and for cache misses, the offload forwards the requests to the backend server. The client recovers from losses of RPCs by retrying after a timeout, similar to key-value cache RPC in production [73]. The MTP-based client achieves the same workflow by establishing a connection to itself via the cache and backend, which are two *chained pathlets* in the path of this connection, and encapsulating each RPC into an MTP message. In this workflow, the messages are *mutated* with the appended values and can be *reordered* due to the cache's direct reply. Loss recovery is provided by the MTP stack.

The backend is allocated a single CPU core which runs at ∼1 Mops, and we use a query pattern of 50% hit rate, with which the system should be able to achieve a maximum throughput of ∼2 Mops. We add to both the cache and backend MTP header parsing logic, as well as to the backend pathlet feedback logic that reflects the RPC queue occupancy. We set both the UDP-based retry timeout and MTP RTO to 125μs, which is ∼25 times the RTT to the backend server. Note that this setup doesn't require dual RTOs for MTP because the delays at both pathlets are predictable.

We let the client generate read operations in an open-loop manner at variable percentages of the max throughput with Poisson inter-op arrival pattern, and observe the achieved throughput and tail op latency, as shown in Figure 4. The MTP-based client can sustain over 95% of system throughput whereas the UDP-based client starts falling below the offered load at 80%. Also, the MTP-based client sees no more than 4x p99 op latency relative to that at zero load, while the tail latency skyrockets with the UDP-based client starting from 75% load. This is because at high loads, the UDP-based client overflows the server and causes huge amounts of spurious retransmission (center figure) that wastes the server throughput, and this is not the case with MTP that provides pathlet CC, which limits the RPC buildup and results in negligible drops and retransmissions. At lower loads, the latency of the MTP-based client is slightly higher due to the extra processing of the MTP stack. Such a delay is necessary and inevitable in providing transport functions, including reliability and congestion control [33, 38, 58, 71].

Component	UDP-Based	MTP-Based
Cache (P4)	618	687
Client (C++)	825	423
Backend (C++)	323	323

Table 1: **Lines of code comparison between UDP-based and MTP-based NetCache components.**

Integration Cost. MTP is of low cost to integrate. Table 1 shows the lines of code (LoC) of UDP- and MTP-based NetCache components. MTP-based cache adds, in addition to the UDP-based, 69 lines of P4, which mainly includes the MTP header definition and parsing logic. The additional Tofino resource consumption is negligible with only 0.3% more crossbar and 2.3% more gateway usage. The MTP-based client is of much fewer LoC than UDP-based because the MTP-based client does not need the timeout-retry logic, which along with DPDK setup is handled by the MTP stack. Also, `libmtp` is light-weight to use. The MTP-based backend uses the same LoC as UDP-based: Coding packet IO with the MTP middlebox wrapper is of similar complexity to DPDK.

8.2 Microbenchmarks

For microbenchmarks we use CloudLab [21] as our testbed. We use nodes with AMD EPYC 3.0GHz 16-core CPUs and 128GB DRAM interconnected by 25 Gbps Ethernet. We place our reference middleboxes on the path between the network interface and the MTP stack emulating SmartNIC processing cores [52, 54]. We assign each middlebox on a dedicated CPU core. Packets that arrive at the host are first handled by the middlebox, which assembles the message and, after processing time, re-packetizes the processed message, and transmits the packets to the MTP stack via a ring buffer.

Though MTP makes no assumption on pathlets' service times, we evaluate MTP by making the middleboxes emulate two commonly-studied long-tail service time distributions: exponential and bimodal [19, 24, 36, 51, 54, 66].

8.2.1 Dual RTOs with PTX and PRX ACKs

MTP adopts PTX and PRX ACKs to determine whether the message is being buffered and processed by a pathlet, which enables using dual RTOs to detect fabric drops ("fabric RTO") and failures of message processing pathlets ("pathlet RTO"). We show the benefits of this with a testbed experiment.

We use our message generator (§7) to issue a flow of 128KB messages from one node to another in a closed loop. The receiver node enables our reference middlebox. The processing time is drawn from either an exponential distribution with a mean of 100 μs, or a bimodal distribution of a similar mean with 95%-ile of 50μs and 5%-ile of 1 ms. The receiver randomly drops 1% of the incoming packets from the interface, which is equivalent to fabric drops from the middlebox's and MTP stack's points of view.

Figure 5 (left) shows a comparison of goodput with a single per-message end-to-end RTO versus with dual RTOs based on

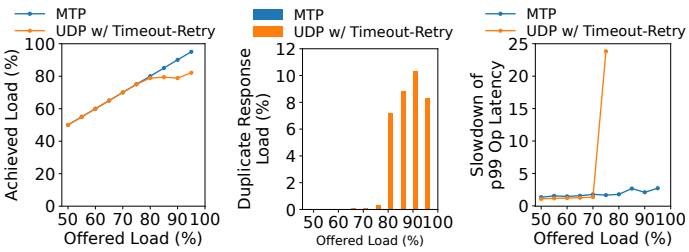

Figure 4: **Left, Center: achieved throughput and retransmission rate as percentage of system throughput, respectively; Right: p99 op latency slowdown relative to unloaded op latency.**

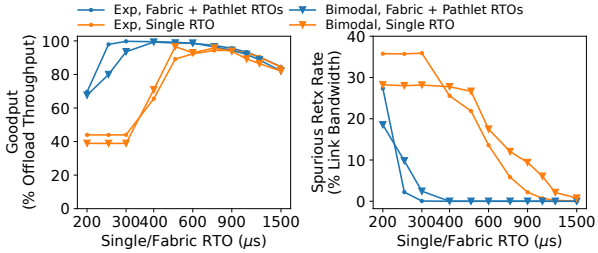

Figure 5: **Achieved throughput with respect to RTO (left) and spurious retransmission rate at the reference middlebox (right).**

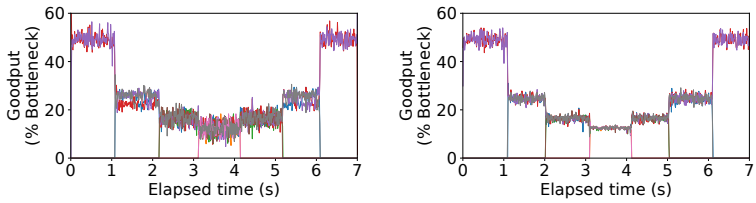

Figure 6: **Convergence under exponential pathlet processing time distriburion with legacy (left) and MTP (right) CC.**

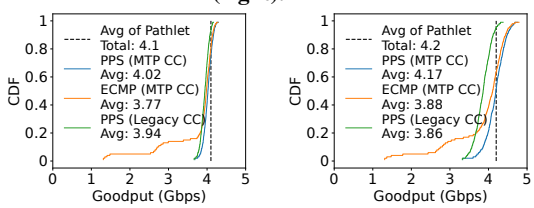

Figure 7: **Per-10ms total goodput with exponential (left) and bimodal (right) pathlet processing times.**

PTX and PRX ACKs. When dual RTOs are used, the X-axis is the fabric RTO because it is in effect as we set the pathlet RTO loosely to 4 ms.

Generally, both overly short and long RTOs cause goodput degradation. Long RTOs impair the sender's ability to quickly recover from losses. Short RTOs cause false positives, where the sender retransmits the messages when they are actually not lost. The right figure shows the rate of packets received at the offload that are spurious retransmissions (or "false positives") and hence dropped. The middlebox determines that a packet is a false positive if it has buffered the same packet of the same message. The message can be pending for processing (received in full), being processed, or waiting for other packets to arrive. We find that MTP's dual RTO design leads to a wider range (400-1050 μs) of fabric RTO choices where MTP achieves >90% goodput with zero false positive (hence no waste of link bandwidth) for both processing time distributions because the PRX and PTX ACKs allow the fabric RTO to not account for the middlebox's unpredictable processing time, whereas such range does not exist for single RTO.

8.2.2 Congestion Control

We compare MTP's CC solution with early multi-bit pathlet feedbacks, reacted by Swift-inspired CCA and PPS, to a legacy solution, where pathlets provide legacy ECN feedback, marking the CE bit in packets when they are congested (>50% buffer occupancy), and the receiver reflects the per-packet ECN back to the sender. We use DCTCP [8] to react on the ECN.

Convergence. We start 8 flows, 2 at each time, of 4KB messages from 4 sender nodes towards one receiver node that has a bottleneck middlebox. We configure the middlebox such that the processing time is drawn from either a exponential distribution averaging 12 μs or a bimodal distribution of 95% 6 μs and 5% 120 μs. The middlebox has a 32KB message buffer, which is roughly 4 times the bandwidth-delay product (BDP). Messages go through this middlebox before entering the receiver MTP stack.

Figures 6 compare how MTP flows converge based on the legacy and MTP's CC solution under exponential processing time distribution. The results for bimodal distribution can be found in Appendix D.1. Each line in the figures represents the throughput of a flow averaged every 10 ms. Most notably, as more flows share the middlebox, legacy CC fails to converge whereas MTP stably converges to a fair share. Early and multi-bit pathlet feedback allows MTP to perform AIMD based on the extent of congestion collected from each feedback than having to wait for at least a round trip to collect and smooth the congestion signals as with single-bit ECN [8].

Proactive Pathlet Switching (PPS). We show how PPS improves performance in addition to congestion control. We use a similar topology as above, with additionally a secondary middlebox of the same type on another node, and provide it to the sender-side MTP stack as an alternative pathlet. We configure the two middleboxes to be asymmetric such that the "secondary" incurs either exponential processing times of 24 μs or bimodal of 95%-ile 12 μs and 5%-ile 240 μs. We generate 4 closed-loop flows, all initially towards the "primary" pathlet, and expect PPS to distribute the flows across both pathlets. PPS randomly chooses a middlebox if the buffer occupancy is above 60% for 3 consecutive feedbacks (MTP CC) or round trips (legacy CC). We use ECMP as a baseline and rehash the flows every 100 ms.

Figure 7 shows the cumulative distributions of the total application-observed throughput every 10 ms. The achieved throughput can at times exceed the total of the pathlets' average throughput because of the long-tail processing time distributions. We find that for both distributions MTP with

PPS can achieve a total goodput that is ∼98% of the average total throughput of the two pathlets, whereas with ECMP can only achieve ∼90%. This is because PPS can quickly redistribute the flows based on congestion, despite random choice having a small chance of mapping all flows to the same pathlet, whereas ECMP cannot recover from such collision until next rehashing. The legacy CC combined with PPS achieves slightly lower average throughput than MTP due to the previously shown convergence problem.

This subsection shows that our CC solution based on MTP's primitives is effective in the face of typical processing time distributions, and we also evaluate MTP's CC with multiple pathlets in Appendix D.2. However, this is not necessarily the only possible way to use the primitives, and it is not our goal to innovate on the CCA. There are known limitations to DCTCP that have been addressed by other CCAs [11,15,25,27,50,60,61]. We leave a systematic study of CC for INC to future work, noting that the similar approaches to evolve from DCTCP may also be used to improve the CC performance in MTP.

8.2.3 ACK Overheads

MTP leverages PTX and PRX ACKs to communicate message states in the network and pathlet feedbacks, in addition to the E2E ACKs. These extra packets can impose overhead on both link bandwidth and the endpoints' processing. We quantify such overhead with an experiment, where one sender node sends messages to one receiver node in a closed-loop manner, with varying numbers of pathlets in between, as well as different message sizes and enabled ACK types (pathlet ACKs + feedbacks vs. feedbacks only). We use 2 CPU cores for the MTP stack in this experiment.

Figure 8 shows the percentage of link bandwidth consumed by ACK packets. The 0-pathlet bars reflect the overhead of E2E ACKs only. In general, the ACK bandwidth overhead is linear in the number of pathlets and the inverse of message size. This is expected because each pathlet ACKs on a per-message basis. Enabling both pathlet ACKs and feedbacks incurs around twice the bandwidth consumption of feedbacks only, because with the former, each pathlet ACKs twice (PRX, piggybacked by feedback, and PTX) per message, whereas with the latter the pathlet sends back only one feedback packet for each message. The worst case occurs with MTU-sized (4KB) messages, 2 pathlets and with both pathlet ACKs and feedbacks enabled, using 6% of link bandwidth, which is negligible. Note that most (if not all) existing L7 INC works place two or fewer pathlets in a path.

Figure 9 shows a breakdown of CPU cycles spent by the sender-side MTP stack with MTU-sized messages, as percentages of total CPU cycles. The total height of a bar represents the total cycles spent on the receive (RX) routine, which consists of four parts: 1) congestion control update (blue), which runs the CCA upon feedback; 2) message state update (orange), which resets the timer and switches between the fabric

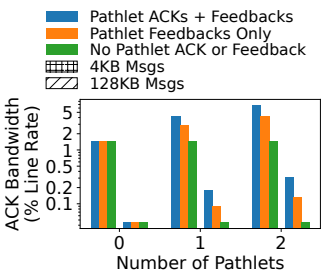

Figure 8: **Link bandwitdh overhead of MTP ACKs.**

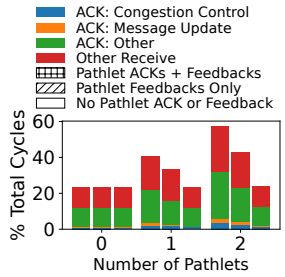

Figure 9: **Sender MTP stack CPU cycle breakdown.**

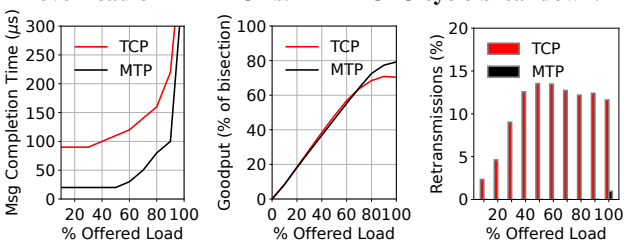

Figure 10: **Left: p99 message completion time; Center: average goodput achieved across the network; Right: retransmissions as percentage of the flows' original packets.**

and pathlet RTOs; 3) other ACK handling (green), which includes updating statistics and preparing CC input from statistics (pathlet feedback, ECN, etc. within a round trip); and 4) other RX logic (red), which involves packet header parsing and connection state lookup. Similar to link bandwidth usage, more CPU cycles are consumed with more pathlets and pathlet ACKs enabled, which incur higher ACK rates. Nonetheless, with 2 pathlets, the total CPU usage of RX is around 55%, still allowing the transmit logic to saturate the 25Gbps link. This is of higher throughput and message rate than some of the well-optimized user-space TCP [33] and software RDMA [58] stacks with the same number of cores.

In comparison, UDP does not have ACKs and hence does not incur similar bandwidth and CPU overheads. However, UDP also lacks essential transport functions such as reliability and congestion control. Building basic reliability upon UDP requires at least end-to-end ACKs which will incur overhead similar to MTP in the 0-pathlet case.

8.3 Large-Scale Simulation

To study MTP's support for reordering at scale, we use ns-3 simulations [7]. We simulate a fat-tree topology with 128 nodes with an over-subscription factor of two. We use 100 Gbps links with varying delays to model asymmetry—50% of aggregation-core links have a delay of 2 μs and the rest have a delay of 4 μs. The switches have a buffer size of 975 KB per port,which closely matches datacenter switches.

We generate *all-to-all* traffic with one-packet messages of 1 KB and a flow size of 1 MB. We use TCP as a baseline, and both TCP and MTP use the DCTCP [8] for congestion control (recall that MTP uses DCTCP for link congestion).

We leverage packet spraying to induce message reordering at scale (our messages are one-packet), instead of simulating L7 offloads. The reordering is exacerbated by the difference in path delays in our fat tree. Results are shown in Figure 10.

The left figure shows the 99%-ile message completion times with respect to load, and the center figure shows the goodput. MTP reduces tail message completion times by about 65% (speed up of 3.6x) across all loads. MTP is also able to operate at higher loads (i.e., beyond 80%) without saturating whereas TCP saturates saturates earlier (i.e., after 60% load).

To understand why MTP's performance is better, the right figure show the number of packet retransmissions as a percentage of the flows' original number of packets. We observe that TCP suffers from 10–15% packet retransmissions and MTP nearly eliminates such overhead as it is robust to reordering. Also, TCP saturates at around 60% load, so the percent of retransmitted packets does not increase after 60% as many flows do not finish and get backlogged indefinitely. We believe this is because MTP can precisely respond to congestion using per-message signals and not misinterpreting reordering as drops or congestion. Further, we show MTP's operation with message mutation and intercept in Appendix E.

9 Discussion

In this section, we discuss the problems that may arise when applying MTP to real-world production scenarios, and the potential approaches to tackle them.

Scalability. In §8.2.3, we have shown that MTP's ACK packets incur reasonable overhead, to both link bandwidth and CPU, with up to 2 pathlets. Though we have argued that this is the case with most existing L7 INC works, more pathlets may be required in a path with the emergence of more INC ideas, or with the mixing of offloads from different applications, which can result in higher ACK overheads. One potential approach to optimize the ACK overheads is reducing unnecessary ACKs. In our experiments, when the dual-RTO mechanism is enabled, all messages would trigger PTX and PRX ACKs. This is not always necessary if the pathlet's processing delay is short most of the time, in which case the pathlet can start sending pathlet ACKs only when long delay is imminent. Similarly, not all messages need to trigger congestion feedback, especially when the pathlet is not heavily loaded. Also, the CPU overhead of ACKs can be mitigated by offloading the MTP stack onto a dedicated ASIC, similar to RDMA.

Streaming. MTP does not natively support streaming, because doing so requires storing transport state in the pathlet for handling losses and out-of-order arrival of data segments, which would complicate MTP and prevent some offload hardware from supporting it. Nevertheless, pathlets that need streaming can first have the sender break down the stream into single-packet MTP messages. MTP can provide reliable per-message delivery and congestion control, on top of which reordering mechanisms can be implemented at the pathlets and endpoints.

Security. Though out of our scope, security remains an open problem for, not just MTP, but INC in general, because INC involves examining and tampering with packet payload by the network, which is exactly what today's transport-layer security (TLS) strives to prevent. In an effort to resolve this, mcTLS [62] extends data privacy and integrity to middleboxes and enables explicitly controlling each middlebox's read/write access to the data being transferred. It may be complementary to MTP and provide similar security features: MTP's handshake can be amended with a similar key exchange, and a TLS record naturally fits in an MTP message. We leave further investigation into security issues to future work.

10 Other Related Work

There is a significant amount of recent research on developing new CCAs, including pHost [25], ExpressPass [15], NDP [30], Homa [61], dcPIM [13], HPCC [50], PINT [11] and BFC [27]. MTP is intentionally designed to be orthogonal and complementary to these new algorithms as datacenter operators can switch between CCAs. For example, MTP's pathlet feedback may be leveraged to communicate the "clearance to send" in receiver-driven CC [13, 15, 25, 30, 61], or it can be seen as a form of in-band network telemetry which has enabled more precise CC [11, 50]. We leave the study on applying more CCAs to MTP to future work.

The idea of using pathlets for LB and CC in MTP is inspired by previous work that uses pathlets for inter-domain routing in the Internet [26]. MTP itself can be thought of as a practical realization of the classical application-level framing idea [16] applied to transport for INC-enabled DCNs.

11 Conclusions

This paper presents MTP, a new message transport protocol designed to work with INC. Through end-to-end testbed experiments, we found that MTP improves the performance of an existing INC application. We also showed that MTP provides effective reliable delivery and congestion control for INC through microbenchmarks and simulations. As INC adoption increases in datacenters, we believe that message-based transport protocols such as MTP that treat offloads as first-class citizens will become invaluable for scaling application performance.

Acknowledgements

A MTP Packet Header

Listing 1 shows the MTP packet header formats.

```
struct mtp_hdr_t {      // MTP header
  uint16_t src_port;    // source port
  uint16_t dst_port;    // destination port
  uint16_t len;         // length of this header and payload
  uint16_t checksum;    // packet checksum
  uint32_t msg_no;      // message number
  uint16_t seg_no;      // segment number within the message
  struct {
    uint8_t msg_ack : 1;   // E2E ACK
    uint8_t prx_ack : 1;   // PRX ACK
    uint8_t ptx_ack : 1;   // PTX ACK
    uint8_t feedback : 1;  // pathlet feedback follows
    uint8_t reserved : 4;
  } flags;
  uint32_t msg_len;     // total byte length of message
  uint8_t vc;           // virtual channel
}; // packed struct

struct mtp_feedback_t {  // MTP pathlet feedback header
  uint32_t pathlet_id;   // pathlet instance identifier
  uint8_t feedback;      // feedback value
}; // packed struct
```

Listing 1: MTP header formats.

B MTP Connection State

Table 2 shows the state maintained per connection.

Transmission (TX) Connection State	
`tx_msgs[]`	Message descriptors for TX, each containing a message number, message length, pointer to payload, next-to-send segment number.
`tx_vcs[]`	TX virtual channels, each containing a last message number and pointer to the occupying message descriptor.
`cc_state[]`	CC state for link and each pathlet, each piece containing a cwnd, cwnd occupancy and CCA-specific statistics (§C)
`lb_state[]`	LB state for each type of multi-instance pathlets, containing statistics for PPS (§6.2)
Receive (RX) Connection State	
`rx_msgs[]`	Message descriptors for RX, each containing a message number, message length, pointer to payload, and bitmap that marks received segments.
`rx_vcs[]`	RX virtual channels, each containing a last message number and pointer to the occupying message descriptor.

Table 2: **MTP Connection State.**

C MTP Congestion Control Algorithm

Algorithm 1 shows the implementation details of our Swift-inspired CCA.

D Additional Congestion Control Evaluation

D.1 Convergence

Figure 11 shows the convergence of per-flow goodput with legacy and MTP CC under bimodal pathlet processing time distribution. This time distribution does not cause severe fluctuation in goodput with many flows, even with legacy CC. Despite this, MTP CC still mitigates the divergence of legacy CC with 4 flows (1-2 and 4-5 seconds).

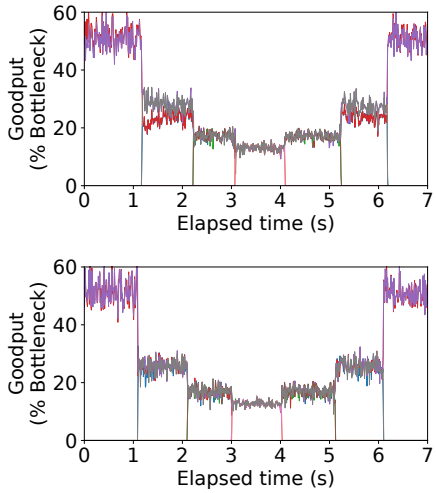

Figure 11: **Convergence under bimodal pathlet processing time distriburion with legacy (upper) and MTP (lower) CC.**

D.2 Multiple Pathlets

There can be more than one pathlet on a path, and it is important that MTP handles this. We evaluate MTP's CC with pathlet chains with different bottleneck locations. We use the topology in Figure 12, which represents a scenario where multiple paths share a bottleneck pathlet after some

Algorithm 1: MTP CC and PPS Algorithms

Data: $active_pathlet_{type} \forall type \in path$

Procedure on_rx_pathlet_feedback(*pathlet, feedback, msg_seg_num*)

```
    /* Update cwnd with Swift                                   */
    if feedback > 127 then
        cwnd_pathlet ← (0.4 + 0.6 · 128/feedback) · cwnd_pathlet
    else
        cwnd_pathlet ← (1 + msg_seg_num/(2·cwnd_pathlet)) · cwnd_pathlet
    end
    /* Decide whether to switch pathlet                         */
    type ← typeof(pathlet)
    if pathlet = active_pathlet_type ∧ feedback > 160 then
        high_congestion_count ← high_congestion_count + 1
    else
        high_congestion_count ← 0
    end
    if high_congestion_count = 3 then
        active_pathlet_type ← random(type)
        high_congestion_count ← 0
    end
```

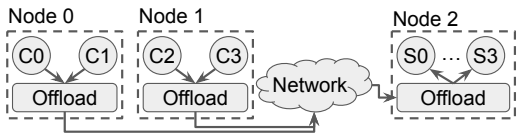

Figure 12: **Multi-pathlet topology. Two client processes on each of Node 0 and 1 send messages to a server process running on Node 2. Messages go through both client- and server-side offloads (pathlets). The bottleneck is the pathlet on Node 2.**

	Exponential (12 μs)		Bimodal (95% 6 μs, 5% 120 μs)	
CC	Avg	Stdev	Avg	Stdev
MTP	5.24	0.179	5.18	0.363
Legacy	5.30	0.360	5.04	0.544

Table 3: **Average and standard deviation of per-10 ms aggregate goodput in Gbps in chained pathlet topology.**

other pathlets. The offloads' processing times are drawn from distributions described in Table 3. We use the message generator as the client to generate 8KB messages (2 segments) in closed loops, set the offload buffer to 96KB, and configure the MTP stack to use MTP or legacy CC.

Table 3 shows the statistics on the total goodput across all flows for every 10 ms. We find that MTP and legacy CC achieve similar average goodput but the legacy CC yields 100% more standard deviation for exponential distribution and 50% more for bimodal distribution. This is due to the drawbacks of legacy end-to-end single-bit feedbacks, similar to the convergence problem discussed in Section 8.2.2.

E Simulation Results

We use a dumbbell topology to study MTP's operation with message mutation and intercept. The topology consists of 8 nodes on each of two sides of the bottleneck. All links are 10 Gbps and 10 μs.

Operation with Message Mutation. We make eight clients from one side send 4KB (4-segment) messages in a closed-loop manner to eight servers on the other side. We simulate

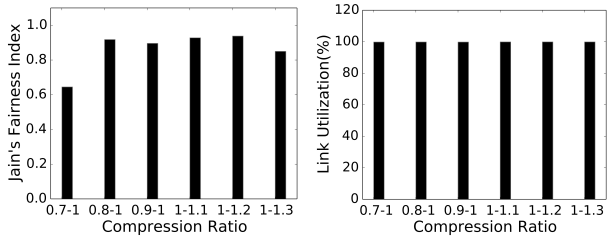

Figure 13: **MTP operation with mutation.**

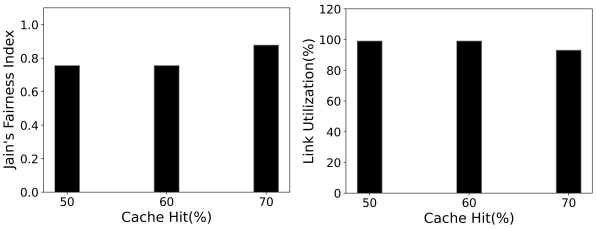

Figure 14: **MTP operation with intercept: fairness (left) & link utilization (right)**

an offload on the switch that (de)compresses data before the bottleneck link with an average processing delay of 2 μs. This represents not only compression engines in the real world but also other offloads such as HTTP load balancer that can change the message size [17]. The offload randomly chooses a compression ratio within a given range. A ratio > 1 means a decrease in message size.

Figure 13 shows the Jain's fairness index across all clients (left) and the utilization of the bottleneck link (right). We observe that MTP achieves good fairness as well as 100% utilization even as the offload decreases or increases the payload size by as much as 30%. However, fairness begins to deteriorate somewhat as the range expands beyond 20% (increase or decrease). We believe that this is due to DCTCP, which is not optimal for handling sudden data size changes in the network, and an optimized CCA for mutation is warranted, which we leave for future work. Note that TCP would fail to operate correctly in such cases.

Operation with Message Intercept. Using the above topology and workload we simulate an offload, which opportunistically intercepts a message. We vary the intercept rate from 50% to 70% (i.e., with 70% intercept rate, only 30% of messages will reach the dumbbell bottleneck). MTP remains unaffected by message intercept. We observe in Figure 14 that MTP achieves good fairness and full utilization of the bottleneck link even as the offload intercepts 50%–70% of messages. Both TCP and RDMA would fail to operate correctly in such cases.

ONCache: A Cache-Based Low-Overhead Container Overlay Network

Abstract

Recent years have witnessed a widespread adoption of containers. While containers simplify and accelerate application development, existing container network technologies either incur significant overhead, which hurts performance for distributed applications, or lose flexibility or compatibility, which hinders the widespread deployment in production.

We carefully analyze the kernel data path of an overlay network, quantifying the time consumed by each segment of the data path and identifying the *extra overhead* in an overlay network compared to bare metal. We observe that this extra overhead generates repetitive results among packets, which inspires us to introduce caches within an overlay network.

We design and implement ONCache (**O**verlay **N**etwork **Cache**), a cache-based container overlay network, to eliminate the extra overhead while maintaining flexibility and compatibility. We implement ONCache using the extended Berkeley Packet Filter (eBPF) with only 524 lines of code, and integrate it as a plugin of Antrea. With ONCache, containers attain networking performance akin to that of bare metal. Compared to the standard overlay networks, ONCache improves throughput and request-response transaction rate by 12% and 36% for TCP (20% and 34% for UDP), respectively, while significantly reducing per-packet CPU overhead. Popular distributed applications also benefit from ONCache.

1 Introduction

Containers [9, 21] are becoming increasingly popular for distributed application deployment due to their flexibility and lightweight nature. By bundling an application along with all its dependencies and configuration files into one container image, containers bring forth the ability to *build once and run anywhere*. Furthermore, containers leverage the host OS kernel instead of emulating an entire OS, and thus are more lightweight than virtual machines. Container orchestration tools such as Kubernetes [35], Docker Swarm [22], etc., further reduce container management complexity by facilitating features like auto-deployment, auto-scaling, and auto-high-availability [8].

Technology	Performance	Flexibility	Compatibility

Table 1: *Compare container networking technologies.*

Container networks play a key role in enabling communication between containers and supporting distributed applications. Ideally, a container network should offer low-overhead, high-performance networking while preserving flexibility and compatibility. However, none of the existing container networks fully satisfy these expectations, as outlined in Table 1.

Hurt flexibility. Containers in the host network share the host IP address and must coordinate ports on the host, constraining deployment flexibility. Bridge networks or device virtualization techniques (such as Macvlan/IPvlan/SR-IOV [64]) allow containers to have their own IP addresses and directly forward container packets to the underlay network. However, these networks require either all hosts to be in the same L2 network or the underlay network to be capable of routing container packets, imposing restrictions on container placement, migration, or network configuration.

Poor performance and high overhead. Container overlay networks utilizing tunneling techniques (e.g., VXLAN [41]) completely decouple containers and the underlay network, facilitating the configuration of container IP addresses regardless of the underlay network. Nonetheless, it incurs significant overhead [37, 38, 65, 74]. Our experiments show that compared to bare metal, the throughput of a single TCP flow in a tunnel-based overlay network is about 11% lower, with

the TCP request-response transaction rate being around 29% lower. Moreover, CPU utilization is much higher in both experiments. While certain techniques [36, 37, 59] endeavor to enhance overlay networks by distributing ingress packet processing across multiple CPU cores, the processing overhead of overlay networks remains significant.

Hurt compatibility. Slim [74] and its follow-up works [12, 39, 40] implement overlay networks via socket replacement, enabling containerized applications to utilize the host's sockets. While they maintain low overhead and some degree of flexibility in overlay networks, they do not inherently support non-connection-based protocols (e.g., UDP, ICMP) or container live migration. Additionally, they may conflict with tunneling-headers-based policies in the underlay network.

To attain high performance, flexibility, and compatibility at the same time, we design and implement ONCache (**O**verlay **N**etwork **Cache**), a container overlay network featuring a cache-based and low-overhead fast path. ONCache can be seamlessly integrated into existing standard overlay networks and has been tested with Antrea [1] and Flannel [28].

Our detailed contributions are summarized as follows:

1. We carefully analyze the kernel data path of popular container overlay networks (Antrea and Cilium) alongside bare metal, quantifying the time consumption of each segment of the overhead. Our analysis reveals the *extra overhead* incurred by container overlay networks. However, the overhead disperses across the kernel data path, presenting a significant challenge in mitigating it while preserving essential functionalities. (§2.2)
2. We identify the *invariance property* within the extra overhead, indicating that the processing results of the extra overhead are repetitive among packets. This property inspires us to use caches in overlay networks. (§2.4)
3. We propose a cache-based fast path for container overlay networks. The fast path bypasses the extra overhead without losing flexibility and compatibility. (§3)
4. We evaluate ONCache with microbenchmarks and popular distributed applications. Results demonstrate significant improvement of ONCache in throughput (12% higher with iperf3), latency (36% higher transaction rate), and CPU utilization (26% lower per-transaction) compared to the standard overlay networks, approaching performance akin to that of bare metal. Applications such as Memcached, PostgreSQL, and Nginx all derive benefits from ONCache. (§4)

ONCache's source code is publicly available at `https://github.com/shengkai16/ONCache`.

This work does not raise any ethical issues.

2 Background and Motivation

We analyze inter-host container networks, where overlay networks stand out for the superior flexibility and compatibility. After quantifying the detailed overhead of overlay networks and exploring recent efforts aimed at mitigating this overhead, we provide the motivation of ONCache.

2.1 Inter-host Container Networks

Container networks play a key role in facilitating communication among containers and with the external world. Below, we focus on inter-host container networks, which are classified based on the IP addresses utilized by *applications* and the *physical network*.

Both use host IP addresses. Host networks fall into this category. Containers within host networks share the host's network namespace and utilize the host's IP address. Host networks offer performance comparable to that of bare metal (where applications directly execute on the host) [65]. Nonetheless, host networks demand coordination of ports among containers residing on the same host, thereby substantially limiting application flexibility. This limitation renders host networks seldom used in production [66].

Both use container IP addresses. Bridge networks and device virtualization techniques, such as Macvlan, IPvlan, SR-IOV, fall into this category. In these networks, each container is assigned a unique IP address and is isolated from the host namespace. In bridge networks, all the containers are connected to Open vSwitch (OVS) [1], bridge [28], or similar entity, relying on them to forward packets to the physical network. Networks employing device virtualization techniques emulate multiple virtual interfaces with different IP addresses on each physical interface, with each virtual interface being attached to a container. These networks deliver performance akin to that of bare metal due to their simple data paths.

However, owing to their utilization of container IP addresses in the physical network, the above approaches exhibit poor flexibility. To route container IP addresses, one must either (1) place all hosts into one L2 network or (2) install and manage routing rules for container IP addresses within the physical network. These requirements impose constraints on container placement, migration or network configuration.

App uses container IP addresses and the physical network uses host IP addresses. Overlay networks fall within this category. In overlay networks, each container has its own IP address, and container packets are encapsulated using a tunneling protocol (e.g., VXLAN [41] or GENEVE [29]) before being transmitted to the physical network. Overlay networks completely decouple containers from the physical network, thereby ensuring flexibility for both. However, tunneling incurs extra overhead and hurts performance (see §2.2).

***Takeaway* #1** Overlay networks decouple applications from the physical network, allowing for application deployment without concern for physical network configuration, and vice versa. Given the superior flexibility of overlay networks, we focus on analyzing and improving overlay networks.

Table 2: *Overhead breakdown of different networks. All values, except for the end-to-end latency in the last row, are in nanoseconds. BM stands for bare metal. Ours, i.e., ONCache, is proposed in §3 and evaluated in §4. "*" denotes the extra overhead compared to bare metal. Due to the limitations of the measurement tool, there is an error of about 200 ns.*

2.2 Analysis of Overlay Network Overhead

Prior studies [37,38,65,74] have shown the poor performance of overlay networks. We further quantify the overhead of two common overlay networks: Antrea [1] (v1.9.0) and Cilium [13] (v1.12.4), in comparison with bare metal.

Our analysis of the networks follows these steps. First, we qualitatively deconstruct the egress and ingress data paths using flame graphs [27], which provide comprehensive function call stacks on the data path. Next, we identify the exact functions (alongside their call stacks) that represent each segment of the overhead from the flame graphs. Finally, we measure the execution time for each function using the extended Berkeley Packet Filter (eBPF) and subsequently calculate the execution time for each segment of the overhead. The detailed analysis method is provided in Appendix A.

Table 2 presents the deconstructed overhead and the execution time for each segment of the overhead. Each listed execution time is the average of all the timing samples within a 1-second 1-byte TCP request-response (RR) test. We primarily analyze the overhead within bare metal and Antrea ("*" denotes the extra overhead compared to bare metal), while the distinct overhead within Cilium is also discussed. ONCache (ours) is analyzed in §4.

Application network stack. The application network stack directly interacts with applications. On the egress path, the application writes data to the socket. The application network stack then allocates a socket buffer (i.e., skb) for the data and encapsulates the packet layer by layer. Conversely, on the ingress path, the network stack decapsulates the headers and releases the socket buffer. Additionally, netfilter [47] filters packets on both the ingress and egress paths. Conntrack [18], as a component of netfilter, tracks connection (not TCP connections, defined by, for example, 5-tuple: source IP address, source port, destination IP address, destination port, and transport protocol) states and facilitates stateful filters to address probes and denial-of-service attacks. The execution of netfilter and conntrack depends on the system configuration.

Veth pair*. Containers run applications within individual network namespaces and employ veth pairs [69] to connect with the host namespace. Traversing veth pairs incurs overhead, which includes transmit queuing on the sender veth and software interrupt scheduling on the receiver veth. In Cilium, although the overhead of traversing veth pairs can be mitigated on the ingress path through bpf (Berkeley Packet Filter) redirect [71], it still exists on the egress path [17].

OVS*. OVS filters packets and intra-host routes packets between containers and the host interface. These filtering and routing actions are described by flows. The overhead in OVS can be categorized into connection tracking, flow matching, and action execution. Despite OVS employing a cache to expedite flow matching [53], connection tracking still consumes a substantial amount of CPU time. Cilium implements similar functionalities as OVS in eBPF [16]. However, the overall eBPF execution time is similar to that of OVS.

VXLAN[1] network stack*. The VXLAN network stack performs egress and ingress routing for VXLAN packets and encapsulates or decapsulates the outer headers (including VXLAN header, UDP header, IP header, and MAC header) to or from the packets. In Antrea, VXLAN routing is accelerated by OVS, resulting in notably low routing overhead. Additionally, conntrack tracks connections, and netfilter filters packets at this stage.

Link layer. On the egress path, the link layer queues and transmits packets to the network; on the ingress path, it allocates socket buffers and receives packets from the network.

***Takeaway* #2** The *extra overhead* in overlay networks, in-

[1]We take VXLAN as an example in following discussion. The analysis is similar for other tunneling protocols.

cluding veth pair, OVS (or similar entity), and the VXLAN network stack, incurs significant overhead and degrades network performance. Given its dispersion across various parts of the data path, mitigating the overhead while preserving essential functionalities presents a significant challenge.

2.3 Related Works on Overlay Networks

There are some recent efforts that aim at improving the performance of overlay networks.

Socket replacement. Slim [74] introduces a socket replacement mechanism that improves container overlay network performance. It establishes TCP connections in the host namespace and replaces TCP sockets in containers by those in the host namespace. While improving TCP performance, Slim exhibits notable limitations. Firstly, it does not support non-connection-based protocols such as UDP and ICMP, or container live migration, thereby constraining its compatibility. Secondly, Slim packets are not tunneling packets, which impacts underlay network policies that match on tunneling headers. Furthermore, Slim must establish an overlay connection for service discovery during connection setup, resulting in prolonged setup time. Some subsequent works [12, 39, 40] follow Slim's idea and improve connection setup time. However, they still suffer from the former two shortcomings.

CPU load balancing. Linux scaling techniques, such as Receive Packet Steering (RPS) and Receive Flow Steering (RFS) (and their hardware counterparts Receive Side Scaling (RSS) and Accelerated RFS (aRFS)) [59], improve performance by distributing ingress packet processing across multiple CPU cores and trying to reduce cache miss rate. Falcon [37] and mFlow [36] explore different strategies for distributing packet processing across multiple cores. However, they improve network performance at the cost of higher CPU utilization. Additionally, they only take effects on the ingress path and cannot further improve performance if the bottleneck lies in the egress path.

***Takeaway* #3** Despite many efforts to improve overlay networks, none of them simultaneously maintains low overhead, high performance, high flexibility and high compatibility.

2.4 Motivation: the Invariance Property

Based on the analysis in §2.2, we further classify the processing of the extra overhead into following types: connection tracking, packet filtering, intra-host routing, namespaces traversing and outer-header processing [2]. Among these overhead types, namespaces traversing does not yield any processing result, while the other four exhibit an *invariance property*.

Invariance in connection tracking. To the best of our knowledge, all common connection trackers (e.g., those in netfilter [2], OVS [51], Cilium [15]) have an established state, which signifies that the connection tracker has observed two-way communication of a connection. Once in the established state, the connection does not switch to another state until its completion.

Invariance in packet filtering. Packet filters can be classified into two types: stateless and stateful. Stateless filters only match on packet fields, typically the 5-tuple. Stateful filters also take into account the connection state, which is provided by the connection tracker. While OVS and netfilter contain numerous filters, the final decision to allow or deny packets with the same 5-tuple remains unchanged once the flow enters the established state.

Invariance in intra-host routing. If the container IP addresses are within the same subnet, layer-2 routing is enough, and the packet can be directly forwarded to the target interface. Otherwise, layer-3 routing is necessary and the MAC addresses should be modified before forwarding the packet. In both scenarios, the intra-host routing decisions are invariant for packets destined to the same container IP address.

Invariance in outer-header processing. On the ingress path, the outer headers are simply removed after checking fields such as destination and Time-to-Live (TTL). The correctness of the payload is ensured by the checksum of the inner headers. The egress path encapsulates the outer headers, whose most fields are related to routing and network configuration. On the same host, these fields are invariant for packets destined to the same container IP address: (1) The outer MAC header stores the MAC addresses, VLAN, and Ethernet type, which are invariant. (2) The IP addresses, protocol, TTL, differentiated services code point (DSCP), etc. in the outer IP header are invariant. Length, identification (ID), checksum fields vary among packets, but they can be easily updated with little computation. (3) In the outer UDP header, the destination port (VXLAN set to 4789), and the checksum (VXLAN set to 0)[3] are invariant [41]. The source port is calculated by simply hashing the 5-tuple of the inner headers. The length field can also be easily updated. (4) The VXLAN header stores the VXLAN network identifier (VNI), which does not change in an overlay network.

***Takeaway* #4** The extra overhead of overlay networks exhibits an invariance property. This observation motivates us to introduce *caches* to eliminate the extra overhead.

3 ONCache

ONCache is a container overlay network that offers a cache-based fast path with low overhead, high performance, flexibility, and compatibility. It is essentially a plug-in of standard overlay networks such as Antrea, Flannel. ONCache adopts a fail-safe design: when the fast path is unavailable, the traffic seamlessly falls back to the standard overlay network.

[2] If Kubernetes ClusterIP Service [62] is enabled, inter-host container traffic also needs Network Address Translation (NAT), as discussed in §3.5.

[3] While UDP checksum is necessary for certain tunneling protocols such as GENEVE, the computational overhead is low.

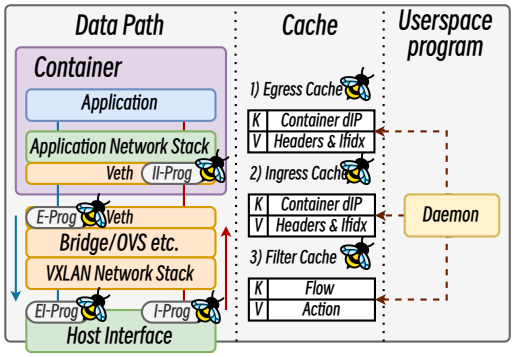

Figure 1: *Architecture of ONCache. ONCache consists of 4 eBPF programs in the data path, 3 eBPF maps, and 1 user space program. The components with the eBPF logo ("bee") represent eBPF programs or eBPF maps. dIP is short for destination IP address.*

eBPF Program	Abbr.	Hook Point
Egress-Prog	E-Prog	TC ingress of the veth (host-side)
Ingress-Prog	I-Prog	TC ingress of the host interface
Egress-Init-Prog	EI-Prog	TC egress of the host interface
Ingress-Init-Prog	II-Prog	TC ingress of the veth (container-side)

Table 3: *Hook points of the four eBPF programs.*

Define cache: Inspired by the invariance property discussed in §2.4, ONCache defines three caches—the egress cache, the ingress cache, and the filter cache—on each host to store the invariant results of the extra overhead. The detailed design of these caches is introduced in §3.1.

Initialize cache: ONCache relies on a standard overlay network to initialize the cache. In the event of a cache miss, ONCache passes the packet to the standard overlay network for processing and stores the processing results in caches if the packet's flow reaches the established state. See §3.2 for the detailed design.

Utilize cache: Upon a cache hit, ONCache filters the packet using the cached filtering results, constructs a tunneling packet using the cached outer headers, and then redirects the packet to the target interface by the cached routing decision. The cache-based fast path eliminates the *expensive* repetitive processing of *multiple layers*, as analyzed in §2.4, by several lightweight cache lookups. The detailed design is described in §3.3.

Maintain cache: ONCache ensures that the outdated cache entries are appropriately evicted when network-changing events (including container deletion, migration, and filter modification) happen. This is discussed in §3.4.

Cache compatibility: ONCache focuses on inter-host container networking and is also compatible with various traffic and features in the network. This is discussed in §3.5.

Optional improvements: We provide two optional improvements to further enhance performance. As they require kernel or tunneling protocol modifications, they are not applied as default designs. This is described in §3.6.

For ease of implementation and deployment, we implement ONCache with eBPF [24, 70]. eBPF is a technology that runs sandboxed programs within a privileged context like the Linux kernel, thereby safely and efficiently extending the capabilities of the kernel. eBPF programs are attached to kernel hook points (e.g., TC (traffic control) or XDP (eXpress Data Path) [31]) and are triggered each time the kernel executes through the hook points. eBPF stores data in a map data structure residing in kernel space, called eBPF map. Numerous prior works leverage eBPF for networking [4, 44, 56, 67, 72].

ONCache includes the following components, as shown in Figure 1: (1) four eBPF programs for packet processing and forwarding, with their hook points listed in Table 3; (2) three eBPF maps per host serving as the egress cache, the ingress cache, and the filter cache; (3) one user space daemon. The implementation of ONCache are much simpler compared to Slim and Falcon. The core functionalities can be realized with only 524 lines of eBPF C code, whereas Slim requires 2380 lines of code. Falcon, implemented with 606 lines of kernel code, is harder to implement and debug than eBPF. The core source code is shown in Appendix B.

Our idea diverges fundamentally from other cache-based network techniques. Prior works, such as OVS [53, 58] and Andromeda [20], leverage caches to accelerate flow/rule matching on their data paths. However, as analyzed in §2.2, the container overlay network remains suboptimal even with the utilization of the OVS cache, revealing the insufficiency of caching results of a individual layer. In contrast, ONCache is the first *cross-layer* cache within the container overlay network, which considers the extra overhead as a whole and caches the results once. Consequently, ONCache effectively eliminates the extra overhead compared to prior works.

3.1 The Cache Definition

ONCache contains three caches on each host, as shown in Figure 1: the egress cache, the ingress cache, and the filter cache. These caches are implemented using eBPF Least Recently Used (LRU) hash map, which evicts the least recently used elements to store new elements when the map is full.

The egress cache stores the outer headers and egress intra-host routing results, which are invariant for packets destined to the same container IP address. The routing results include the new inner MAC header (for L3 routing) and the egress host interface. To reduce the memory usage of the egress cache, we divide it into two levels: <*container destination IP address (dIP)* → *host dIP*> and <*host dIP* → *outer headers, inner MAC header, host interface index*>.

The ingress cache stores the ingress intra-host routing results, which are invariant for packets destined to the same container IP address. The structure of the ingress cache is <*container dIP* → *inner MAC header, veth (host-side) index*>.

The filter cache stores the filtering decision of each flow in the established state. Essentially, it functions as a flow whitelist, recording the allowed flows. By default, a flow is

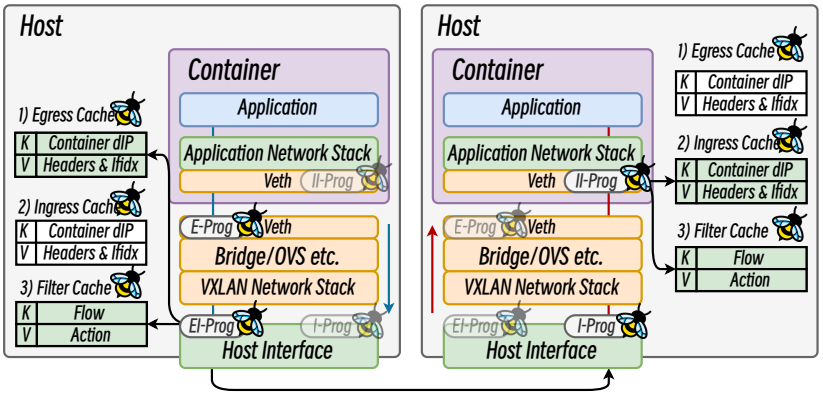

Figure 2: *The cache initialization process of ONCache. EI-Prog/II-Prog update the entries (green shaded) when the initialization requirements are met.*

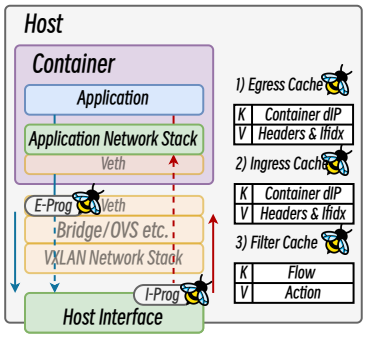

Figure 3: *Journey of an overlay packet in ONCache. EI-Prog/II-Prog are skiped over. The dash lines denotes the redirect path.*

defined by the 5-tuple (source IP address, source port, destination IP address, destination port, and transport protocol). One may also adjust the flow definition as required, e.g., adding a DSCP field to support DSCP filters.

In order to minimize cache misses, the capacity of the caches should be adjusted according to the cluster scale and concurrent flow number. Consider the largest cluster in Kubernetes [60], which has a maximum of 110 containers per host, 5k hosts, and 150k total containers. With up to 1M concurrent flows per host, to minimize cache misses, the egress/ingress/-filter cache will take up at most 1.56 MB/2.2 KB/20 MB of memory space per host, respectively (See Appendix C for details). This memory usage is negligible in modern servers.

3.2 Cache Initialization

If ONCache encounters a cache miss while trying to forward a packet, it will pass the packet to the fallback overlay network and try to initialize the cache meanwhile. The cache initialization process is depicted in Figure 2.

Initialize the Egress Path. When an egress container packet reaches the veth (host-side), Egress-Prog, which is hooked here, tries to forward the packet. If either the egress cache or the filter cache misses for the packet, Egress-Prog adds a *miss* mark to the packet. We reserve one bit within DSCP field of the inner IP header as the *miss* mark.[4] Egress-Prog then passes the packet to the fallback overlay network.

The fallback overlay network proceeds to forward, filter, and encapsulate the packet. Besides, we configure the overlay network to add an *est* mark to the packet if its flow reaches the established state. We use another bit in the DSCP field as the *est* mark. The aforementioned action only requires either minor adjustments to two OVS flow rules or the addition of one rule in netfilter, as detailed in Appendix B.2.

After being processed by the fallback overlay network, the packet reaches the host interface, where Egress-Init-Prog checks if the following requirements are met to initialize the caches: (1) the packet is a tunneling packet (e.g., a VXLAN packet); (2) the packet has the *miss* mark and the *est* mark.

If all requirements are met, Egress-Init-Prog initializes the egress cache by storing <*container dIP* → *outer headers, inner MAC header, host interface index*> into the cache. ONCache derives the host interface index from `sk_buff` struct, and the other fields from the tunneling packet. Additionally, the flow is whitelisted in the filter cache. Finally, the packet is sent out from the host interface.

Initialize the Ingress Path. Upon receiving a tunneling packet at the host interface, Ingress-Prog, which is hooked here, queries the cache and tries to forward the packet. If either the ingress cache or the filter cache misses for the packet, Ingress-Prog adds the *miss* mark to the packet and passes it to the fallback overlay network.

The fallback overlay network proceeds to process the packet, and add the *est* mark to the packet if its flow reaches the established state.

Then the packet reaches the veth (container-side), where Ingress-Init-Prog checks if the packet has both the *miss* and the *est* mark. If so, the program initializes the cache by storing <*container dIP* → *inner MAC header*> to the ingress cache and whitelisting the flow in the filter cache. <*container dIP* → *veth (host-side) index*> in the ingress cache is maintained by ONCache daemon upon container provisioning.

3.3 Cache-based Fast Path

We present the cache-based fast path of ONCache (Figure 3). The fast path is designed to be fail-safe and transparent to both applications and the underlay network. For packets that cannot be forwarded by the fast path, ONCache passes them to the fallback overlay network instead of dropping them.

3.3.1 The Egress Fast Path

The egress fast path is implemented by Egress-Prog, which handles an egress container packet in the following steps:

[4] We reserve 2 bits in total within the inner IP headers' DSCP field and require the network not to use these 2 bits for differentiated services.

Step #1: Cache retrieving. Egress-Prog first checks if the packet's flow is whitelisted in the filter cache and retrieves <*container dIP* → *outer headers, inner MAC header, host interface index*> from the egress cache. Any cache miss triggers a cache initialization process, as described in §3.2.

Additionally, Egress-Prog conducts a *reverse check* by verifying whether the container source IP address exists in the ingress cache and if the reverse flow is also whitelisted in the filter cache. If the reverse check is not satisfied, Egress-Prog passes the packet to the fallback overlay network. This is necessary because for a flow, the eviction of caches for two directions and the expiration of its conntrack entry are asynchronous. Utilizing the fast path only when caches for both directions are ready ensures that if any cache initialization is needed, conntrack can observe traffic in both directions and add *est* mark to packets, thereby ensuring the success of the initialization. See a counterexample in Appendix D.

Step #2: Encapsulating and intra-host routing. Having retrieved the egress cache, Egress-Prog proceeds to rewrite the inner MAC header and add the outer headers to the packet. Two modifications on the outer headers are needed: (1) Updating the length, ID, and checksum fields in the outer IP header, as well as the length field in the outer UDP header; (2) Calculating the outer UDP source port using the same hash function employed by the kernel. Finally, Egress-Prog invokes eBPF helper function `bpf_redirect` to redirect the packet to the cached host interface index.

3.3.2 The Ingress Fast Path

The ingress fast path is implemented by Ingress-Prog, which handles an ingress tunneling packet in the following steps:

Step #1: Destination check. Ingress-Prog first verifies whether destination MAC and IP addresses of the packet match with those of current host interface. TTL is also checked. If the destination check fails, the packet is then passed to the fallback overlay network for final decision.

Step #2: Cache retrieving. Then, Ingress-Prog checks if the packet's flow is whitelisted in the filter cache, and retrieves <*container dIP* → *inner MAC header, veth (host-side) index*> from the ingress cache. Any cache miss triggers a cache initialization process. Besides, the reverse check (described in §3.3.1) is also conducted on the ingress path.

Step #3: Decapsulating and intra-host routing. Ingress-Prog proceeds to strip the outer headers of the packet, rewrite the inner MAC header, and redirect the packet to the destination veth (container-side). The redirection is done by invoking the eBPF helper function `bpf_redirect_peer`.

Although the decapsulation of the outer headers is simplified in ONCache, no functionality is lost. Firstly, the payload is protected by checksums of the inner headers, which are verified by the container network stack. Secondly, the reassembly of fragmented packets is conducted by Generic Receive Offload (GRO) before reaching Ingress-Prog. Moreover, no other functionalities rely on the outer headers.

3.4 Cache Coherency

An overlay network is subject to change, necessitating ONCache to ensure cache coherency when changes occur. While container provisioning is inherently handled by cache initialization, ONCache handles other changes by the user space program, ONCache daemon.

Upon container deletion or unexpected container failures, ONCache daemon deletes the related caches. This prevents a new container with an old IP address from mistakenly utilizing outdated cache entries.

Upon other changes, including container migration or filter updates, ONCache employs a *delete-and-reinitialize* mechanism with four steps to ensure that the changes take effect immediately and properly in the fast path: (1) Pausing cache initialization by disabling OVS or netfilter from adding the *est* mark. (2) Removing the cache entries affected by the network change (the affected packets start using the fallback overlay network). (3) Applying the network change in the fallback overlay network (the network change takes effect immediately). (4) Resuming cache initialization (the cache entries are reinitialized and the affected packets start using the fast path again).

3.5 Cache Compatibility

Work with various traffic. ONCache is designed to accelerate inter-host container traffic and is not responsible for other types of traffic, such as intra-host container traffic, container-to-host-IP traffic, or container-to-external-IP traffic. These types of traffic are handled by the fallback overlay network.

The ClusterIP Service [62] in Kubernetes facilitates container access to a group of containers providing the same functionality via a single ClusterIP. Typically, such services rely on netfilter or IPVS (IP Virtual Server) [33] on the sender host for load balancing and Destination Network Address Translation (DNAT). However, ONCache's fast path bypasses netfilter and IPVS. Nevertheless, ONCache can support ClusterIP akin to Cilium's approach: implementing load balancing and DNAT by eBPF programs and maps [14]. This functionality can be integrated in Egress/Ingress-Prog and be compatible with the cache-based fast path.

Work with data-plane policies. Data-plane policies, such as rate limiting and quality of service (QoS) seamlessly integrate with ONCache. In Linux, these policies are implemented by queuing disciplines (qdiscs). ONCache's fast path does not bypass the qdiscs of the host interface.

Filters not supported by ONCache. Packet-based filters that match on the hash of the overlay packet [74] do not exhibit any invariance property. Besides, while all stateful filters in netfilter [2], OVS [51], Cilium [15] have an established state, there may exist stateful filters without an established state.

ONCache does not natively support such filters, because there is no invariant filter decision that can be cached. Nonetheless, it is feasible to implement such filters in eBPF case by case.

Work with service meshes. Service meshes are increasingly popular in container clusters such as Kubernetes, primarily deployed for functionalities like security, observability, and traffic management [63]. The most common implementations of service meshes employ software proxies called sidecars [73]. A sidecar is a separate process co-located with applications within the application network namespace (e.g., within a Kubernetes Pod [34]), and still relies on the overlay network for communication. Hence, ONCache benefits the communication of sidecar service meshes.

Compatibility with Container Network Interface (CNI). The current implementation of ONCache is based on TC eBPF. For CNIs that do not use TC eBPF in their data path, such as Antrea, Flannel, etc., ONCache can be seamlessly integrated without requiring any code modifications. Conversely, to use ONCache with CNIs that already utilize TC eBPF, such as Cilium, Calico, we need to reimplement ONCache within either the CNI's eBPF programs or the kernel source code.

Container live migration. ONCache is compatible with container live migration [19, 45]. With proper control plane operations (see §3.4), the container connections can be well-maintained. In contrast, Slim only supports cold migration [74], as its container connections are established on the host and become invalid after migration, disrupting the applications inside the containers.

Network debugging. ONCache supports ICMP, thereby enabling common debugging tools such as ping and traceroute. Users can also utilize tools like bpftool [6] to debug ONCache's eBPF programs and maps. Debugging with ONCache is easy and convenient. In contrast, debugging with Slim is much harder. Slim lacks support for ICMP, and there also lacks debug tools for its socket replacement mechanism.

Moreover, ONCache is compatible with Linux techniques such as segmentation offload [61], checksum offload [10], and scaling techniques [59]. See Appendix E for details.

3.6 Optional Improvements

We introduce two optional improvements for the fast path. Unlike the default design of ONCache, these optional improvements require either kernel or protocol modifications.

Optimizing the redirect data path. ONCache uses `bpf_redirect` and `bpf_redirect_peer` to redirect packets on the egress and ingress path, respectively. As shown in Figure 4 (a), the two redirect functions are asymmetric, and the egress redirect path fails to eliminate the namespaces traversing overhead. Our speculation is that a symmetric egress redirect (Figure 4 (b)) requires hooking networking eBPF programs in container namespaces, which may conflict with user applications. Nevertheless, we are still curious about the potential benefit of optimizing the egress redirect data path.

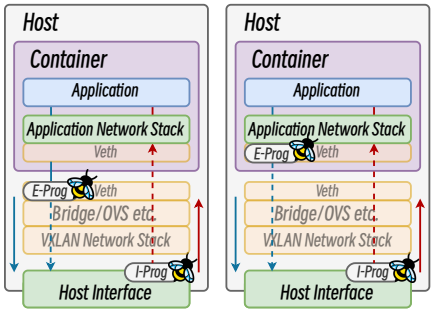

Figure 4: *The fast path in (a) ONCache without rpeer; (b) ONCache with rpeer.*

We design and implement a new eBPF redirect function in the Linux kernel, called `bpf_redirect_rpeer`. It provides a reversed path compared to `bpf_redirect_peer`, redirecting packets from the egress port of the veth (container-side) to the egress port of the host interface, as depicted in Figure 4 (b). By leveraging `bpf_redirect_rpeer`, the hook point of Egress-Prog changes to TC egress of the veth (container-side), enabling ONCache to further mitigate the namespaces traversing overhead on the egress path.

Optimizing the tunneling protocol. Traditional tunneling protocols like VXLAN introduce transmission overhead due to the outer headers, typically tens of bytes (e.g., 50 bytes for VXLAN). To eliminate this transmission overhead, we propose and implement a rewriting-based tunneling protocol.

With the new tunneling protocol, the fast path of ONCache works as below: (1) Egress-Prog modifies container source/destination IP/MAC addresses of an egress container packet to the host ones and writes a *restore key* to an idle field (e.g., DSCP) of the packet. Then the packet is redirected to the underlay network. (2) Ingress-Prog restores all the addresses to their original values according to the restore key and redirect the packet to the destination container. The mapping between the restore key and the container source/destination IP/MAC addresses is cached during cache initialization. See Appendix F for more detail.

4 Evaluation

We evaluate ONCache (without optional improvements by default) with microbenchmarks in §4.1 and popular distributed applications in §4.2. In both sections, ONCache's performance can be further improved by the optional improvements, at the cost of kernel/protocol modification. ONCache with optional improvements is evaluated in §4.3.

Our testbed is built on top of a base Kubernetes [35] cluster (v1.23.6), including API server, placement engine, etcd, etc. We run the experiments on Cloudlab [23] with three c6525-100g nodes, each equipped with an AMD EPYC 7402P 24-core processor@2.80 GHz. The processor uses hyperthreading. Each machine has 128 GB ECC memory and a dual-port Mellanox ConnectX-5 Ex 100 Gb interface. We do not

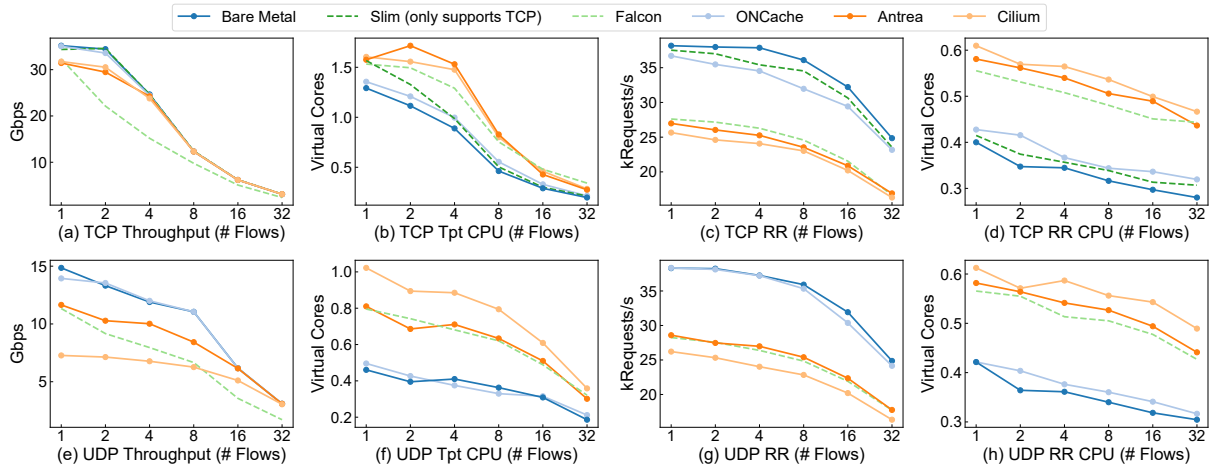

Figure 5: *TCP and UDP microbenchmark results of bare metal, Slim (only supports TCP), Falcon (Linux kernel v5.4), ONCache, Antrea and Cilium. Both Cilium and Antrea provide standard overlay networks. All data is the average of a single flow. CPU utilization is measured on the receiver host, normalized by throughput or RR, and scaled to Antrea's throughput or RR.*

change Cloudlab's default configurations of segmentation offload [61], checksum offload [10], and scaling techniques [59]. We use Ubuntu 20.04 with Linux kernel version 5.14. ONCache is deployed as a plugin of the Antrea (encap mode).

4.1 Microbenchmarks

4.1.1 Throughput and Latency

We utilize iperf3 [32] to measure throughput and netperf [48] to measure Request-Response (RR) transaction rate. The RR test measures the rate of one-byte round-trips performed sequentially over a connection, wherein a higher transaction rate indicates lower end-to-end latency. We measure CPU utilization on the receiver host in all experiments using mpstat [46]. Both TCP and UDP tests are executed.

In all settings, we conduct parallel tests. Multiple container pairs are deployed on a pair of hosts, with all server containers residing on one host and all client containers on the other. Each container pair starts testing simultaneously, enabling the evaluation of ONCache's parallel performance.

To represent performance of standard overlay networks, which serves as baseline, we select the most widely used CNIs, Antrea [1] and Cilium [13]. We take bare metal as upper bound for overlay networks. To compare ONCache with prior works discussed in §2.3, we conduct microbenchmarks on Slim[5] and Falcon, which represent the ideas of socket replacement and CPU load balancing, respectively.

TCP microbenchmarks. ONCache significantly improves both throughput and RR performance while consuming less CPU resource. The per-flow throughput, RR, and CPU utilization results are shown in Figure 5 (a) – (d).

Compared to Antrea, ONCache improves TCP throughput by 11.53% and 13.96% in 1 and 2-parallel tests. In 4, 8, 16, and 32-parallel tests, all container networks saturate the 100 Gb physical network. ONCache reduces per-byte CPU utilization by 13.94% - 34.87% in different parallel tests. The throughput and CPU utilization of ONCache are very close to those of Slim and bare metal. The throughput of Falcon (only provides implementation in the kernel v5.4) is significantly lower. The reason is that the kernel v5.4 inherently exhibits lower bandwidth compared to the kernel v5.14 in our testbed.

RR performance of ONCache in all parallel tests outperforms Antrea by 35.81% to 40.91%, with a decrease in per-RR CPU utilization ranging from 26.02% to 32.03%. The RR results of ONCache exhibit a slight gap to those of Slim. Overhead, including egress namespace traversing, eBPF execution, and outer headers MTU overhead, contributes to this gap and can be mitigated by the optional improvements proposed in §3.6. As the RR test does not overwhelm any CPU cores, Falcon only slightly improves the RR results[6].

UDP microbenchmarks. In contrast to Slim, ONCache also benefits UDP traffic, as shown in Figure 5 (e) – (h). UDP throughput of ONCache is 19.68% - 31.76% higher than Antrea in 1, 2, 4, 8-parallel tests. In 16 and 32-parallel tests, the throughput remains the same due to bandwidth bottleneck. Moreover, per-byte CPU utilization is lower by 29.73% - 47.98% in all tests. The throughput gap between ONCache

[5] Slim does not support UDP, only the TCP microbenchmark is performed.
[6] In our testbed, the kernel version does not affect RR results.

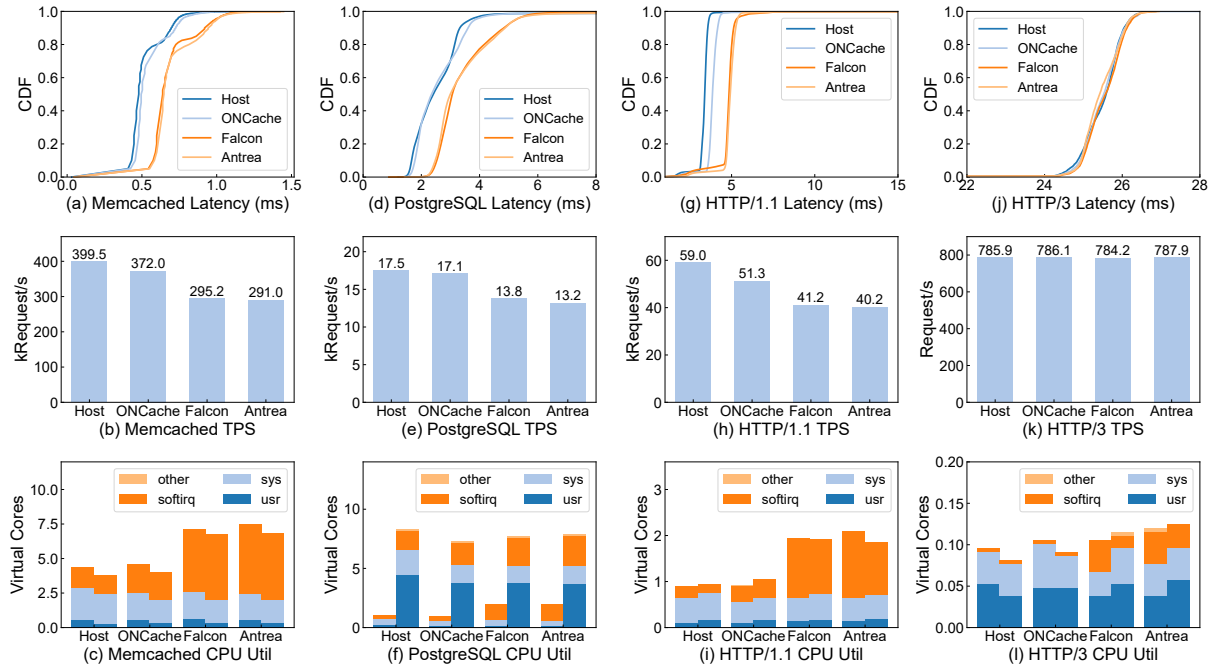

Figure 7: *The evaluation results of applications. Figures in each row present: the latency, the transaction rate (TPS) of all clients, and the CPU utilization of the client (left bar) & the server (right bar). To ensure a fair comparison, we normalize the CPU utilization by TPS and scale it to Antrea's TPS. Softirq stands for software interrupt request.*

and bare metal is less than 6%.

ONCache improves UDP RR performance by 34.13% - 39.12% in all tests, with per-RR CPU utilization reduced by 27.54% - 31.59%. There is also a small gap to Slim caused by the same reasons as in the TCP RR experiments.

Overhead quantifying. We quantify ONCache's overhead by the method proposed in §2.2 and present the results in Table 2. As expected, ONCache eliminates all the extra overhead, except for egress namespaces traversing overhead, which is addressed by `bpf_redirect_rpeer` proposed in §3.6. Although incurring eBPF execution overhead, ONCache still contributes to a significant reduction in overall network stack latency. The quantitative analysis aligns consistently with the microbenchmark results previously presented.

4.1.2 Cache Overhead

Cache initialization. We use netperf's Connect-Request-Response (CRR) test to measure TCP connection setup time and show the cache initialization overhead. In CRR, each RR transaction needs a new TCP connection, which requires additional cache initialization.

The CRR results are shown in Figure 6 (a). ONCache is better than Antrea but worse than bare metal. This is because ONCache relies on Antrea to handle the first 3 packets before caches are initialized. ONCache performs the same as Antrea in this part. Then the round trip of 1 byte (Request-Response part) goes through the fast path, which performs better than Antrea. Falcon does not benefit CRR compared to Antrea due to the same reason as in TCP RR. Slim performs significantly worse because it needs to first establish an overlay connection for service discovery, which incurs several extra RTTs.

Cache interference. We conduct an iperf3 test concurrently with continuous cache entry updates to show potential cache interference overhead. In this experiment, all cache capacities are set to 512, and the cache replacement policy is LRU. We use a script to continually insert 1000 redundant cache entries to the egress cache and subsequently delete them for 2 rounds. The test consumes about 8 seconds. As shown in the first 8 seconds of Figure 6 (b), the iperf3 flow exhibits no significant throughput fluctuation.

Cache scalability. We conduct a TCP RR test with a full egress cache containing 150,000 entries (for the largest Kubernetes cluster as mentioned in §3.1). As expected, the RR performance remains unaffected, showcasing the inherent scalability of hash maps.

4.1.3 Functional Completeness

Data-plane policies. We test whether data-plane policies, such as rate limiting, function correctly with ONCache. As shown in Figure 6 (b), in the absence of rate limiting, the throughput reaches about 39 Gbps. Then we limit the rate to 20 Gbps on the host interface and the throughput drops to about 18.5 Gbps. Upon removal of the rate limit, the throughput returns to its original level.

Packet filters. We test whether packet filters work properly with ONCache. During an iperf3 test with ONCache, we apply a simple packet filter which denies this iperf3 flow using the delete-and-reinitialize mechanism proposed in §3.4. As

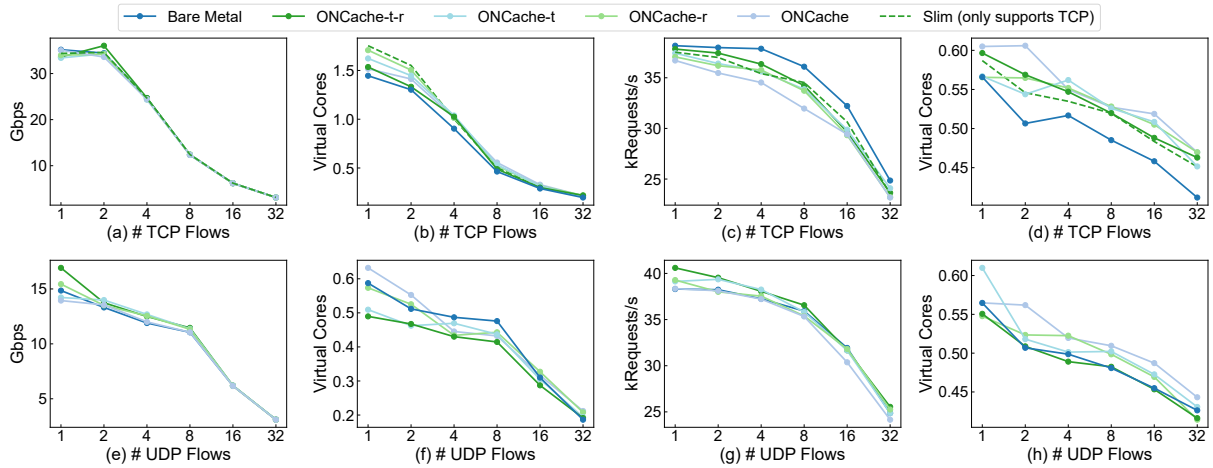

Figure 8: *TCP and UDP microbenchmark results of bare metal, ONCache with redirect rpeer (ONCache-r), ONCache with rewriting-based tunneling protocol (ONCache-t), ONCache with both (ONCache-t-r), and ONCache with neither (ONCache). The CPU utilization is normalized by throughput or RR and scaled to bare metal's throughput or RR.*

expected, the throughput drops to 0, as shown in Figure 6 (b). The throughput recovers upon removing the filter.

Container live migration. We evaluate whether ONCache works properly with container live migration. Since Kubernetes does not natively support live migration, we imitate it by modifying the host IP address and VXLAN tunnels while the container remains alive. As shown in Figure 6 (b), the throughput drops to 0 when migration starts (the host IP address is changed) and recovers once the migration finishes (VXLAN tunnels are updated) after about 2 seconds.

Both the packet filter and container live migration experiments induce network changes and require using the delete-and-reinitialize mechanism (proposed in §3.4) to apply the changes. Thus these experiments also demonstrate the effectiveness of the delete-and-reinitialize mechanism.

4.2 Applications

We evaluate ONCache on three real-world applications: in-memory key-value store Memcached [42], database PostgreSQL [55], and web server Nginx [50]. We take Antrea as performance baseline and Docker host network [21] as upper bound. Falcon is also evaluated. As Slim's performance is akin to that of the host network, it is omitted from this section. Notably, Slim only supports TCP, limiting its compatibility.

Memcached. We deploy a pair of containers on two hosts. One container runs a Memcached [42] server (v1.6), while the other runs a standard Memcached benchmark tool memtier [43] (v2.0.0) as a client. Upon the start of the experiment, the client spawns 4 threads, with each thread starting 50 connections. The ratio of SET and GET requests is 1:10. Memtier runs as fast as possible. We record CPU utilization by mpstat on both hosts during the experiment.

ONCache achieves much lower latency and higher transaction rate than Antrea. Figure 7 (a) is the CDF graph of the latency of GET requests. The average latency is reduced by 22.71%, while the 99.9 percentile latency is reduced by 27.69%. The latency gap relative to the host network is within 6%. The transaction rates are shown in Figure 7 (b). ONCache outperforms Antrea by 27.83%, while has a 7% gap compared to the host network.

ONCache also significantly reduces per-transaction CPU utilization, as shown in Figure 7 (c). The per-transaction CPU utilization of ONCache is 38.91% and 40.98% lower on the client and the server, respectively. The utilization remains 4.09% and 6.62% higher than that in the host network.

PostgreSQL. We deploy a PostgreSQL database [55] (v15.3) and its benchmark tool, pgbench [54], on a pair of containers on different hosts. Pgbench implements the TPC-B benchmark, creating a database with 5 million banking accounts and executing 50 clients concurrently. Pgbench runs as fast as possible. We measure CPU utilization by mpstat.

ONCache benefits PostgreSQL's latency and transaction rate, as shown in Figure 7 (d)(e). Compare to Antrea, ONCache reduces the average latency by 22.34% and the transaction rate by 29.40%, while having a gap of 2.30% and 2.54% to the host network, respectively. ONCache also reduces CPU utilization, as shown in Figure 7 (f). The per-transaction CPU utilization is reduced by 51.84% and 7.26% for the client and the server, respectively. The reduction of the server is smaller due to relative high user CPU utilization. ONCache reduces soft interrupt utilization on the server by 27.36%.

Nginx. To evaluate performance of HTTP servers, we conduct load tests on HTTP/1.1 and HTTP/3 [57], representing TCP-based and UDP-based HTTP, respectively. SSL is disabled for HTTP/1.1 and enabled for HTTP/3. We employ Nginx [50] (v1.25.1) and h2load [30] (v1.55.1) in the experiment. H2load runs 100 clients for HTTP/1.1 and 10 clients for HTTP/3. Each client issues 2 concurrent streams and requests a 1 KB file from the server. H2load runs as fast as possible.

ONCache improves latency and transaction rate for HTTP/1.1, as shown in Figure 7 (g) and (h). ONCache re-

duces HTTP/1.1 request latency by 21.53% and improves the transaction rate by 27.43%. There remains a performance gap between ONCache and the host network (15.04% for latency and 13.12% for transaction rate). The gap is caused by the same reason as analyzed in TCP RR, as the transaction rate is high enough to expose overhead. For HTTP/3, the performance is notably poorer and remains consistent across different networks, as shown in Figure 7 (j) and (k). This could potentially be attributed to the experimental QUIC support of Nginx [26].

ONCache reduces per-transaction CPU utilization for both HTTP/1.1 and HTTP/3, as shown in Figure 7 (i) and (l). For HTTP/1.1, CPU utilization is reduced by 56.26% for the client and 43.52% for the server. For HTTP/3, the reduction is 11.80% and 26.76% for the client and the server, respectively.

4.3 Evaluation for Optional Improvements

We evaluate ONCache with redirect rpeer (ONCache-r), rewriting-based tunneling protocol (ONCache-t), and both of them (ONCache-t-r) by the methods described in §4.1. The results are shown in Figure 8. The baseline in this section is ONCache without the optional improvements.

The optional improvements benefit RR transaction rate, as shown in Figure 8 (c)(g). ONCache-t, ONCache-r, and ONCache-t-r improve 1-parallel TCP RR performance by 1.96%, 0.97%, and 3.08%, respectively (2.04%, 2.43%, and 5.87% for UDP). For multi-parallel tests, the optional improvements also benefit RR performance. ONCache-t-r provides the most improvement in RR performance, nearly equaling the sum of those of ONCache-t and ONCache-r, and achieves nearly the same RR performance as Slim.

The optional improvements generally reduce CPU utilization, as shown in Figure 8 (b)(d)(f)(h). The CPU utilization reduction varies across different experiments, due to noise from other processes in the system.

We also evaluate the optional improvements with the applications used in §4.2. The results are presented in Appendix G.

5 Discussion

Why using TC hook? There are two main types of eBPF hooks for networking: XDP and TC [5]. Compared to XDP, TC eBPF programs do not require driver support, can redirect packets with lower overhead, are compatible with Linux traffic control (tc) module, and can be hooked on both ingress and egress ports. Therefore, TC is a better choice for ONCache.

Security of eBPF-based ONCache. Only processes that run by privileged user (root) or have the capability `CAP_BPF` can load eBPF programs and read/write eBPF maps, unless the privileged user enables unprivileged eBPF [25][7]. Thus, the eBPF components of ONCache are protected by the eBPF permission control. Additionally, ONCache's fast path resides in kernel mode and is inaccessible from applications. In contrast, Slim has serious security issues because it exposes host namespace file descriptors to containers, thereby breaking resource isolation provided by Linux namespaces. Slim's kernel module could mitigate the security issues, but resource isolation is still undermined.

[7] Although there are userspace eBPF implementations [68] that do not necessitate the privilege at all, they execute eBPF programs in userspace and differ from the eBPF adopted by ONCache.

6 Related Works

Cache in network virtualization. OVS [53, 58] employs a cache to accelerate flow matching. However, as analyzed in §2.2, there is still significant extra overhead in overlay networks. Andromeda [20], a VM cluster network virtualization stack, maintains a cache of routing and filtering decisions, sharing a similar idea with OVS. Nevertheless, none of the prior works quantify container overlay networks and employ a cross-layer cache to bridge the performance gap between container overlay networks and bare metal, as ONCache does.

eBPF-based container networks. ONCache differs significantly from existing eBPF-based container networks like Cilium [13] and Calico [7]. For example, in Cilium, the eBPF-based data path aims to replace netfilter in the host network stack with eBPF programs and is effective where container packets are directly forwarded to underlay network [17]. However, as analyzed in §2.2, Cilium fails to improve overlay networks and the extra overhead still exists. In contrast, ONCache aims to eliminate the extra overhead with the proposed cache, as shown in Table 2.

Service mesh sidecar optimization. While a sidecar simplifies traffic management, policy enforcement, network security, etc., it incurs significant overhead. Zhu et al. [73] proposed MeshInsight to quantify the overhead of service mesh sidecars, and works such as SPRIGHT [56], mRPC [11] optimize sidecars by different mechanisms. However, these works focus on optimizing the overall intra-host service mesh architecture, rather than the inter-host container communication.

7 Conclusion

We design and implement ONCache, a cache-based container overlay network that effectively narrows the performance gap between bare metal and overlay networks without losing flexibility and compatibility. In both microbenchmark and application experiments, ONCache significantly outperforms standard overlay networks in terms of throughput and latency while reducing CPU utilization. ONCache can be seamlessly integrated with existing CNIs such as Antrea, Flannel, etc.

A Quantitatively Analyzing Network Stacks

In this section, we describe how we quantitatively analyze network stacks. We analyze the overhead incurred during the execution of a 1-byte TCP RR test conducted using NPtcp [49].

Firstly, we perform a qualitative analysis of overhead in different data paths with two steps: (1) Utilizing the perf tool [52], we profile network stack functions for a duration of 10 seconds and subsequently employ a flame graph generator [27] to generate flame graphs. (2) According to the flame graphs, we classify network stack functions into different segments of the overhead, e.g., the application network stack, OVS, etc.

Next, we time the network stack functions using eBPF one by one. As the network stack functions may execute in both the application network stack and the VXLAN network stack, we need to distinguish them by their call stacks. We implement two eBPF programs leveraging the BPF Compiler Collection (BCC) [3] tool. These programs are hooked to `kprobes` and `kretprobes` hook points, executing at the entry and return points of each specific function, respectively. They capture the current call stack along with the timestamp, and store the function (with the call stack) and its execution time in an eBPF map. For each function, we record all the execution time samples within one second and compute the average of these samples, which serves as the final result, as shown in Table 2.

B The Core Code of ONCache

In this section, we present core code of ONCache's eBPF programs to help to understand the design of ONCache.

B.1 The Local Cache Definition

The code in this section implements functionalities that are described in §3.1.

The egress cache:

```
struct egressinfo {
    unsigned char outer_header[64];
    __u32 ifidx;
};
struct bpf_elf_map SEC("maps") egressip_cache = {
    .type = BPF_MAP_TYPE_LRU_HASH,
    .size_key = sizeof(__be32),
    .size_value = sizeof(__be32),
    .pinning    = PIN_GLOBAL_NS,
    .max_elem = 4096
};
struct bpf_elf_map SEC("maps") egress_cache = {
    .type = BPF_MAP_TYPE_LRU_HASH,
    .size_key = sizeof(__be32),
    .size_value = sizeof(struct egressinfo),
    .pinning    = PIN_GLOBAL_NS,
    .max_elem = 1024,
};
```

The ingress cache.

```
struct ingressinfo {
    __u32 ifidx;
    unsigned char dmac[ETH_ALEN];
    unsigned char smac[ETH_ALEN];
};
struct bpf_elf_map SEC("maps") ingress_cache = {
    .type = BPF_MAP_TYPE_LRU_HASH,
    .size_key = sizeof(__be32),
    .size_value = sizeof(struct ingressinfo),
    .pinning    = PIN_GLOBAL_NS,
    .max_elem = 1024,
};
```

The filter cache.

```
struct action {
    __u16 ingress;
    __u16 egress;
};
struct bpf_elf_map SEC("maps") filter_cache = {
    .type = BPF_MAP_TYPE_LRU_HASH,
    .size_key = sizeof(struct fivetuple),
    .size_value = sizeof(struct action),
    .pinning    = PIN_GLOBAL_NS,
    .max_elem = 4096,
};
```

B.2 Cache Initialization

The code in this section implements functionalities that are described in §3.2.

Initialize the Egress Path. `TC_ACT_OK` indicates the kernel to proceed with the usual packet processing. ONCache uses `TC_ACT_OK` to pass the packet to the fallback overlay network.

```
// Checks if miss and est marked.
if ((inner_iph->tos & 0xc) != 0xc) return TC_ACT_OK;
// Update filter cache
struct fivetuple tuple_;
if (parse_5tuple_e(inner_iph, data_end, &tuple_)) return
     TC_ACT_OK;
struct action eaction_ = {
    .egress = 1,
    .ingress = 0
};
if(bpf_map_update_elem(&filter_cache, &tuple_, &eaction_,
     BPF_NOEXIST)) {
    struct action* action_ =
     bpf_map_lookup_elem(&filter_cache, &tuple_);
    if (action_) action_->egress = 1;
}
// Update egress cache
struct egressinfo egressinfo_;
initegressinfo(&egressinfo_, skb);
if(bpf_map_update_elem(&egress_cache, &outer_iph->daddr,
     &egressinfo_, BPF_NOEXIST))
    return TC_ACT_OK;
if(bpf_map_update_elem(&egressip_cache, &inner_iph->daddr,
     &outer_iph->daddr, BPF_NOEXIST))
    return TC_ACT_OK;
// Erase the TOS mark.
set_ip_tos(skb, 50, 0);
```

```
// Drop packets reported as invalid by conntrack.
table=ConntrackState, priority=210,ct_state=+inv+trk,ip actions=drop
// Forwarded tracked Service packets
table=ConntrackState, priority=200,ct_state=-new+trk,ct_mark=0x10/0x10,ip\
    actions=load:0x1->NXM_OF_IP_TOS[3],load:0x1->NXM_NX_REG0[9],\
    resubmit(,AntreaPolicyEgressRule)
// Forwarded tracked non-Service packets
table=ConntrackState, priority=190,ct_state=-new+trk,ip \
    actions=load:0x1->NXM_OF_IP_TOS[3],resubmit(,AntreaPolicyEgressRule)
// Match the first packet of untracked connection and forward it
table=ConntrackState, priority=0 actions=resubmit(,PreRoutingClassifier)
```

Figure 9: *Parts of OVS flows in Antrea. The action that we introduce is highlighted in red font, through which we set a predefined DSCP bit to 1 if the flow reaches established state.*

Initialize the Ingress Path.

```
// Checks if miss and est marked.
if ((iphdr->tos & 0xc) != 0xc) return TC_ACT_OK;
// Update ingress cache
struct ingressinfo* ingressinfo_ =
     bpf_map_lookup_elem(&ingress_cache, &iphdr->daddr);
if (!ingressinfo_) {
    return TC_ACT_OK;
} else {
    __builtin_memcpy(ingressinfo_->dmac, eth->h_dest,
     ETH_ALEN);
    __builtin_memcpy(ingressinfo_->smac, eth->h_source,
     ETH_ALEN);
}
// Update filter cache
struct fivetuple tuple_;
if (parse_5tuple_in(iphdr, data_end, &tuple_)) return
     TC_ACT_OK;
struct action eaction_ = {
    .egress = 0,
    .ingress = 1
};
if(bpf_map_update_elem(&filter_cache, &tuple_, &eaction_,
     BPF_NOEXIST)) {
    struct action* action_ =
     bpf_map_lookup_elem(&filter_cache, &tuple_);
    if (action_) action_->ingress = 1;
}
// Erase the TOS mark.
set_ip_tos(skb, 0, 0);
```

Extra configuration on OVS or netfilter. The addition of the *est* mark can be realized through either OVS or netfilter.

For OVS, this action requires modifying two OVS flows, as shown in Figure 9. Originally, the two flows are intended for forwarding non-new-state tracked packets. We utilize them to add the *est* mark to packets meanwhile. The actions that we introduce are highlighted in red font, through which we set a predefined DSCP bit to 1 if the flow reaches established state.

Alternatively, this action can be independently realized by adding a new rule in netfilter as follows.

```
iptables -t mangle -A FORWARD -m conntrack --ctstate
     ESTABLISHED -m dscp --dscp 0x1 -j DSCP --set-dscp 0x3
```

B.3 Cache-based Fast Path

The code in this section implements functionalities that are described in §3.3.

B.3.1 The Egress Data Path

Step #1: Cache retrieving.

```
struct fivetuple tuple_;
if (parse_5tuple_e(iphdr, data_end, &tuple_)) return
     TC_ACT_OK;
struct action *action_ =
     bpf_map_lookup_elem(&filter_cache, &tuple_);
if (!action_ || !(action_->ingress & action_->egress)) {
    set_ip_tos(skb, 0, 0x4);
    return TC_ACT_OK;
}
__be32* nodeip_ = bpf_map_lookup_elem(&egressip_cache,
     &iphdr->daddr);
if (!nodeip_) {
    // TOS 0x4 is used as miss mark
    set_ip_tos(skb, 0, 0x4);
    return TC_ACT_OK;
}
struct egressinfo* egressinfo_ =
     bpf_map_lookup_elem(&egress_cache, nodeip_);
if (!egressinfo_) {
    set_ip_tos(skb, 0, 0x4);
    return TC_ACT_OK;
}
struct ingressinfo* ingressinfo_ =
     bpf_map_lookup_elem(&ingress_cache, &iphdr->saddr);
if (!ingressinfo_ || !ingressinfo_complete(ingressinfo_))
    return TC_ACT_OK;
```

Step #2: Encapsulating and intra-host routing.

```
// Prepend the outer headers
if (bpf_skb_adjust_room(skb, 50, BPF_ADJ_ROOM_MAC,
     BPF_F_ADJ_ROOM_FIXED_GSO |
     BPF_F_ADJ_ROOM_ENCAP_L3_IPV4 |
     BPF_F_ADJ_ROOM_ENCAP_L4_UDP|
     BPF_F_ADJ_ROOM_ENCAP_L2(14)|
     BPF_F_ADJ_ROOM_ENCAP_L2_ETH)))
    return TC_ACT_OK;
// Boundary check
...
// Headers includes 50B of outer hdr and 14B inner MAC hdr.
__builtin_memcpy(data, egressinfo_->headers, 64);
set_lengthandid(skb, skb->len);
// Set the UDP source port
__u32 hash = bpf_get_hash_recalc(skb);
__be16 sport = get_udpsport(hash);
bpf_skb_store_bytes(skb, UDP_PORT_OFF, &sport,
     sizeof(sport), 0);
// Packet redirecting
action = bpf_redirect(egressinfo_->ifidx, 0);
return action;
```

B.3.2 The Ingress Data Path

Step #1: Destination check.

```
struct bpf_elf_map SEC("maps") devmap = {
    .type = BPF_MAP_TYPE_HASH,
    .size_key = sizeof(int),
    .size_value = sizeof(struct devinfo),
    .pinning    = PIN_GLOBAL_NS,
    .max_elem = 8,
};

struct ethhdr *outer_eth = data;
int ifindex = ctx->ifindex;
struct devinfo *devinfo_ = bpf_map_lookup_elem(&devmap,
    &ifindex);
if (!devinfo_ || maccmp(outer_eth->h_dest, devinfo_->mac,
    ETH_ALEN)) return TC_ACT_OK;
// Check if Ethernet frame has IP packet and set IP hdr ptr
if (outer_eth->h_proto != bpf_htons(ETH_P_IP)) return
    TC_ACT_OK;
struct iphdr *outer_iph = (struct iphdr *)(outer_eth + 1);
if (outer_iph->daddr != devinfo_->ip) return TC_ACT_OK;
```

Step #2: Cache retrieving.

```
struct fivetuple tuple_;
if (parse_5tuple_in(inner_iph, data_end, &tuple_)) return
    TC_ACT_OK;
struct action *action_ =
    bpf_map_lookup_elem(&filter_cache, &tuple_);
if (!action_ || !(action_->ingress & action_->egress)) {
    set_ip_tos(skb, 50, 0x4);
    return TC_ACT_OK;
}
struct ingressinfo* ingressinfo_ =
    bpf_map_lookup_elem(&ingress_cache,
    &inner_iph->daddr);
if (!ingressinfo_ || !ingressinfo_complete(ingressinfo_)) {
    set_ip_tos(skb, 50, 0x4);
    return TC_ACT_OK;
}
if (!bpf_map_lookup_elem(&egressip_cache,
    &inner_iph->saddr)) return TC_ACT_OK;
```

Step #3: Decapsulating and intra-host routing.

```
if (bpf_skb_adjust_room(ctx, -50, BPF_ADJ_ROOM_MAC, 0))
    return TC_ACT_OK;
// Boundary check
...
// Set new MAC
struct ethhdr *eth = data;
__builtin_memcpy(eth->h_dest, ingressinfo_->dmac,
    ETH_ALEN);
__builtin_memcpy(eth->h_source, ingressinfo_->smac,
    ETH_ALEN);
// Packet redirecting
action = bpf_redirect_peer(ingressinfo_->ifidx, 0);
return action;
```

C Calculation of the Maps Size

As per the cache definitions described in §3.1, the sizes of cache entries are specified as below: 8 bytes for the egress cache (first level), 72 bytes for the egress cache (second level), 20 bytes for the ingress cache, and 20 bytes for the filter cache.

To eliminate cache eviction by the LRU mechanism for a cluster with a maximum of 110 containers per host, 5k hosts, 150k total containers, and up to 1M concurrent flows per host, we need the egress cache (first level) to have 150k entries, the egress cache (second level) to have 5k entries, the ingress cache to have 110 entries, and the filter cache to have 1M entries.

Consequently, the sizes of the caches can be calculated as follows: the egress cache is 8 B * 150k + 72 B * 5k = 1.56 MB, the ingress cache is 20 * 110 = 2.2 KB, and the filter cache is 20 B * 1M = 20 MB.

D An Example to Understand Necessity of Reverse Check

We further use a counterexample to show the necessity of reverse check.

Let's consider a scenario where ONCache only checks the egress cache on the egress data path. Initially, flow f enters the established state in conntrack, and all caches for f are initialized. Consequently, all packets of flow f go through ONCache's fast path. However, since flow f bypasses the conntrack module in the fallback overlay network, its conntrack entry eventually expires after a predefined duration. Subsequently, if flow f is evicted from the ingress cache by LRU mechanism, it can still leverage the egress fast path but becomes ineligible for the ingress fast path. Ideally, we envision ONCache to reinitialize the ingress cache for flow f. But unfortunately, flow f cannot re-enter the established state in conntrack because conntrack records a flow as established only upon observing packets in both directions [2]. Consequently, the ingress cache for flow f can never be reinitialized and flow f can no longer utilize the ingress fast path.

E Compatibility Discussions

Segmentation offloads. Segmentation offloads, such as Generic Segmentation Offload (GSO) and Generic Receive Offload (GRO) [61], enable network interfaces to segment and reassemble packets. The hooking points of all ONCache eBPF programs are TC. On the egress path, GSO happens after TC [5]. Thus GSO and other hardware segmentation mechanisms of the host interface are not bypassed by the fast path. On the ingress path, GRO happens prior to TC [5], posing no conflicts with ONCache. Hence, ONCache is compatible with segmentation offload techniques.

Scaling techniques. Linux scaling techniques, including Receive Packet Steering (RPS) and Receive Flow Steering (RFS) (and their hardware counterparts Receive Side Scaling (RSS) and Accelerated RFS (aRFS)) [59], employ different CPU load balancing strategies on the ingress data path. They are all compatible with ONCache: RSS and aRFS are hardware mechanisms; RPS and RFS are in software but happen

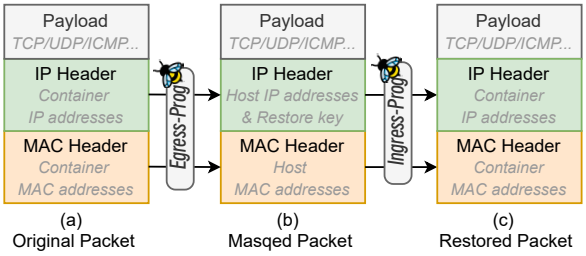

Figure 10: *The changes of a container packet forwarded by ONCache with the rewriting-based tunneling protocol. (a) The original packet from containers. (b) The masqueraded packet. (c) The restored packet.*

before Ingress-Prog on the ingress path.

Checksum offloads. Checksum offloads, including transmitting and receiving checksum offload [10], are often enabled to reduce checksum overhead. As they are hardware mechanisms, ONCache is compatible with them.

F Rewriting-based Tunneling Protocol

This section describes how the rewriting-based tunneling protocol works in ONCache.

The rewriting-based tunneling protocol operates by substituting the encapsulation of outer headers in traditional tunneling protocols, with the rewriting of inner headers. The modifications to packet headers along the data path are depicted in Figure 10.

New caches. The egress and ingress caches are redesigned to accommodate the rewriting-based tunneling protocol.

The egress cache stores data used on the egress path, structured as <*container sdIP → host interface index, host sdIP, host sdMAC, restore key*>[8].

The ingress cache stores data used on the ingress path, structured as <*host sIP & restore key → veth (host-side) index, container sdIP, container dMAC*>. To accommodate the new initialization process described later, the ingress cache is divided into two maps. The first is the ingressIP cache: <*host sIP & restore key → container sdIP*>, while the second is the ingress cache: <*container dIP → container dMAC, veth (host-side) index*>.

The new packet journey. On the sender host, Egress-Prog retrieves <*container sdIP → host interface index, host sdIP, host sdMAC, restore key*> from the egress cache. Subsequently, Egress-Prog conducts the *masquerading* process by modifying the container source/destination MAC/IP addresses to those of the host.

To ensure the masqueraded packet can be restored on the receiver host, ONCache additionally writes a restore key to the packet. Then the receiver host utilizes the restore key in conjunction with the host IP addresses to restore container source/destination MAC/IP addresses. The restore key is allocated during cache initialization and is stored in the egress cache. The user has the flexibility to designate a specific field to accommodate the restore key within the packet. This field can be any available field in the IP header, such as ID, DSCP, or Option. The capacity of the restore key depends on the width of the chosen field. After writing the restore key to the packet, referred to as the masqueraded packet, Egress-Prog redirects it to the host interface using either `bpf_redirect` or `bpf_redirect_rpeer`.

On the receiver host, Ingress-Prog restores the masqueraded packet. Ingress-Prog retrieves <*host sIP & restore key → veth (host-side) index, container sdIP, container dMAC*> from the ingress cache, and writes the container IP and MAC addresses back to the headers. After restoring, the packet is redirected to the destination veth using `bpf_redirect_peer`.

The new cache initialization. The initialization for MAC and IP addresses, as well as interface indexes, remains akin to the original design (as described in §3.2), and the allocation of the restore key is newly added. The restore key is allocated on the receiver host and subsequently delivered to the sender host. This ensures that the masquerading operation utilizes the restore key only after the receiver host recognizes it. The initialization of the filter cache is the same as that described in §3.2 and is therefore omitted in this section. ONCache utilizes a round-trip of tunneling packets to initialize the cache. The process is shown in Figure 11 and encompasses four steps:

Step #1 (tagged in Figure 11 ①): Upon encountering a cache miss, Egress-Prog passes the packet to the fallback overlay network. Then the packet reaches Egress-Init-Prog after undergoing processing within the fallback overlay network. Egress-Init-Prog parses the headers and stores <*container sdIP → host interface index, host sdIP, host sdMAC*> to the egress cache. It also allocates a restore key for the reverse flow, chosen randomly or sequentially, and writes <*host sIP & restore key → container sdIP*> to the ingressIP cache. As a hash map, the ingressIP cache naturely ensures the uniqueness of the restore key. To deliver the restore key to the peer host, Egress-Init-Prog writes the restore key into the user-defined field within the inner header. Finally, the packet is transmitted to the underlay network.

Step #2 (tagged in Figure 11 ②): Upon receiving a tunneling packet on the receiver host, Ingress-Init-Prog continues the initialization. It parses the restore key contained within the packet, and stores <*container sdIP → restore key*> to the egress cache. Next, it stores <*container dIP → container dMAC*> to the ingress cache (<*container dIP → veth (host-side) index*> is maintained by the user space daemon). Finally, the packet is forwarded to the destination application.

The above two steps fill up half of fields within the egress cache and ingress cache on both hosts. Subsequently, the reply of this tunneling packet goes through a similar yet reverse

[8] sIP = source IP address; dIP = destination IP address. Similarly, for sMAC, dMAC, sdIP, and sdMAC.

process (tagged in Figure 11 ③④), thereby completing the entire initialization process.

G Application Evaluation for Optional Improvements

This section, we show the application evaluation results for the optional improvements. The evaluation results of ONCache-r, ONCache-t, ONCache-t-r, and the host network are listed in Table 4. The listed values are relative to ONCache.

The application evaluation reveals the following key findings: (1) Both the rewriting-based tunneling protocol (ONCache-t) and `bpf_redirect_rpeer` (ONCache-r) improve latency and TPS performance across all applications, except for HTTP/3. They also reduce per-transaction CPU utilization for PostgreSQL and HTTP/1.1. (2) With both optional improvements, ONCache-t-r generally achieves the best latency, TPS, and CPU utilization across all applications, except for HTTP/3. Notably, the performance of ONCache-t-r closely rivals that of the host network.

Due to the constraints of the experimental QUIC support of Nginx, the absolute result values of HTTP/3 across different implementations exhibit slight variations. Consequently, the evaluation results of HTTP/3 are inconclusive.

GREEN: Carbon-efficient Resource Scheduling for Machine Learning Clusters

Kaiqiang Xu[1], Decang Sun[1], Han Tian[2], Junxue Zhang[1], Kai Chen[1]
[1]*iSING Lab, Hong Kong University of Science and Technology* [2]*USTC*

Abstract

This paper explores the problem of scheduling machine Learning (ML) jobs while also taking into account the reduction of carbon emissions in the cluster. Traditional cluster schedulers for ML jobs mainly focus on optimizing job completion time (JCT), but do not consider the environmental impact of their decisions, resulting in a suboptimal carbon footprint. To address this issue, we propose GREEN, an ML cluster scheduler that is both time-efficient and carbon-efficient. At its core, GREEN uses a unique carbon-aware scheduling algorithm that reduces carbon footprint with minimized impact on JCT. Additionally, it leverages the temporal flexibility of ML jobs to reduce carbon emissions by shifting workloads to less carbon-intensive times, while still maintaining overall daily capacity. Our experiments using real ML jobs workload demonstrate that GREEN can achieve up to 41.2% reduction in cluster-wide carbon footprint and 12% reduction in peak power consumption, while incurring 3.6%-5.9% time efficiency tradeoff compared to existing methods.

1 Introduction

Machine Learning (ML) workloads currently constitute 8% of the 54 GW global data center demand and are projected to increase to 15-20% by 2028 [3]. Current production clusters handle a large volume of ML jobs, supported by fast parallel computing infrastructures using GPU devices. These setups, termed ML-as-a-Service (MLaaS) clusters, enhance utilization and reduce costs by allowing multiple users to share resources [33]. Given the rising concern about AI's environmental impact, there is a pressing need for a new cluster resource management strategy to mitigate the environmental footprint of ML processing, especially in the pursuit of global carbon neutrality [1, 26].

Existing cluster resource schedulers for ML jobs primarily focus on optimizing metrics related to job completion time (JCT) for time efficiency. However, their optimization practices may result in inefficient energy usage [39]. For example, schedulers like Pollux [20], Optimus [19], and Themis [14] optimize throughput by dynamically adjusting GPU allocation and job hyperparameters but neglect variations in jobs' power consumption during scaling and reconfiguration. Zeus [39] balances the tradeoff between energy consumption and time efficiency, but it lacks consideration for resource allocation among multiple jobs with different energy characteristics.

More importantly, energy usage is *not* the only factor that contributes to the carbon footprint. Carbon intensity, representing carbon emissions per unit of energy consumed, can vary significantly over time [18] and considering this temporal variation is crucial in reducing the carbon footprint of ML clusters [34]. ML training jobs often span days or weeks, during which they are intermittently paused and resumed based on their priority [33]. Therefore, these jobs have a level of temporal flexibility – the timing of job execution can be shifted as long as the total allocated resources are preserved within a specified time frame (e.g., 24 hours). By exploiting this flexibility, schedulers can align job power consumption with carbon intensity fluctuations, effectively reducing the overall carbon footprint. However, existing energy-aware optimizations [23, 39] overlooked carbon intensity and job flexibility's combined effect on cluster-wide environmental impact.

This paper presents GREEN, a novel carbon-efficient cluster scheduler that aims to reduce the overall carbon footprint of the cluster while achieving comparable time efficiency performance to prior work. GREEN utilizes a carbon-aware scheduling algorithm that balances the cluster-wide JCT and carbon footprint by considering various carbon-related factors, including the *energy efficiency* of each job, which derives from how effectively energy usage contributes to a job's training progress. Additionally, the algorithms exploit the temporal flexibility of ML jobs to reduce grid carbon emissions by automatically shifting workloads to greener hours with lower carbon intensity while still maintaining overall daily capacity.

GREEN makes carbon-aware decisions on scheduling by taking into account carbon-related factors. Specifically, GREEN employs a carbon tracker (§4) to monitor the energy consumption and other runtime metrics of ML jobs throughout their execution, and uses a factor model to compute the *energy efficiency* (the change in energy usage as the job progresses) for each job and *carbon footprint* (the accumulated carbon emissions based on energy usage).

GREEN proposes two optimizers (§5) for optimizing energy efficiency and reducing carbon footprint in ML clusters. The *Energy Efficiency Optimizer* scales resources allocated to jobs, taking into account the scalability demonstrated by the amount of energy consumption for a job when scaling, while the *Carbon Footprint Optimizer* dynamically rearranges job priorities for peak load shifting, minimizing cluster-wide carbon emissions while ensuring fairness in resource allocation.

To enable the co-optimization of these two optimizers, GREEN's scheduling algorithm (§6) incorporates a Multi-

level Feedback Queue (MLFQ) mechanism. The upper queue, guided by the *Energy Efficiency Optimizer*, emphasizes energy efficiency by scaling out jobs that achieve greater progress with lower energy consumption. The lower queue retains the progress and decisions made in the upper queue and utilizes the *Carbon Footprint Optimizer* to minimize the carbon footprint by relocating high-power-consuming jobs to "greener" hours with lower carbon intensity.

GREEN optimizes cluster-wide carbon footprint but has a non-goal: GREEN avoids altering job-level configurations (e.g. model hyperparameters) as in some existing ML schedulers [20, 39]. This design choice makes GREEN non-intrusive to the user's ML implementation and becomes orthogonal to optimization techniques that are provided in ML frameworks at the single-job level, such as adaptive hyperparameters and learning rate decay, which would otherwise conflict with job-level optimizations in cluster schedulers.

We evaluate GREEN using two types of workloads: (1) a production ML cluster used by a research institution with over 500 active academic users, and (2) a real-world machine learning workload trace from Alibaba [33]. We compare the performance of GREEN to state-of-the-art cluster schedulers under these workloads, and report on time metrics including JCT and makespan, as well as energy metrics including carbon footprint and peak power usage. Our results show that GREEN achieves significant reductions in the cluster's carbon footprint (up to 41.2%) and peak power draw (up to 12%), while maintaining comparable time efficiency to prior work, with a tradeoff of 3.6%-5.9% in average JCT.

We summarize our contributions as follows:

- We present a factor model to calculate carbon-related metrics and factors, including Carbon Intensity Curve (CIC), carbon footprint, and energy efficiency, providing important signals to the scheduler.
- We propose a carbon-efficient scheduler that scales out jobs while ensuring energy efficiency, and moves high-power jobs to greener hours to reduce carbon footprint without compromising fairness in resource allocation.
- We implement and evaluate GREEN with the real workload in a 32-node production cluster and the ML job trace from a large-scale enterprise cloud, and results show that GREEN can achieve up to 41.2% carbon footprint reduction, by trading <5.9% in average JCT.

2 Background and Motivations

This section discusses related work on ML cluster schedulers and energy-aware systems under a wider context.

2.1 ML Cluster Scheduling

A machine learning (ML) cluster is a shared environment where multiple users can submit training jobs that compete for limited resources. The cluster scheduler is responsible for managing job queues and allocating resources, with the goal of optimizing performance metrics such as job completion time (JCT) and resource utilization. This setup is commonly referred to as Machine Learning-as-a-Service (MLaaS) [33].

Schedulers	Scale-Adapt.	Energy-Aware	Carbon-Aware	Model-Agnostic
Gandiva / AntMan	✗	✗	✗	✗
Tiresias	✗	✗	✗	✓
Optimus	✓	✗	✗	✓
Pollux	✓	✗	✗	✗
Zeus	✗	✓	✗	✗
GREEN	✓	✓	✓	✓

Table 1: Characteristics of representative cluster schedulers.

Studies in ML job clusters explore optimization techniques in different directions. We classify these works based on key characteristics and present representative ones in Table 1.

① **Scale-Adaptive (or Elastic)**. Scale-adaptive schedulers dynamically adjust resource allocation (i.e., number of GPUs) for jobs based on their efficiency in speeding up tasks. Pollux [20] assesses statistical efficiency in ML training, measuring progress per unit of data processed. Optimus [19] builds predictive models for job-specific system throughput to determine scalability.

In the energy-aware context, jobs have different energy characteristics when scaling out, therefore, varying scheduling decisions can lead to different outcomes in energy consumption, affecting overall power consumption. This renders some scheduling decisions less favorable than others in the energy context. For instance, Pollux may prioritize scaling out jobs with lower speedup potential, preventing stragglers and enhancing average JCT. However, this approach directs more resources to jobs with lower energy utilization.

Non-scale-adaptive schedulers overlook the scalability of ML job performance under allocated resources. Tiresias [7] and Gandiva [35], for instance, require users to set a fixed number of GPUs throughout execution, limiting cluster-side performance optimization possibilities.

② **Model-Agnostic**. Some schedulers control model hyperparameters or require prior knowledge of a job (e.g., a specific pattern). Pollux [20] dynamically adjusts DNN hyperparameters (e.g., learning rate, per-GPU batch size) for improved statistical efficiency. Gandiva [35] uses a time-slicing approach for a group of jobs running the same DNN model. AntMan [36] uses a specialized framework for fine-grained GPU-sharing. A recent work, GreenFlow [6], dynamically allocates GPUs and optimizes job-level configurations to reduce average JCT under a carbon emission budget.

However, modifying job configurations introduces compatibility and usability challenges. Key hyperparameters, such

as per-GPU batch size and learning rate, are highly sensitive in ML workloads and exhibits intricate behaviors, especially in modern model architecture such as transformer-based models. Enforcing control over these hyperparameters not only requires additional engineering overhead on users to integrate with external schedulers but also conflicts with model-level optimizations in ML frameworks. Similar concerns have been highlighted in recent scheduler research [11].

③ **Energy-Aware.** GPU power consumption, which varies with utilization, is a key driver of ML models' overall energy usage. For instance, an NVIDIA H100 GPU consumes between 150W at low utilization and over 700W at peak load. Optimizing job energy efficiency thus requires accounting for GPU utilization. Zeus [39] optimizes the trade-off between energy consumption and time efficiency for individual jobs but does not address cluster-wide resource allocation across jobs with varying energy profiles. Meanwhile, prior research on energy-aware optimizations primarily targets generic workloads without leveraging ML-specific characteristics and requirements, as discussed in §2.2.

Design Space of GREEN. GREEN embodies all three attributes discussed above: scale-adaptive, model-agnostic, and energy-aware. Specifically, GREEN achieves energy and time efficiency comparable to prior work, without modifying job-level settings such as model hyperparameters. This approach preserves the non-intrusiveness of GREEN within the user's ML implementation and ensures GREEN's compatibility with both existing and future job-level optimization techniques in ML frameworks (as discussed in §9).

2.2 Carbon-aware Resource Scheduling

When addressing carbon-aware scheduling, it is important to recognize that reducing energy consumption may not be the sole goal. In optimizing for a lower carbon footprint, the focus shifts to carbon intensity, which measures emissions per kWh of power consumption.

Carbon Intensity ($kgCO_2/kWh$) signifies carbon emission per kilowatt-hour of electricity. It can be publicly obtained from public sources as a grid characteristic. Figure 1 illustrates hourly carbon intensity averages using data from UK [18], revealing daily variation.

The conceptual model below calculates carbon footprint.

$$\texttt{FOOTPRINT}_{\texttt{job}} = \int Power_{host} \times Carbon\ Intensity\ dTime$$

The model tracks device power and then integrates the product of power and carbon intensity over time. This integral is essential as both power and carbon intensity are time-varying.

An intuition is that during low carbon intensity time, more optimal scheduling decisions might be possible by moving high-power jobs to these lower periods. Certain ML training jobs exhibit flexibility for this time-shifting. This is because ML model training can span over weeks, or even months for large models, during which they are intermittently paused and resumed based on their scheduling priority [33]. The timing of job execution can be shifted as long as the total allocated resources are preserved within a specified time frame (e.g., 24 hours). By exploiting this flexibility, schedulers can align job power consumption with carbon intensity fluctuations, effectively reducing the overall carbon footprint.

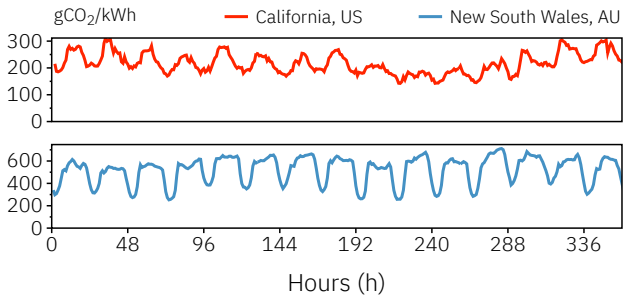

Figure 1: Daily pattern of historical carbon intensity, using data from August 2023 [16]. The carbon intensity of energy supplied by the electric grid depends on the energy sources.

Next, we briefly discuss existing work in carbon-aware scheduling, focusing on the limitations of these approaches in the ML cluster context.

Power and Resource Throttling. Google's CICS [23] imposes a limit on cluster capacity during periods of high carbon intensity. Some approaches [6, 39] utilize Dynamic Voltage and Frequency Scaling (DVFS) to enforce GPU power limits, which directly caps energy usage. However, these methods reduce energy consumption essentially by *scaling back the work performed*. In the MLaaS context, where ML clusters often operate at high occupancy, imposing power or resource limits reduce cluster capacity, leading to a negative impact on overall job completion time (JCT).

Lack of Capacity Constraints. EcoVisor [28] and WaitAWhile [34] use scheduling strategies that do not account for resource competition between jobs. CarbonScaler [8] requires a user-specified job deadline and can scale jobs using unlimited, on-demand cloud resources to meet the deadline. GAIA [9] focuses on cloud environments with on-demand resources, aiming to balance carbon footprint, time performance, and resource cost. In contrast, the MLaaS setting involves static cluster resources, leading to competition between jobs. In this context, the scheduler must make dynamic decisions on resource allocation while adhering to the cluster's resource constraints.

In summary, we observe that prior approaches to carbon-aware scheduling often overlook resource constraints, either throttling jobs during periods of high carbon intensity—leaving resources underutilized—or elastically scaling jobs with unconstrained on-demand capacity, disregarding resource limitations. Meanwhile, some systems require additional user input, such as predefined job deadlines [8] or

carbon budgets [6], which are often difficult for ML workloads due to their unpredictable execution characteristics.

To bridge this gap, we propose GREEN, a resource scheduler for ML jobs that operates strictly within available resource capacity. GREEN exploits characteristics of ML workloads to monitoring and reduce the cluster-wide carbon footprint while preserving time efficiency.

2.3 Motivation and Challenges

We consider the opportunities missed by existing job schedulers to reduce cluster-wide carbon footprint.

Motivation 1: Available resources are not allocated in a way that optimizes energy utilization. Prior ML cluster schedulers focuses on JCT optimization without addressing cluster-wide energy efficiency. As discussed in §2.2, these approaches are either energy-unaware [7, 14, 20] or emphasize at the single-job level [39]. Consequently, they do not effectively optimize for clusters where jobs' energy characteristics vary and resource allocation impacts cluster-wide energy consumption.

Opportunity: The cluster scheduler should determine the appropriate level of resources to allocate to a job, taking into account its scalability in both speed and energy consumption.

Motivation 2: Temporal flexibility of workload is not exploited to reduce carbon footprint. As ML models may take days or weeks to train, ML jobs are generally not sensitive to minor variations in progress during the process. This indicates that they have a certain degree of temporal flexibility. While we also observe the fact that carbon intensity (described in §2.2) varies substantially over time of day, we can exploit the temporal elasticity to consume energy when the electricity grid is less carbon-intensive.

Opportunity: The cluster scheduler should apply temporal shifting to flexible workloads, moving up or delaying them to "greener" hours with lower carbon intensity.

Challenges: The key challenge lies in making carbon-aware scheduling decisions without introducing significant performance degradation. To achieve this, the scheduler must:

- Preserve cluster efficiency: New scheduling and scaling mechanisms must maintain overall cluster efficiency, ensuring job execution speed remains comparable to state-of-the-art schedulers.
- Ensure resource fairness in temporal shifting: When shifting flexible workloads temporally, the total resource allocation over a given period (e.g., 24 hours) must be preserved to prevent job starvation.

3 GREEN Overview

GREEN is a GPU cluster scheduler designed to minimize the carbon footprint of ML job execution, while preserving time efficiency on par with existing ML job schedulers.

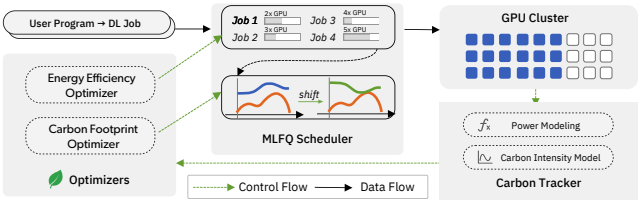

Figure 2: An overview of GREEN's system components and workflow

Workflow. As depicted in Figure 2, GREEN processes user-submitted jobs and allocates resources across them. Being model-agnostic, GREEN makes no assumptions of user implementation under specific frameworks. Similar to existing ML cluster schedulers [7, 20, 29] in the MLaaS setting [33], GREEN optimizes cluster-wide metrics without providing direct SLO or deadline guarantees for individual jobs.

Carbon Tracker (§4). Carbon tracker is the essential component for profiling. It makes GREEN carbon-aware by monitoring factors including per-job energy consumption throughout ML job execution as well as estimating the carbon footprint using the carbon-intensity model. These factors serve as important inputs for GREEN's carbon-related optimizers and scheduling algorithm described below.

Optimizers (§5). We propose two optimizers employed in GREEN: (1) the Energy Efficiency Optimizer, which allocates resources to jobs in a way that maximizes energy efficiency in the cluster, taking into account per-GPU energy-to-progress efficiency, and (2) the Carbon Efficiency Optimizer, which minimizes the cluster-wide carbon footprint by dynamically adjusting job priorities for peak load shifting.

MLFQ Scheduler (§6). The scheduling algorithm utilized by GREEN resembles a Multilevel Feedback Queue (MLFQ), allowing for different scheduling strategies based on varying job states. Two scheduling queues are managed by the aforementioned optimizers, in a synergistic manner: the upper queue emphasizes energy efficiency by scaling out jobs that achieve greater progress with lower energy consumption, while the lower queue maintains the scaling decision from the upper queue and minimizes the carbon footprint by shifting high-power-consuming jobs to greener hours with lower carbon intensity.

4 Carbon Tracker

GREEN is carbon-aware as it monitors per-job energy consumption throughout the execution of an ML job, and estimates carbon footprint using a carbon-intensity model.

4.1 Modeling Power Draw

The job's power draw P_{job} at time t can be estimated with:

$$P_{\texttt{job}}(t) = P_{gpu}(t) + P_{cpu_model}(t) + P_{static}$$

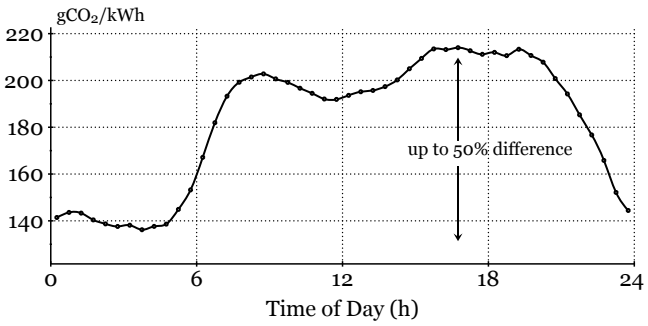

Figure 3: Carbon Intensity Curve (CIC): plotted with average carbon intensity values for each hour of the day in a 3-month period [18]. Y-axis is not zero-based.

We use NVML (NVIDIA Management Library) to read the power draw of GPUs $P_{\texttt{gpu}}$ in real-time. For CPU power consumption, we employ the model [22] to estimate power consumption $P_{\texttt{cpu}}$ in kW from CPU usage. Additionally, to factor in other devices like DRAM and motherboard, which are less influenced by their load, we use a static value $P_{\texttt{static}}$ to represent their power draw.

For the actual calculation, we discretized the equation into a step function with 30-second intervals to minimize measurement overhead. Notably, NVML power readings may not always be accurate [38], but our method remains adaptable to any measurement source, including external power meters for direct hardware power assessment.

4.2 Estimating Carbon Footprint

Carbon Footprint refers to the cumulative amount of carbon emissions generated since the start of a job. These emissions are measured in units of kilograms of carbon dioxide ($kgCO_2$).

Carbon Intensity. We introduce the Carbon Intensity Curve (CIC) as our carbon intensity model (Figure 3).

$$\texttt{FOOTPRINT}_{\texttt{job}}(T) = \int_0^T P_{\texttt{job}}(t) \cdot CIC(t)dt$$

The equation above defines the carbon footprint. By calculating the integral of $P_{job} \cdot CIC$ over time t, the result reflects both power consumption and carbon intensity over time.

Carbon intensity data is publicly accessible online in many regions [16, 31]. In our implementation, we make use of historical carbon intensity data, as it usually exhibits consistent daily pattern over a period of time. GREEN's carbon footprint optimizer can adapt to any pattern of CIC (§5.2), and recent work [28] proposes a software-based energy system to retrieve energy usage and carbon intensity in real-time.

5 GREEN Optimizers

This section introduces two optimizers in GREEN's scheduling algorithm: Energy Efficiency Optimizer (§5.1) allocates resources to jobs to maximize energy efficiency, taking into account the scalability of per-GPU energy-to-progress efficiency. Carbon Footprint Optimizer (§5.2) reduces the cluster-wide carbon footprint by dynamically adjusting job priorities to shift peak loads to greener hours.

5.1 Energy Efficiency Optimizer

The objective of GREEN's Energy Efficiency Optimizer is to determine the appropriate level of resources to allocate to a given job, maximizing energy efficiency in the cluster. This objective is motivated by the observation that a job's scalability measured in energy efficiency may differ from its performance scalability (e.g., training throughput), leading to suboptimal cluster-wide energy efficiency.

Definition. To quantify energy efficiency, we formulate it as the derivative of job progress $Progress_{\texttt{job}}$ with respect to total accumulated energy usage $\texttt{W}_{\texttt{job}}$, as shown in Equation 1.

$$\texttt{EFFICIENCY}_{\texttt{job}}(t) = \frac{\mathrm{d}Progress_{\texttt{job}}(t)}{\mathrm{d}\texttt{W}_{\texttt{job}}(t)} \tag{1}$$

This formulation enables the scheduling algorithm to leverage two key pieces of information:

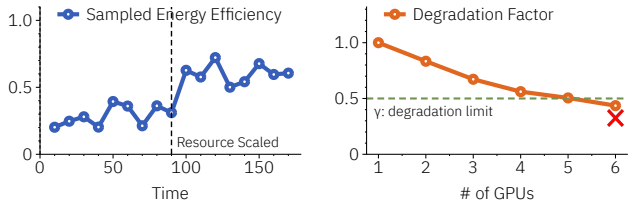
- Jobs with higher energy efficiency are able to make more progress with the same power consumption when compared to jobs with lower energy efficiency.
- By allocating more computing resources to a job, GREEN can observe changes in energy efficiency and learn about the job's scalability. Ideally, there would be no decrease in energy efficiency when scaling out a job.

The unit of energy efficiency is *not* important, as long as it can be considered as a unit of work done over a unit of power consumption. This is because our focus is on observing its relative change ratio during the job's execution, and the unit cancels out in the calculation.

Calculation of Energy Efficiency. In Equation 1, energy efficiency is defined as a function of time, and to obtain this function for an actual job run, GREEN needs to approximate it using runtime data. There are two built-in methods for GREEN to measure the progress of a job, depending on whether the progress of a job can be directly obtained during its runtime.

If job progress is available, GREEN calculates the efficiency function by sampling progress for a duration of time as defined in Equation 2.

$$\texttt{EFFICIENCY}_{\texttt{job}}(t) = \frac{Progress_{\texttt{job}}(t) - Progress_{\texttt{job}}(t-\Delta t)}{\texttt{W}_{\texttt{job}}(t) - \texttt{W}_{\texttt{job}}(t-\Delta t)} \tag{2}$$



(a) Energy Efficiency **(b)** Degradation Factor

Figure 4: An example of energy efficiency calculation. *Left*: Energy efficiency data sampled before and after resource scaling, with the unit being % of progress per kWh. *Right*: Degradation factor over the number of GPUs, obtained by averaging efficiency data per GPU.

The variable Δt represents the time elapsed since the most recent job scaling event. GREEN tracks job progress by recording the number of completed epochs and finding the ratio of completed epochs to the total epochs. This method works well because ML training repeats in rounds and each training epoch takes roughly the same amount of time.

If job progress cannot be directly obtained, such as when training large models with long epoch time, GREEN can approximate progress using the job's training throughput $Throughput_{\texttt{job}}$, i.e., the number of data samples trained over a duration of time, as shown in Equation 3.

$$\texttt{EFFICIENCY}_{\texttt{job}}(t) = \frac{\Sigma_{t'=t}^{t-\Delta t} Throughput_{\texttt{job}}(t')}{\texttt{W}_{\texttt{job}}(t) - \texttt{W}_{\texttt{job}}(t-\Delta t)} \quad (3)$$

When progress measurements are not available, the formula represents an absolute value of the progress made (i.e., throughput) during that duration of time.

Figure 4a shows an example of the energy efficiency collected before and after one scaling event.

We make note that retrieving job throughput is a common practice in today's cluster schedulers [20, 39], in practice, it often just requires a simple log print by the job.

Job Scaling with Energy Efficiency. Dynamic job scaling plays a crucial role in enhancing the performance of ML cluster JCT [20]. GREEN employs the energy efficiency metric, as defined earlier, to make scaling decisions.

For each job that is prepared to run, it commences with one GPU (or the minimum number of GPUs necessary for the job). We introduce an efficiency degradation factor, which represents the proportion of per-GPU energy efficiency decline relative to the initial job energy efficiency:

$$\texttt{DEGRADATION}_{\texttt{job}}(\texttt{t}) = \frac{\texttt{EFFICIENCY}_{\texttt{job}}(\texttt{t})}{\texttt{EFFICIENCY}_{\texttt{job}}(\texttt{t}_0)} \quad (4)$$

where $\texttt{EFFICIENCY_job}(\texttt{t}_0)$ represents the job's energy efficiency with the minimum GPU required, which is profiled at the beginning time (t_0) of the job's execution.

In subsequent scheduling rounds, the job will receive an additional GPU if its efficiency degradation factor remains above a threshold γ. For instance, with γ at 0.9, it means that the job's energy efficiency must not decrease by more than 10% to be eligible for scaling out. The value of γ is dynamically adjusted according to both the cluster-wide occupancy rate and job characteristics to prevent over- or under-allocation of resources. Additionally, A maximum resource cap prevents well-scaled jobs from taking up all GPU resources. More details about GREEN's adaptive strategy can be found in §6.4.

Figure 4b demonstrates an example of the change in energy efficiency during scaling. The unit of energy efficiency cancels out, as we only use its relative change in percentage as a scheduling factor during job execution. This scaling approach reduces the cluster's carbon footprint by allocating more resources to jobs that efficiently utilize energy for progress.

Relation with Single-job Optimizations. The design of the Energy Efficiency Optimizer is orthogonal to previous optimizations on the job-level. GREEN optimizes the energy efficiency with resource allocation strategies, while earlier work such as [39] takes resource allocation as an input, and investigates job-level parallelization and configurations to optimize efficiency. These optimizations can be combined and utilized together to enhance overall energy efficiency.

5.2 Carbon Footprint Optimizer

The Carbon Footprint Optimizer in GREEN aims to reduce the cluster-wide carbon footprint through peak load shifting. This is achieved by dynamically adjusting job priorities in scheduling.

The job priority is calculated as a combination of two factors, namely the Carbon Factor and the Shifting Factor, with higher priority values indicating lower scheduling priorities.

$$\texttt{PRIORITY}_{\texttt{job}} = \left(\frac{\texttt{FOOTPRINT}_{\texttt{job}}}{\texttt{DEGRADATION}_{\texttt{job}}}\right) \cdot \texttt{SHIFTING}_{\texttt{job}} \quad (5)$$

An input t, denoting the system time, exists for all factors defined above and is omitted for readability.

Carbon Factor. The carbon factor is calculated by dividing a job's accumulated carbon footprint, denoted as $\texttt{FOOTPRINT}_{job}$ (§4), by its energy efficiency degradation factor represented by $\texttt{DEGRADATION}_{job}$ (Equation 4).

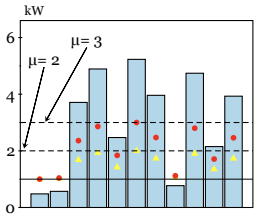
The Carbon Factor serves as the foundation for job priority and exhibits two essential properties:

(1) It tracks the carbon emissions produced during a job's execution, similar to the Least-Attained-Service (LAS) algorithm, while taking environmental impact into account. This factor helps achieve fair resource allocation among all jobs.

(2) It penalizes jobs with poor energy efficiency by dividing their carbon footprint by the degradation factor. This method enables energy-efficient jobs that are scaled out by the Energy Efficiency optimizer to complete earlier, thereby enhancing overall JCT. It also helps to avoid the unnecessary occupation of the cluster's computing resources.

$\texttt{SHIFTING}_{\texttt{job}}$	if $P_{job} \leq \widetilde{P}$	if $P_{job} > \widetilde{P}$
if $CIC_t \leq \bar{I}$	$P^*_{\texttt{job}}$	$1/P^*_{\texttt{job}}$
if $CIC_t > \bar{I}$	$1/P^*_{\texttt{job}}$	$P^*_{\texttt{job}}$

(a) Function for Shifting Factor



(b) $P^*_{\texttt{job}}$ Example

Figure 5: Left: Piecewise function for calculating Shifting Factor. Right: $P_{\texttt{job}}$ (bar) and $P^*_{\texttt{job}}$ when $\mu = 2$ (yellow dots) or $\mu = 3$ (red dots).

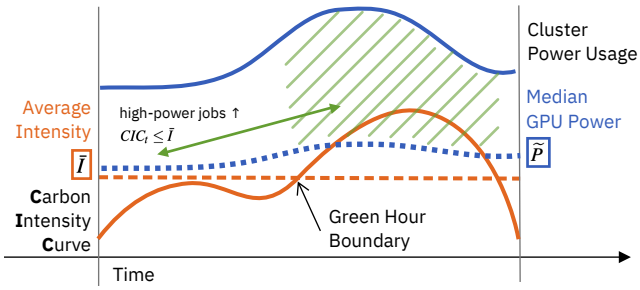


Figure 6: High-power jobs have higher priority when carbon intensity is below $\bar{I}$, and are assigned a small shift factor according to Table 5a to be scheduled earlier. The curve shown in figure is pre-shifting.

Shifting Factor. Temporal job shifting follows a heuristic that favors delaying high-power consumption jobs to "greener" hours with low carbon intensity and prioritizing low-power-consumption jobs during high-carbon-intensity periods.

The core idea behind the shift factor calculation is to adjust job priorities based on the current carbon intensity level relative to the daily values and the job's power consumption level relative to all unfinished jobs.

A piecewise function is employed, as outlined in Figure 5a, to achieve this using $\widetilde{P}$ and $\bar{I}$ as boundary values, dividing the shifting factor calculation into four quadrants:

1) *Average carbon intensity*, denoted by $\bar{I}$, is calculated using historical carbon intensity data, the hours with carbon intensity lower than $\bar{I}$ are considered to be *greener hours*.

2) *Median GPU power consumption*, denoted by $\widetilde{P}$, is obtained by finding the median GPU power draw over all profiled or running jobs. The jobs with GPU power draw higher than $\widetilde{P}$ are considered to be *high-power jobs*.

The piecewise function for calculating shifting factors rescales the job's power consumption $P_{\texttt{job}}$ to $[1, \mu]$, denoted as $P^*_{\texttt{job}}$, as defined below:

$$P^*_{\texttt{job}} = \frac{(P_{\texttt{job}} - P_{min})}{(P_{max} - P_{min})} \times (\mu - 1) + 1 \tag{6}$$

The parameter μ (≥ 1) controls the scale of $P^*_{\texttt{job}}$ (example shown in Figure 5b) and hence the degree of temporal shifting, with larger values causing more job shifting. When $\mu = 1$, temporal shifting is essentially disabled, as the shifting factor is always scaled to 1. Evaluations show that $\mu = 2$ effectively balances the two factors to achieve both time and carbon efficiency (see sensitivity experiments in §A.2).

Figure 6 depicts an example usage of the piecewise function: when the current carbon intensity is lower than $\bar{I}$, the high-power jobs are assigned with a small shifting factor according to Figure 5a, resulting in higher job priority.

The optimizer can adapt to any pattern of carbon intensity changes, as it dynamically calculates the boundary values $\bar{I}$ and $\widetilde{P}$ based on given CIC and job power consumption.

Impact on Cluster-wide and Individual JCT. Deferring high-power tasks does not necessarily lead to a delay in the cluster-wide job completion time (JCT). This is because the scheduler swaps the daily computation resources assigned to high-power and low-power jobs in the temporal dimension but preserves daily capacity for a job. Analysis in §6.4 detailed the discussion about how GREEN avoids starvation for both long and short jobs. Meanwhile, our evaluation in §8.2.2 also provides empirical evidence to support the statement.

6 Putting It Together: MLFQ Scheduling

GREEN's scheduling algorithm resembles a Multilevel Feedback Queue (MLFQ), which employs different scheduling strategies based on job states (Figure 7).

6.1 Upper Queue: Online Profiling and Scaling

The upper queue utilizes the Energy Efficiency (EE) Optimizer (§5.1) to determine the scale of computing resources allocated to each job, ensuring that jobs with higher energy efficiency receive a greater share of energy. The logic is shown in Algorithm 1 lines 3-11.

Upon submission to the cluster, new jobs are placed at the end of the upper queue and profiled for potential scaling.

When a job is initially submitted for execution, it starts with a single GPU (or the minimum number of GPUs necessary for the job). Repeatedly for each scheduling round, GREEN iterates through the queue in the first-come-first-serve (FCFS) order, and evaluates the energy efficiency degradation factor to determine a job's eligibility for further scaling (lines 4-7). When there are multiple jobs in this queue, the additional unit of computing resources is allocated to them in FCFS order until the cluster reaches its maximum capacity (lines 7-8).

Queue Transition. The job will not leave the upper queue as long as it is still eligible for scaling. Jobs transition to the lower queue once the EE optimizer has completed the scaling process. Transitioning between queues does not necessarily interrupt the job's execution, as it may remain eligible to run based on the priority assigned in the lower queue.

6.2 Lower Queue: Peak Load Shifting

The lower queue employs the Carbon Footprint (CF) Optimizer (§5.2) to conduct peak load shifting by relocating

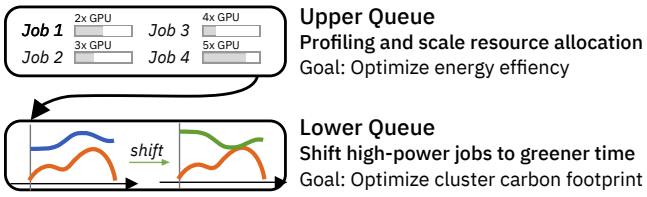

Figure 7: MLFQ enables two optimizers to work together. The upper queue determines the job's spatial placement (number of GPUs), while the lower queue decides the temporal aspect (time to run) to achieve different optimization goals.

energy-intensive jobs to greener hours with lower carbon intensity, thus reducing the cluster-wide carbon footprint. The core scheduling logic is shown in Algorithm 1 lines 12-17.

The lower queue determines job priorities using the CF optimizer, while inheriting resource scaling decisions from the upper queue. Partial execution from online profiling, is considered part of the running time, and the work completed during this phase is retained as part of the job progress.

In the lower queue, GREEN calculates each job's priority based on two factors (§5.2): the carbon factor, which considers job energy consumption while ensuring fairness in resource allocation, and the shifting factor, which moves high-energy-consuming jobs to hours with lower carbon intensity. GREEN sorts jobs by their priorities and schedules them for execution in descending order.

6.3 Scheduler Workflow

The scheduling workflow consists of both active and passive components.

Active scheduling, shown in Algorithm 1, operates in rounds to assign job priorities and preempt lower-priority jobs. It ranks jobs for immediate execution at the top (triggering preemption), followed by jobs in the FCFS upper queue, and then those in the lower queue ordered by the priorities calculated (line 12).

To limit excessive preemption, the interval between active scheduling, known as the time quantum, is set to 30 minutes. Our findings in §A.2 show that this interval length does not significantly influence overall outcomes, as long as it is not excessively short.

Passive scheduling comes into effect in the intervals between active scheduling rounds. During these periods, when a job finishes and releases resources, the scheduler deploys the passive strategy to avoid idling. This passive strategy starts the next job based on its rank in the latest active scheduling without recalculating priorities or triggering preemptions.

Job SLO and Preemptions. Similar to existing cluster schedulers [7, 20, 29] used in MLaaS environments [33], GREEN prioritizes global cluster efficiency rather than providing strict Service Level Objectives (SLOs) or deadline guarantees for individual jobs. GREEN assumes all jobs are preemptible, which may not align with workloads requiring strict execution guarantees. In real-world deployments, GREEN's scheduling policy may be overridden to prevent preemptions for jobs with specific requirements.

Algorithm 1: Carbon-efficient MLFQ Scheduling

Input:
- Jobs in Upper and Lower Queue: $\mathcal{J}_\mathcal{U}, \mathcal{J}_\mathcal{L} \in \mathcal{J}$
- Cluster Capacity and Upper Queue Cap: $\mathcal{C}$ and θ
- Current Timestamp: t

```
1  begin
2      Allocation A = { }
3      for Job J ∈ J_U ordered by DEGRADATION_J do
4          if DEGRADATION_J = ΔEFFICIENCY_J ≥ γ then
5              Scale out J with one more GPU
6              A = A ∪ J
7              if Capacity(A) > θ × C then
8                  break
9          else
10             Remove J from J_U and add to J_L
11     end
12     PRIO_J = (FOOTPRINT_J / DEGRADATION_J) · SHIFTING_J  ∀J ∈ J_L
13     for Job J ∈ J_L ordered by PRIORITY_J do
14         A = A ∪ J
15         if Capacity(A) > C then
16             break
17     end
18     Signal jobs ∀J ∈ J / A for preemption
19     Allocate GPUs for ∀J ∈ A
20 end
```

6.4 Starvation Avoidance

Starvation Avoidance for Short Jobs. In the upper queue, where job scaling occurs, as a job progresses and could potentially be complete, it implicitly favors jobs with lower GPU consumption. This approximates the short-job-first (SJF) strategy, improving average JCT and avoiding starvation of shorter jobs. The scaling process in the upper queue also eliminates the need for a separate profiling stage. In the lower queue, the carbon footprint-based factor has an LAS-like behavior, which deprioritizes and preempts longer-running jobs over time, making room for shorter jobs. In §8.2.2, we quantitively evaluate the impact on cluster-wide and individual JCTs.

Starvation Avoidance for Long Jobs. To prevent starvation of longer jobs during peaks of new job submissions (when new jobs enter the upper queue and gain priority over existing long jobs in the lower queue.), a knob for the capacity cap is enforced in the upper queue. Default of 30%, this cap limits the total cluster capacity available to jobs in the upper queue. Upon reaching this cap, the scheduler prioritizes the jobs by their degradation factors, skips the remaining upper queue and considers the lower queue (Line 3-11 in Algorithm 1).

7 Implementation

We implement GREEN with Slurm [25]. Slurm is an open-source job cluster management system widely used to manage computing clusters. See Appendix B for our open-source plan.

Scheduler Implementation. GREEN's scheduler workflow is implemented as a Slurm scheduler plugin that supports custom policies to set job priorities in Slurm's job queue. The scheduler plugin communicates with an external daemon process, which stores CIC data, collects job energy statistics from profiler agents running on each compute node, and returns scheduling decisions to the scheduler plugin.

Energy-efficient Job Termination. We adopt the popular checkpoint-restart methods [20] for job scaling and preemption. However, the method may lose intermediate results since the last checkpoint, wasting computational resources. GREEN sends a `SIGTERM` signal with a 120-second grace period to ML jobs upon termination, allowing jobs to save a checkpoint after completing the current iteration and exit gracefully. The time for checkpointing and subsequent restart is recorded as part of the job's execution time.

8 Evaluation

We evaluated GREEN using time and energy metrics, comparing them against five baseline schedulers under a real-world ML workload and a trace-driven simulation workload.

8.1 Experimental Setup

Testbed. Our testbed cluster consists of 32 compute nodes. Each node is equipped with 2 Nvidia RTX 3090 GPUs, 20 CPU cores, and 64GB RAM, interconnected with the Mellanox ConnectX5 NIC. The nodes are managed by Docker, and all run on 64-bit Ubuntu 18.04 with CUDA v11.1.

Baseline Schedulers. We compare GREEN to 5 schedulers, representing the state-of-the-art in their respective categories, as introduced in §2. For schedulers that are not scale-adaptive, we preset each job's GPU allocation to the point where GREEN achieves the best energy efficiency.

1) *Tiresias* [7]. Tiresias adopts Least-Attained-Service (LAS) scheduling for ML clusters.

2) *GAIA's Carbon-Time* [9]. GAIA's Carbon-Time policy schedules jobs to start at times that minimize carbon emissions, allowing a maximum delay specified by parameter W. We set W to 12 hours, as suggested by the original paper.

3) *EcoVisor* [28]. EcoVisor enforces carbon-aware policies for jobs. We extend and implement its policy: jobs are queued in arrival order if the carbon intensity is higher than the threshold (set 10th percentile of the CIC in use).

4) *Pollux* [20]. Pollux is the state-of-the-art ML scheduler, jointly optimizing job hyperparameters and cluster resource allocation. Pollux is not model-agnostic and not energy-aware.

5) *Zeus* [39]. Zeus adjusts model hyperparameters and GPU power limits for individual jobs. We use Tiresias to allocate resources across jobs in our evaluation.

ML Workload. We collected 791 jobs from real users over a 24-hour period on a university-managed production cluster [32], containing self-contained job packages (code, data, configs). We replayed these jobs in our testbed following their original submission timeline. Our evaluation, with 791 jobs, is about 5 times larger than prior work (e.g., Pollux with 160 jobs [20]). The training duration of each job ranged from 1 minute to 37 hours (detailed in Table 2) and involved large ML models for tasks such as image classification (ResNet-50 [10], ShuffleNet [41]), speech recognition (DeepSpeech2 [2]), and natural language processing (BERT [5], GPT-2 [21]).

Pollux and Zeus are not model-agnostic and require job-specific configurations. Since user-submitted jobs may have incompatible implementations, we invested 100 man-hours to manually adjust them. Over 55% of the 791 jobs had unresolvable issues, such as unsupported learning rate scalers or gradient optimizers, while about 25% were excluded due to non-standard ML model implementations. Ultimately, we adjusted 150 jobs for non-model-agnostic evaluations (§8.2.3).

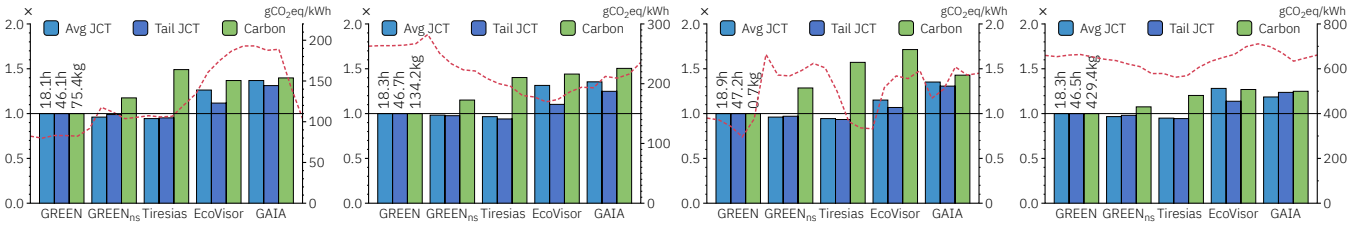
JCT Measurements. Typical ML cluster schedulers (as seen in baseline schedulers) operate in multi-tenant ML clusters where users submit jobs that run independently without deadline constraints. This workflow is also known as MLaaS [33]. The cluster scheduler allocates resources to optimize cluster-wide metrics like average JCT. In our testbed evaluation, we replayed jobs on their original timeline and calculated individual JCTs as the time from submission to completion — including queueing and preemption, with each job's running time determined by its user program.

Carbon Footprint Estimation. We tracked energy consumption to estimate emissions (details in §4), following a calculation method consistent with existing carbon-aware systems [8, 23, 28, 34]. In our evaluation, we used historical hourly carbon intensity data from Electricity Maps [16] for August 2023 across four regions: California, USA; the United Kingdom; Sweden; and Poland. These regions represent diverse combinations of carbon intensity and variability. Figure 8 presents the 24-hour carbon intensity patterns for each region in their respective subfigures with dotted red lines.

GREEN's scheduling algorithm (§5) dynamically computes boundary values for job shifting based on a given Carbon Intensity Curve (CIC). In our evaluation, we provide a 48-hour CIC to GREEN, representing typical carbon intensity patterns. For the year-long simulator experiments, a new 24-hour CIC is provided for every 24 hours to GREEN using consecutive historical data in 2023 to evaluate GREEN's adaptability to long-term, seasonal changes in carbon intensity.

8.2 Testbed Experiments

GREEN reduces the cluster-wide carbon footprint by up to 41.2%, with a trade-off of up to 3.6%-5.9% in average JCT and 5.1%-7.1% in tail JCT under a real ML workload when



(a) United Kingdom **(b)** California, USA **(c)** Sweden **(d)** Poland

Figure 8: Cluster-wide carbon footprint and JCT were evaluated across four regions with different carbon intensity profiles. The dotted red line shows the 24-hour carbon intensity pattern (right axis). The results are shown as ratios to GREEN (left axis).

compared to state-of-the-art cluster schedulers.

8.2.1 Cluster-wide Carbon Footprint

Figure 8 shows that GREEN reduces the cluster-wide carbon footprint by up to 41.2% (32.2% on average across 4 regions). When evaluating GREEN without job shifting over time (shown as GREEN_{ns}, meaning 'no shifting'), it achieves an average carbon reduction of 21% across the four regions.

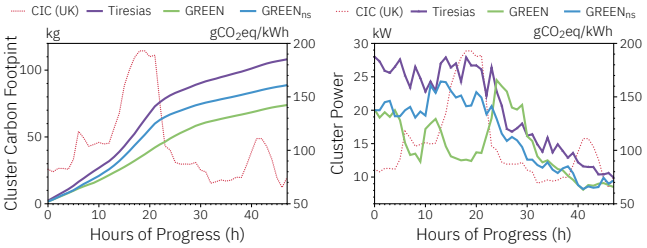
Performance variations across regions. Regions with high variability in carbon intensity see more significant carbon footprint reductions due to job shifting during greener hours, such as the UK and Sweden (Figure 8a and 8c). As GREEN makes dynamic adjustments of the shifting threshold based on the carbon intensity profile, the average carbon intensity does not substantially affect the reduction percentage. However, we make a note that while the reduction percentage can be significant (over 30%), the absolute carbon footprint reduction may be minimal in areas like Sweden, where carbon intensity is comparatively low (less than 1% relative to other regions). In such cases, job shifting might introduce unnecessary overhead. These practical considerations are also noticed in recent literature [9, 30] and are further discussed in §9.

Carbon Footprint and Power Consumption. By monitoring energy efficiency during job scaling, GREEN avoids allocating additional resources to jobs with low energy efficiency. Figure 9a demonstrates the carbon footprint curve of GREEN, showing how the growth rate during high carbon intensity hours is lower than the other baselines. Figure 9b shows that GREEN reduces the cluster-wide power consumption. Under the UK CIC trace, GREEN achieves a 12% peak power reduction (from 28kW to 24.5kW) and a 25% decrease in total energy consumption (from 966kWh to 725kWh). This result shows another benefit of GREEN: physical clusters are typically designed and billed based on peak demand, and lower peak power usage reduces the required power capacity.

Comparison with Carbon-aware Baselines. GREEN outperforms GAIA and EcoVisor by 25.2% in average JCT across 4 regions. GAIA and EcoVisor delay job starts until the estimated carbon footprint is lower, often leaving resources idle during high carbon intensity periods. In contrast, GREEN dynamically calculates the job shifting threshold and prioritizes lower-power jobs during high-intensity periods, reducing power usage without leaving resources idle.

GAIA and EcoVisor exhibit higher carbon footprints because, in the multi-tenant ML cluster setting (targeted by GREEN, Tiresia, Pollux, and similar cluster schedulers), resource capacity is static: when jobs are delayed to a greener hour, idle resources still consume a baseline level of energy.

It is important to note that GAIA and EcoVisor are effective in their intended cloud environments, where resources are requested on demand by users, and idle resources do not incur additional costs or carbon emissions. Our evaluation extends their policies for multi-tenant ML cluster setting, where resource competition and constraints are factors.



(a) Cluster-wide carbon footprint **(b)** Cluster-wide power draw

Figure 9: Cluster-wide carbon emission accumulation and power draw over the evaluation period (the same period shown in Figure 10). The dotted red line shows CIC on the right axis.

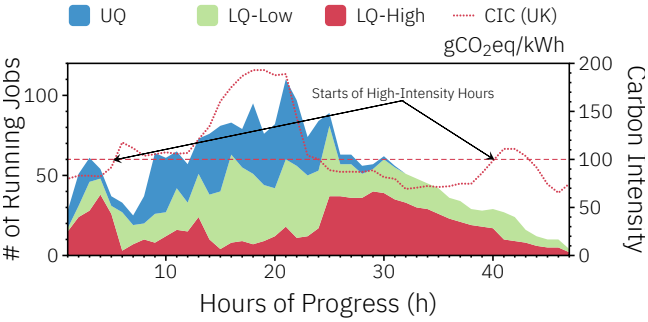


Figure 10: Job scheduling timeline showing the number of high- and lower-power jobs (left axis) responding to carbon intensity changes. UQ: Upper Queue; LQ-High/LQ-Low: Lower Queue's high/low-power jobs. The dotted red line represents the CIC and its boundary value (right axis).

Job Size (% of Total Jobs)	JCT Increase	
	Average	Tail
Extra Small Jobs (0-9 minutes, 22%)	−0.5%	−0.4%
Small Jobs (10-59 minutes, 30%)	1.7%	1.2%
Medium Jobs (1 - 10 hours, 30%)	4.4%	4.8%
Large Jobs (≥ 10 hours, 18%)	6.9%	5.8%

Table 2: GREEN's impact on individual JCTs compared to Tiresia across 4 job size categories.

8.2.2 JCT Performance

Figure 8 shows that GREEN maintains comparable JCT to baseline schedulers. Compared to the best-performing baseline, Tiresia, GREEN shows a 3.6%-5.9% increase in average JCT and a 5.1%-7.1% increase in tail JCT. With time-shifting disabled (GREEN_{ns}), the difference is smaller at 1.7%-1.8%, while still achieving a 21% reduction in carbon footprint.

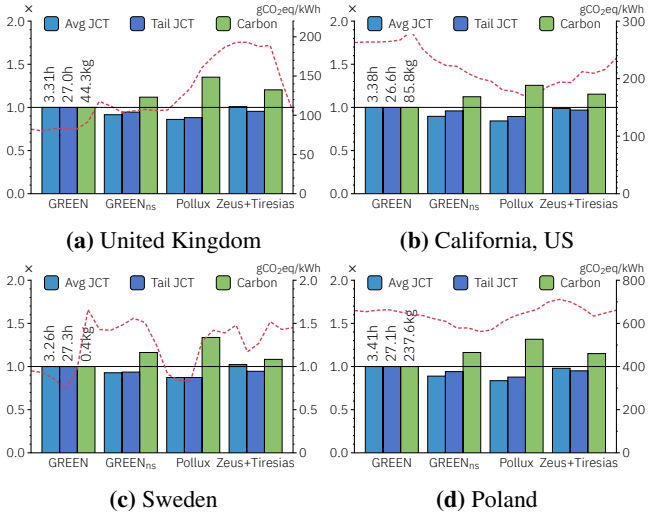
Cluster-wide Job Timeline. Figure 10 illustrates the job scheduling timeline in our testbed. During the transition between high and low carbon intensity hours, job priorities are swapped — lower-power jobs take precedence in high-intensity periods to reduce cluster power consumption. This adjustment is also reflected in Figure 9b, where power draws decrease during high carbon intensity hours. As shown in the figure, not all high-power jobs are stopped during high-intensity periods. They still run when (1) lower-power jobs do not fully utilize available resources or (2) high-power jobs have smaller carbon terms (§5) and gain higher priority.

Impact on Individual JCTs. Table 2 shows the evaluation of GREEN's impact on jobs' individual JCTs by comparing with Tiresia (the best JCT baseline) across 4 size categories based on total running time. GREEN had a maximum JCT increase of 6.9% for large jobs and a decrease of 0.5% for smaller jobs, demonstrating its effective use of MLFQ to prioritize shorter jobs while avoiding starvation of longer ones.

To understand the trade-off between overall JCT and carbon consumption, we conducted sensitivity analyses to evaluate how different extents of time shifting impact this trade-off. The results are provided in Appendix A for interested readers.

8.2.3 Non-Model-Agnostic Baselines

Figure 11 shows that GREEN reduces the carbon footprint by 23.9% on average across four regions compared to Pollux, with trade-offs of 17.2% in average JCT and 13.4% in tail JCT. Given that Pollux outperforms prior model-agnostic schedulers like Tiresia and Optimus by over 50% [20], this highlights GREEN 's ability to balance speed and carbon efficiency while remaining model-agnostic. GREEN also outperforms the combined Zeus (single-job energy optimization with GPU power limits) and Tiresia solution, achieving a 12.7% carbon footprint reduction with a similar average JCT.



(a) United Kingdom **(b)** California, US

(c) Sweden **(d)** Poland

Figure 11: Non-model-agnostic baselines evaluated with 150 compatible testbed jobs. Results are shown as ratios to GREEN (left axis), with CIC in dotted red lines (right axis).

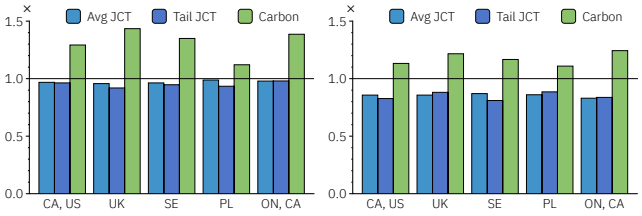
8.3 Trace-Driven Simulator Experiments

We conducted a year-long simulator experiment to evaluate GREEN's adaptability to seasonal changes in carbon intensity.

Simulator Construction. The simulator operates as a step-based discrete-time system with a 1-minute granularity, resulting in 518,400 steps for a full year. Each step performs three tasks: (1) calculate job progress and carbon footprint based on GPU time, progress factor (%/minute), current CIC, and power draw; (2) check the job trace for new job arrivals and adding them to the queue; (3) call the simulated scheduler to adjust jobs based on scheduling policies.

For workload simulation, we sample 400 job submissions from a 24-hour window in Alibaba's cluster workload trace [33] and repeat this process 365 times to construct a year-long trace with 146,000 jobs. The trace provides submission times and durations but lacks model-specific details. Following prior simulation methodologies in Pollux and Zeus, we categorize jobs by duration and map them to training jobs from our production workload (§8.1). To accurately model job execution, we pre-run jobs under varying configurations (e.g., GPU count, batch size) and record progress factors and power consumption. This enables the simulator to infer job progress and energy usage based on scheduling decisions. Additionally, we track checkpoint-resume overheads for each job category for preemptions to ensure simulation fidelity.

Performance Analysis. Figure 12 shows our simulation results. We evaluated GREEN across five regions, including Ontario, Canada, and compared it to the best-performing baselines, Tiresias and Pollux. The simulator showed improvement patterns across regions similar to our testbed results (showing better performance in high-variance locations). Compared to Tiresias, GREEN reduced the carbon footprint by 31.6%, with a 5.1% increase in average JCT and 7.5% in tail JCT.



(a) Tiresias **(b)** Pollux

Figure 12: Baselines evaluated in a year-long simulation across 5 regions. Results are shown as ratios to GREEN.

Job Size (% of Total Jobs)	JCT Increase	
	Average	Tail
Extra Small Jobs (0-9 minutes, 16%)	−0.1%	−0.3%
Small Jobs (10-59 minutes, 38%)	2.4%	4.7%
Medium Jobs (1 - 10 hours, 36%)	5.5%	8.0%
Large Jobs (≥ 10 hours, 8%)	5.9%	6.1%

Table 3: GREEN's impact on individual JCTs compared to Tiresia in the simulator, breaking down by job sizes.

Compared to Pollux, GREEN achieved a 21.1% reduction in carbon footprint with a 15% increase in both average and tail JCT. We also report individual JCT impact in Table 3. Overall, the results show that GREEN adapts to seasonal carbon intensity variations to deliver carbon and time efficiency.

9 Applicability and Limitations

We discuss the applicability of GREEN's core designs.

Carbon Tracking and Forecasting. While GREEN effectively reduces carbon emissions through optimized GPU scheduling, several broader factors influence ML clusters' overall carbon footprint. Notably, *embodied carbon*—the emissions associated with hardware manufacturing, transportation, and lifecycle—is not considered in GREEN's model. Additionally, GREEN does not account for *data center Power Usage Effectiveness (PUE)*, which captures energy overheads from cooling, power distribution, and auxiliary infrastructure. We note that scheduling has a limited impact on carbon emissions from these factors. Recent work has shown that carbon-aware scheduling should not account for embodied carbon emissions, as they represent a sunk cost [4]. Similarly, PUE optimization is typically addressed at the data center design level and largely independent of workload scheduling.

GREEN dynamically adjusts workload execution based on carbon intensity forecasts, leveraging publicly available carbon data to estimate emissions. However, inaccuracies in carbon intensity predictions can lead to suboptimal scheduling decisions, and incorporating more accurate forecasting methods [15] could improve scheduling effectiveness. Furthermore, integrating real-time carbon intensity data directly from data centers presents an opportunity to enhance carbon-aware scheduling, which remains an open research challenge.

Scheduling Mechanism. GREEN's scheduling mechanism supports diverse ML task types and GPU heterogeneity, as its carbon tracking methods can generalize across various ML training regimes. However, GREEN is not well-suited for inference workloads, which are latency-sensitive as they respond to user requests in real time. The preemption-based scheduling mechanisms used by GREEN may introduce unexpected interruptions for inference tasks.

We also identified the following cases where GREEN's scheduling approach may have limited effectiveness:

- Special carbon intensity patterns: In regions with consistently low carbon intensity (e.g., Sweden), significant emission reductions are harder to achieve. Similarly, when carbon intensity remains stable, temporal job shifting may not be effective and could cause unnecessary scheduling overhead from frequent preemptions.
- Long job starvation: While GREEN includes starvation mitigation mechanisms, long-running jobs in highly congested clusters may still experience delays due to its LAS-based scheduling. Like Tiresias [7], a starvation threshold that resets job priority can be used to prevent starvation.

Integration with ML Frameworks. System research in ML is progressing quickly, with significant improvements in frameworks and optimization methods [12, 17, 27, 40]. Previous studies [33] show that GPU usage can vary widely across ML workloads depending on the optimization techniques used, which also affect power consumption. GREEN is designed to be *non-intrusive*, meaning it can schedule ML tasks without requiring users to change their code. Therefore, it is *orthogonal* to job-level optimizations, allowing it to work with both current and future ML system improvements.

10 Conclusion

GREEN utilizes a carbon-intelligent algorithm to schedule, scale, and shift workloads to optimize cluster-wide environmental and efficiency performance. We evaluate GREEN under real ML workloads in a production cluster and show that it can achieve significant carbon footprint reductions while maintaining time efficiency comparable to existing work.

Acknowledgments

We thank our shepherd, Noman Bashir, and the anonymous reviewers from NSDI 2025, as well as reviewers from our previous submissions, for their valuable feedback. GREEN was developed and evaluated on the TACC cluster [37] at the Hong Kong University of Science and Technology. This work is supported in part by the Hong Kong RGC TRS T41-603/20R, GRF 16213621, NSFC 62062005, 62402407. Han Tian and Kai Chen are the corresponding authors.

A Deep Dive Experiments

In the deep dive experiments, we inspect the effectiveness of each GREEN's design component and also conduct a sensitivity analysis of the parameter used in the scheduling algorithm.

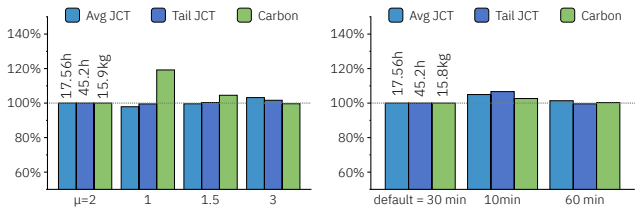
A.1 Understanding the Optimizers

Impact of Energy Efficiency Optimizer (§5.1). The optimizer allocates more resources to jobs with higher energy efficiency. We evaluate the impact of energy-efficiency-based scaling by fixing the number of GPUs to 1 and 2. Our results in Table 4 demonstrate that dynamic scaling decisions impact both energy consumption and execution speed, as evidenced by its worse performance in both carbon footprint and JCT.

Impact of Carbon Footprint Optimizer (§5.2). We replaced the carbon term with an LAS factor: the number of GPU hours consumed by the job. The results, as presented in Table 4, indicate that the cluster-wide carbon footprint increases by approximately 16%, as jobs with higher energy efficiency are no longer prioritized for scaling. We then disabled the temporal shifting by fixing the Shifting Factor to 1. While JCT performance improves slightly, the cluster-wide carbon footprint increases by 20%, as GREEN no longer moves high-power tasks to greener hours.

Scheduler	Job Completion Time		Carbon
	Average	Tail	
Energy Efficiency Optimizer			
GREEN	17.56h	45.20h	15.88kg
No scaling (1 GPU)	19.91h	48.89h	18.38kg
No scaling (2 GPU)	18.53h	46.57h	16.71kg
Carbon Footprint Optimizer			
GREEN	17.56h	45.20h	15.88kg
Carbon Factor = GPU hours	18.30h	47.15h	18.52kg
No Shifting	17.19h	44.99h	18.93kg

Table 4: Ablation experiments of GREEN optimizers.



(a) temporal shifting **(b)** scheduling interval

Figure 13: Sensitivity test of μ (§5.2). μ controls the level of temporal shifting. A larger μ value will shift more high-power jobs to greener hours. Sensitivity test of scheduling interval (§6.3). 30-minute or longer interval works well because carbon intensity changes slowly, allowing less frequent preemptions.

A.2 Sensitivity Analysis

Extent of Temporal Shifting (Figure 13a). In §5.2, we set $\mu\,(\geq 1)$ in controlling temporal shifting. Our tests indicate that setting $\mu = 2$ optimizes the balance between relevant factors. A too high μ skews scheduling, prioritizing high-power jobs unfairly due to an amplified shifting term.

Length of Scheduling Interval (Figure 13b). The interval in MLFQ scheduling influences preemption frequency (§6.3). Our default is 30 minutes, and sensitivity analysis reveals that its exact length has minimal impact on outcomes. This is because carbon intensity, despite significant absolute variations, changes slowly, allowing less frequent preemptions without compromising overall cluster optimization.

B Artifacts

GREEN is designed and evaluated as a scheduler policy on the TACC cluster [32] at the Hong Kong University of Science and Technology. We will release GREEN's source code in TACC's open-source repo [24], which includes the scheduler implementation as a Slurm plugin, a daemon program, and a profiler agent, along with scripts and traces for submitting jobs to the scheduler. More details on our cluster operation and analysis can be found in [13, 37].

The Benefits and Limitations of User Interrupts for Preemptive Userspace Scheduling

Linsong Guo, Danial Zuberi, Tal Garfinkel, Amy Ousterhout
UC San Diego

Abstract

Preemptive scheduling promises to mitigate head-of-line blocking and enable flexible scheduling while retaining a simple programming model. Despite this, preemption is underutilized in server-side software today. Instead, high-performance datacenter systems and language runtimes often rely on cooperative concurrency, or else use preemption only at very coarse timescales, limiting its effectiveness. A key reason that preemption is underutilized today is that existing preemption mechanisms have high and unpredictable overheads.

Intel recently introduced support for user interrupts, a new feature that offers an opportunity to change this. By enabling interrupts to be sent and received entirely in user space, user interrupts can significantly lower the overhead of preemption. In this paper, we shed light on how user interrupts impact the landscape of preemption mechanisms. We build two user-level schedulers that leverage user interrupts for low-overhead preemption. We find that user interrupts are not a panacea. For example, they provide limited benefits when other software layers constrain the kinds of scheduling policies that can be used. Still, user interrupts can match or exceed the performance of existing mechanisms for all but the highest preemption rates, while achieving much more consistent overheads and retaining a user-friendly programming model.

1 Introduction

Datacenter applications today suffer from high tail latency. For example, a recent study of remote procedure calls (RPCs) at Google showed that 90% of RPC methods were capable of completing in hundreds of microseconds or less, and yet 90% of them had median latencies in the milliseconds, with even higher tail latencies [52]. A myriad of factors contribute to this high tail latency, one of which is queuing of requests at servers. When requests have variable service times, as is the case for Google's RPCs, short requests can queue behind long requests and suffer from *head-of-line blocking*.

Head-of-line blocking is common because many applications have tasks with heterogeneous service times. For example, in hybrid transactional and analytical processing (HTAP) databases [47], short transactional tasks coexist with long-running analytical tasks and may be delayed by them unless the database is provisioned with extra resources [28,35,36,41]. A well-known way to reduce head-of-line blocking without over-provisioning is preemption [39, 56]. With preemption, a scheduler periodically interrupts running tasks, giving shorter, more urgent tasks an opportunity to run and complete quickly. However, preemption is underutilized today.

Though kernel schedulers do implement preemption, they typically do so only at millisecond timescales, which is not sufficient to ensure sub-millisecond tail latencies. Furthermore, kernel-based scheduling adds microseconds of overhead to scheduling operations [23]. As a result, many users turn to userspace schedulers and runtimes instead, employing an *M:N* threading model that schedules *M* user-level threads across *N* kernel threads [6, 10, 33, 37, 45, 49, 57]. We focus on such user-level schedulers.

Today's user-level schedulers rarely implement preemption. Most runtime systems and programming languages eschew preemption in favor of cooperative concurrency, which runs tasks to completion and relies on the developer to manually yield cores as needed (e.g., async tasks in Rust and coroutines in C++). Runtimes like Go [6] that do implement preemption do so only at coarse granularities (every 10 ms) so applications cannot rely on them to provide sub-millisecond tail latency. Similarly, high-performance kernel-bypass systems in datacenters also commonly rely on cooperative concurrency [25, 33, 45, 48, 49, 57].

One reason that preemption is underutilized is the high and unpredictable overheads of the typical mechanisms for user-level preemption today: signals and compiler instrumentation. With *signals*, a dedicated timer thread determines when a user-level thread should be preempted and sends a signal to interrupt it [6, 53]. This involves transitioning to the kernel and back on both the timer core and the core of the preempted thread, adding significant overhead on each preemption (§2.1), resulting in practical limits on preemption frequency.

In contrast, with *compiler instrumentation*, the compiler inserts code throughout a program that checks if it should voluntarily yield the CPU [6,24,37,43], for example, by polling a variable in shared memory. Here, the overhead of each check is much lower than a signal, so it can sometimes enable more efficient fine-grained preemption. However, the checking overhead is hard to predict, as it is heavily dependent on program control flow. Thus this approach can also result in overheads that are high, variable, and workload dependent (§2.2).

Fortunately, a new hardware feature called *user interrupts* recently introduced in Intel's Sapphire Rapids CPU offers the potential for a better approach. User interrupts offer a new way to send and receive inter-processor interrupts entirely in userspace, eliminating the multiple kernel transitions required to send and receive signals (§2.3).

In this work, we seek to understand the potential benefits of user interrupts for preemptive scheduling. We ask: *can user interrupts improve our ability to achieve fine-grained preemptive scheduling with low and predictable overheads, compared to existing approaches?* We answer this question with a measurement study and analysis of two user-level schedulers. While we are not the first to utilize user interrupts for preemptive scheduling [32, 38, 42], we are the first to shed light on the tradeoffs between user interrupts and compiler-based approaches, and to analyze fine-grained preemptive scheduling in the context of a widely used runtime (the Go runtime).

We began by studying the performance impact of preemption with each mechanism on a collection of different workloads (§2). We found, unsurprisingly, that user interrupts consistently outperform signals, reducing the per-preemption overhead from 2.4 μs to 0.4 μs. Consequently, user interrupts enable more frequent preemption at the same cost. In contrast, with compiler instrumentation, overheads can be quite low, but are unpredictable and workload dependent. We investigated several mitigations from other work [37] such as loop unrolling, but we found that rather than solving this problem, they merely shift the costs and complexity to other parts of the system. We also found that the overhead of compiler instrumentation is impacted little by the preemption frequency. Thus, compiler instrumentation shines for ultra-high frequency preemption, e.g., every 5 μs or less, but with a larger preemption quantum, the relative performance depends on the application and user interrupts often provide lower overhead.

Next, we built two user-level schedulers that perform preemptive scheduling with user interrupts (§3). First, **Aspen-KB** extends Caladan [33]—a highly optimized **k**ernel-**b**ypass runtime—with support for user interrupts, allowing us to explore the limits of user-level preemption with user interrupts. Aspen-KB also has support for signals and compiler instrumentation, which makes apples-to-apples comparisons among all three mechanisms possible, without the confounding effects of different scheduling algorithms, programming languages, or runtimes. Second, **Aspen-Go** extends the popular Go runtime, enabling comparisons between preemption mechanisms in the context of a runtime that is used by millions of developers. Both Aspen-KB and Aspen-Go leverage known techniques but carefully apply them to optimize for fine-grained preemptive scheduling. They are available at `https://github.com/LinsongGuo/aspen.git`.

We analyzed the performance of Aspen-KB and Aspen-Go by running applications such as key-value stores (RocksDB [15] and BadgerDB [1]) and a data analysis application (DataFrame [2, 50]) (§4). We have two key findings.

First, in the context of the kernel-bypass runtime Aspen-KB, we found that user interrupts enable Aspen to achieve much better performance than signals. Compared to compiler instrumentation, user interrupts generally deliver better or similar performance when the preemption quantum is greater than 10 μs. With an extremely small quantum (10 μs or lower), compiler instrumentation may offer a small performance benefit over user interrupts. However, compiler instrumentation requires manual intervention to determine whether loop backedges, function calls, or both should be instrumented, and to determine the optimal depth for loop unrolling. Thus, *user interrupts are the best choice for most applications*, due to their improved usability and similar or better performance.

Second, in contrast, we found that user interrupts provided only modest benefits for preemptive scheduling in Aspen-Go. The reason for this is that significantly shrinking the preemption quantum (e.g., to less than 50 μs) proved counterproductive. The design of Go constrains the kinds of scheduling policies that are possible, making preemption less effective at avoiding head-of-line blocking, and every preemption comes at the cost of software overheads in the Go runtime. With preemption at the coarse granularity of 50 μs, replacing signals with lower-overhead user interrupts provides only a small benefit. Thus, *when a system is not fully designed for fine-grained preemptive scheduling, user interrupts provide limited benefits*.

2 Preemption Mechanisms

Three preemption mechanisms are available to userspace schedulers today: signals (§2.1), compiler instrumentation (§2.2), and user interrupts (§2.3). Here, we explore how these mechanisms work and why the first two can have high and unpredictable overheads. We then examine user interrupts (§2.3) and how they can offer lower and more consistent overheads.

2.1 Signals

Signal-based preemption [6, 53, 54] involves two key components: a timer thread and a signal handler. The timer thread typically runs on its own core and is responsible for determining when user-level threads should be preempted.

To preempt a user-level thread running on kernel thread k, the timer thread sends a signal to k. The signal triggers the invocation of k's signal handler function, on the core that k is currently running on. The signal handler then calls into the user-level scheduler, which selects the thread to run in the next quantum. The primary limitation of signal-based preemption is that the signal handler is expensive, incurring multiple costly OS context switches, which ultimately limits preemption frequency.

To explore the basic overhead of each of our three mechanisms, including signals, we ran the following experiment. A dedicated *timer core* sends a notification (signal, user interrupt, etc.) to a single application core at a regular interval (the *preemption quantum*). This notification triggers the application core to run an empty signal-handler function that immediately returns to the application thread. As there is no context switch to a different thread and the scheduler is not invoked, this benchmark illustrates the minimum possi-

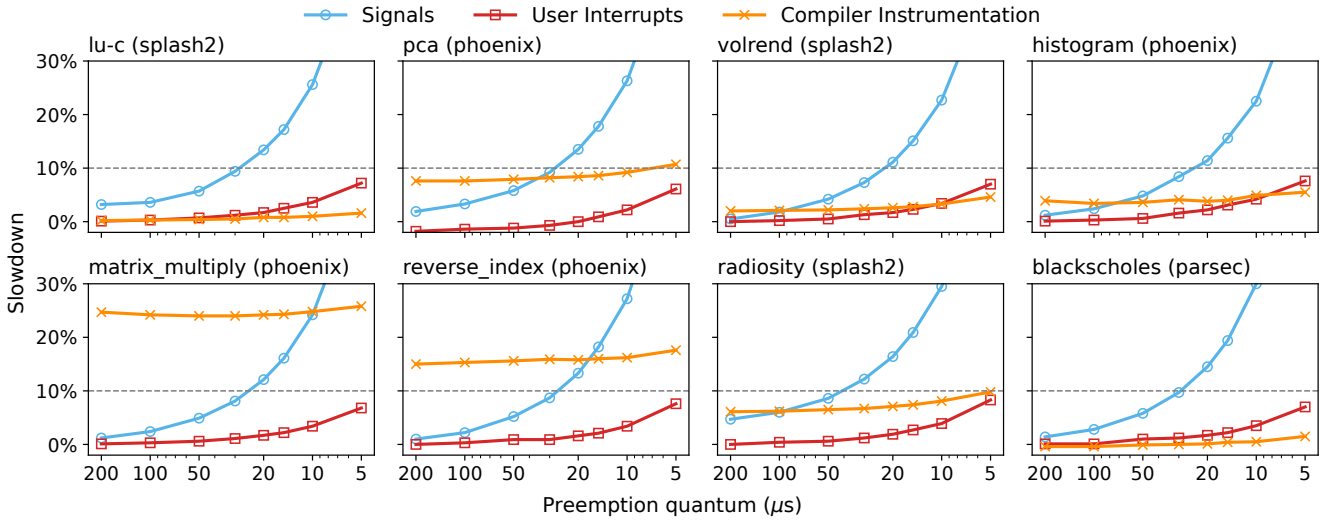


Figure 1: Slowdown of eight programs with different preemption mechanisms. The preemption quantum (x-axis) represents the time between consecutive preemptions and the slowdown (y-axis) indicates how much slower the program runs (as a percentage) compared to running without preemption. For a slowdown tolerance of 10% or less, user interrupts support a 5 μs preemption quantum, while signals support about 30 μs. Compiler Instrumentation is implemented using Concord [37].

ble overhead of each mechanism. We ran this experiment with 24 programs from three benchmark suites: Splash-2 [16], Phoenix [13], and Parsec [26]. In addition, we report the end-to-end cost of preemption (including context switching to a different thread) for latency-sensitive applications in §4.2.

The full results for all benchmark programs are provided in Appendix C. For a representative set of eight programs, Figure 1 shows how much slower each program runs (y-axis) due to receiving periodic signals (blue lines), as we vary the preemption quantum (x-axis). With a large quantum, the slowdown is negligible. For example, with a quantum of 100 μs, the slowdown for most programs is around 3%. However, as the frequency increases so does the cost, so that with a preemption quantum of 10 μs, the eight programs each experience a slowdown of roughly 25% or more, due to the overhead of signals.

Overall, handling a single signal on an application core slows down the program by about 2.4 μs. The dominant cost is the transitions between user and kernel space to receive and deliver the signal; these add up to about 1.4 μs. The remaining cost is due to factors such as additional branch mispredictions and cache misses that occur within the program, due to running kernel code and accessing kernel data structures while handling the signal. Leveraging virtualization features to use normal hardware interrupts rather than signals can reduce the per-signal overhead to 0.6 μs [39], but in practice it can be challenging to deploy systems that require these features.

2.2 Compiler Instrumentation

With compiler instrumentation, preemption is implemented by inserting code at specific points throughout an application that checks if the currently running user-level thread should yield the CPU. Typically, checks are added at function entry points and loop back edges, ensuring that the thread will yield regardless of control flow.

Similar to signals, compiler instrumentation typically relies on a timer thread. However, in this approach, the timer thread indicates that a user-level thread should yield by updating a shared variable in memory. This variable is periodically checked (polled) by the user-level thread to determine if it should yield. While each check is relatively inexpensive, the polling frequency depends on program control flow. Consequently, polling overhead varies across workloads and can be quite high and difficult to predict. This raises several issues. In code with tight loops or small recursive functions, these costs can become prohibitive [14]. Also, at higher preemption frequencies, polling may not take place often enough to ensure that a thread always yields in a timely manner.

Different approaches have been explored to mitigate the problem of overhead. For example, in its first decade Go only instrumented function entry points, to avoid the impact of polling in tight loops. Unfortunately, this required that programmers understand how Go's preemption mechanism worked and manually added explicit calls to the Go scheduler in loops when needed. Aside from the added cognitive burden this imposed, when overlooked, this could lead to high latencies and even program freezes that were difficult to debug [14]. When Go developers attempted to add checks to loop back edges they found that while this only increased the average runtime on a suite of benchmarks by around 7%, at worst it could increase runtime for an individual benchmark by as much as 96% [14]. Thus, they abandoned this approach in favor of signals.

Recent systems have attempted to address these overhead challenges through a collection of different approaches, such as loop unrolling [37, 43]. We use Concord [37] as a repre-

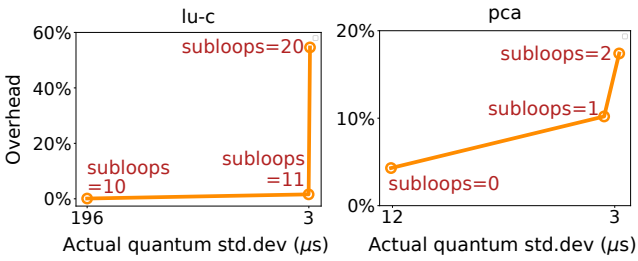

Figure 2: Small changes to the subloops parameter in Concord's compiler instrumentation can significantly impact preemption overhead and timeliness (standard deviation of the measured interval between preemptions). The x-axis uses a log scale.

sentative example that employs compiler instrumentation and reduces polling overhead by placing probes more strategically. We re-run the microbenchmark described above (§2.1), using Concord's LLVM passes to instrument each program. Figure 1 (orange lines) shows the results. While compiler instrumentation can achieve low overhead for some programs (such as *lu-c* and *blackscholes*) when they are well configured, other programs (*pca*, *matrix_multiply*, *reverse_index*) still suffer from significant overhead due to tight loops.

Furthermore, it is non-trivial to find a good configuration for each program, as there are multiple parameters that need to be tuned. For example, Concord features a parameter called `subloops` that limits the number of sub-loops in which probes can be inserted within each outermost loop. Slight variations in this parameter can result in large changes in preemption timeliness and overhead, as shown in Figure 2. For *lu-c* (left), setting `subloops` to 10 results in a high standard deviation of preemption intervals, indicating poor timeliness, while increasing the value to just 11 brings the standard deviation to an acceptable level. Further increasing `subloops` to 20 or more increases preemption overhead to greater than 50%. Similarly, in the benchmark *pca*, increasing `subloops` from 0 to 2 raises the overhead by more than 13%.

Another parameter than can be tuned with compiler instrumentation is the degree of loop unrolling; Concord uses loop unrolling to reduce preemption overhead in programs with tight loops. While loop unrolling can indeed reduce overhead for some programs, such as *blackscholes*, excessive unrolling can increase pressure on the instruction cache and microop cache [11], potentially causing some programs to run more slowly [3, 4]. For example, configuring *matrix_multiply* to unroll loops four times results in a preemption slowdown of 31%, compared to 25% without loop unrolling. Figure 1 illustrates the performance of compiler instrumentation under the best configuration of these parameters that we could find, but tuning these parameters required significant manual effort.

2.3 User Interrupts

Recently Intel's Sapphire Rapids CPUs [20] introduced support for sending inter-processor interrupts directly in user space, via *user interrupts*. Similar to signals, user interrupts enable asynchronous preemption that avoids the polling overheads imposed by compiler instrumentation. In contrast with signals, user interrupts avoid the costly overheads of transitions between kernel and user space.

Normally, inter-processor interrupts (IPIs) are sent from one core to another by programming the APIC from the kernel. This directs control flow to go through the interrupt vector table on the receiving core when an interrupt is delivered. Unfortunately, when communicating user-space events from one core to another, i.e., with signals, this requires multiple expensive protection boundary crossings.

User interrupts offer an alternative by providing a hardware fast path for sending and receiving interrupts. User space code cannot simply be allowed to send interrupts to other processes without access control, so, similar to other kernel-bypass mechanisms, user interrupts delegate access control to the operating system. For a *sender thread* to send user interrupts to a *receiver thread*, both must register with the kernel first. Once registration is complete, the kernel does not participate in the sending and receiving of user interrupts. The processor can directly consult a kernel-managed table about where to route interrupts, allowing a sender thread to ensure that user interrupts are delivered to a specific receiver thread.

To measure the overhead of receiving user interrupts, we again configure a timer core to periodically interrupt an application running on a separate core, this time by sending user interrupts. Figure 1 (red lines) shows that, as with signals, the program slowdown increases as the preemption frequency increases. However, the overhead of handling a single user interrupt is much lower than that of handling a signal—only 0.4 μs compared to 2.4 μs—so the slowdown remains tolerable down to much smaller quantum sizes. User interrupts have so much lower overhead because they avoid transitions between user and kernel space as well as extra branch mispredictions and cache misses within the program.[1] Thus, for a given acceptable amount of application slowdown, user interrupts can enable much more frequent preemption. For example, for a slowdown of at most 10%, user interrupts can support a preemption quantum of 5 μs, whereas for signals this is only about 30 μs.

While user interrupts uniformly outperform signals, the comparison with compiler instrumentation is more nuanced. For small quanta (10 μs or lower), Concord can achieve lower overhead than user interrupts for some programs such as *lu-c*. In contrast, for larger quanta (greater than 10 μs), the slowdown from user interrupts is lower or at least comparable to that of compiler instrumentation, especially in programs with tight loops, where it is 15–25% lower, as seen in *matrix_multiply* and *reverse_index*. This is because, regardless of the quanta, programs using compiler instrumentation must

[1] For example, using perf [12] to measure the *linpack_bench* program [8], we observed that user interrupts result in 29% fewer L1 cache misses and 12% fewer branch mispredictions compared to signals at a 5 μs quantum.

check the instrumented probes at the same locations as they would for smaller quanta, whereas user interrupts incur overhead only when preemption actually occurs.

2.4 Summary

We find that user interrupts consistently provide lower overhead than signals, across all programs we evaluated. While the overhead of compiler instrumentation can be lower than that of user interrupts for very fine-grained preemption with some programs, this overhead varies significantly and can be quite high. Furthermore, striking a good balance between preemption overhead and timeliness can require careful tuning of multiple parameters. While it may be possible to mitigate some of these issues with more sophisticated compiler techniques, with existing approaches to compiler instrumentation, fine-grained preemption remains fragile, entailing unpredictable and potentially high costs. User interrupts offer a compelling alternative due to their consistent overheads, which remain low for all but the highest preemption frequencies.

3 Preemptive User-Level Schedulers

To understand how user interrupts impact preemptive scheduling in practice, we implemented preemptive user-level scheduling in two different runtime systems. The two systems allow us to explore different regions of the design space. First, Aspen-KB extends Caladan [33], a user-level runtime and scheduler implemented in C that uses kernel-bypass networking and is heavily optimized to achieve microsecond-scale latencies. Second, Aspen-Go extends the popular Go runtime, which relies on the underlying operating system's network stack and is designed for programmer productivity rather than bleeding-edge performance. At a high level, these two runtime systems have similar overall architectures. Each runtime core has its own runqueue(s) of user-level threads (or goroutines) and runtime cores balance work using work stealing.

To enable preemptive scheduling, both runtime systems dedicate one core in each runtime to act as the timer core. The timer core periodically sends user interrupts to runtime cores, preempting the currently running user threads. Note that the timer core is not required to process incoming or outgoing packets (though in Go it may), enabling the timer core to scale to support larger numbers of cores than in systems where the timer core is also responsible for processing all incoming network traffic and dispatching packets to cores [37, 39, 43].[2]

In the remainder of this section, we describe four general factors that impacted the design of both of these preemptive schedulers (§3.1), as well as the specific design and implementation of our kernel-bypass scheduler Aspen-KB (§3.2) and Go-based scheduler Aspen-Go (§3.3).

[2]This decision involves a tradeoff. Distributed load balancing via work stealing enables better scalability than systems in which a centralized core dispatches incoming tasks, such as Shinjuku [39], Concord [37], or TQ [43]. Yet, this comes at the cost of potentially less effective load balancing [44].

3.1 Design Factors

3.1.1 Unnecessary Preemptions

Existing systems implement a preemption policy that issues preemptions to all runtime cores at a given interval to preempt all currently running tasks [37,38,42]. However, preemption is not always necessary—for example when there are no queued tasks for a core to run or when a thread has just yielded voluntarily—and preempting unnecessarily slows down running tasks. Eliminating these unnecessary preemptions can significantly reduce overhead.

To reduce the number of preemptions as much as possible, the timer core requires visibility into all sources of queued work (e.g., threads, incoming network packets) so that it can determine if there is another task that the core could handle. In addition, the timer core needs visibility into when context switches between user-level threads occur, so that it can avoid preempting a thread that just began running.

3.1.2 Non-Preemptible Code

User-level threads are not always safe to preempt, often because of nonreentrant code. For example, code that may not be safe to preempt includes:

Scheduler code that holds locks. Since the thread scheduler runs in userspace, a user interrupt may arrive while a thread is executing scheduler code. If that thread holds a lock that protects scheduler state, then it may be unsafe to preempt it, because it will not be possible to acquire the scheduler's lock to reenter the scheduler and context switch to a different user-level thread. This is an example of non-reentrant code.

Other code that holds locks. In addition, preempting other code that holds locks may lead to poor performance, e.g., if it delays critical functionality such as polling the network stack, or if it prevents other threads from being able to run.

Application code that uses kernel-level-thread state. Existing applications often rely on state that is associated with a kernel-level thread. For example, thread-local storage (TLS) is associated with kernel-level threads, and many library functions such as `malloc` rely on TLS [27, 54]. When existing applications are ported to use user-level threads, regions of code that use TLS or library functions that use TLS may not be safe to preempt. This is because multiple user-level threads can reside on the same kernel-level thread, thus sharing the same kernel-thread-local state. As a result, preemption may cause them to have interleaved access to the same state, resulting in incorrect behavior.

In some cases, non-preemptible code is isolated in distinct regions of code, e.g., in calls into the scheduler or to `malloc`. Existing runtimes typically handle these kinds of non-preemptible code by detecting when a signal arrives during non-preemptible code, and deferring or skipping the preemption. For example, in Go, the runtime consults metadata generated by the compiler to determine if the program is at

Task	Rate of Non-Preemptible Code Regions	Use of Extended Registers
SPEC-mcf	only a few	none
linpack_bench	only a few	continuously
base64	only a few	only at initialization
RocksDB GET	4 calls/μs	30 calls/μs
RocksDB SCAN	0.039 calls/μs	38 calls/μs

Table 1: The frequency of non-preemptible code regions and vector register usage across four programs. Numbers in the table with the unit "calls/μs" represent the number of calls into functions involving non-preemptible code or extended registers per microsecond.

an unsafe point, and simply returns to the interrupted goroutine if so [6]. In other runtimes, the linker or developer wraps non-preemptible regions of code so that the runtime can track whether it is currently executing code that is not safe to preempt. If a signal arrives during one of these regions, the signal handler defers the preemption until the user-level thread exits the region [27, 33, 37, 45].

User interrupts provide a promising new approach to handling non-preemptible code, which is to defer interrupt delivery in hardware. With this approach, preemption is deferred by using the new `clui` and `stui` instructions to disable and reenable delivery of user interrupts. The benefit of this approach is that if multiple user interrupts arrive within a region of non-preemptible code, only one will be delivered when user interrupts are reenabled; this interrupt coalescing avoids the 0.4 μs overhead of receiving each unnecessary user interrupt.

However, we found that hardware-based deferral can add significant overhead, because of the cost of the current hardware instructions and because non-preemptible code regions can be short and frequent. We found that a single pair of `stui` and `clui` instructions costs about 18 ns. This is much lower than the 600 ns required to mask and unmask signals, but is still non-trivial. Table 1 shows that some programs execute non-preemptible regions of code infrequently, but that requests for RocksDB [15], a key-value store, frequently call `malloc` and `free`. Deferring preemption in hardware would slow down RocksDB GET requests by 7%, whereas deferring preemption in software adds only 1-2 ns of overhead for each region of code (less than 1% slowdown overall).

3.1.3 Extended Registers

When context switching between user-level threads, it is essential to properly save and restore registers, including extended registers such as SIMD or matrix registers. Table 1 presents the frequency and usage patterns of extended registers in some application code. With compiler instrumentation, the compiler can save caller-saved registers, including extended registers if necessary. In contrast, with user interrupts, the hardware only saves the flags, instruction pointer, and stack pointer, requiring the user-level scheduler to save extended registers. Our approach conservatively saves all registers that might be used.

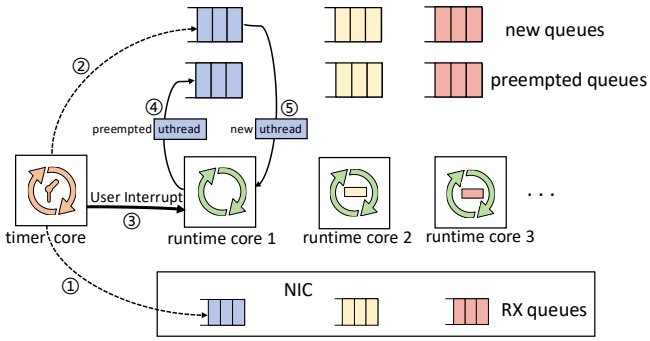

Figure 3: Architecture of Aspen-KB. To preempt a user thread on a runtime core, the timer core first checks if there are pending tasks in its RX queue ① or *new queue* ②. If so, the timer core sends a user interrupt to the runtime core ③. Then, the currently running user thread is suspended and added to the *preempted queue* ④ and the core dequeues and runs the next thread from the *new queue* ⑤.

While this increases the saved state size per thread (e.g., by 2 KB), our measurements show that the overhead is negligible in most cases. A detailed discussion of this and alternative approaches is provided in Appendix A.

3.1.4 Head-of-Line Blocking

Even with periodic preemption of running threads, head-of-line blocking can still occur. First, if the network stack is not polled frequently, newly arriving tasks can experience queueing delays there while lower priority tasks occupy the CPU. Second, if newly runnable tasks are enqueued to a runqueue behind preempted tasks, the new tasks must wait for each preempted task to run for a preemption quantum before they are able to run. Prior work has addressed the latter problem by identifying the task type during processing in the network stack and explicitly prioritizing latency-sensitive tasks [30, 39], but we avoid this approach because task types or service times are not always available a priori. Instead, to prevent head-of-line blocking throughout the runtime, we focus on frequently polling for incoming network packets and prioritizing newly incoming tasks over preempted tasks.

3.2 Kernel-Bypass Preemptive Scheduler

Our first preemptive user-level scheduler, Aspen-KB, is built by extending Caladan [33], a user-level runtime and scheduler implemented in C. Figure 3 shows the architecture of Aspen-KB. Aspen-KB bypasses the kernel for both threading and networking. Each core in each runtime has its own runqueue of user-level threads and its own RX queue which it polls to receive incoming packets. Runtime cores balance work—including both threads and incoming packets—among themselves using work stealing. Aspen-KB dedicates one core per runtime to serve as the timer core.

Unnecessary preemptions. In Aspen-KB, the timer core checks if preemption is necessary at a fixed preemption quan-

tum. However, the timer core may choose not to preempt every runtime core. The timer core has visibility into incoming packet queues (RX queues) and scheduler state (a timestamp indicating when the currently running thread started running) via shared memory, and only preempts the currently running thread if it has been running for at least the preemption quantum and there is other work (incoming packets, runnable threads, etc.) available on that core. We found that this approach significantly reduces the rate of preemptions (§4.4).

Head-of-line blocking. Aspen-KB avoids head-of-line blocking with two techniques. First, it polls the RX queue for newly arriving packets after every preemption; the overhead from this is small due to the kernel-bypass network stack. Second, each core employs a simple two-queue scheduling approach. This is a simplified variant of multi-level feedback queues [29] in which newly runnable threads are initially enqueued to the *new queue*, but once they are preempted, they are enqueued to the *preempted queue* instead. Each core prioritizes the new queue over the preempted queue and uses a longer quantum (e.g., 100 μs) for the preempted queue. With this approach, the system requires no a priori knowledge of how long each thread will run for, and latency-critical threads that run for less than the preemption quantum are still handled quickly.[3]

Implementation. We built Aspen-KB by extending Caladan [33] with a timer core, scheduler features to support user interrupts, and the two-queue scheduling approach. Aspen-KB handles extended registers by saving all general-purpose and AVX-512 registers on every context switch. Additionally, it extends Caladan's shim layer to fully support kernel-level-thread state, including TLS. Specifically, each user-level thread maintains a private copy of its kernel-level-thread state, preventing interleaved access to the same state. Aspen-KB does not modify Caladan's software-based approach to handling non-preemptible code, which defines the functions `preempt_disable()` and `preempt_enable()` to disable and re-enable preemption, respectively, and wraps them around non-preemptible scheduler code. All modifications are implemented in 1,849 LOC. Running an application on Aspen-KB requires a `makefile` to link it with the runtime.

To enable an apples-to-apples evaluation of different preemption mechanisms, we also implement signal-based preemption and compiler instrumentation in Aspen-KB. To implement *signal-based preemption*, we modify Aspen-KB's timer core to send signals in lieu of user interrupts. To implement *compiler instrumentation*, we integrate Concord's approach into Aspen-KB [37]. Specifically, we borrow Concord's LLVM instrumentation passes and apply them to applications. The instrumented applications then run on Aspen-KB, and Aspen-KB's timer core preempts user-level threads by writing to shared memory.

[3] Under overload conditions, preempted threads can languish in the preempted queue. However, we assume that a load balancer will prevent any server from operating in a continuously overloaded state.

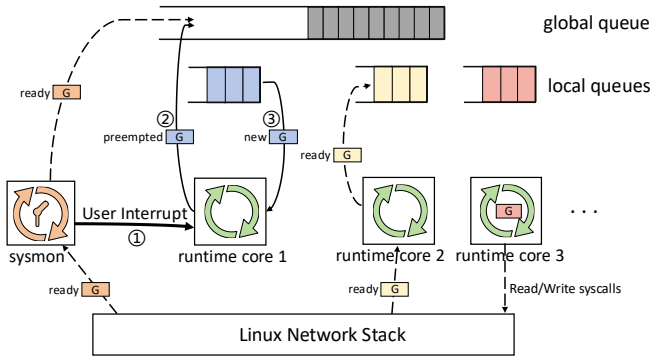

Figure 4: Architecture of Aspen-Go. To preempt a goroutine on a runtime core, sysmon sends a user interrupt to the core ①, triggering it to suspend the current goroutine and place it in the global queue ②, and dequeue a new goroutine from the local queue ③. When an application invokes Go's network APIs, the Go runtime issues a nonblocking system call on its behalf (core 3). To handle I/O completions, runtime cores poll the network stack and add readied goroutines to their local runqueue (core 2). Sysmon can poll as well, but places goroutines in the global queue.

While Junction [32]'s implementation bears similarity to Aspen-KB's—both extend Caladan [33] with support for user interrupts—Aspen-KB differs in its two-queue scheduling approach, its support for compiler instrumentation and signal-based preemption, and how it handles extended registers.

3.3 Go-Based Preemptive Scheduler

Our second preemptive user-level scheduler, Aspen-Go, is built by extending the Go runtime [6] (Figure 4). The Go runtime is designed to support high concurrency and implements user-level scheduling via lightweight threads called goroutines. The scheduler maintains one queue of runnable goroutines for each active core in the runtime, as well as a global queue for preempted goroutines or those that become runnable when a system call returns; goroutines in per-core queues are prioritized over those in the global queue. For networking, Go relies on the underlying operating system's network stack. To perform network I/O, the runtime typically issues non-blocking system calls (e.g., `read` and `write`), and a runtime component called *netpoller* handles polling for completion of those operations (e.g., via `epoll` or `kqueue`).

As described above (§2.2), Go implements two forms of preemption. First, it leverages compiler instrumentation by instrumenting function entry points. To handle programs that do not contain frequent function calls (e.g., those with tight loops), Go also uses signals for periodic preemption [14]. A dedicated thread called *sysmon* preempts running goroutines periodically (every 10 ms by default). The sysmon thread also polls the network stack for incoming packets occasionally, if no other runtime core has polled the network stack for at least 10 ms. The sysmon thread sleeps when it is inactive.

Our goal with Aspen-Go is not to overhaul the Go runtime, but rather to make the minimal set of changes necessary in

order to support fine-grained preemption with user interrupts. We configured the sysmon thread to busy spin instead of sleeping, to enable precise preemption at fine granularity, and additionally made the modifications described below.

Unnecessary preemptions. The sysmon thread has visibility into when a context switch last occurred on each core, and so it can skip preemptions when the current goroutine has been running for less than the preemption quantum. However, because the Go runtime relies on the OS's network stack, the sysmon thread cannot easily determine whether there are packets queued or not. Thus if the current goroutine has exceeded its quantum, the sysmon thread will preempt it, even if there is no other work (e.g., goroutine or packet) available.

Head-of-line blocking. In Go, solely decreasing the preemption quantum provides little performance benefit for networked applications, because incoming packets are not necessarily processed in a timely manner. Incoming packets can be received in one of three ways: (1) an application issues a non-blocking read to check for packets for a specific connection, (2) the scheduler invokes the netpoller to check for incoming packets on any connection; this only occurs when there are no runnable goroutines in the local or global runqueue, or (3) the sysmon thread invokes the netpoller every 10 ms. Thus the Go scheduler generally prioritizes runnable goroutines over incoming network packets. Even with fine-grained preemption of goroutines, packets can remain queued in the network stack until all goroutines in the local and global runqueues have completed or the sysmon thread invokes the netpoller.

To minimize head-of-line blocking in the network stack, the scheduler could invoke the netpoller after every preemption, to check for newly arriving packets. However, in Go, this requires a system call, adding at least 2 μs of overhead to every preemption. We found that this degrades performance prohibitively, especially for applications that rarely perform network I/O. Instead, Aspen-Go modifies the sysmon thread to invoke the netpoller more frequently, every 100 μs. While this allows queued packets to be processed much more quickly, it does not entirely eliminate head-of-line blocking. This is because once sysmon processes incoming packets and marks their corresponding goroutines as runnable, it enqueues them to the global runqueue (to avoid contention for per-core runqueues), where they must queue behind preempted goroutines.

An alternative approach for those willing to tolerate more significant changes to Go would be to leverage a kernel-bypass network stack. For example, this could be done using Junction [32]. In this case, polling the network would be much cheaper and could be performed more frequently. However, given our goal of making minimal modifications to Go and to how it can be deployed, we do not adopt these approaches.

Implementation. We modified the Go runtime (version 1.21) to support preemption via user interrupts and modified the sysmon thread as described above. Additionally, Aspen-Go disables preemption at `Lock()` and re-enables it at `Unlock()` to prevent preemption in critical sections. This is particularly useful since locks are commonly used in networking packages such as `fasthttp`. These modifications amount to 733 LOC.

4 Evaluation

We answer four questions in this evaluation:

1. How do different preemption mechanisms impact the tail latency and throughput of applications in Aspen-KB and Aspen-Go? (§4.1)
2. What is the cost of an individual preemption in Aspen-KB and Aspen-Go? (§4.2)
3. How does the preemption mechanism impact the ideal choice of preemption quantum? (§4.3)
4. What is the impact of Aspen-KB's design decisions? (§4.4)

Experimental setup. We conduct experiments using two dual-socket servers, each with 28-core Intel Xeon Gold 5420+ CPUs operating at 2.0 GHz and 256 GB of RAM. Each server is equipped with a 100 Gbits/s Mellanox ConnectX-6 Dx NIC and the two NICs are connected via a 100GbE Mellanox SN2700 switch. We disable hyperthreads because we found that our workloads achieved higher performance in this configuration. We disable TurboBoost, frequency scaling, and c-states. Both of our servers run Ubuntu 22.04.4. Our load-generating machine uses kernel version 6.8.0 while our server machine uses a custom kernel provided by Intel that is based on kernel version 6.0.0 and supports user interrupts [9, 20].

Kernel-bypass systems evaluated. Ideally we would directly compare Aspen-KB against state-of-the-art systems that use other preemption mechanisms, such as Shinjuku [39] and Concord [37]. However, comparing against these systems is challenging. First, both were designed to run with an older kernel version (4.4.185), which is not supported by Aspen-KB. Second, all three systems use different policies for load balancing work across cores; Shinjuku dispatches work from a single centralized queue, Concord uses JBSQ [40], and Aspen-KB uses work stealing. These differences in load-balancing policy could significantly impact performance for multicore experiments [44], making it difficult to isolate the impact of the preemption mechanism itself.

Instead, we evaluate five variants of Aspen-KB (§3.2). This includes preemptive schedulers with *signal*-based preemption[4] and *user-interrupt*-based preemption (the default version of Aspen-KB). For compiler instrumentation, we evaluate *Concord*, which uses Concord's default configuration that instruments both function calls and loop backedges [37]. We also evaluate *Concord fine-tuned*, in which we carefully configure the subloops parameter, degree of loop unrolling, and whether function calls are instrumented, to achieve the

[4] Shinjuku uses virtualization hardware to further lower the overhead of preemption [39], so its performance would likely fall between that of our signal-based approach and our user-interrupt-based approach.

best performance for each application. We also evaluate *non-preemptive*, a run-to-completion baseline, by running Aspen-KB with preemption disabled. Unless stated otherwise, we configure the non-preemptive baseline to dedicate 25 cores to the evaluated application, and all other systems to dedicate 24 cores to the application and 1 core to the timer.[5]

Go variants evaluated. We evaluate Go under five configurations. *Unmodified* Go refers to the standard Go runtime, version 1.21, which uses both compiler instrumentation and signal-based preemption, every 10 ms. We also applied fine-grained preemption on it, triggering every 50 µs. The remaining configurations run Aspen-Go, as described above (§3.3). *Aspen-Go UINTR* and *Aspen-Go Signals* use user interrupts and signals, respectively. We also evaluate compiler instrumentation alone (*Aspen-Go Compiler*) by disabling preemption via signals or user interrupts. Unless stated otherwise, we configure 8 cores for the application and 1 for sysmon. Go dynamically adjusts its core usage, so at any given time it may use fewer cores.

Workloads. We evaluate three applications:

1. RocksDB [15] (version 5.15.10), a popular key-value database developed by Facebook, runs on Aspen-KB. We run bimodal workloads that include GET and SCAN operations, which take about 1 μs and 260 μs, respectively.
2. C++ DataFrame [2] (version 1.19.0), a data analysis application, runs on Aspen-KB. Our evaluation runs a workload with *decay*, *ad* (Accumulation/Distribution), *rmv* (Rolling Mid Value), *ppo* (Percentage Price Oscillator) and *kmeans*. Each task type makes up 20% of the total number of tasks.
3. BadgerDB [1] (version 1.6.2), a fast key-value database in Go, runs on Aspen-Go. We populate the database with 10 million keys. Our evaluation involves a bimodal workload, with GET operations taking about 5 μs and RangeSCAN operations around 800 μs.

We generate load using Caladan's load generator [33]. For RocksDB and DataFrame, the load generator is configured to send requests over UDP with a Poisson arrival distribution. For BadgerDB, it generates requests over HTTP connections, also following a Poisson arrival distribution.

4.1 Application Performance

In this section, we evaluate the impact of different preemption mechanisms on end-to-end application performance in Aspen-KB and in Aspen-Go. Because the preemption quantum that yields the best performance varies across preemption mechanisms and workloads, we show results with the best-performing quantum. We define the "best" quantum as the preemption quantum for which short operations achieve the highest throughput while tail latency remains below a threshold (e.g., in RocksDB, GET tail latency of at most 50 μs).

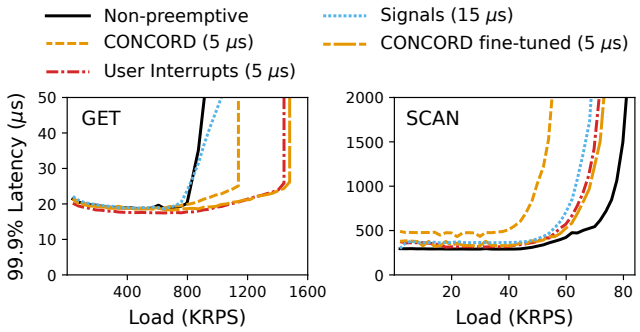

Figure 5: RocksDB performance in Aspen-KB under different preemption mechanisms. The workload is 95% GET and 5% SCAN. KRPS on the x-axis represents kilo-requests per second.

4.1.1 RocksDB (Aspen-KB)

RocksDB [15] exemplifies applications that benefit from an extremely low preemption quantum, as it has short-running GET tasks, which typically take less than 1 µs. Figure 5 shows the results of running RocksDB with 95% GET requests and 5% SCAN requests; experiments with different distributions of GET and SCAN requests (95.5%/0.5% and 50%/50%) yielded similar conclusions.

User-interrupt-based preemption. As shown in Figure 5, user interrupts (UINTR) are able to mitigate head-of-line blocking and significantly improve performance compared to a system without preemption. For example, for a tail latency limit of at most 50 μs, user interrupts improve GET throughput by 58.2% compared to the non-preemptive system.

Signal-based preemption. In contrast, signal-based preemption provides little benefit for GETs compared to no preemption and it increases the tail latency for SCANs compared to most other approaches. There are three reasons for this lackluster performance. First, as illustrated above, receiving a signal entails an overhead of about 2.4 μs (§2.3), which can increase execution time for SCANs by up to 16.7% with a preemption quantum of 15 μs. Second, with signals, the timer thread suffers from poor scalability (§4.4), due to the overhead of sending signals. For this workload, the timer core can only trigger 43% as many preemptions with signals as it can with user interrupts; it is not able to reliably sustain the target preemption quantum. Finally, receiving signals also exhibits poor scalability due to lock contention [54], so adding additional timer cores does not improve performance.[6]

Compiler instrumentation. Compiler instrumentation can yield similar improvements as user-interrupt-based preemption, as illustrated by the "CONCORD fine-tuned" lines in

[5] We also dedicate one core to Caladan's IOKernel. The IOKernel is responsible for reallocating cores across applications, but we disable this. Thus in our experiments the IOKernel is only used during initialization; this functionality could be combined with the timer core in the future.

[6] Note that Shinjuku's virtualization-based approach reduces the overhead of sending/receiving interrupts to 14%/48% of the overhead with signals and enables Shinjuku to scale to support at least 22 cores [39].

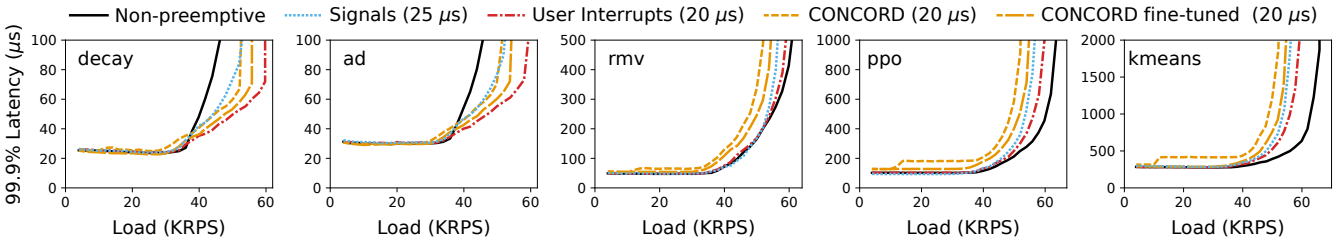

Figure 6: DataFrame performance in Aspen-KB under different preemption mechanisms. Each task type constitutes 20% of the total task count.

Figure 5. However, achieving this performance required deviating from Concord's default instrumentation. With the default instrumentation, a single SCAN operation triggers over 95,000 preemption checks, resulting in a 31.2% slowdown with a 5 μs quantum (as shown by "CONCORD"). GET operations suffer similarly. In the fine-tuned variant, we disable instrumentation of function calls, which are frequent in RocksDB. This reduces the number of preemption checks per SCAN to 5,000 and decreases the slowdown to only 2.3%.

4.1.2 DataFrame (Aspen-KB)

We evaluate DataFrame [2] with a workload that includes 2 short tasks (*decay* (5 μs) and *ad* (7 μs)), one medium task (*rmv* (28 μs)), and two longer tasks (*ppo* (75 μs) and *kmeans* (250 μs)). Because its tasks are longer than the short GETs in RocksDB, DataFrame generally performs best with a longer preemption quantum. Figure 6 shows the results.

With a tail latency limit of 100 μs, user interrupts achieve the highest throughput for the two types of short-running tasks, about 30% higher than the non-preemptive system and 9% higher than the fine-tuned Concord. For longer tasks, user interrupts do sacrifice some throughput compared to the non-preemptive system. However, with the 20 μs preemption quantum, user interrupts typically cause less than 2% slowdown for programs (§2.3), thus improving the throughput of short requests with minimal sacrifice.

Compiler instrumentation improves performance for short tasks, but at the cost of significant throughput for longer tasks. Despite efforts to fine-tune Concord's parameters (the number of instrumented subloops and loop unrolling count), both *rmv* and *ppo* still experience significant preemption overhead (3.3 μs) due to tight loops (§4.2). In contrast, user interrupts incur only 0.37 μs and 0.32 μs of overhead, respectively.

4.1.3 BadgerDB (Aspen-Go)

We ran BadgerDB [1] with unmodified Go and Aspen-Go to evaluate how effectively different Go variants can mitigate head-of-line blocking. As shown in Figure 7, simply decreasing the preemption frequency (e.g., to 50 μs) in unmodified Go does not significantly reduce head-of-line blocking. This is because even with frequent preemption, the unmodified Go runtime does not attempt to poll incoming packets from network stack as long as there are available goroutines in

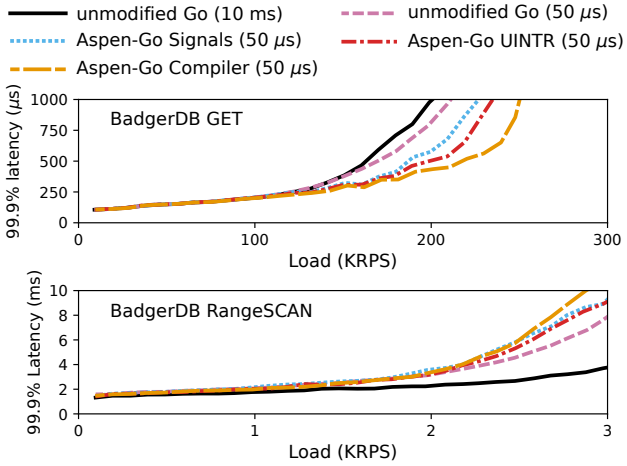

Figure 7: BadgerDB performance with unmodified Go and Aspen-Go. The workload consists of 99% GET and 1% RangeSCAN.

local or global queues (§3.3). As a result, the incoming packets remain blocked in the network stack and more frequent preemption only adds extra slowdown to running goroutines.

In contrast, Aspen-Go UINTR can achieve 17.5% higher throughput for GET requests than unmodified Go (while maintaining a tail latency of at most 1000 μs), primarily because Aspen-Go actively polls ready packets from the network stack, allowing them to run earlier than in the unmodified version. However, the performance gains from user interrupts in Aspen-Go are significantly smaller than those in Aspen-KB for the following reasons. First, goroutines resulting from newly arrived packets may be placed at the back of the global runqueue (e.g., if they are polled by sysmon) and still need to wait, whereas new user threads in Aspen-KB can be placed in local queues dedicated to new threads and processed more quickly. Second, sysmon cannot detect whether packets are queued or not due to its lack of visibility into the Linux network stack, and thus longer tasks are preempted even when there are no other tasks to handle. Third, the cost of context switching during preemption in Aspen-Go is higher than in Aspen-KB (§4.2). Overall, the design of the Go runtime makes it difficult to adopt some policies that could help reduce head-of-line blocking.

Finally, compiler instrumentation (Aspen-Go Compiler) achieves 6% higher GET throughput than user interrupts, for two reasons. First, polling at function calls serves multiple purposes beyond preemption and, therefore, cannot be disabled in

Aspen-Go UINTR/Signals. Thus, Aspen-Go-UINTR/Signals still incur the overhead of polling. Second, even though these systems are configured with the same preemption quantum (50 μs), Aspen-Go UINTR/Signals experiences 22% fewer preemptions than Aspen-Go Compiler, making it less effective at mitigating head-of-line blocking. This is because with compiler instrumentation, preemptions occur only at safe points, whereas user interrupts or signals can be delivered anywhere and are ignored if they arrive at unsafe points. In the BadgerDB workload, most unsafe points occur during the execution of `memmove`, which is heavily used in Go, e.g., in assignment statements.

4.1.4 Summary and Takeaways

We found that the preemption mechanism does not significantly impact performance in systems like Go, which are not fully designed for fine-grained preemption. Below, we summarize key takeaways for Aspen-KB and similar low-overhead, kernel-bypass preemptive systems.

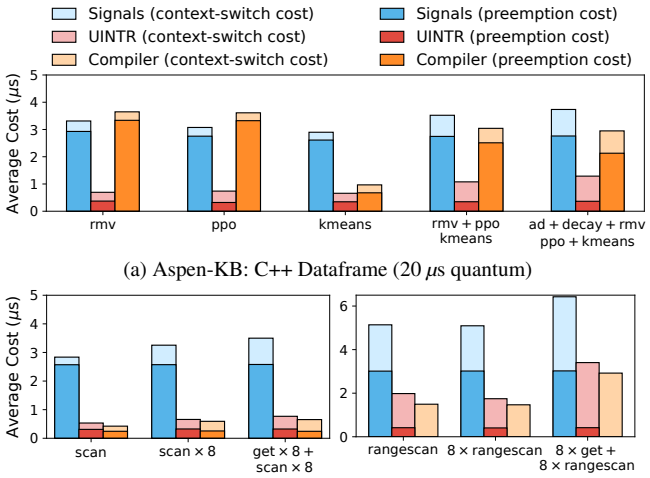
The best choice of preemption mechanism for a given application depends on the optimal preemption quantum. One heuristic for determining a reasonable preemption quantum is that it should be at least as long as the tail runtime of "short" tasks, i.e., tasks that should not be preempted. The guidance in § 4.3 can help more precisely identify the optimal quantum, which might be longer than the runtime of short tasks in order to avoid over-preemption. In either case, if the chosen preemption quantum is at least 10 μs, user interrupts generally deliver better or similar performance compared to compiler instrumentation. The DataFrame results and some benchmark programs in Figure 1 illustrate this.

In scenarios where extremely low quanta (less than 10 μs) are necessary, compiler instrumentation may offer better performance, as long as an application is not dominated by tight loops (§2.2). However, the performance gains are limited, as observed in the RocksDB results. This is because compiler instrumentation only reduces the overhead of the preemption mechanism and does not address the context switching overhead (§4.2). Overall, we conclude that user interrupts are likely a better choice for the majority of applications.

4.2 The Cost of Preemption

In Figure 1 we measured the cost of preempting a thread, executing an empty handler function, and then immediately returning to the same thread (*preemption cost*). In this section, we also report the *context-switch cost* of preemption, which includes the costs of traversing the scheduler, context switching to a different thread, and any resulting cache contention. Together, the preemption cost and context-switch cost represent the total overhead incurred per preemption.

Figure 8 illustrates the preemption and context-switch costs for various preemption mechanisms, applications, and task combinations. Each application uses its optimal quantum as identified in §4.1. The Aspen-Go results (Figure 8c) compute costs relative to a different baseline than those in Aspen-KB. In Go, compiler instrumentation is used for multiple purposes (e.g., to check if more stack space is needed) and cannot easily be disabled. Thus all data in Figure 8c is collected with compiler instrumentation enabled and we cannot quantify the preemption cost associated with compiler instrumentation.



(a) Aspen-KB: C++ Dataframe (20 μs quantum)

(b) Aspen-KB: RocksDB (5 μs)

(c) Aspen-Go: BadgerDB (50 μs)

Figure 8: The costs of preemption (*preemption cost*) and context switching (*context-switch cost*), for 3 applications. The x-axis represents different task combinations, e.g., $get \times 8 + scan \times 8$ indicates that 8 GET tasks and 8 SCAN tasks run concurrently on one core.

We make four observations. First, with larger preemption quanta, the compiler instrumentation costs are amortized over fewer preemptions, yielding higher per-preemption costs, as illustrated by the higher costs for Dataframe than for RocksDB; this is consistent with Figure 1. Second, the context-switch cost in Aspen-KB is not negligible and can even exceed the preemption cost in some workloads (e.g., with 8 GET tasks and 8 SCAN tasks). This further indicates that, although compiler instrumentation may incur lower overhead than user interrupts in some workloads, the improvement in total cost is relatively small. Third, context-switch costs are slightly higher with user interrupts than with compiler instrumentation for some workloads, e.g., 36% higher for the *rmv*, *ppo*, *kmeans* combination. This may be due to saving extended registers (§3.1.3), which is unique to user interrupts. Finally, the context-switch cost in Aspen-Go is higher than in Aspen-KB (1.3-3.0 μs vs. 0.2-0.9 μs), mainly because of the Go runtime's more complex scheduler logic (e.g., checking safepoints). Despite this, user interrupts and compiler instrumentation still incur significantly lower total cost compared to signals.

4.3 Preemption Quantum

We evaluate how the preemption quantum impacts performance in Aspen-KB by running RocksDB with several different preemption quantum. In each case, we determine the

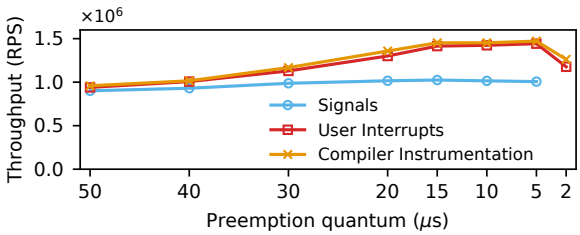


Figure 9: RocksDB GET throughput with different quanta.

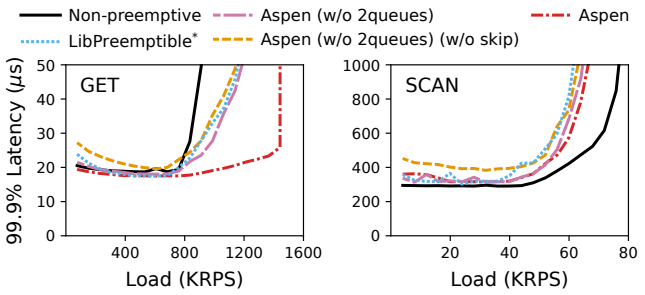

Figure 10: RocksDB performance achieved by LibPreemptible*, Aspen-KB, and other variants. "w/o 2queues" indicates that the 2-queue policy is disabled, while "w/o skip" means that the policy of skipping unnecessary preemption is disabled.

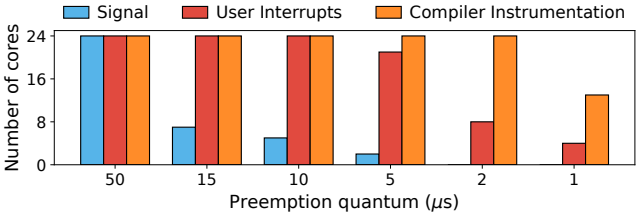

Figure 11: The number of application cores that a single timer core can support under the three preemption mechanisms.

max GET throughput for which GET operations maintain a tail latency of 50 μs or less; Figure 9 shows the results. For all mechanisms, decreasing the preemption quantum improves performance up to a point; beyond this point, the overhead of extra preemptions outweighs the benefits of mitigating head-of-line blocking and throughput degrades. For both user interrupts and compiler instrumentation, the best quantum for this workload is 5 μs; for signals it is 15 μs. The best quantum depends on the workload; across different applications and ratios of GET/SCAN requests in RocksDB, we have observed ideal quanta for user interrupts ranging from 2 μs to 20 μs.

In Aspen-Go, we found that with a slowdown tolerance of at most 5%, signal-based preemption limits the quantum to no lower than 100 μs. In contrast, user interrupts further reduce it to 30–50 μs, providing tighter tail latency guarantees (Appendix B).

4.4 Impact of Aspen-KB's Design Decisions

Preemption Polices. We evaluated the effectiveness of Aspen-KB's policies and compare them to the approach of LibPreemptible [42], a recent system that uses user interrupts for preemption. We run Aspen-KB with various policies disabled, and also approximate LibPreemptible's policies in Aspen-KB. Specifically, for a given load, we test different preemption quanta and select the best result as LibPreemptible's result, modeling its ability to find a suitable quantum through adaptive adjustment. This approximation achieves the best possible performance for a workload that does not have significant variation over time; we denote this as LibPreemptible*.While LibPreemptible's APIs allow users to use two queues to prioritize short requests over long, the user-defined queue for preempted tasks must be shared across all cores, as users can not control which cores tasks run on. Thus it would be difficult to support a two-queue policy in a scalable way with LibPreemptible, so we do not apply the two-queue policy to LibPreemptible*.

Figure 10 show the performance of RocksDB achieved by LibPreemptible, Aspen-KB, and other variants of Aspen-KB. Aspen-KB's two-queue policy yields significant performance improvements for both kinds of requests, by allowing incoming requests to be prioritized, and by reducing the amount of preemptions experienced by longer SCAN requests. The policy of skipping unnecessary preemptions benefits SCAN requests the most at lower loads, when there is less likely to be another task to run. Under such load, even though the preemption quantum is 5 μs, most preemptions can be skipped and the interval between consecutive preemptions is typically more than 30 μs.

Compared to LibPreemptible*, Aspen-KB handles head-of-line blocking more effectively, keeping the tail latency of short requests low. This is largely because of Aspen-KB's two-queue policy. Furthermore, Aspen-KB reduces the slowdown to preempted tasks. LibPreemptible adjusts the preemption quantum based on past latencies and offered load but updates slowly (every 10 seconds), making it unresponsive to real-time load changes. Instead of explicit quantum adjustments, Aspen-KB skips unnecessary preemptions, allowing rapid, real-time adaptation based on the current load.

Timer Scalability. We evaluated the scalability of Aspen-KB's timer core. To stress the timer core, we run a workload that consists of long-running tasks so that the timer core needs to issue a preemption to each core every preemption quantum. We vary the quantum, and for each quantum measure the maximum number of application cores to which the single timer core can reliably send at least 99% of the expected number of preemptions. Figure 11 shows the results.

With a preemption quantum as large as 50 μs, all three mechanisms are able to support all 24 cores that are available to them. With this large quantum, the timer core mostly calls `rdtsc` and busy-spins. With smaller quanta, the timer scalability depends on the cost of triggering preemptions, which varies significantly across the three mechanisms. Sending a signal takes 1.7 μs, a user interrupt 200 ns, and the compiler-based approach incurs negligible overhead, requiring just a

single shared memory write. Consequently, with a 5 μs quantum, the timer scales to only 2 cores with signals but reaches 22 with user interrupts and 24 with compiler instrumentation. This benchmark represents a lower bound on the performance of the timer core; in more realistic workloads one timer core can typically support more application cores due to Aspen-KB's preemption policy, which can skip 70% of preemptions.

5 Related Work

User-level threading. To avoid the overhead of kernel-based scheduling, many systems schedule threads in userspace, adopting an *M:N* threading model. Examples include the Go runtime [6], μThreads [18], Caladan [33], Arachne [49], and many others [10, 21, 37, 45, 53, 54, 57]. Aspen-KB and Aspen-Go are examples of such user-level schedulers.

Preemption mechanisms. Many existing user-level schedulers adopt cooperative concurrency; those that are preemptive typically employ signal-based preemption or compiler instrumentation. For example, Go [6] and Argobots [53] use signal-based preemption. Shinjuku improves upon signals by virtualizing the APIC for lower overhead IPIs [39].

Compiler instrumentation can be implemented with or without a timer core. With a timer core, the compiler inserts instrumentation that checks shared memory—which is written to by the timer core—to determine when the core should yield. Go [6], Wasmtime [19], and Concord [37] take this approach. Alternatively, the instrumentation itself can estimate how much time has elapsed, by tracking the number and/or duration of instructions that have elapsed, and yield the CPU once the metric exceeds a threshold [24, 34, 43].

Both user-level interrupts [46, 51] and user-level exceptions [55] were first proposed decades ago. The new "user interrupts" feature in Intel CPUs makes user-level interrupts available as a preemption mechanism for userspace schedulers today [20]. LibPreemptible [42], Junction [32], and Skyloft [38] use user interrupts for core scheduling or timeslicing. These works are complementary to ours; none studies how user interrupts compare to compiler instrumentation, addresses head-of-line blocking within the network stack, or studies fine-grained preemptive scheduling in the context of a widely used runtime such as Go. Finally, xUI proposes processor extensions that further reduce the overhead of receiving user interrupts [22]; these can be used to improve the performance of both Aspen variants.

6 Conclusion

Preemption can allow us to build more efficient and responsive systems by enabling precise scheduling and mitigating head-of-line blocking. We explored implementing preemption with user interrupts, a new hardware feature. We found that when a system is not constrained by its scheduler's design, user interrupts can offer performance comparable to or better than compiler-instrumentation, while offering a simpler developer experience and more predictable performance.

A Extended Registers

When context switching between user-level threads, care must be taken to ensure that the appropriate registers are saved and restored. This includes any extended registers that are being used by the preempted thread, such as SIMD registers or matrix registers.

When compiler instrumentation is used as the preemption mechanism, preempting a user-level thread simply involves calling a function. In this case, the registers that are in use are known at compile time, and the compiler can save just the caller-saved registers that are in use, including extended registers if necessary [31].

In contrast, with user interrupts, the user-level scheduler is responsible for saving almost all registers. When a user interrupt is delivered, the hardware saves the flags, instruction pointer, and stack pointer. The compiler also saves general-purpose callee-saved registers if they are used by the interrupt handler function [17]. However, the scheduler is responsible for saving any additional registers, including SIMD registers. The scheduler typically has no knowledge of which registers a program is using at runtime, and thus for correctness must conservatively save all extended registers.

We ran a microbenchmark program to measure the cost of saving extra extended registers. In this benchmark, multiple user-level threads perform pointer chasing, each within their own independent region of memory. All threads run on the same core; we preempt them periodically and measure the overhead per preemption. We found that, in the worst case, saving all AVX-512 registers (2 KB) could add over 700 ns of overhead to each preemption, compared to saving only the general-purpose registers. This worst-case overhead occurred when the memory accessed collectively by the threads just barely fit into a given cache layer (e.g., the L1 cache), so that the extra memory consumed by saving extra registers caused evictions to the next layer of cache. These evictions make the benchmark program run much slower, as the chasing pattern was deliberately designed to be highly random, minimizing the effectiveness of cache prefetching. However, for other memory region sizes, the overhead of saving all AVX-512 registers per context switch in this benchmark program remained below 40 ns.

We considered three alternative approaches for handling extended registers. First, one could defer preemption during code that uses them, but unfortunately this approach does not work well for many applications. As shown in Table 1, some workloads such as linpack use SIMD registers continuously throughout their execution, with no clear point to defer preemption to. With RocksDB operations, SIMD registers are confined to specific functions, but these functions are called so frequently that deferring preemption would slow down operations by several percent.

A second approach is to use the instructions `XSAVEC` and `XRSTOR` to save and restore registers, as in prior work [32].

These instructions detect which "state components" are in use and save only active components [7]. However, we found that using these instructions added 100-150 ns to each context switch, compared to only 10-30 ns when saving all AVX-512 registers one by one, due to the high fixed costs of these instructions. Furthermore, these instructions track state components only at coarse granularity (e.g., all AVX-512 registers are in the same state component), limiting their ability to optimize which registers are saved.

Finally, it may be possible to reduce overheads by having the compiler identify the set of registers that are used by each program and create custom functions that save and restore only those registers. For the applications we evaluated, saving and restoring all AVX-512 registers on every context switch yielded sufficiently low overhead, but if register state continues to grow in the future, or if applications use additional extended registers such as matrix registers, it may be beneficial to explore this approach.

B Preemption Quantum in Aspen-Go

We ran several microbenchmarks on both Aspen-Go UINTR and Aspen-Go Signals to gain a broader understanding of the preemption overhead at different preemption quanta in Aspen-Go. For each benchmark program, we ran 10 goroutines of the same program concurrently on a single core, with preemption occurring at every quantum. These microbenchmarks are from the benchmark suite [5], which Go developers used to measure preemption slowdown [14]. Figure 12 presents the results. With a slowdown tolerance of at most 5%, using signals as the preemption mechanism limits the quantum to no lower than 100 μs. In contrast, user interrupts provide finer-grained preemption, allowing for preemption quanta as small as 30-50 μs.

C Preemption Slowdown

Table 2 presents the preemption overhead of three mechanisms—signals, user interrupts, and compiler instrumentation—measured across 24 programs from the Splash-2, Phoenix, and Parsec benchmark suites. Section 2 highlights representative benchmarks and compares the three preemption mechanisms.

Abstract

Securing network traffic within data centers is a critical and daunting challenge due to the increasing complexity and scale of modern public clouds. Micro-segmentation offers a promising solution by implementing fine-grained, workload-specific network security policies to mitigate potential attacks. However, the dynamic nature and large scale of deployments present significant obstacles in crafting precise security policies, limiting the practicality of this approach. To address these challenges, we introduce a novel system that efficiently processes vast volumes of network flow logs and effectively infers the roles of network endpoints. Our method integrates domain knowledge and communication patterns in a principled manner, facilitating the creation of micro-segmentation policies at a large scale. Evaluations with real-world deployment demonstrate that our solution significantly surpasses existing algorithms in role inference accuracy. We implement our solution as an end-to-end system and demonstrate that it is up to 21.5× more cost-efficient than Apache Flink, a widely used open-source stream processing system.

1 Introduction

The growth and criticality of public clouds are accompanied by persistent security threats. Prominent security incidents, such as those involving SolarWinds [2], Midnight Blizzard [71], and Snowflake [68], reveal a spectrum of attack vectors from compromised credentials to exploited software providers and trust chains. These incidents often lead to massive leaks of sensitive data, significant economic losses, and deterioration of customer trust [1, 86, 87]. Consequently, there is a pressing need for the development of enhanced security technologies to protect the integrity of data centers.

One promising solution that has emerged is *micro-segmentation* [89], a technique grounded in the zero-trust security model [63, 78]. Recognizing that preventing every cyberattack is a nearly unattainable task, micro-segmentation operates under the assumption that every endpoint can be compromised. It therefore aims to contain the impact of potential breaches by creating isolated μsegments within the network. Under this model, resources in different μsegments can only communicate with each other if explicitly permitted by a set of fine-grained, workload-specific policies. This restrictive approach significantly limits the potential damage of a breach. Several vendors have already introduced micro-segmentation offerings [28, 41, 55, 88]. The market for micro-segmentation is worth several billion dollars in annual revenue and boasts a robust growth rate of over +20% year-over-year [25].

However, two significant challenges arise when implementing micro-segmentation on a large scale: precise security policies and cost-effective monitoring. First, existing solutions [28, 41, 55, 88] rely on human administrators to assign a μsegment label to *every* endpoint. This μsegment creation process necessitates a deep understanding of the workloads and continuous updates to keep up with changes in software or environment. This manual approach does not scale for large systems that leverage millions of resources [72] and have large teams owning different parts of cloud software [19, 33, 45]. Mislabeling or outdated labels can result in legitimate access being denied or unnecessary exposure to potential attacks. Second, a micro-segmentation solution necessitates the capability to observe and monitor network behavior. This involves the near real-time gathering and analysis of network telemetry, a process that can inflate costs significantly. Indeed, leading solutions [28, 55] add a substantial *extra* cost to the infrastructure, such as virtual machines (VMs) and containers, ranging from 16% to as high as 71%. This financial burden presents a considerable obstacle to their extensive adoption.

Objectives and Techniques. We introduce ZTS (Zero Trust Segmentation), a novel micro-segmentation system designed for large-scale public cloud networks. The objective of ZTS is to facilitate the creation of precise, scalable security policies, while also offering a cost-effective solution for gaining visibility into network behavior and conducting efficient monitoring. ZTS consists of two core components:

(1) Deployment-Specialized Auto-Segmentation: To gen-

* These authors contributed equally.

erate μsegments on a large scale, we introduce a novel auto-segmentation algorithm predicated on the inference of network endpoints' roles. Our algorithm is grounded in the observation that within a large deployment, a multitude of network nodes often fulfill identical roles, such as replicas, microservices, lambdas, etc. These roles can be designated as the μsegments, as nodes performing the same function can adhere to the same network security policy. A key insight underpinning our role inference algorithm is that the definition of role varies across different functionalities and deployments. As such, our algorithm judiciously combines domain-specific knowledge, communication patterns, and deployment-specific information. This approach then generates an autoencoder that is uniquely tailored to each deployment, thereby enhancing its accuracy in inferring roles and μsegments.

(2) Cost-Effective Communication Graph Generator: To minimize the costs of observing and monitoring network behavior, we carefully design a unique system architecture that efficiently generates a complete communication graph from a large volume of network flow logs at a very low cost. Our architecture leverages compute endpoints (e.g., VMs) to process and batch a substantial number of network flow logs into a database endpoint (e.g., SQL servers) and employs advanced query optimization techniques to construct communication graphs. This design enables our system to accommodate large-scale deployments with a minimal amount of compute, memory, and network resources.

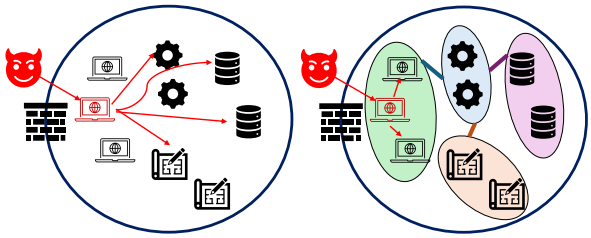
Implementation and Evaluation. We build ZTS as a complete micro-segmentation system that provides continuous communication graph generation, advanced role inference for auto-segmentation, and security policy authoring and enforcement. To evaluate the accuracy of our auto-segmentation algorithm, we curate ground truth data across 11 first-party and third-party deployments, encompassing communication graphs with tens of thousands of nodes and millions of edges. Our evaluation demonstrates that our role inference algorithm significantly outperforms state-of-the-art algorithms [56, 59, 72, 93], achieving an average Adjusted Rand Index (ARI) [53][1] improvement of 0.37.

To evaluate cost-effectiveness in network observation and monitoring, we implement an alternative communication graph generator using Apache Flink [38], a popular open-source stream processing system. Our evaluation across different deployments shows that ZTS is 7.5× faster than Apache Flink at only 35% of the cost, making it 21.5× more cost-efficient. Deploying ZTS only introduces an extra 0.5% of the cost of the VMs, which is significantly cheaper than existing micro-segmentation solutions.

Contributions. We make the following contributions:

- We introduce a novel algorithm that infers network endpoints' roles by incorporating domain-specific knowledge and deployment-specific information in a principled manner. This approach significantly enhances the accuracy and scalability of micro-segmentation.
- We design a cost-effective system architecture for generating communication graphs from network flow logs, which reduces resource usage and operational costs in implementing micro-segmentation at a large scale.
- We build an end-to-end micro-segmentation system and show significant improvements in role inference accuracy and cost-efficiency compared to existing solutions, validated using large-scale real-world deployments.

[1] ARI is a widely used metric for measuring clustering quality, adjusted for chance. It ranges from -0.5 for highly discordant clusterings to 1.0 for identical clusterings.



(a) Without Micro-segmentation (b) With Micro-segmentation

Figure 1: An example of how micro-segmentation prevents lateral movement by attackers.

2 Background and Motivation

We begin by providing background on micro-segmentation, followed by a detailed discussion of the major challenges in realizing this concept in practice.

2.1 Micro-Segmentation

Micro-segmentation [89] is a security technique that involves dividing a network into smaller, more manageable, so-called, *μsegments*, each with its own set of security controls. The concept emerged as a response to the increasing complexity and interconnectivity of modern IT environments, where traditional perimeter-based defenses proved insufficient. As illustrated in Figure 1(a), a compromised network node permits an attacker to propagate laterally across other nodes without limitations, potentially resulting in significant data breaches and system damage. However, by implementing micro-segmentation, as depicted in Figure 1(b), each μsegment effectively minimizes the attack surface. This is achieved by confining communications to predefined pathways, thereby enhancing the containment of breaches. Today, micro-segmentation is considered a core component of zero-trust security architectures [63, 78].

Deploying a micro-segmentation solution involves two key phases to ensure effective implementation and enhanced security. The first phase is *μsegment definition and policy authoring*, where administrators conduct a comprehensive assess-

Figure 3: Applying other segmentation strategies, inspired by prior work, on K8s PaaS's IP-graph

ment of the current network architecture and communication patterns. This is often facilitated by generating a comprehensive communication graph using network flow logs from the workloads. Following this assessment, administrators define the relationships between assets and μsegments, authoring security policies that specify which μsegments can communicate with each other and under what conditions. A pair of resources can communicate with each other only if explicitly allowed by the policies; i.e., the default will be to deny [34, 39].

The second phase is *implementation and monitoring*, where these security policies are enforced using a micro-segmentation platform, which may involve configuring virtual firewalls and security controls at the hypervisor or network level. Once implemented, the system should be continuously monitored to ensure compliance with the defined policies. Additionally, μsegments and policies need to be regularly updated to accommodate changes in configurations, deployments, and workloads.

2.2 Challenges in Authoring Security Policies

While creating micro-segmentation may appear straightforward in simple examples, such as in Figure 1, in practice, creating and maintaining μsegments can be a daunting challenge for administrators. To illustrate this issue, we examine three real-world deployments in Table 1.

Figure 2 depicts the unsegmented IP-level communication graphs for each deployment. As these graphs show, the number of nodes and communication patterns can quickly become complex. Our interviews with developers reveal that even they often do not fully understand these graphs, as communication can be initiated by various layers in a complex software stack. The current state-of-the-art requires a human

	#IPs mon.	Graph Size: #nodes (#edges)		#Records
		IP Graph	IP-port Graph	/minute
Portal	4	4K (5K)	13K (13K)	332

KQuery	1400	6K (1.3M)	12M (79M)	2.3M

Table 1: Cloud deployments and some aspects of their communication graphs that we built and analyzed in this paper. The source telemetry is flow-level summaries every minute with schema as in Table 3.

administrator to manually tag each node with a μsegment label so that the system can suggest security policies. However, this approach is neither scalable nor error-free. Our investigation of real-world deployments (detailed in Table 5) reveals that only 12% to 23% of network nodes possess useful information—such as machine functions, tags, or function-based names—that could potentially serve as μsegment labels. However, the availability and consistency of such information exhibit considerable variation across different deployment scenarios. Furthermore, administrators need to stay updated on all role changes—such as when workloads migrate, scale up, or scale down [13], or when a software update alters communication behavior—which occurs frequently in large-scale deployments.

Study of Existing Role-Inference Algorithms. Could an algorithm assist with μsegment labeling? Fundamentally, there are far fewer roles than resources in a cloud setting because, for redundancy and scalability, it is common for multiple resources to share the same role. Intuitively, nodes that play the same role share communication patterns and may be inferred based on the similarity of neighbors a resource communicates with and the nature of the conversation. This is similar to the role inference problem in the graph mining literature [51, 58]. Figure 3 presents the outcomes using some established tech-

Core #	VM	Illumio	Illumio vs. VM	Akamai	Akamai vs. VM
2	$549		65%		71%
4	$1,100	$354	32%	$390	35%
8	$2,194		16%		18%

Table 2: Pricing comparison between Azure general-purpose VMs [7], Illumio Core [14], and Guardicore Segmentation [3]. All pricing represents annual costs, normalized to a single VM and shown in US Dollars. The pricing for Illumio Core and Guardicore Segmentation was from Azure Marketplace.

niques on one deployment. There are clear discrepancies among them, and it is unclear which one is more correct.

To deepen our understanding, we conduct a study utilizing popular, state-of-the-art role inference algorithms, including (1) Jaccard: similarity of neighboring nodes [59], (2) SimRank [56]: graph structural similarity, (3) GAS [93]: structural embeddings with graph neural networks, and (4) CloudCluster [72]: grouping nodes based on the adjacency matrix. We curate ground truth data for 11 real-world deployments (details in Section 6.2). The full results are summarized in Table 6 (Section 6.2). Our findings indicate that, although certain algorithms demonstrate good performance in specific deployments, none consistently achieve high performance across a diverse range of deployments. Additionally, the performance of all algorithms diminishes as the scale of deployments increases. Overall, existing algorithms tend to produce role inference results that significantly deviate from the ground truth, with none achieving an average Adjusted Rand Index (ARI) greater than 0.5.

Our analysis reveals that effective and consistent role inference for micro-segmentation remains a major challenge in practice, attributable in part to several factors: (1) The phenomenon driving role similarity in cloud communication graphs—namely, identical code executing across multiple resources for redundancy and scalability—does not stem from human interactions, unlike in social and product recommendation graphs [51]. (2) Structural resemblance within a communication graph does not guarantee role similarity; thus, an algorithm capable of harnessing additional communication attributes is necessary to differentiate such instances. (3) Given that the optimal role inference algorithm may vary among deployments or evolve over time, a dynamic, learning-based algorithm that adjusts according to feedback could potentially surpass all static approaches.

2.3 Cost of Micro-Segmentation Solutions

Micro-segmentation is an expanding market with solutions from multiple vendors [28, 41, 55, 88]. We examine the costs associated with two leading vendors specializing in micro-segmentation platforms [28, 55], comparing these expenses to the infrastructure costs of VMs with varying core counts.

As Table 2 shows, the pricing of both solutions is comparable and incurs significant extra costs, constituting 16% to 71% of the total VM costs. Although licensing fees may not directly equate to computational costs, this analysis highlights the substantial financial burden on organizations seeking to implement micro-segmentation.

Our analysis finds that the primary cost of micro-segmentation lies in the collection and analysis of network telemetry to achieve near real-time network visibility. This involves the continuous processing of extensive network flow logs to generate a comprehensive view. Initial attempts with off-the-shelf solutions, such as Apache Flink [38] and Apache Spark [92], proved to be cost-prohibitive, adding over 10% to the overall VM expenses.

Summary. The lack of an effective role inference algorithm for network endpoints, coupled with the high costs of network behavior monitoring, are significant barriers to achieving the full potential of micro-segmentation. These challenges form the core of our design requirements for ZTS.

3 Overview of ZTS

We introduce a novel end-to-end system, ZTS, specifically designed to facilitate micro-segmentation in public cloud environments at scale, while maintaining cost efficiency. The system achieves scalable security policy formulation with an innovative role inference algorithm, which integrates network domain knowledge and communication patterns based on the characteristics of each deployment. The algorithm allows for effective collaboration with deployment owners or network administrators to fulfill the diverse requirements of various deployments. Additionally, ZTS minimizes the costs associated with micro-segmentation through a cost-efficient communication graph generator. Figure 4 provides an overview of the ZTS architecture.

Telemetry and Graph Generator. The input to ZTS consists of network flow telemetry, which periodically summarizes the network flows generated by cloud assets such as VMs and containers within a deployment. Most major cloud providers offer this telemetry with minimal impact on customer workloads [10, 11, 17] (Section 5.1 provides more details). This telemetry stream is processed by ZTS's *communication graph generator* (① in Figure 4) to produce a communication graph, similar to those in Figure 2, where each node represents an IP address and each edge summarizes all flows between the corresponding IP pairs. Section 5.2 outlines the detailed system architecture of our communication graph generator.

Policy Authoring. During the security policy authoring phase, ZTS's *role inference trainer* (② in Figure 4) facilitates the creation of μsegments by inferring the roles of each network endpoint. The role inference trainer takes into account: (1) communication patterns from the graphs, (2) detailed information from flow telemetry (e.g., communication ports), (3) information from cloud resources (e.g., asset type), and (4)

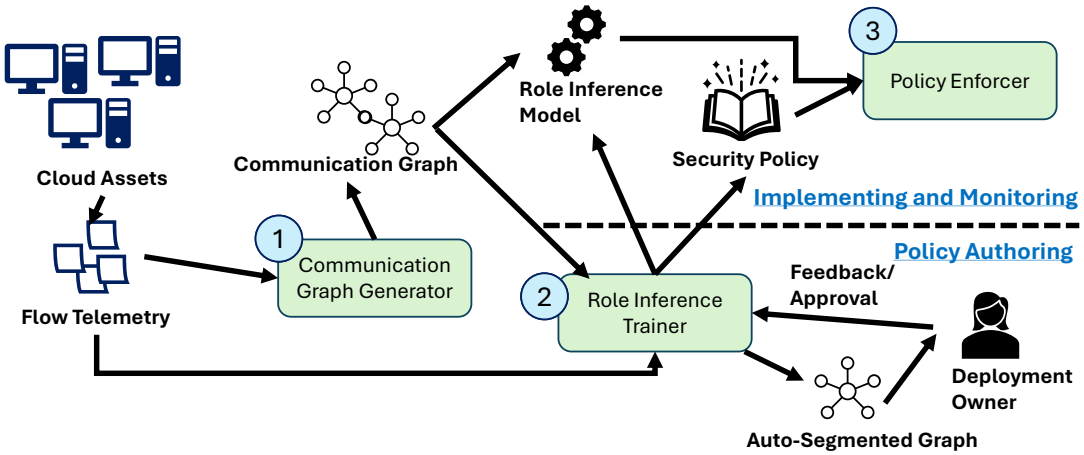

Figure 4: Overview of ZTS.

feedback from the deployment owner (e.g., tags of a subset of assets). The trainer iteratively collaborates with deployment owners to stabilize the micro-segmentation and suggests security policies for each μsegment based on the auto-segmented graphs. Section 4 describes the details of our role inference algorithm.

Implementing and Monitoring. The policy authoring phase generates a role inference model and a set of security policies. During the implementation phase, the *policy enforcer* (③ in Figure 4) maps these security policies from the μsegment level to the IP address level and writes the low-level policies into network security controllers (e.g., [8]) for enforcement. ZTS continuously detects role changes and infers roles for new network endpoints using the role inference model. These changes are applied by the policy enforcer and sent to deployment owners for periodic reviews and model retraining.

4 Role Inference

4.1 Problem Formulation

Our data collection procedure described in §5 enables the construction of a featured IP graph $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathbf{A}, \mathbf{X})$. The node set $\mathcal{V}$ of cardinality $|\mathcal{V}| = N$ contains all IP addresses in the network, and a directed edge in $\mathcal{E}$ exists between two IPs if traffic was measured from one to the other. The total amount of traffic (measured in bytes) from node i to node j is encoded by the entry A_{ij} of the directed adjacency matrix $\mathbf{A} \in \mathbb{R}^{N \times N}$. Notice that we can interpret the i-th row $\mathbf{a}_i^\top$ of $\mathbf{A}$ as features associated with node i capturing the total traffic that this node sent to every other IP in the network. The matrix $\mathbf{X} \in \mathbb{R}^{N \times D}$ contains additional node features, where the i-th row $\mathbf{x}_i^\top$ collects the D features associated with IP i. These features encapsulate information beyond the total traffic sent to other IPs, which is already encoded in $\mathbf{A}$. This includes details such as the primary ports used by an IP, statistical information about the connections—such as the mean and variance of bytes per connection or bytes per packet—and even the count of graphlets [26] or motifs [84] within the communication graph to which a given node belongs. Additionally, they encompass system-related information, such as names and cloud resource SKU information. Our goal is to leverage the information in $\mathcal{G}$ to cluster the IPs into roles $\mathcal{R}$, where two IPs within the same cluster have similar activity. Ultimately, this can allow us to perform communication graph visualization and network management at the role level (instead of the IP level), thus facilitating the generation of rules and improving interpretability (§2.1). The procedure to achieve this goal is detailed next and summarized in Figure 5.

4.2 Infusing Domain Knowledge into Role Inference

In principle, we can concatenate $\mathbf{a}_i$ and $\mathbf{x}_i$ to generate a summary of the activity of IP i, and use these representations to cluster all IPs. However, notice that there is noise and redundancy in these representations, motivating a dimensionality reduction procedure. To be more precise, even if two IPs have the same role, we would not expect the corresponding rows of $\mathbf{A}$ to be identical [72]. Instead, we can think of these as noisy measurements of the canonical activity of that role. In order to recover these main modes of activity, we can perform principal component analysis (PCA). Similarly, the different features in $\mathbf{X}$ originate from the traffic data, so we can expect redundancy among the features, leading to an effectively rank deficient matrix. Based on these considerations, we perform a two-step dimensionality reduction procedure where we first apply a linear method (PCA) followed by a non-linear method (autoencoder). Formally, we consider the singular value decomposition (SVD) of $\mathbf{X} = \mathbf{U}\Sigma\mathbf{V}^\top$ and keep only the top p components to form $\tilde{\mathbf{X}} = \mathbf{U}_p\Sigma_p$, where $\mathbf{U}_p \in \mathbb{R}^{N \times p}$ contains the p leading (left) singular vectors and $\Sigma_p \in \mathbb{R}^{p \times p}$ is a diagonal matrix containing the corresponding singular values. We select p such that the amount of variance that needs to

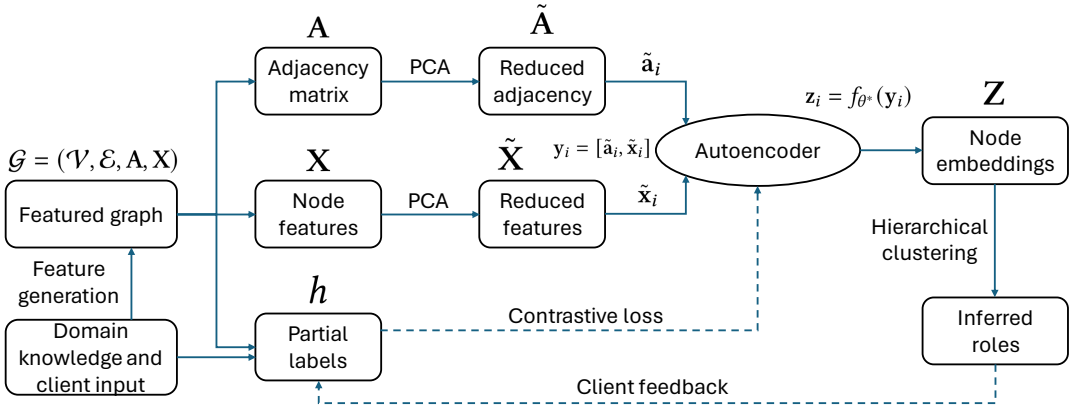

Figure 5: Role inference pipeline. Node embeddings, obtained through an autoencoder, are hierarchically clustered to group the nodes into role classes. Domain knowledge and potential client input is incorporated through feature generation and partial role labels.

be explained is greater than a pre-specified threshold, and we use 99% as a default value in our experiments. A similar procedure is followed to obtain $\tilde{\mathbf{A}} \in \mathbb{R}^{N \times p}$. We denote the concatenation of the i-th rows of $\tilde{\mathbf{A}}$ and $\tilde{\mathbf{X}}$ by $\mathbf{y}_i = [\tilde{\mathbf{a}}_i, \tilde{\mathbf{x}}_i] \in \mathbb{R}^{2p}$.

We further reduce the dimensionality of $\mathbf{y}_i$ via an autoencoder regularized by a contrastive loss. To do so, we assume that we have access to the true roles of a small subset of the IPs. This can be achieved either by relying on domain-inspired rules, such as specific ports associated with pre-established roles, names given to the virtual machines, or an IP-based lookup table, or by obtaining feedback from the network administrator. We denote this partial labeling heuristic as $h : \mathcal{V} \to \mathcal{R} \cup \emptyset$ such that $\hat{r}_i = h(i)$ is the estimated role of node i. Notice that the heuristic might not have enough information to determine the role of a given node. In these cases, $\hat{r}_i = \emptyset$. Let us denote by $\mathcal{L}$ the set of nodes assigned some role label by this heuristic, i.e., $\mathcal{L} = \{i \in \mathcal{V} \,|\, \hat{r}_i \neq \emptyset\}$. Respectively denoting by $f_\theta : \mathbb{R}^{2p} \to \mathbb{R}^d$ and $g_\psi : \mathbb{R}^d \to \mathbb{R}^{2p}$ the parametric encoder and decoder (both multi-layer perceptrons) of our autoencoder, we train the parameters θ and ψ so as to minimize the loss

$$L(\theta, \psi) = \sum_{i \in \mathcal{V}} \|\mathbf{y}_i - g_\psi(f_\theta(\mathbf{y}_i))\|_2 - \tag{1}$$

$$\alpha \sum_{r \in \mathcal{R}} \sum_{\substack{i,i' \in \mathcal{L} \\ h(i)=h(i')=r}} \log \left(\frac{\exp(\mathrm{sim}(f_\theta(\mathbf{y}_i), f_\theta(\mathbf{y}_{i'}))/\tau)}{\sum_{\substack{i'' \in \mathcal{L} \\ h(i'') \neq r}} \exp(\mathrm{sim}(f_\theta(\mathbf{y}_i), f_\theta(\mathbf{y}_{i''}))/\tau)} \right).$$

In (1), sim is a pre-specified similarity measure in the embedding space (such as cosine similarity), τ is a scalar temperature parameter, and α controls the relative weight between both terms of the loss. Notice that the first term in (1) is the classical autoencoder loss that seeks to minimize the difference between the input and output, while the second term pushes together the embeddings of nodes known to have the same role (and separates those known to have different roles). Denoting by θ^* and ψ^* the parameters that minimize the loss in (1), we consider the embedding $\mathbf{z}_i = f_{\theta^*}(\mathbf{y}_i)$ as our concise representation of the activity of IP i, which we gather in the matrix $\mathbf{Z} \in \mathbb{R}^{N \times d}$. Finally, similar to prior work [72], we implement a hierarchical agglomerative clustering algorithm to $\mathbf{Z}$ to obtain our inferred roles for the IPs in the network.

We want to emphasize the following aspects of our role inference algorithm:

1) *User input and feedback*: The labeling heuristic h permits the incorporation of user input into the embeddings $\mathbf{Z}$ through the contrastive loss term in (1). Moreover, after executing the role inference procedure once, the user can be consulted regarding the clusters identified, in a manner similar to active learning [80]. This could involve querying the user about clusters that are the least separable. If discrepancies are found between the clustering output and the user's understanding, the user's knowledge can be fed back seamlessly into h, resulting in improved role inference.
2) *Incorporation of domain knowledge*: Unlike generic role inference methods for graphs [58], domain experts have prior knowledge of what shapes the role of an IP in a network in terms of, e.g., ports used and traffic statistics. Both the partial labeling heuristic h and the node features $\mathbf{X}$ are ideal vehicles to infuse this domain knowledge into our role inference method.
3) *Relation to existing work*: Our pipeline (Figure 5) subsumes most existing methods that cluster nodes based on structural similarities [49, 72]. For example, the method in CloudCluster [72] boils down to performing clustering directly on the rows of $\tilde{\mathbf{A}}$, the adjacency matrix after dimensionality reduction. The incorporation of the autoencoder and, more importantly, the consideration of node features $\mathbf{X}$ and partial labels h constitute key additions with respect to this baseline. We emphasize their value both with a toy example (§4.3) as well as in real-world networks (§6.2).

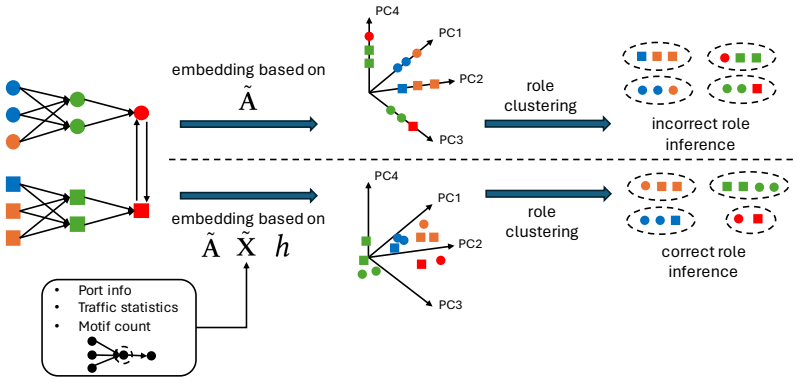

Figure 6: Illustrating the value of domain knowledge. The incorporation of domain knowledge through node features and partial labels leads to the correct inference of roles in the toy network under study.

4.3 Illustrating the value of our proposed pipeline

Let us consider a simple toy network shown in Figure 6-left, where the $N = 12$ nodes have been colored according to their role and the shapes (circles versus squares) represent the top and bottom subnetworks. Traffic originates from two classes of nodes corresponding to different services (blue and orange), this is then relayed through the green nodes to the red nodes. This can be an idealistic representation of a microservice architecture, where the blue and orange nodes are different microservices, the green nodes are the memory object caching systems, and the red nodes are the databases.

We first analyze the roles inferred in this toy network based solely on the adjacency (structural) embeddings $\tilde{\mathbf{A}}$ in Figure 5. Recall that, as explained in §4.2, this is effectively the method proposed in CloudCluster [72]. Assuming that all communication links in Figure 6 have similar total load, the adjacency matrix $\mathbf{A}$ has four dominant principal components. To see this, notice that the rows of $\mathbf{A}$ encode who a given node is talking to, and there are four distinct cases in our toy network (the green circles, the green squares, the red circle, or the red square). Moreover, in $\tilde{\mathbf{A}}$, all the nodes will have an embedding lying on top of one of these four principal components, as shown in Figure 6. Given this marked separation in $\tilde{\mathbf{A}}$, CloudCluster outputs the (incorrect) role labels in Figure 6-top right, irrespective of the specific hierarchical clustering algorithm of choice. This undesirable outcome is resolved by incorporation of $\mathbf{X}$ and h as in our proposed pipeline. For example, the incorporation of port-based features can help distinguish the blue from the orange nodes. Similarly, adding features based on small motifs such as the one illustrated in Figure 6 can bring the embeddings of all green nodes together (notice that only green nodes are at the center of these motifs). Additionally, partial labels of, e.g., blue nodes in the top and bottom parts of the network will help bring the embeddings of all blue nodes together through the contrastive loss in (1). As a result, the 4-dimensional embedding in Figure 6 is more informative than that solely based on $\tilde{\mathbf{A}}$, thus ultimately leading to the correct role inference.

Comparison (and combination) with other baselines. The description of the example above was centered on highlighting the benefits of our proposed pipeline with respect to CloudCluster [72], a state-of-the-art method for extracting roles developed within the networking community. However, it is also important to establish our advantages with respect to more traditional (not domain specific) role inference methods in graphs. This includes simple algorithms based on Jaccard similarity [59] as well as more sophisticated structural embeddings such as SimRank [56] and GAS [49]. Notice that two nodes are deemed close to each other by Jaccard if they share similar neighbors. This essentially means that the similarity of two nodes is given by the similarity between their corresponding rows of $\mathbf{A}$. Consequently, Jaccard inherits the same limitations established for CloudCluster in the example above. Other structural embeddings [30, 49, 56] go beyond comparing similarities in the one-hop neighborhoods and can detect that, e.g., both pairs of green nodes play a similar role in the network. Nonetheless, these methods do not incorporate node features or partial labels, thus falling short of our proposed solution. In our evaluation, we show how our proposed pipeline improves upon all these baselines in real networks. Finally, notice that if the structural embeddings output by any of the existing methods are preferred to the reduced adjacency in Figure 5, we can simply replace $\tilde{\mathbf{A}}$ with the embeddings from any of these methods and implement our pipeline *talis qualis*. In this sense, we can think of our pipeline as a principled way of combining structural embeddings with domain knowledge through node features and partial labels, irrespective of the structural embedding of choice.

5 Low-Cost Telemetry and Analytics

In this section, we discuss the rationale behind our choice of telemetry and our experience in building a cost-effective and scalable communication graph generator for ZTS.

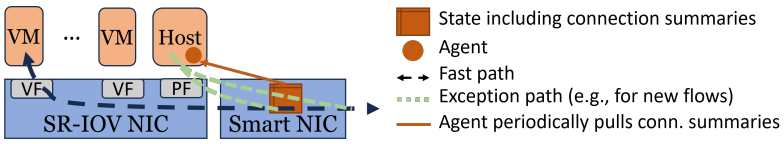

Figure 7: Illustrating how one can capture connection summaries with zero impact to VMs in a public cloud.

Time	Local		Remote		#Packets		#Bytes	
	IP	Port	IP	Port	Sent	Rcvd.	Sent	Rcvd.

Table 3: Schema of connection summaries.

	Azure	AWS	GCP
Name	NSG Flow Logs	VPC Flow Logs	
Agg. Intrvl	1 min	1 min	5s or higher
Content	As illustrated in Table 3		
Sampling	N/A	N/A	3% of Pkts, 50% of Flows
Price	about 0.5$/GB to collect		

Table 4: Details on available connection summaries at three large cloud providers.

5.1 Telemetry Source

As Section 3 mentions, the telemetry source for ZTS is network flow (or connection) summaries [10, 11, 17]. Tables 3 and 4 depict the data format and key details. We select this telemetry source because it (i) can be gathered with minimal disruption to customer workloads, (ii) is cost-effective, allowing for continuous collection, and (iii) is tamper-proof. Consequently, connection summaries are readily accessible to all customers across major cloud providers. Rather than developing a custom telemetry source, we opportunistically use the widely available connection summaries, which contributes to the practical viability of our system.

Cloud providers typically gather connection summaries using programmable NICs directly attached to all hosts in public clouds (Figure 7). These NICs perform various network functions [5, 6, 12, 35, 64, 75]. Connection summaries are stored in smartNIC memory, and an agent on the host periodically retrieves and forwards these summaries to a cloud store or service endpoint. Relative to capturing packet traces [21], logging in the kernel [62, 79] and sampling packets on switches [22], the method in Figure 7 has a few advantages. The size of the logs and memory usage are proportional to the number of concurrent flows. Since these cards already maintain per-flow state [23, 35], recording a few additional counters imposes minimal overhead. Importantly, the impact on customers is minimal; the performance interference from updating a few counters is negligible compared to the extensive network function processing occurring in network virtualization [23, 24, 43, 47]. Additionally, the same functionality can be implemented in the software stacks that handle network virtualization [43].

Collecting packet traces requires the network stack to copy packets, which is more costly compared to the method of generating flow summaries described in Figure 7, especially at NIC speeds reaching 400Gbps. Packet processing elements in switches typically do not have memory to spare to record per-flow state [15, 16], so they sample packets and summarize them at the control CPUs [22, 66]. Some cloud providers use a similar approach, sampling packets and flows to further reduce costs when generating connection summaries [11]. The cost-effective nature of connection summaries enables cloud providers to offer telemetry collection services at a price that makes continuous monitoring required for micro-segmentation feasible, typically $0.25 to $0.5 per GB of collected telemetry [4, 18, 20]. The total telemetry collection cost depends on the number of VMs and connection records generated per hour. In our study, this amounts to approximately $8 to $19 per VM per year. This telemetry is then securely stored to prevent tampering by customers, who do not have access to the host, ensuring availability even if VMs are breached. Customers incur additional storage costs for the telemetry, which can be minimized with an appropriate retention policy. These telemetry collection and storage costs are common to all micro-segmentation solutions and are in addition to the costs illustrated in Table 2. It is also possible that customers have telemetry collection and storage enabled for other monitoring use cases. Hence, we consider these costs orthogonal to our study's scope. Although alternatives like network stack hooks such as eBPF are beneficial, deploying agents on every VM in a public cloud is difficult due to the diverse OS types and the limited control providers have over guest OSes. Even if these agents are deployed, their telemetry can be compromised by malicious code within the VM, making them less reliable during breaches compared to the connection summaries used by our system.

5.2 System for Graph Generation

Our primary goal is to use systems that are available in most large public clouds today to build an analytics system that can analyze roughly 1000 VMs worth of telemetry (e.g., connection summaries at one minute granularity) using a handful of VMs worth of resources. This is roughly a 0.5% surcharge, and such a low COGS is crucial for extensive adoption.

The structure and volume of our telemetry source present challenges in designing a scalable, low-cost analytics system. Cloud providers organize telemetry into numerous small files (e.g., one JSON file per hour per VM) with connection summaries embedded as delimited strings within nested JSON structures. The structuring of the telemetry as many small files is a consequence of the design described in Figure 7, while the nested JSON keeps files compact in representing relationships between flows and various cloud resources. The

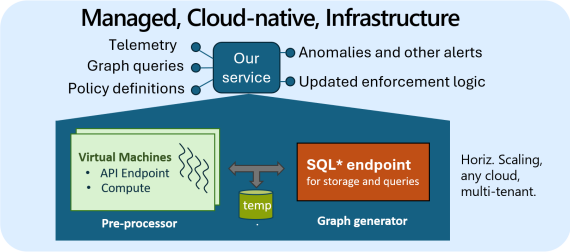

Figure 8: Our analytics system architected as a software-as-service (SaaS) that can adapt to load.

analytics system must efficiently process these small files, unroll nested JSON structures, and parse delimited strings to extract connection summaries. Additionally, it should integrate other information streams, such as IP Address Managers (IPAM) and Virtual Network (VNET) configurations, to enrich the summaries with domain knowledge for the role inference pipeline. The huge volume of connection summaries thus extracted (e.g., #records/min in Table 1) can result in very large communication graphs (e.g., an IP graph is roughly 10x to 100x the number of monitored VMs) requiring careful considerations to keep the processing time and cost low.

Given the telemetry structure, we faced a design choice between a stream processing system for consuming the large influx of small JSON files to generate graphs in real time, and a batch processing system that generates graphs from batched connection summaries. We chose the latter and separated the compute-intensive JSON processing from graph generation, resulting in two processing phases. This approach allows us to pipeline and parallelize the pre-processing stage, preparing batched connection summaries in an optimal format for large batch processing systems, resulting in low-latency processing.

Our system is architected as an always-on, cloud-native service as shown in Figure 8. We structure our system into two main components: (1) a pre-processor that leverages scalable compute resources to handle the large telemetry volume, (2) a graph generator based on a batch processing SQL system [9] to generate the communication graphs from the batched connection summaries. For low-latency graph generation, the batch processing system should be able to generate and complete an efficient query execution plan to process the connection summary batches into graphs. Naïvely, this is a group-by-aggregation query. That is, accumulate the byte, packet, and connection counts between pairs of nodes. The memory need is proportional to the number of node pairs in the graph which would be prohibitive for very large graphs. One mitigation we employ is to focus on the heavy hitters. That is, remote IPs and ephemeral ports that do not individually account for a sizable share of traffic are collapsed together. In fact, the graph sizes in Table 1 collapse IPs contributing less than 0.1% of bytes, packets or connections into one node in the IP-graph. Further, we optimize our query to use Common Table Expressions (CTEs) to eliminate intermediate materialization and to effectively use the system query planner. This approximation and the ability of the SQL system to handle large graphs by effectively using the available memory and disk resources allow us to construct communication graphs on subscriptions with 1000s of VMs in real time using just a few machines worth of resources.

We iterate over our system design and implementation over several developer months as shown in Figure 9, introducing several optimizations: (1) retiring our serverless PaaS system to a custom implementation of our pre-processor, (2) normalizing the tables and related query optimization to improve the batch processing performance and (3) optimizing resource management on the batch processing system. Such iterations enable us to keep pace with some of the large deployments in in Table 1 and keep cost low (e.g., 3 boxes for 5000 VMs).

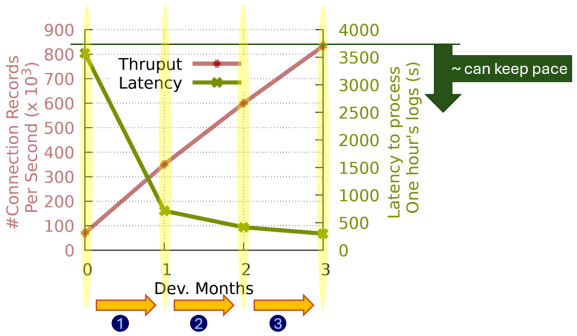

Figure 9: Iterative optimizations applied to our analytics system.

6 Evaluation

We seek to address the following key questions:

- Does the role inference algorithm developed by ZTS demonstrate significantly higher accuracy compared to existing algorithms in real-world applications?
- Does enhanced role inference contribute to the development of improved security policies?
- To what extent can ZTS's graph generator reduce costs compared to existing alternative systems?

6.1 Methodology

Datasets. To evaluate the effectiveness of our role inference algorithm, we curate a dataset comprising network telemetry from 11 real-world deployments within a large public cloud. This includes both first-party and third-party applications of varying sizes, patterns, and requirements. Due to infrastructure differences, the first six deployments utilize telemetry consisting of 5-tuples and flow summaries, while the latter five deployments use telemetry consisting of 5-tuples and process information, and the latter telemetry was also enabled at a larger scale. We conduct developer interviews to ascertain the role of each IP address in each deployment, which becomes the ground truth label in the communication graph. Table 5 summarizes the characteristics of the datasets.

	Telemetry	Graph Size		
		#nodes	#edges	#roles
Deployment A	Flow summary	200	500	14
Deployment B		200	5,000	28
Deployment C		500	9,000	21
Deployment D		200	3,000	28
Deployment E		100	100	12
Deployment F		100	2,000	17
Deployment G	Flow+Process summary	1,500	5,000	30
Deployment H		1,900	17,000	20
Deployment I		12,000	150,000	60
Deployment J		25,000	165,000	84
Deployment K		5,200	90,000	87

Table 5: Real-world deployments used in role inference evaluation: The graph sizes are rounded to preserve workload confidentiality.

Role-inference Baselines. We compare ZTS's role inference algorithm with four baselines that we discussed in §2.1 and §4.3: (1) Jaccard [59], (2) SimRank [56], (3) GAS [49], and (4) CloudCluster [72]. As for clustering algorithms, we use the hierarchical clustering algorithm described in CloudCluster [72] to infer roles for methods that output node embeddings (GAS, CloudCluster, and ours), and we use the Louvain community detection algorithm [37] for methods that output similarity scores (Jaccard and SimRank).

Hyperameters. We use the default hyperparameters from the corresponding papers for the baselines. For our algorithm, we set α in Equation 1 to 20 and τ to 0.05. Our autoencoder is a three-layer neural network with an encoded embedding size that is $\frac{2}{3}$ the size of the input embedding. We train our autoencoder for 1000 epochs with a learning rate of 0.002 and a weight decay of 0.001. To simulate existing asset tags and deployment of owner feedback, we randomly select 10% of the labels as h in our training pipeline. We find that our algorithm performs similarly well across a wide range of values for α, τ, and different autoencoder network architectures.

6.2 Role Inference Performance

Results Summary. Table 6 summarizes the Adjusted Rand Index (ARI) [53] between each role inference algorithm and ground-truth role labels. The ARI measures the quality of clustering and is widely used in role inference literature because it is adjusted for chance. We make three major observations.

First, ZTS's role inference algorithm significantly outperforms all baselines in all but one deployment. The average ARI of our algorithm is 0.77, while the average ARI for Jaccard, SimRank, GAS, and CloudCluster are only 0.33, 0.43, 0.39, and 0.34, respectively. This result demonstrates the effectiveness of ZTS's role inference algorithm in real-world deployments. The only deployment where ZTS does not outperform the best baseline is Deployment C, where our algorithm achieves an ARI of 0.96 compared to the best baseline's ARI of 0.97. This is because the ground truth of Deployment C is partially derived from the Jaccard method, which makes the Jaccard method perform particularly well in this deployment. Despite this, our algorithm still achieves a similar ARI in this deployment.

Second, the performance of state-of-the-art role inference algorithms varies drastically across different deployments. CloudCluster [72] generally performs well for smaller deployments (Deployments A to F) but lags behind other graph mining methods in larger deployments (Deployments G to K). This is partly because the adjacency matrix in larger deployments tends to be more sparse and noisy, and CloudCluster cannot find structural similarities effectively without diving deeper into the graph structures. The performance variation across deployments also underscores the criticality of incorporating domain-specific knowledge and developer insights into role inference processes, as varying deployment environments display distinct traits, and no single static algorithm can universally cater to all cases.

Third, all algorithms tend to perform better at smaller scales (A to F) than at larger scales (G to K). The average ARI of the baseline algorithms decreases from small to large deployments by 0.18, 0.19, 0.20, and 0.64 for Jaccard, SimRank, GAS, and CloudCluster, respectively. ZTS also sees performance degradation from small to large deployments, but at a more moderate 0.14, even with a much better starting point compared to the baselines. These results highlight the necessity of evaluating role-inference algorithms using large-scale deployments to better understand performance in practice. This also means that the performance gap between ZTS and other baseline algorithms increases with the deployment scale.

6.3 Role Inference and Security Policy

To evaluate the correlation between role inference performance and quality of the corresponding security policy, we conduct an assessment of *auto policy generation*. We collect telemetry data from the five larger deployments (Deployments G to K) over one day as the training set. We then infer the roles of each node daily using role inference algorithms. Cluster identities are aligned across different days based on node similarity. Each role is treated as a μsegment, allowing a pair of μsegments to communicate if such communication exists in the training set. We subsequently use telemetry data from the same deployment, four days after the training set, to evaluate the policy violation rate. This rate is defined as the fraction of edges that violate the security policy derived from the training set and the inferred roles. Table 7 summarizes the results.

As Table 7 shows, the security policy generated based on ZTS incurs a significantly lower policy violation rate than the policy generated using other baselines. This is mostly because, while the roles do not change often, the underlying communicating nodes can vary significantly across different days (e.g., talking to a different replica of the same role). If

	Jaccard	SimRank	GAS	CloudCluster	ZTS
Deployment A	0.47 ± 0.00	0.49 ± 0.01	0.50 ± 0.00	0.78 ± 0.00	$\mathbf{0.88 \pm 0.04}$
Deployment B	0.37 ± 0.00	0.33 ± 0.00	0.50 ± 0.09	0.81 ± 0.00	$\mathbf{0.85 \pm 0.03}$
Deployment C	$\mathbf{0.97 \pm 0.00}$	0.93 ± 0.00	0.89 ± 0.00	0.78 ± 0.00	0.96 ± 0.01
Deployment D	0.40 ± 0.00	0.06 ± 0.00	0.16 ± 0.06	0.50 ± 0.00	$\mathbf{0.63 \pm 0.05}$
Deployment E	0.55 ± 0.00	0.60 ± 0.00	0.33 ± 0.14	0.72 ± 0.00	$\mathbf{0.75 \pm 0.02}$
Deployment F	0.32 ± 0.00	0.10 ± 0.00	0.44 ± 0.06	0.73 ± 0.00	$\mathbf{0.90 \pm 0.03}$
Deployment G	0.44 ± 0.00	0.38 ± 0.02	0.41 ± 0.03	0.24 ± 0.00	$\mathbf{0.64 \pm 0.00}$
Deployment H	0.18 ± 0.00	0.14 ± 0.01	0.48 ± 0.01	0.18 ± 0.00	$\mathbf{0.61 \pm 0.03}$
Deployment I	0.41 ± 0.02	0.34 ± 0.01	0.25 ± 0.00	0.06 ± 0.00	$\mathbf{0.70 \pm 0.01}$
Deployment J	0.32 ± 0.00	0.14 ± 0.00	0.10 ± 0.01	-0.01 ± 0.00	$\mathbf{0.85 \pm 0.00}$
Deployment K	0.38 ± 0.00	0.13 ± 0.00	0.11 ± 0.02	-0.09 ± 0.00	$\mathbf{0.65 \pm 0.02}$

Table 6: The Adjusted Rand Index (ARI) between each role inference algorithm and ground-truth role labels. ARI is bounded below -0.5 for highly discordant clusterings and 1.0 for identical clusterings, being close to 0.0 for random labeling regardless of cluster or sample size. We report the mean and standard deviation across 10 runs for each experiment.

	Jaccard	SimRank	GAS	CloudCluster	ZTS
Deployment G	2.1%	11.1%	3.2%	38.4%	0.1%
Deployment H	3.5%	3.8%	2.3%	4.7%	0.2%
Deployment I	6.9%	5.2%	17.3%	6.1%	1.8%
Deployment J	6.5%	9.2%	8%	11.8%	0.7%
Deployment K	7.7%	8.3%	16%	20.7%	2.1%

Table 7: The policy violation rate of auto-generated security policies using role inference results and observed network behavior

the role inference algorithm does not assign the μsegment correctly, these changes will incur many policy violations. Note this evaluation is meant to assess how role inference algorithms can facilitate policy authoring, and the system is not designed to fully automate the process. Hence, a fraction of policy violations in a fully automated setting is expected.

6.4 Cost Effectiveness

To assess the cost of ZTS's graph generation system, we conducted a comparative analysis between our batch processing-based implementation and an alternative solution based on the open-source stream processing system, Apache Flink [38]. Our Flink implementation jointly handles the JSON file preprocessing and graph generation. Our choice of Flink for this alternative solution is based on two considerations. First, Flink is an enterprise-ready system with strong community support, making it a practical choice for our large-scale deployment. Second, we chose Flink over Spark [92], another popular open-source data processing system, because it has demonstrated superior performance in both streaming and batch processing with lower resource consumption [73], which aligns with our experiences with Spark in this context.

Our evaluation involved real-world telemetry data from regional deployments of two first-party services within a prominent public cloud. The details of these regional deployments are summarized in Table 8.

deployment	#nodes	data volume (#recs/hr)
Regional-Portal-Product (D1)	92	1.6M
Regional-K8s Paas (D2)	88	3.9M

Table 8: Characteristics of the regional deployments used in the evaluation of the analytics system. We use regional deployments to preserve workload confidentiality.

COGS. We run ZTS on an infrastructure consisting of a single 8-CPU VM with 32G of memory and 1 compute-unit of the batch processing system that costs in total $845/month. Similarly, Apache Flink runs on a single 64-CPU VM with 256G of memory, and this infrastructure costs in total $2406/month. We choose a larger VM for Apache Flink because its parallelism can benefit from more CPUs and memory so that it can achieve more competitive performance.

Dataset	ZTS	Flink
D1 (1hr)	78	344
D2 (1hr)	109	590
D1 (10hrs)	444	576
D2 (10hrs)	753	1195

Table 9: Processing completion times (in seconds) for the regional deployments. We report both single and multi-hour telemetry processing.

Completion Time. We compare the telemetry processing completion time for both 1-hour and 10-hour datasets across regional deployments. Our system consistently outperforms Apache Flink, as demonstrated in Table 9. Notably, Apache Flink can process a maximum of 5 hours' worth of data concurrently, resulting in its completion time for 10 hours of telemetry being merely double that of 1 hour. Conversely, ZTS delivers superior completion times in all instances while incurring only 35% of the COGS.

Scaling. We also evaluate the scaling behavior of both systems by scaling the telemetry volume by $10\times$ for the regional de-

ployments. We observe that our system outperforms Apache Flink even more significantly in this case, as shown in Table 10. ZTS is 7.5× faster than Apache Flink with only 35% of the COGS, or 21.5× more cost efficient. This is because Apache Flink is not designed to handle such large volumes of data, and its performance degrades significantly as the volume of data increases. In contrast, our system is designed to handle large volumes of data and can scale much better as the volume of data grows.

Dataset	ZTS	Flink
D2 (scaled by 10x)	765	5748

Table 10: Processing completion times (in seconds) for the scaled regional deployment.

It is worth noting that even when utilizing the SQL query optimizations discussed in Section 5.2, the Flink-based streaming system is not as cost-effective as our batch processing system for the scale of telemetry we consider. While Flink and Spark are designed for a wider range of use cases, our results highlight the importance of application-specific design and implementation to achieve significant cost savings, addressing a key obstacle to adopting micro-segmentation systems. We leave the exploration of our batch processing system's applicability to other use cases for future work.

7 Related work

Our key contributions are as follows:

- A novel role inference algorithm for nodes in communication graphs that incorporates domain knowledge and communication patterns.
- A low-cost system that constructs complete and dynamic communication graphs in cloud environments.
- Analysis over communication graphs from many large-scale real deployments.

Here we discuss related work in these areas.

Graph mining and analyses. Existing research on general temporal graph mining [29, 60, 74, 76] largely focuses on social networks, with limited studies addressing challenges in communication networks [57, 83]. Our work tackles novel issues specific to the networking context by analyzing network structures, communication patterns, and incorporating domain-specific knowledge to enhance the inference and application of security policies.

Network telemetry. Many systems analyze passively collected network-wide telemetry [42, 62, 65, 79], but have not achieved widespread deployment or consistent net positive revenue. Highly accurate and scalable sketching algorithms offer estimated answers to network telemetry queries [36, 67, 82, 91, 94], yet they lack generality, addressing only specific query types. Systems like PingMesh [48] and MALT [70] offer insights into network performance and topology but do not measure actual communication flow along data paths. Additionally, most research focuses on packet traces from a few collection points [32, 44, 54, 61, 69, 81], leaving the scalability and generalizability of these techniques to provide network-wide summaries uncertain.

Role inference in graphs and networks. Node embeddings have been utilized to encapsulate structural similarities within graphs [58]. These structural embeddings can subsequently be aggregated through clustering to facilitate role discovery or inference. The majority of existing methods adhere to a two-step procedure, initially discerning structural attributes associated with each node and subsequently transposing these attributes into an embedding space using various techniques [58]. These techniques encompass low-rank matrix factorization [50, 51], random walk-inspired methods [27, 77], and approaches based on (graph) neural networks [49, 85]. Within the domain of networking, the closest work CloudCluster [72], is also based on structural similarities. Section 4 and Section 6.2 discuss the shortcomings of these approaches and evaluate these predominant approaches. In contrast to these methods, our approach allows for the flexible integration of domain-specific knowledge through meticulously crafted node features coupled with a contrastive loss function. Furthermore, it is worth noting that should any existing structural embeddings be deemed more appropriate, our algorithm is designed to integrate them seamlessly into our processing pipeline.

Other studies have leveraged network traffic to infer attributes of certain segments within the communication graph. For instance, Xu et al. [90] classify internet hosts according to traffic similarities, utilizing this classification to identify malicious activities. In the realm of cloud services, patterns of network traffic have been instrumental in pinpointing network nodes or flows that may be compromised [31, 46, 52], as well as selecting suitable candidates for migration [40].

8 Conclusion

In this work, we show that realizing the vision of micro-segmentation at a large scale remains a difficult challenge. We present an end-to-end system that consists of an effective role inference algorithm for network communication graphs and a unique system implementation that drastically reduces the cost of generating communication graphs for network behavior understanding and monitoring. Using 11 large-scale real deployments, we demonstrate the system's capability to more accurately infer roles and generate communication graphs with minimal expense. We hope the findings and insights from our work will stimulate further research to ease the burden of securing public clouds with micro-segmentation.

Abstract

As a state-of-the-art technique, RDMA-offloaded container networks (RCNs) can provide high-performance data communications among containers. Nevertheless, this seems to be subject to the RCN scale—when there are millions of containers simultaneously running in a data center, the performance decreases sharply and unexpectedly. In particular, we observe that most performance issues are related to RDMA NICs (RNICs), whose design and implementation defects might constitute the "scalability wall" of the RCN. To validate the conjecture, however, we are challenged by the limited visibility into the internals of today's RNICs. To address the dilemma, a more pragmatic approach is to *infer* the most likely causes of the performance issues according to the common abstractions of an RNIC's components and functionalities.

Specifically, we conduct *combinatorial causal testing* to efficiently reason about an RNIC's architecture model, effectively approximate its performance model, and thereby proactively optimize the NF (network function) offloading schedule. We embody the design into a practical system dubbed ScalaCN. Evaluation on production workloads shows that the end-to-end network bandwidth increases by 1.4× and the packet forwarding latency decreases by 31%, after resolving 82% of the causes inferred by ScalaCN. We report the performance issues of RNICs and the most likely causes to relevant vendors, all of which have been encouragingly confirmed; we are now closely working with the vendors to fix them.

1 Introduction

Containers have become a pivotal technology in cloud computing and serverless computing [34, 35, 56, 70], which allow developers and service operators to deploy applications or functions onto the cloud rapidly and conveniently. Different from a heavyweight and full-fledged virtual machine, a container is merely a lightweight and standalone software bundle that includes all the code and dependencies needed by a specific application [30, 43]. The portability, lightweight, and isolation characteristics make containers an ideal choice for running a variety of tasks in the cloud, such as training foundation models [27, 31, 64] and building microservices [51, 53].

Container networks enable containers to communicate with each other seamlessly based on their hosts. To achieve high-performance data communications, almost all of today's container service providers (CSPs) utilize RDMA NICs (RNICs) to offload data traffic and network functions (NFs) from the host OS to dedicated hardware (RNICs) [35, 57]. The resulting RDMA-offloaded container network (RCN) is reported to have at least three times of performance gain compared to the traditional network stack inside the host OS [35, 39, 40], paving an efficient and generic network runtime for cloud applications and stateful/statelss functions.

Nevertheless, as a mainstream CSP, we observe that the performance gain of the RCN seems to be subject to its scale. During our two-year (03/2021 – 03/2023) operations on a production RCN (which involves ∼8K hosts equipped with ∼40K RNICs, serving 0.5M active containers simultaneously on average and ∼1M containers at peak hours), we notice that the end-to-end performance in terms of bandwidth and latency often decreases sharply and unexpectedly. For instance, when the number of active containers grows from 0.4M to 0.8M, the end-to-end bandwidth can decrease by 87%, and the packet forwarding latency can increase by 34×. In other words, there are "scalability walls" in the production RCN, which is rarely understood as existing studies mostly examine the RCN in small-scale and controlled settings [35, 58].

From Phenomena to Symptoms. To deeper understand the problem, we built a continuous monitoring infrastructure on top of our production RCN. It gathers cross-layer runtime data on each host, such as container resource consumptions, virtual switch flow tables, kernel logs, and RNIC statistics, during our monitoring period from 04/15/2023 to 04/15/2024.

The collected data reveal that the scalability wall of the RCN mainly (94%) manifests eight symptoms as listed in Table 1. They occur when an RNIC's aggregated throughput or latency is not at the expected level as in their official specifications (referred to as a *performance issue*). These symptoms come from different RCN layers such as the virtual switch (i.e., Open vSwitch), the kernel driver, and hardware, but are surprisingly all related to RNICs. In total, they have caused 13,396 performance issues during our monitoring period.

- Symptom S1 manifests on the virtual switch when there are 7K+ container flows running over an RNIC. The victim flows repetitively fall back to software processing, thus incurring significant performance degradation (>18×).
- The interactions between the RNIC's driver and hardware can cause kernel stagnation (S2) or crash (S3), especially when the driver creates or deletes flows, thus blocking the execution of all containers on the victim host.
- The remaining five symptoms occur at the layer of RNIC

Table 1: RNIC-related symptoms of the "scalability wall" in our production RCN, as well as their most likely causes.

No.	Symptom	Layer	Ratio	Most Likely Cause (C1 – C8)
S1	Repetitive flow re-offloading	Virtual Switch	17.1%	Flow entries in the RNIC are deleted although they are not aged.
S2	Kernel stagnation	RNIC driver	5.9%	The driver cannot handle the timeout of the RNIC's executing an operation.
S3	Kernel crash on new flows	RNIC driver	5.2%	The driver frees a null pointer when the RNIC fails to create a flow entry.
S4	Slow flow state maintenance	RNIC hardware	11.4%	Flow deletion in the RNIC takes much longer (9×) time than expected.
S5	Intermittent software forwarding	RNIC hardware	15.3%	Flow counters are not updated timely. The virtual switch reads a "dirty" value.
S6	Poor performance of specific flows	RNIC hardware	29.9%	Flow entries with different masks are queried sequentially in the RNIC.
S7	PCIe link down when unbinding VFs	RNIC hardware	8.4%	Race condition emerges when the RNIC cleans up allocated resources.
S8	RNIC unresponsiveness	RNIC hardware	6.8%	VXLAN encapsulation contexts exceed the RNIC's buffer capacity.

hardware. For example (S6), a specific flow's performance can be persistently poor when ∼10K flows are offloaded to the RNIC hardware (we did not discover any anomalies in the software stack). Even if the workload drops off greatly (e.g., from ∼10K to 600 flows) afterwards, the performance cannot recover in a short time.

From Symptoms to Causes. Given the various symptoms, we wish to figure out their root causes, so that we can take measures to proactively optimize the performance or at least prevent further degradation. Unfortunately, we encounter a key challenge that we have very limited visibility into the internals of today's commodity RNICs [32, 36]. The internal design of RNICs is mostly close-sourced and hardly mentioned in their specifications. Resorting to the vendors also turns out to be ineffective in most cases, since they have neither encountered nor understood such "elusive" symptoms. After all, these symptoms are only manifested in large-scale deployments that involve extremely complicated workloads/environments and push the RNIC's capability to its limit, which are not easy for the vendors to reproduce and analyze. Furthermore, we are not allowed to share real-world workloads with the vendors, making their troubleshooting difficult, if not impossible.

To address this, a more pragmatic approach is to *infer* the most likely causes according to common abstractions of an RNIC's components and functionalities. An RNIC on a host provides RDMA verb functionalities (e.g., `read` and `write`) to each hosted container, which allow the container to operate on the resources in the RNIC's conceptual components (e.g., send/receive queues). Besides, today's RNICs in data centers all implement *match-action* based embedded switch (or *eSwitch* for short) components to support hardware-accelerated packet switching [38, 41, 55], which are widely used for efficient container network virtualization. Our approach fundamentally differs from the existing blackbox testing techniques [67] or whitebox analyses [54], as it leverages the domain knowledge of RNICs' common architecture to construct a highly likely RNIC model for actual testing and optimization, and thus is more of a "greybox" approach.

With the common abstractions of an RNIC, however, we are still confronted with a prohibitively enormous search space, stemming from the components' possible combinations and the functionalities' possible configurations. For example, highly configurable eSwitch tables can have $O(k^n)$ possible matchers, where n is the number of tables and k is the average number of table entries. We conduct *combinatorial causal testing* to overcome the difficulty in a principled way. First, we leverage topological restrictions across components to efficiently construct valid component combinations (i.e., the architecture model of the RNIC). This is achieved by inspecting components' dependencies to filter out the combinations that lead to packet loops or unreachability, which reduces the magnitude of combinations to a quadratic polynomial level.

We then test the RNIC's functionalities with real and synthetic workloads on each valid architecture model. Once a symptom occurs, we perform a *local sensitivity analysis* [19] to deduce the causal relations between the RNIC's input (workload) and manifested performance. Specifically, we strategically tune the value of each dimension (e.g., the number of table entries) in the workload to test whether the symptom can be eliminated or alleviated. If so, the component(s) related to this dimension are a likely cause of the symptom, which might lie in a critical path of the RNIC's packet processing pipeline. Next, we fine-check each concerned component in the critical path by means of *permutation removal* [15], which eliminates the component whose removal would not influence the performance. In this way, we sort out the critical path(s), pinpoint the most likely causes, and effectively approximate the RNIC's performance model for a valid architecture model. Eventually, we choose the architecture model that best matches the actual performance as the final reference.

Optimization, Evaluation, and Validation. Based on the above efforts, we are able to proactively optimize the NF offloading schedule for every RNIC, by reorganizing the offloaded flows to minimize the estimated processing time over the critical path for each flow. Also, we avoid triggering the inferred design/implementation defects of the RNIC by transforming the risky functionality inputs to their equivalents that are unlikely or less likely to cause performance issues.

We implement the whole design into a practical system dubbed ScalaCN, and conduct extensive experiments based on real-world production workloads with six different kinds of RNIC devices (NVIDIA ConnectX-4, -5, -6, -7, BlueField-3, and Intel E810). On average, ScalaCN improves the end-to-end bandwidth by 1.4× and reduces the latency by 31%, after resolving 82% of the inferred causes of performance issues (the remaining 18% are due to hardware limits). Its major overhead comes from continuous monitoring and optimiza-

tion operations, with <5% usage on a single CPU core.

We have reported all performance issues and their most likely causes to relevant vendors, all of which have been encouragingly confirmed. In detail, the vendors have released patches on the driver and firmware to fix the root causes C1, C2, C3, and C5. For the remainder (C4, C6, C7, and C8), we are now closely collaborating with the vendors to fix them as they involve the intricate co-tuning of software and hardware.

Contribution. This work makes the following contributions.

- We conduct the first study to uncover the scalability wall in a large-scale RCN, and pinpoint the culprit to be RNICs.
- We conduct combinatorial causal testing based on RNICs' common abstractions, to efficiently approximate their internals and infer the root causes of performance issues.
- We devise an effective method to accommodate RNICs to RCN scaling. Evaluation on real-world workloads and the feedback from vendors confirm its efficacy. We are now gradually deploying ScalaCN over the production RCN.

The code and data involved in this work have been released in part at https://scala-cn.github.io.

2 Background

Container networks enable transparent data communications among containers, and they are currently realized in three major approaches [35, 70] as listed in Table 2. Different approaches provide different levels of connectivity among containers and different levels of isolation with the host network. Today's mainstream container services widely adopt the overlay (or overlay-like) mode to organize container networks [2, 4, 7, 13, 26], since this mode enables accessibility across hosts while preserving isolation.

Figure 1 shows the typical architecture of an overlay-based container network. Two hosts (A and B) are connected via physical switches/routers in the underlay network. Each overlay container on a host has its own IP address within the same VXLAN [42] subnet. For example, a container on Host A has the IP address 172.16.122.1 within the VXLAN subnet 172.16.122.0/24. When two containers communicate with each other, the software virtual switch on the host OS will determine to which port the packet should be forwarded, and perform VXLAN encapsulation for packets (if needed). For container communications across hosts, the encapsulated packets will go through the hardware NIC and the underlay network.

Hardware Offloading with RDMA NICs. In practice, manipulating and forwarding container packets with software switches is resource-consuming. This is because container applications (e.g., large model training) often generate a large volume of network traffic which is processed by the kernel [3, 6] and the user-space software switch, incurring significant CPU overhead and processing latency [22, 39].

To alleviate the packet processing overhead on the host OS, today's mainstream container service providers (CSPs) take

Table 2: Different modes of container networking, where "isolation" refers to *network* isolation from the host OS.

Mode	Mechanism	Connectivity	Isolation
Bridge	Virtual bridge	Host only	In-bridge
Host	Namespace sharing	Cross-host	No isolation
Overlay	VXLAN	Cross-host	In-overlay

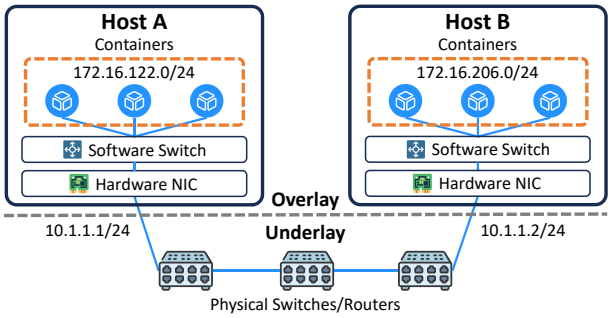

Figure 1: Example of overlay-based container networks.

advantage of the hardware offloading functionality [38, 47] with the single-root IO virtualization (SR-IOV) technique of RDMA NICs (RNICs) [28, 63]. This brings two significant performance benefits. First, all the containers can communicate with each other through the RDMA protocol, without needing the intervention of the OS. Second, the CPU-intensive tasks such as packet forwarding and VXLAN encapsulation also bypass the software stack, i.e., they are all moved from CPUs to RNICs for more efficient processing.

The resulting RDMA-offloaded container network (RCN) significantly improves the network performance. A representative example is illustrated in Figure 2. When the traffic is delivered using TCP, the average end-to-end bandwidth is 21.17 Gbps and the average packet forwarding latency is 87.31 us. When VXLAN encapsulation and packet switching are offloaded to an NVIDIA ConnectX-6 RNIC, the bandwidth grows to 50.31 Gbps, and the latency drops to 54.51 us. If we further use the RDMA protocol to transmit packets, the bandwidth remarkably increases to ∼180 Gbps and the latency decreases to merely 2.7 us.

3 Motivation

Despite the merits of RNIC offloading, an RCN's performance seems to be subject to its scale—during our one-year operations, we noticed that once the network workload hits a "scalability wall", a variety of performance issues occurred and severely hurt the QoS (Quality of Service).

3.1 Continuous Monitoring Infrastructure

To deeply understand the scalability wall, we built a continuous monitoring infrastructure on top of our large-scale production RCN, which carries ∼1,500 PB of traffic for ∼0.5 million containers every day during our monitoring period (from Apr. 15th, 2023 to Apr. 15th, 2024).

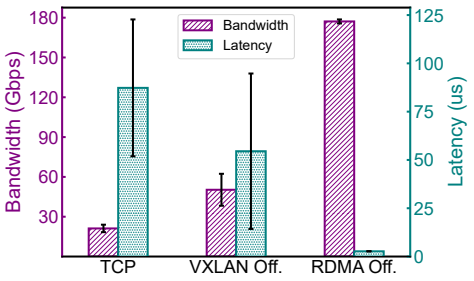

Figure 2: Performance comparison with and without hardware offloading (Off.) in a container network.

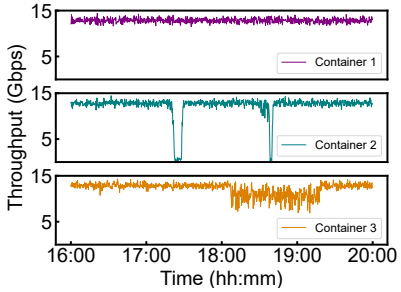

Figure 3: Performance issues caused by S1, where the virtual switch repetitively re-offload flows.

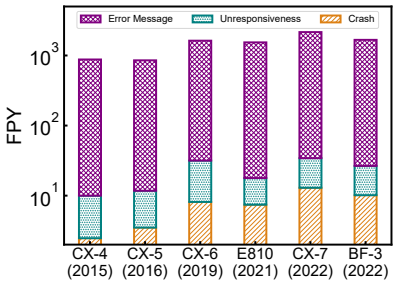

Figure 4: Kernel instability in terms of failures per year (FPYs). Here the RNICs are sorted by release date.

All containers in our RCN are Docker [9] containers. We use Kubernetes [10] to orchestrate Docker containers together with the container network interface (CNI) [8] plugin that we developed in-house. Each host in our RCN is equipped with one to eight RNICs, which are NVIDIA ConnectX-4 (CX-4), ConnectX-5 (CX-5), ConnectX-6 (CX-6), ConnectX-7 (CX-7), BlueField-3 (BF-3), or Intel E810 (E810). We balance the load of these RNICs when binding them to containers. We deploy Open vSwitch (OVS) [46] on each host as the software virtual switch to handle packet forwarding. When containers initiate a flow, the OVS will use the `TC` [5] utility to offload packet processing tasks to the RNIC.

Our continuous monitoring infrastructure gathers basic performance data across different layers on each host as follows, so that we can be aware of the RCN status in time. These data are transformed into concrete states of network components, and indexed in our log services for aggregation and analysis.

- *RNIC and Kernel Statistics.* We collect packet sending and receiving rates as well as packet drops of the RNIC through Linux `sysfs`. We also collect logical flow entries recorded by the kernel using `netfilter` and `conntrack` to track the states of all RDMA connections.
- *OVS Offloading Status.* The OVS determines what packet manipulations should be applied to an RCN flow and whether it needs to be offloaded to the RNIC. To monitor these events, we gather OVS information including table hits, misses, and losses of flow lookups [46].
- *CNI Events.* We collect crucial events on resource allocations triggered by the CNI plugin. We monitor the creation of containers, as well as the allocations of VXLAN subnets, IP addresses, and VFs (virtual functions that containers are one-to-one bound to) of RNICs.

3.2 Symptoms of Performance Issues

Our collected data reveal 14,251 performance issues regarding the scalability wall of the production RCN during our monitoring period. The eight major symptoms are listed in Table 1, accounting for 94% of the performance issues. Although these symptoms come from different layers of the RCN, such as the virtual switch, the kernel driver, and the hardware, they are all related to the RNICs which were supposed to bring high-performance data communications among containers.

Virtual Switch. When the number of flows offloaded to an RNIC increases to a threshold, e.g., 7K+ over a CX-6 RNIC, the virtual switch would repetitively re-offload the flows (Symptom S1). This accounts for 17.1% of RNIC-related performance issues. When this occurs, the end-to-end performance on the affected containers greatly fluctuates.

Figure 3 shows our production traces regarding S1. The three containers are used for training the same AI model with the same configurations (e.g., QoS and VF quotas). The throughput of Container 1 keeps stable at around 15 Gbps, which is the expected performance. However, Container 2 and Container 3 both suffer from performance degradation and present two different patterns of performance issues. The throughput of Container 2 periodically drops to $<$1 Gbps (which is nearly 18$\times$ worse) and then recovers to $\sim$15 Gbps. The throughput of Container 3 becomes unstable, sometimes fluctuating between 5 Gbps and 10 Gbps for an hour. These issues significantly affect the training process of AI models and oftentimes lead to users' complaints.

By analyzing the logs of the OVS, we find that the OVS repetitively re-offloads the flows for Containers 2 and 3 due to constant lookup misses in the RNIC's flow tables, as if the RNIC is "refusing" to handle them under the high workload.

RNIC Driver. We also find that in our production RCN, the RNIC's driver often makes the kernel unstable when it interacts with the RNIC's hardware, which manifests as S2 and S3 in Table 1. When handling a large number of flows offloaded in a short time (e.g., 1K per second), the kernel can become stagnated (S2) after the driver sends certain operation codes to the RNIC. Through detailed timing on the driver's call stack in the kernel, we observe that the driver seems to be always waiting for the RNIC's response, which however cannot be received in time under the high workload. Worse still, the kernel can even crash (S3) when the driver fails to offload the flows to the RNIC. Even though these symptoms occur less frequently (11.1% in total) than the symptom oc-

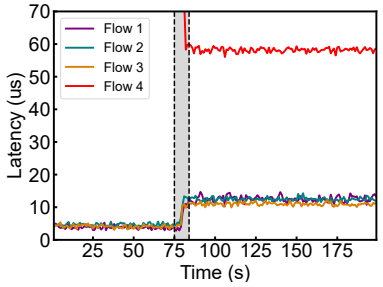

Figure 5: Latency increases when a specific flow (Flow 4) is offloaded.

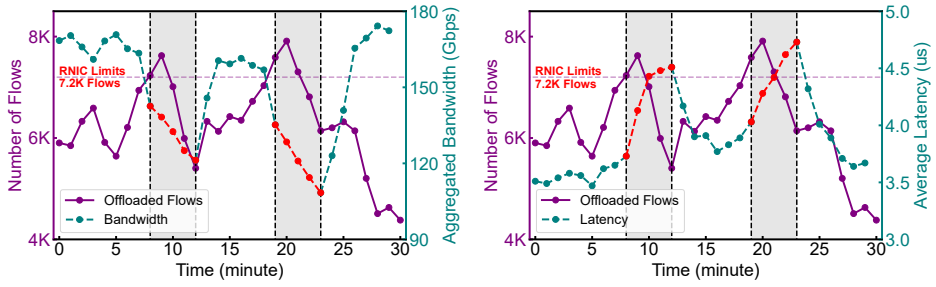

(a) Aggregated bandwidth.

(b) Average packet forwarding latency.

Figure 6: Workload impacts on the RDMA `write` performance of the CX-6 RNIC.

curring at the virtual switch layer, they are more severe since they make all the containers over the host unavailable.

Figure 4 shows the kernel's failures per year (FPY) with regard to different (models of) RNICs in production. RNICs released recently (e.g., E810, CX-7, and BF-3) bring much more FPYs than those released eight years ago (e.g., CX-4 and CX-5) – note that the Y-axis uses a log scale. The reasons are mainly two folds: 1) newer RNICs have more data to be synchronized, and 2) newer RNICs' kernel drivers are more complex but not time-tested enough. In fact, undesired symptoms regarding the RNIC's driver have not been discovered by the vendors as they did not (and have no means to) test the driver and RNICs under a large-scale production RCN.

RNIC Hardware. The majority (71.8%) of RNIC-related performance issues occur at the hardware layer, which are mainly due to the RNIC's internal defects as we did not find any anomalies in the software stack (i.e., the virtual switch and the driver) when these issues occur. Their root causes are much harder to locate and identify, since today's commodity RNICs are usually a black box to their users.

When network flows are offloaded to an RNIC, the software stack needs to maintain the flow states (e.g., to invalidate the flows when they are aged). During this process, we find that state synchronizations from the control plane to the RNIC's hardware can become extremely slow, making the software unable to offload new flows in time and therefore causing performance degradation (S4). Further, even if the control plane has offloaded the flows to the RNIC, these flows can intermittently go into the software stack for being processed, indicating that the RNIC is not functioning properly (S5).

Moreover, when the workload on the RNIC reaches a certain threshold, the performance of specific flows can become extremely poor, which would in turn affect the performance of other flows (S6). As shown in Figure 5, before the offloading of Flow 4, Flows 1–3 all have a desired latency of ∼4 us on the CX-7 RNIC. When the new Flow 4 is offloaded at around 75s, it does not reach the desired packet forwarding latency of ∼4 us but instead bears a high latency of ∼60 us. Meanwhile, the latencies of Flows 1–3 also increase by 3×.

Another example of S6 is shown in Figure 6. It depicts the performance of the RDMA `write` verb of the CX-6 RNIC with different levels of workloads on it. When there are fewer than 7,200 flows offloaded to the RNIC, the performance is in general negatively correlated with the workload. In contrast, when over 7,200 flows are offloaded, as shown in the shadowed areas of Figure 6a and Figure 6b, the RNIC's aggregated bandwidth instantly drops by 13%–37% and the average latency increases by 27%–34%. Even when the workload drops off to a very low level (e.g., only 600 flows), the performance of the RNIC can hardly recover in quite a while (e.g., 6 minutes) but continues to degrade (cf. §4.2).

For the last two symptoms at the hardware layer (S7 and S8 in Table 1), they are more severe than S5 and S6 since they can make all the containers over the host unavailable. For example, when we de-allocate the VFs of an RNIC from the containers, we observe that the PCIe link state sometimes goes down. Also, when we offload too many VXLAN encapsulations to the RNIC (e.g., 10K on the BF-3 RNIC), the RNIC can become unresponsive and unable to handle any flows. Since our RCN supports multi-tenancy, the number of flows can easily reach 10K+ on a single RNIC, which makes this issue very common in production.

3.3 Challenges

According to the long-term monitoring experiences, we notice quite a few performance issues regarding the scalability of the RNICs in production, where RNICs present undesired performance compared with their official specifications. Thus, CSPs desire an effective approach to understanding the practical limitations of RNICs to prevent performance issues in large-scale deployments. Unfortunately, we have very limited visibility into today's RNICs as their internal design and implementations are usually non-public. Although some of the existing studies have conducted comprehensive tests on commodity RNICs [32, 36, 37, 67], they can only discover performance issues but can hardly tell the root causes and the solutions. Besides, it is rather difficult for RNIC vendors to reproduce and understand such "elusive" symptoms happening in large-scale data centers that involve extremely complicated workloads and environments. In addition, we are not allowed to share real-world workloads with the vendors, making their troubleshooting very difficult.

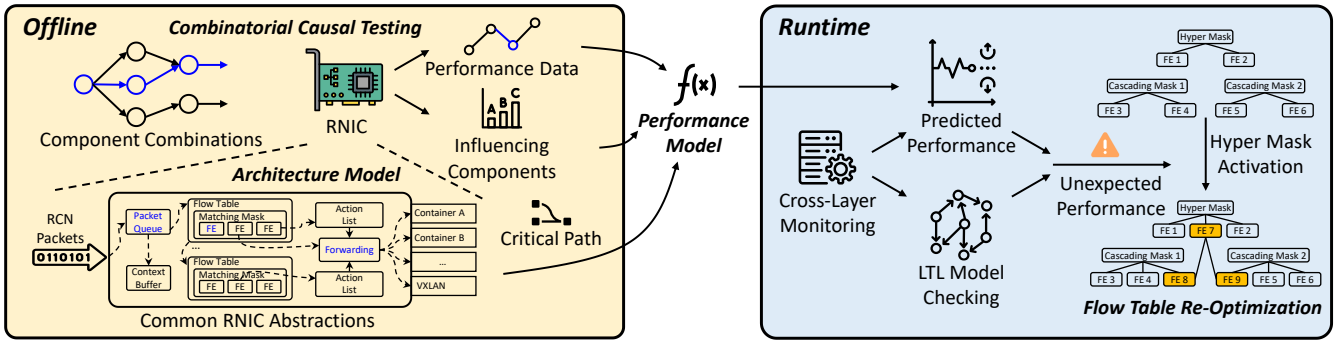

Figure 7: Architectural overview of ScalaCN, a scalable RCN based on the efficient approach of combinatorial causal testing. The blue color of the entities in the offline phase represents their causal relations as a typical example.

4 Design and Implementation

We present ScalaCN, an effective and efficient system for understanding and optimizing RNIC performance in a large-scale RCN through a greybox-like approach. Our key insight obtained from §3 is that the widely existing performance issues on the RNIC's scalability originate from the design and implementation defects of RNICs, which highlights the importance of dissecting the RNICs' internals when these issues occur. Due to the usually non-public implementations of the RNICs, we strive for a more pragmatic approach by *inferring* the most likely causes of the issues according to the common abstractions of an RNIC's components and functionalities.

Figure 7 shows the architecture of ScalaCN, which consists of the offline phase where the combinatorial causal testing is conducted on the RNIC, as well as the runtime phase for RNIC performance prediction and optimization.

- *Combinatorial Causal Testing* (§4.1). In the offline phase, our goal is to reason about the architecture model and approximate the performance model of RNICs based on their common abstractions. However, we are confronted with a prohibitively enormous search space of an RNIC's possible component and functionality combinations. To address this, we first use the topological restrictions among the components to filter out invalid combinations. This significantly reduces the complexity of building architecture models for an RNIC. With respect to each valid architecture model, we further approximate the RNIC's performance model by inferring probable critical paths of the RNIC's packet processing through local sensitivity analysis [19] and permutation removal [15]. Eventually, the most likely performance model becomes our final choice.
- *Performance Interpretation and Prediction* (§4.2). Based on the approximated RNIC's performance model, ScalaCN collects the runtime data of the RNICs and makes the actual predictions on the performance. In this way, ScalaCN prepares to proactively schedule the offloaded network functions. The guidance of the performance model inferred by the combinatorial causal testing enables us to achieve a high prediction accuracy of 98%. We further repair the 2% false predictions by temporal-logic model checking [18, 49].
- *On-Demand Performance Optimization* (§4.3). We do not need the RNIC to always work in its perfect status, but once it is anticipated to undergo a noticeable (empirically set as 5%) performance degradation, we optimize the network function offloading by reorganizing its flow rules to minimize the possible critical path of packet processing in the RNIC hardware. This is achieved by reordering flows with a strong locality into the headmost matching masks in the flow tables that have the lowest delay.

4.1 Combinatorial Causal Testing

Common Abstractions of RNIC Components. As we have mentioned in §2, an RNIC in a production RCN accelerates data communications among containers mainly from two aspects, i.e., RDMA support and packet switching offloading. Specifically, an RNIC provides RDMA verbs (such as the `send`/`receive` and `read`/`write` primitives) to enable each hosted container to use the RDMA protocol to transmit packets without the need for the intervention of the OS. This is typically achieved with the SR-IOV technique [28, 63], where the RNIC is virtualized into multiple virtual functions (VFs) and each VF can be bound to a container.

Besides, an RNIC accelerates the packet switching tasks involved in the RCN. Recall that in Figure 1, an RCN host must be equipped with a virtual switch to decide to which containers a packet should be forwarded (i.e., the switching rules). Also, the virtual switch needs to encapsulate the packet with the VXLAN header (i.e., the applied action) to ensure the packet can cross the underlay network if necessary. These tasks could incur significant overhead if they are all processed in the software stack. Thus, they are offloaded to the RNIC's hardware in the RCN through `TC` or `DPDK` utilities [48].

In other words, the RNIC acts as a programmable switch with RDMA supports to forward packets among the overlay and the underlay. In fact, today's RNICs in data centers all implement *match-action* based embedded switch (or *eSwitch*

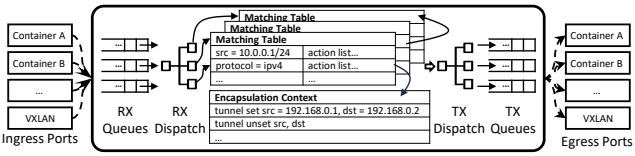

Figure 8: An RNIC's common (abstracted) components in the RCN. The packets come from containers or VXLAN, which are processed by the RNIC and sent to destination ports.

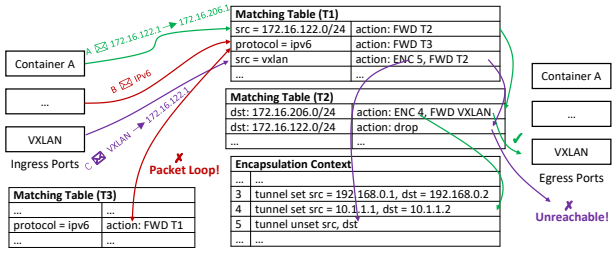

Figure 9: Examples of topological restrictions on the combinations of components.

for short) components to support hardware-accelerated packet switching [38, 41, 55]. This has become the de-facto standard industrial practice and conforms with the kernel's *switchdev* model [1] for handling the data plane in the hardware while keeping the control plane unmodified [12].

Given the above functionalities, we abstract the RNIC's components as shown in Figure 8. Note that we only focus on the *data path* of the RNIC (i.e., the pipeline that processes the packets) since it is the most related to the packet processing performance. Specifically, each container binds to one or more VFs of the RNIC, with which the container can use the RDMA verbs to request the RNIC resources (e.g., queue pairs) and transmit packets through high-performance RDMA protocols. When a packet from the container is received by the RNIC through the VF, it will be enqueued into the container's requested queue pairs and then dispatched to the RNIC's eSwitch component. The eSwitch component is composed of a number of flow tables to match the packets and then apply the recorded actions on them. These tables are offloaded from the control plane in the software stack.

Search Space on Component Combinations. After abstracting the RNIC's components, we aim to infer the likely architecture models of the RNIC. In particular, we need to search for the combinations of components/configurations that are valid inside the RNIC under the environment of our production RCN. If we have such information, we can further reason about the more detailed performance impacts of the RNIC's (abstracted) components and configurations.

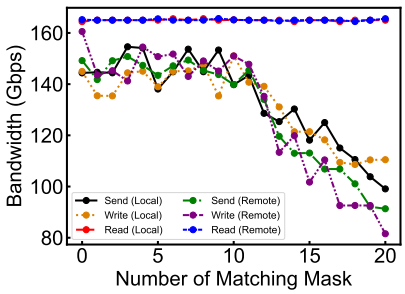
Unfortunately, we are faced with a combinatorial explosion of the possible combinations of the RNIC's components. Today's RNICs are highly programmable and can be offloaded with a large number of combinations of flow tables and RDMA flows. Even for a single flow table offloading, the RNIC can have hundreds of flow entries, each of which can have multiple matching rules and actions. For example, the matcher of a flow entry for NVIDIA CX series RNICs is at least 192 bits long [12], which can cover different protocols, sources, and destinations, from the MAC layer to the transport layer. Each bit of the matching mask is individually configurable. Further, flow tables can be chained together through the forwarding action in each entry of the table for a more flexible packet processing pipeline in the data path, resulting in a more complex structure of the RNIC's components and their interactions during the RCN packet processing.

When putting all possible combinations together, the search space of the combinations is prohibitively large, i.e., $O(k^n)$ possible matchers, where n is the number of tables and k is the average number of table entries. Note that in a production RCN, the actual value of n and k can all be as large as 100.

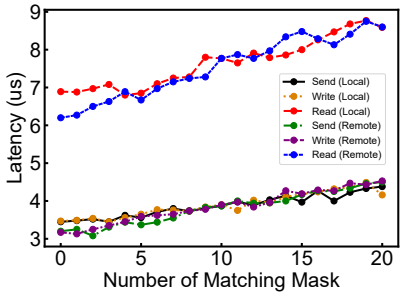
Efficient Searching with Topological Restrictions. In order to reduce the probable combinations of the abstracted RNIC's components and their configurations, we leverage the *topological restrictions* among the components to filter out invalid combinations. Our key idea is that the RNIC's components and configurations are not independent but have strong dependencies and restrictions among them. These restrictions are brought by the network topology and packet reachability.

As shown in the examples of Figure 9, not all the combinations of rules in the table can correctly deliver the packets to the desired destinations. The only valid combination in the figure is the entries of flow tables that packet A goes through. These flow rule configurations enable the RNIC to deliver the packet from container A to the VXLAN interface (i.e., the underlay network). In contrast, the table entries related to Packets B and C violate the topological restrictions. For Packet B, the example combination on flow entries leads to packet loops between flow tables T1 and T3. This is because the IPv6 packets will be forwarded to flow table T3 when they are matched by flow table T2, while T3 will then forward the packet back to T2. Thus, such a combination of flow table entries is not valid in practice. Similarly, Packet C will be forwarded to an unreachable destination, and as a result the corresponding combinations are also invalid. Eventually, we can simply test the eSwitch and queue pair combinations that enable correct end-to-end packet delivery among the containers (i.e., the architecture models of the RNICs), thus reducing the magnitude of component combinations and configurations to $O(k \cdot n^2)$, where k is the number of subnets and n is the average number containers in each subnet.

After pinpointing the valid architecture models in our production RCN for the RNIC, ScalaCN generates test traffic to search for relevant symptoms as we have encountered in Table 1 on each architecture model. To this end, ScalaCN starts to test the flow table combinations from a simple case, i.e., only one flow table. Then, it continuously adds new flow entries to the table with different matching masks, IPs, ports,



(a) Aggregated bandwidth.



(b) Packet forwarding latency.

Figure 10: Sensitivity analysis on the number of matching masks for CX-6.

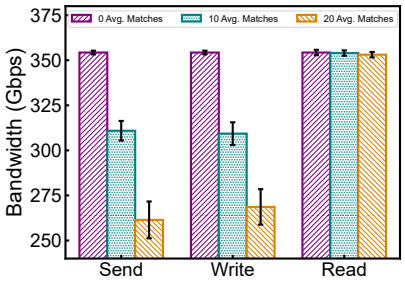


Figure 11: Impacts of the avg. flow table queries of concurrent in-flight packets.

protocols that are reachable in our production RCN, so as to test the RNIC's performance. It also adds forwarding actions to the packet processing rules to connect two flow tables. These rules are installed to the RNIC through the `TC` [5] utility. All these manipulations are conducted with a guarantee that the packets can be correctly delivered. Since we have already filtered out the invalid combinations of the RNIC's components, such testing can be done efficiently and effectively.

Causal Inference. Once the above searching process finds the symptoms (i.e., the performance issues) to occur, ScalaCN conducts a *local sensitivity analysis* to pinpoint the causal relations between the components and the performance issues. ScalaCN incrementally changes each dimension of the input configurations and tests the performance fluctuations. These dimensions come from the test configurations as we mentioned above. During this process, ScalaCN uses the spring-based control model [66] for congestion avoidance to achieve efficient bandwidth testing. If the performance issues can be alleviated or exacerbated after changing the configurations (e.g., increasing or reducing flow tables), we can infer that the corresponding components related to this dimension are likely to lie in the critical path of the RNIC's packet processing.

Here we show an example of the use of local sensitivity analysis to find the possible components that are located in the critical path of the RNIC's packet processing. At first, the searching process of ScalaCN finds that the CX-6 RNIC's performance degrades for certain flows when the number of flow tables increases, whose symptom is similar to S6 in Table 1. However, it is not easy to infer which configurations are likely to be the root cause of the performance issue.

ScalaCN then incrementally changes each testing dimension and examines the resulting performance. Figure 10 shows the performance of CX-6 when a single dimension (i.e., the number of matching masks in offloaded flow tables) of the workload is changed. ScalaCN quickly finds that the RDMA `write` and `send` bandwidth of the CX-6 RNIC is significantly affected by the number of the matching masks in the flow tables, while the `read` verb is hardly affected.

Specifically, the match-action table in RNICs matches packets based on the packet patterns and determines how to process the packet. The offloaded table entries consist of two parts, i.e., the matching mask[1] and (multiple) matching values. The mask indicates which fields of the packets should be matched, while the values specify the content that the packet fields should be if matched. Flow entries with the same mask are grouped and queried together. When the number of masks offloaded to the RNIC increases, ScalaCN finds new flows matched by the newly offloaded masks (i.e., the mask has not been offloaded before) will have a lower performance in the packet processing. Thus, we can infer that the matching masks in the flow tables are likely to lie in the critical path in the RNIC's packet processing. Nevertheless, till now we are still not able to pinpoint the exact components or configurations that really form the critical path in the RNIC.

In order to refine the probable components in the inferred critical path of the RNIC, ScalaCN further performs *permutation removal*. The key idea of this step is to eliminate the components lying in the possible critical path whose removal does not affect the performance of the RNIC. It first sets up a hypothesis H_0 that assumes a specific dimension d is significant to the performance. Then, it permutates the concrete values of the other dimensions, and records the corresponding RNIC's performance. If the probability of the performance degradation is $>95\%$ compared with the tests when d is not set to the current value, we determine that the dimension d is significant (i.e., accept the hypothesis H_0), otherwise we remove the dimension d (i.e., reject the hypothesis H_0)

In this way, we make the critical path more concrete and sort out the real critical paths of the RNIC's packet processing, which guide us to reason about the performance issues and optimize the RNIC's performance. We choose the architecture model with the best accuracy as the final reference.

4.2 Performance Interpretation & Prediction

In this section, we provide detailed interpretations for the symptoms in Table 1, which are then used to predict the

[1] Different vendors have different terminologies on flow tables. NVIDIA names the matching mask as the flow group, while Intel names it as the matching recipe. Although we use the term "matching mask" throughout the paper, its actual meaning is the same as flow group and matching recipe.

RNIC's performance. We conduct a sequential analysis [60] on the packet processing pipeline of the RNICs to validate how packets are delivered and coordinated inside the RNICs.

Flow State Maintenance. We find the possible causes of the state inconsistency problem in the RNICs. First, we note that the flow deletion in the RNICs can sometimes take a much longer time than expected. This symptom is caused by the flow table organization – when a flow is deleted, the RNIC must search the flow table to find the possible flow table dependencies on the specific flow; as a result, if the flow table is large, the deletion process becomes slow, causing S4. Similarly, the flow counters are not updated in time when the RNIC is handling a large number of flows. This makes the software stack determine that the corresponding flow is inactive. Thus, it may delete the offloaded flow from both the software and hardware by mistake, which leads to S1 and S5. These issues mostly happen to the NVIDIA devices.

Flow Tables. With the understanding of matching masks and flow table queries, we demystify the RNIC's performance in Figure 10. For the `read` verb, the local host first requests the remote host's memory address [65]. Its latency increases when the number of local hosts' egress (or remote's ingress) matching masks increase since requesting the addresses involves sending request packets from the local to the remote, which *sequentially* examines the matching masks for the packet's local encapsulation and remote decapsulation.

After the remote host's addresses and keys are requested, the `read` verb only involves packet transmission from the remote to the local [65]. As the number of the remote host's egress-direction masks (or the local host's ingress-direction masks) does not increase, the `read` bandwidth remains stable at 165 Gbps. In contrast, for `send` and `write` verbs, all packets are from the local to the remote. Their bandwidth and latency all degrade when egress-direction masks at the local or ingress-direction masks at the remote increase.

The above also explains the S6 in Table 1. When a matching mask is created, the RNIC sequentially queries the flow table entries. A new mask is queried after the old one, which incurs additional mask query latency. Even if the workload drops off later, the new flow still belongs to the new mask (i.e., it cannot be moved back to the old one which has a lower delay) and the performance cannot recover. We have observe such issues in all the examined NVIDIA and Intel devices. Besides, although the flow tables and matching masks are examined sequentially in the RNIC, the performance of flow matching under the same mask is nearly the same. This indicates that matching values in the RNIC are organized by hash maps under the same group partitioned by the matching mask.

The above micro behaviors of RNICs are actually invisible to the software stack (e.g., OVS) without ScalaCN. As a result, it is difficult for the software stack to schedule the optimal offloading of flow tables and matching masks, which often leads to inferior networking performance in the RCN.

Packet Queuing. We note that before a packet queries flow tables inside the RNIC, it will go through the requested queue in the RNIC. Packet queuing limits concurrent packets processed by an RNIC at the same time. When there is only one flow passing the RNIC, all packets of this flow fill the queue resources and fully utilize the RNIC capacity. However, when there are many flows, queue resources are shared by these flows' requested queue pairs. The bandwidth of a flow is proportional to its allocated queue pairs.

The queued packets affects the RNIC's overall performance jointly with matching mask queries. Figure 11 shows the impacts of queued packets of the CX-7 RNIC. When the average matching mask queries of queued packets increase, the `send` and `write` performance degrades, while that of the `read` verb is still hardly affected as CX-6. For latency, all three verbs are affected by the average matching mask queries similar to the one-flow case (not shown). In other words, an RNIC's overall performance is influenced by the average matching mask queries of queued in-flight packets.

Action Lists and Resource Management. When a packet is matched to a flow table entry, the RNIC applies actions (e.g., encapsulation and forwarding) recorded in the entry. Action lists incur additional delay on packet processing. We notice that VXLAN encapsulation and decapsulation incur performance loss (e.g., $\sim$6% on throughput and $\sim$3% on latency of all examined RNICs). More actions applied on the packet lead to a lower performance. However, as all packets in the overlay-based RCN only require VXLAN actions and port forwarding, such performance loss is constant in our scenario. Further, when the number of offloaded VXLAN actions increases, the corresponding buffers in the RNIC can be exhausted, leading to RNIC unresponsiveness (S2 and S8).

We have reported all the above findings and the inferences on the RNIC's hardware to the relevant vendors, which have been all confirmed. In particular, the inferred causes of S1, S2, S3, and S5 have all been fixed with the driver and firmware updates from the vendors. For the remaining causes, we are closely collaborating with the vendors to fix them.

Performance Prediction. The above combinatorial causal testing provides explainable models for us to understand where the performance issues of RNICs come from. ScalaCN employs the results as a proactive performance predictor to forecast performance degradation. ScalaCN predicts RCN performance on an RNIC basis, i.e., we only focus on monitoring the overall performance of an RNIC.

We use statistical fitting to enable performance prediction on RNICs at runtime. After testing diverse fitting functions including linear functions, polynomial functions, exponential functions, radial basis function [21], and so on, we find that the expected bandwidth BW of various RNIC models can be best fitted with a radial basis function as follows

$$BW(Q_l, Q_r) = u \cdot e^{\frac{-(Q_l-m)^2+(Q_r-n)^2}{2\cdot v^2}} + w, \qquad (1)$$

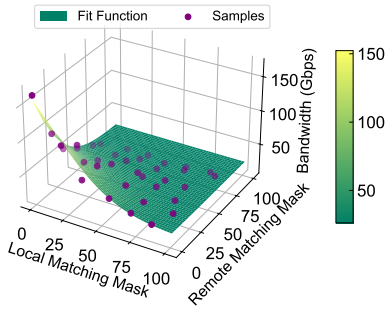

Figure 12: Fitting bandwidth performance of CX-6 with matching masks.

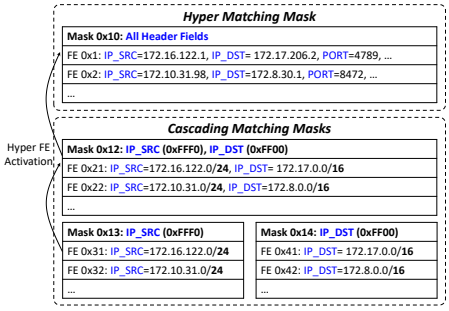

Figure 13: Optimizing RNIC performance by activating the flow entries (FEs).

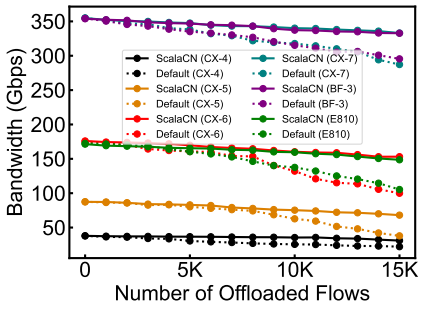

Figure 14: RNIC aggregated bandwidth with and without ScalaCN.

Table 3: Fitting parameters for different RNIC models, where **GD** represents goodness of fit.

RNIC	u	v	m	n	w	a	b	c	GD
CX-4	78.86	39.14	-28.25	-43.19	4.91	0.049	0.063	5.02	0.94
CX-5	148.97	42.34	-29.37	-45.14	12.43	0.051	0.074	4.93	0.93
CX-6	324.47	42.13	-26.92	-49.71	26.28	0.047	0.068	2.69	0.93

BF-3	748.52	48.01	-33.40	-52.42	30.65	0.037	0.043	2.56	0.94
E810	335.64	43.54	-27.01	-49.55	25.16	0.042	0.069	2.74	0.92

where Q_l and Q_r are average matching mask queries of in-flight packets on local and remote hosts' packet queues, e is the natural base, u, v, m, n, and w are fitting parameters. In particular, u and w control the maximum and minimum bandwidth that an RNIC can reach, and m, n, and v jointly determine the sensitivity of bandwidth changes towards the matching mask queries in the RNIC. Although other packet processing processes in RNICs such as access control also add to performance impacts, they are less dynamic and less significant according to our testing, and thus are also considered as a constant influencing factor w.

The above fitting function conforms with our observation that the bandwidth of RNICs is usually non-linear with a high degree of *rotational symmetry* [24] among the input variables as shown in Figure 10a, where the numbers of matching masks on the local and remote hosts have similar performance impacts. Figure 12 shows the fitting process of CX-6 bandwidth with a high goodness of 0.93.

For the latency of studied RNICs, it can be predicted with a linear function (cf. Figure 10b)

$$LAT(Q_l, Q_r) = a \cdot Q_l + b \cdot Q_r + c, \tag{2}$$

where a, b, and c are fitting parameters. Similarly, a and b jointly determine the sensitivity of latency change towards the matching mask queries, and c implies the constant performance influence of action lists. In fact, a linear function is sufficient for latency prediction as it is the simplest function that can achieve a >90% accuracy. Table 3 shows the fitting parameters of our studied RNIC models.

The average flow table query Q of in-flight packets at time t is calculated as $Q(t) = \frac{1}{n}\sum_{i=1}^{n} q_i^t$, where n is the total number of queued packets, and q_i^t is the number of flow table queries that need to be performed on packet i by the RNIC at time t. The number of in-flight packets is measured by the virtual switch statistics. ScalaCN uses a control-theoretic method, i.e., MPC [45], to keep its monitoring overhead under an acceptable threshold, while quickly responding to RCN events.

4.3 On-Demand Performance Optimization

With the performance predictor, ScalaCN monitors and forecasts RCN performance and states. Recall that the results of combinatorial causal testing indicates the matching masks on flow table queries are the key bottleneck of the performance in all the studied RNICs (cf. §4.1 and §4.2). Thus, once ScalaCN predicts that the performance is about to decline, it optimizes the network function offloading schedule by reorganizing the flow tables so as to reduce the flow table queries.

An RCN can have many packet header patterns for masked matching (cf. §4.1). In our production RCN, a host could have different lengths of IPv4 subnet masks. In practice, the OVS and the kernel offload the corresponding matching mask simply in one shot—once there is a new flow pattern, they will create a matching mask in the RNIC without coordinating with the previous ones (as they are not aware of the RNIC's internals). Thus, the RNIC increases matching masks and degrades performance when flow patterns increase.

Hyper/Cascading Masks. ScalaCN optimizes RNIC performance by minimizing matching mask queries on RNIC packet switching, so as to accommodate RCN scale changes. As shown in Figure 13, ScalaCN reorganizes the RNIC's matching masks in an offloaded flow table into two types, i.e., a *hyper* matching mask and *cascading* matching masks. These two types of masks act like a multi-level cache in a CPU. Each flow table has only one hyper mask ahead of all cascading masks, so that it is queried first with minimum delay.

When there is a new flow pattern offloaded from the OVS and the performance is anticipated to noticeably degrade by an empirical threshold of 5%, ScalaCN creates a corresponding cascading matching mask for it. For example in Figure 13, Mask 0x13 and 0x14 match two new flow patterns (i.e., /24 and /16 IP segments). Once ScalaCN detects a packet between two specific containers matched by existing cascading

matching masks, it will *activate* the concrete flow into the hyper matching mask (e.g., FE 0x1 in Mask 0x10). The hyper matching mask performs an exact match on packet headers and is faster than cascading matching masks since it is located at the headmost. In this way, flow packets always only need to query the hyper matching mask after flow creation.

The first several packets of newly created flows can go through cascading matching masks. To further minimize packet queries on cascading matching masks, we re-prioritize them based on two metrics, i.e., the length of its matching masks (*LM*) and the number of packets in the past 60 seconds it matched (*PM*). A longer matching mask (which matches packets with a more specific pattern and a narrower range) and a larger number of matched packets indicate that the cascading matching mask handles many packets with a strong locality. We thus use the locality score $LS = PM \cdot LM$ to quantify the priority of cascading matching masks. We move the cascading mask with a higher *LS* to the front so that an average packet can query the least number of entries. Besides, we warm up the RNIC's flow tables (i.e., offload probable flows) to accelerate flow creation in case of bursty traffic. This is achieved based on a Gaussian mixture model [52] deriving from our long-term analysis of production traffic patterns.

A hyper matching mask can be filled up by flow entries more quickly since each entry can only exactly match one flow. Thus, ScalaCN needs to deactivate aged flow entries from the hyper mask to preserve the on-chip memory for new flows. Here we utilize the least recently used (LRU) policy to update the flow entries in the hyper matching mask. Similarly, we remove a cascading mask in the flow table when it has no active packets for ten minutes. According to our measurements, removing aged entries in the two types of the matching masks will not affect the performance of the RNICs. This is understandable because most packets will hit the hyper matching mask or higher-level cascading matching masks first when lower-level masks are removed.

4.4 Generalizability

Other RNIC Components. We also observe the performance degradation incurred by the resource contention of on-chip SRAM like queue pair context (QPC), which has been reported in previous studies [62, 67]. ScalaCN can also be used to locate the contention of the on-chip memory. To achieve this, we only need to add a configurable "capacity" dimension on the original queue abstractions before modeling the RNIC's components. Our combinatorial causal testing can then be used on these new dimensions by differentiating the tested performance under different workloads. Nevertheless, as a CSP, we can only optimize the RNIC's performance within the scope of the configurable components of the RNICs, while the on-chip memory contention is usually the inherent hardware limits that require re-architecting the RNICs.

Reusability. ScalaCN is designed to be reusable as it is based on the common abstractions of the RNIC's components involved in an RCN. Specifically, all RNICs provide the support for common RDMA verbs and eSwitch, which can be manipulated through the same set of APIs. Also, ScalaCN builds the performance model for the tested RNIC to validate the modeling accuracy in a closed-loop manner, and each fitting parameter in the model can be individually tuned based on the tested performance of the RNIC. The only manual operation is determining the common abstractions of the RNICs in an RCN (which is a one-shot effort), while the rest of the processes can all be automated through ScalaCN's testing framework. With the above principled methodologies, ScalaCN can be easily adapted to new RNICs.

4.5 Implementation

We implement ScalaCN in 38K lines of C/C++ code and 13K lines of Python code. In order to monitor RCN states, we make use of the OVS command line utilities including `dpctl`, `appctl`, and `ofctl` to acquire data path information. In addition, to transform LTL policies into an automaton, we use the LamaConv tool [11] to generate Moore state machines [16]. ScalaCN does not create new RCN flow rules, but works between the OVS and the RNIC kernel driver to determine the equivalent flow table offloading strategies that maximize the RNIC performance. We modify the OVS module for replacing the offloaded rules on the fly.

5 Evaluation

ScalaCN is gradually used in production, so it is evaluated using both microbenchmarks and production workloads.

5.1 Experiment Setup

The basic settings of the experiments are similar to those in §3.1. For microbenchmarks, we use a middle-scale RCN with 50 hosts, each of which is equipped with four RNICs including either CX-4, CX-5, CX-6, CX-7, BF-3, or E810. We directly use real-world traffic generated by the hosted applications (e.g., large model training and microservices) for evaluation. These applications initiate $O(4\text{M})$ different flows in a day on average and carry out 150–400 Gbps aggregated throughput on each RNIC. We measure the packet forwarding bandwidth and latency of RNICs using the RDMA `perftest` utility [14]. Note that we only measure performance among the same model of RNICs since the inter-operation across different models could result in instability or RNIC failures [67]. In fact, the inter-operations of different models of RNICs are avoided in our production RCN.

5.2 Microbenchmarks

Scalability. Figure 14 and Figure 15 show the scalability in terms of the RNIC's aggregated bandwidth and packet forwarding latency. When the number of flows on the RNIC

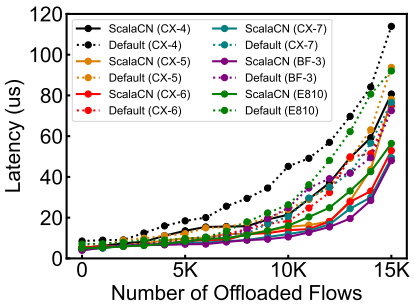

Figure 15: RNIC latency with and without ScalaCN.

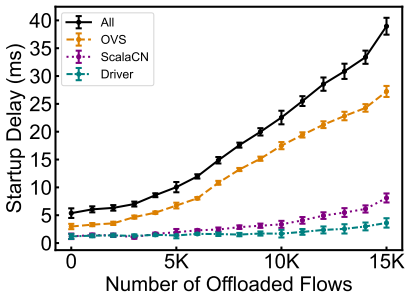

Figure 16: Startup delay of different software-stack components.

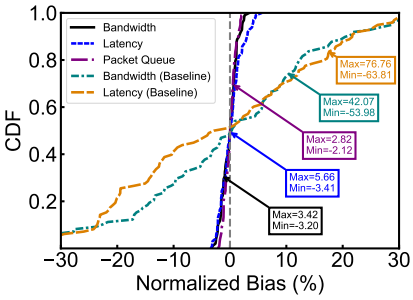

Figure 17: Prediction bias on RNICs' performance.

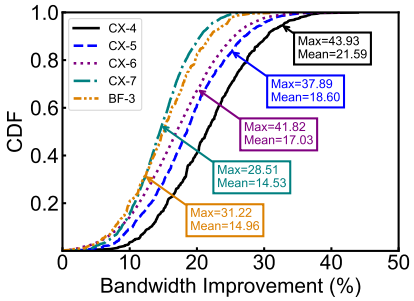

Figure 18: Bandwidth improvement on RNICs in real-world workloads.

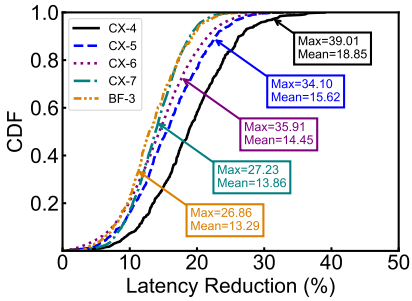

Figure 19: Latency reduction on RNICs in real-world workloads.

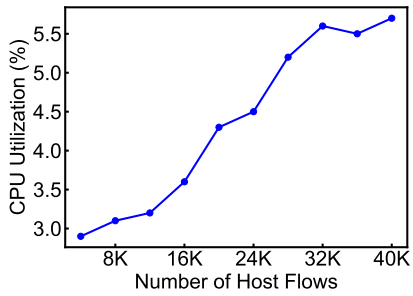

Figure 20: CPU utilization under real-world workloads.

increases, the `send` bandwidth significantly drops on all models with the default OVS offloading strategy. For example, the aggregated bandwidth of the CX-4 RNIC drops by 41%, and the absolute bandwidth drop of the E810 RNIC reaches 70 Gbps. This is because offloading flows to the RNIC intensifies the resource contention inside the packet queue. Meanwhile, the increasing offloaded flows lead to many matching masks created in the RNIC, which increases the processing delay of a packet and thus degrades the throughput. Further, all RNICs present a threshold after which the performance drops more quickly (e.g., 8K for CX-6). Similar trends exist for the RDMA `send` latency as well as `read` and `write` verbs.

In contrast, RNICs' overall aggregated bandwidth with ScalaCN hardly drops. Compared to the default RCN settings with 15K offloaded flows, ScalaCN improves the average aggregated bandwidth of the RNIC by 40.4% and reduces the average packet forwarding latency by 30.5%. This is because ScalaCN proactively reorganizes the RNIC's flow tables when performance degradation is about to happen.

Flow Startup Delay. We measure the startup delay of new flows to show the impacts of ScalaCN on flow initiation with flow table reorganization. Figure 16 depicts the breakdown of the flow startup delay under different numbers of flows. As the RCN scale increases, the startup delay of a flow gradually increases. Nevertheless, most (70%) of the delay is attributed to the OVS, which determines packet forwarding rules in the user space. The additional delay incurred by ScalaCN merely accounts for 18%, which is close to that of the driver (12%). Since the startup delay only affects a couple of packets on flow creation, we feel that such an increase is acceptable given the significant performance improvements of ScalaCN.

Prediction Accuracy. We measure the prediction bias of ScalaCN on the RNIC's performance, and compare it with a baseline prediction method that uses mainstream machine learning techniques (e.g., SVM) with representative flow features like packet loss rate and the number of flows [44, 69]. As shown in Figure 17, ScalaCN achieves a high accuracy on predicting the RNIC's packet queue utilization, with the maximum bias being only +2.82%. Based on this, ScalaCN can further predict the bandwidth and latency with a high accuracy of 98.9% and 98.5%, respectively. In contrast, the baseline method presents poor accuracy, with the maximum bias being -53.98% and +76.76% for bandwidth and latency.

5.3 Real-world Production Workloads

Performance Benefits. We measure the bandwidth improvement and latency reduction on the RNICs that carry our production RCN workloads. As shown in Figure 18 and Figure 19, ScalaCN improves the bandwidth by 17% on an average RNIC, and reduces the average latency by 15%. Also, the maximum bandwidth improvements reach 43.9%, 37.9%, 41.8%, 28.5%, and 31.2% for CX-4/5/6/7, and BF-3, respectively. The latency reductions are 39.0%, 34.1%, 35.9%, 27.2%, and 26.9%, respectively. Similar results exist for the Intel device E810 (not shown due to the space limit).

Different RNIC models benefit differently from ScalaCN. The CX-4 RNIC which was released early benefits the most from ScalaCN. We assume that this is because the early de-

sign of RNICs has a longer delay for each flow table query due to their inferior hardware components. Thus, reducing the number of queries substantially improves efficiency. Note that for the more advanced CX-7 and BF-3 RNICs, ScalaCN still provides considerable performance improvements (i.e., 105 Gbps) since it resolves the hardware bottleneck and reduces the processing complexity for RCN packets.

On the other side, ScalaCN can induce minor performance drops in some cases, in particular the computation-intensive tasks that involve few data communications among containers. The performance drop mainly derives from the flow entry insertion to the hyper matching mask on frequent flow creation. Nevertheless, such a performance drop is trivial ($<$5%) and only occurs to $<$0.03% RNICs in our RCN.

Overhead. ScalaCN needs to continuously monitor the crucial information from software and hardware stacks for performance optimization. As shown in Figure 20, ScalaCN incurs low CPU overheads on different scales of flow offloading. When the host carries more flows, ScalaCN needs to monitor more flow states, and therefore will incur higher CPU overhead. Such overhead is linear to the number of offloaded flows and will finally converge to $\sim$5% on a single core. In the real-world production RCN, the overhead is negligible given the usually tens of CPU cores running on a host.

6 Lessons Learned

Abstraction before Testing. For the performance testing of networking devices such as RNICs and switches, it would be more efficient if we prepare a general abstraction before the actual testing. Such an abstraction can be derived from the hardware datasheet, open-source drivers, and common network APIs. With this abstraction, we can efficiently infer the potential performance bottlenecks and the root causes of the performance issues inside the hardware of commodity devices. In particular, the abstraction helps us identify combinatorial restrictions of the device's input, so that the search space of the performance testing can be largely reduced.

Blackbox Hardware Is Practically Understandable. Although commodity RNICs are mostly close-sourced, we can still shed light on their basic architecture and performance models by concentrating on their critical packet processing pipeline. Based on this realistic insight, CSPs like us can take proactive measures (e.g., optimizing the flow offloading schedule) to mitigate unexpected issues of the RNICs, without the need to modify or re-architect the RNIC (which is costly and at least takes time). Even if we cannot accurately profile the behavior of an RNIC, we can validate some of its key metrics like bandwidth and latency to determine whether a performance degradation is within the acceptable range.

7 Related Work

RNIC Performance Enhancement. Over the past decade, RNICs have gone through a remarkable evolution. Many studies focus on enhancing the performance and scalability of RNICs [25, 29, 33, 59, 62, 63]. SRNIC [63] is a scalable architecture based on FPGA, which minimizes on-chip data structures. StaR [62] balances state maintenance between two communication ends to improve scalability. These studies mostly focus on addressing resource contentions (i.e., hardware limits) of the on-chip memory, while ScalaCN focuses on the on-chip packet processing pipeline that is rarely touched in previous work but is more important for the large-scale use of RNICs. Unlike hardware limits that require re-architecting the hardware, focusing on the packet processing pipeline provides us with an opportunity to enhance the performance even if we have limited visibility into the RNIC's internals.

Troubleshooting Data Center Networks. There have been plenty of studies on troubleshooting data center networks. Most of them focus on verifying the correctness of control-plane rules [17, 20, 23, 50, 61, 68]. Minesweeper [17] and Plankton [50] are two representative approaches to validating network configurations. However, these methods all assume that the underlying RNICs will not fail, and the states as well as performance statistics in the software stack always stay consistent. Such an assumption in fact does not always hold in the production RCN, since RNICs' capability limits can only be discovered in large-scale settings. In contrast, we dissect the RNICs' scalability walls in a large-scale production RCN. This enables us to design ScalaCN to practically address the performance issues when the network quickly scales up.

8 Conclusion

This work presents our efforts towards understanding and mitigating the scalability limit of RCN in a large-scale production environment. In particular, we leverage the efficient approach of *combinatorial causal testing* to interpret the performance issues of RNICs. The derived architecture and performance models guide us to reliably infer the bottlenecks inside RNICs and devise an effective method to overcome the bottlenecks. RNIC vendors' feedback validates our multifold findings and comprehensive evaluation results confirm the efficacy of our solution. In a broader sense, our work provides a principled approach to extracting the high-level mechanisms of proprietary hardware devices, which can benefit a wider range of fields such as hardware testing, verification, and security.

Acknowledgments

We acknowledge Container Network and High-Performance Network teams in Alibaba Cloud that contributed to the success of ScalaCN. We thank our shepherd, Mariano Scazzariello, and the anonymous reviewers for their valuable comments and suggestions. Appendix

A Design Details

State Validation. While the performance predictors enable ScalaCN to predict RNIC performance, we still need an effective approach to validating whether the RCN is running in the correct states to make up for possible prediction errors. We take advantage of the linear temporal logic (LTL) [18, 49] to model the expected behaviors RNICs according to the causal testing results. We choose LTL because it can describe the transitions of system states over time. It acts as a test oracle to validate the state correctness and actual performance of the RCN. For example, we use LTL policies "if a flow is offloaded, the RNIC should create a flow entry for it." and "a new flow entry should not be created until a flow is offloaded" to validate the states of RNIC flow entry creation. These two policies can be represented in LTL formulas [49] as $FL_OFFLD \rightarrow \bigcirc FE_CREATE$ and $\neg FL_CREATE \ \mathbf{U} \ FE_OFFLD$. ScalaCN encodes LTL policies to build the LTL validation automaton.

Figure 21 shows the example for the above two specifications. States S_0 and S_1 are undetermined states, S_2 is the error state (i.e., an RCN state inconsistency is detected), and S_3 is the accept state (i.e., the RCN stays correct). If a flow entry is created at the initial state S_0 (without flows offloaded), the automaton goes into the error state and indicates a state inconsistency. If a flow is offloaded to RNICs twice, ScalaCN also determines an inconsistency. Only when the OVS offloads a flow and the RNIC creates the corresponding flow entry, ScalaCN will determine that the RCN stays correct.

It is also possible that ScalaCN cannot identify any issues in the software and hardware stack, but the performance is still very poor (e.g., due to the hardware aging, erosion, or some other environmental factors). To handle these unexpected scenarios, we have a passive monitor on the container network besides ScalaCN. Such a monitor will notify the control plane immediately about the unexpected performance degradation, and the control plane will temporarily disable the allocations of these RNICs to the containers.

Flow Table Manipulations. The flow table policies are initially generated by the software switch. For example, when a new flow is created, it cannot be found in the flow table of an RNIC. In this condition, the RNIC cannot handle the new packet pattern and will transfer the processing of the packet to the software OVS, which will cause a lookup miss event [46] to the OVS. The OVS will then determine which port (i.e., VFs or VXLAN interfaces) this new packet should be sent to and whether it needs encapsulations or decapsulations. After processing the first packet of a new flow, the OVS also offloads the corresponding processing rules to the RNIC hardware. The key problem here is that the OVS is not aware of the RNIC's hardware architecture, and thus cannot offload the optimal flow rule schedule. In particular, it cannot well determine if the flow tables should be reorganized when the number of flow patterns increases. In contrast, ScalaCN can proactively transform these flow rules to the equivalent ones that minimize the overall flow processing delay for the RNIC.

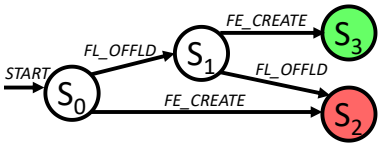

Figure 21: An example automaton from LTL specifications.

Flow Table Locality. The concept of "locality" of a flow rule/table in ScalaCN means that it is frequently hit by the RCN packets. Matching masks with more bits set to "true" indicates that it can match more concrete flows if the table capacity is unlimited. However, it also occupies more flow table entries as each entry is more concrete (e.g., an extreme case is that the full-bit matching of the hyper mask requires each entry to match exactly one specific five-tuple). So the flow table is filled up more quickly for the hyper mask. Considering these two aspects, ScalaCN prioritizes the masks that have a wider range of pattern matching capability and a higher hit rate to the front of the flow table.

B Additional Evaluation Results

Convergence Speed of Causal Testing. ScalaCN completes the entire testing and discovers the performance bottlenecks for each of the tested RNIC models in 3.6 hours on average, which is 60× faster than the brute-force testing that goes through all the possible configurations in more than 9 days. Since our testing is based on the common abstractions of the RNICs in an RCN, the convergence speed for different RNICs is similar. These results demonstrate the effectiveness of our combinatorial causal testing approach in building a high-quality model for the RNICs in a greybox manner.

Impacts on Small Bursty Flows. As we have discussed in §4.3, the introduction of a hyper mask may cause a certain degree of performance degradation for small bursty flows, since their flow rules are not initially prioritized in the whole flow table. We conduct a set of experiments to evaluate the performance of ScalaCN on these small bursty flows, and find that the negative impacts are negligible compared with the performance without ScalaCN. This is because by default the OVS still needs to process the first packet of these small bursty flows without ScalaCN, which usually incurs the same high delay (e.g., tens of milliseconds) due to the lookup miss as in the case with ScalaCN. Also, the first packet of these small bursty flows has a higher probability to be processed by the first cascading mask in ScalaCN due to mask re-prioritizing. Thus, the first-packet latency is still acceptable (e.g., <5 us increase) with RNIC offloading. After the new flow is offloaded to the hyper mask (i.e., the second packet), such a performance degradation will be eliminated.

Eden: Developer-Friendly Application-Integrated Far Memory

Abstract

Far memory systems are a promising way to address the resource stranding problem in datacenters. Far memory systems broadly fall into two categories. On one hand, paging-based systems use hardware guards at the granularity of pages to intercept remote accesses, which require no application changes but incur significant faulting overhead. On the other hand, app-integrated systems use software guards on data objects and apply application-specific optimizations to avoid faulting overheads, but these systems require significant application redesign and/or suffer from overhead on local accesses. We propose Eden, a new approach to far memory that combines hardware guards with a small number of software guards in the form of programmer annotations, to achieve performance similar to app-integrated systems with minimal developer effort. Eden is based on the insight that applications generate most of their page faults at a small number of code locations, and those locations are easy to find programmatically. By adding hints to such locations, Eden can notify the pager about upcoming memory accesses to customize read-ahead and memory reclamation. We show that Eden achieves 19.4–178% higher performance than Fastswap for memory-intensive applications including DataFrame and memcached. Eden achieves performance comparable to AIFM with almost 100× fewer code changes.

1 Introduction

As the memory requirements of datacenter applications increase without a commensurate decrease in DRAM costs, datacenter operators are increasingly concerned by memory stranding. At the same time, host interconnects are delivering higher bandwidth and lower latency [20, 25, 27, 28, 30, 36]. As a result, there is a renewed interest in far-memory systems which enable servers to access under-utilized DRAM on other servers or pooled on dedicated devices within a rack or cluster. Recent efforts have explored a range of issues that arise including prefetching, access models, and fault tolerance [8, 13, 16, 24, 26, 39, 42, 43, 45, 50, 52, 53] but they all make sacrifices along at least one dimension: performance, developer effort, or flexibility.

Existing far-memory systems generally take one of two approaches. Paging-based systems like Infiniswap [24], Fastswap [13] and their extensions [12, 39, 50] rely on *hardware guards* to intercept accesses to remote memory: the microprocessor checks if a page is not locally present and in such case triggers a page fault to fetch it remotely [9]. This approach works with unmodified applications and incurs little overhead on local accesses, but suffers from two issues. First, page faults are expensive because they require trapping into the kernel—which takes on the order of a microsecond, making it impractical to context switch to a different task while waiting for a page fetch to complete (which takes 5–6 μs in our RDMA cluster). As a result, systems such as Fastswap busy wait on page fetches, wasting CPU cycles and limiting performance [13]. Second, their transparent page-based approach does not provide the kernel with the information needed to implement application-specific policies to improve performance (e.g., custom prefetching or eviction).

Alternatively, app-integrated systems such as AIFM [42] and Carbink [53] manage memory in user space at object granularity and rely on *software guards* to intercept remote accesses: applications use remotable pointers which, when dereferenced, check if the data is remote and if so fetch it. Their user-space implementation avoids the overheads of kernel-moderated page faults and makes use of the CPU during a remote fetch by switching to a different lightweight user-level thread. In addition, by operating at object granularity, they can expose data-structure-specific access patterns to the runtime to enable application-specific optimizations. However, app-integrated systems must pay the cost of software guards even on local accesses, and require significant developer effort to port applications to use remotable pointers. Systems like TrackFM [45] and Mira [26] employ compiler techniques to decrease the porting effort but still incur software guard overheads and require source code access to all of the library dependencies of the application, which may be infeasible in many scenarios (§2.1).

We propose Eden, a page-based system that combines software and hardware guards to expose memory access patterns without imposing a disruptive object-based interface. Eden is based on the insight that far-memory applications tend to generate their page faults at a small number of code locations, and those locations are easy to find programmatically. We provide a tool to identify fault locations, and our study of 22 applications shows that, at the median, 12 code loca-

tions cover 95% of page faults. Hence, Eden deploys software guards (code annotations) at these few performance-critical code locations to presage most remote accesses, while relying on hardware guards (page faults) to service the few remaining remote accesses that may occur elsewhere in the application.

The parsimonious use of software guards balances their expressive power against their runtime overhead. By capturing most far memory accesses with code annotations, we avoid almost all expensive kernel-mediated page fetches. Moreover, we show that Eden can effectively coalesce related far memory accesses to provide the same type of application-specific optimizations as systems that resort to object-based interfaces, but with significantly less programmer effort. Finally, by employing software guards only where accesses are likely to be remote, Eden minimizes their overhead.

Based on this insight, Eden asks the developer to instrument these code locations with memory-access hints. By using a hybrid kernel/user-space page management scheme, these hints allow Eden to tailor memory policies to the application (including fetch, eviction, and read-ahead policies) and to leverage a lightweight scheduling framework to run user-level threads during page fetches, thereby improving performance. Specifically, a hint transfers control to Eden's user-space runtime, which checks for page presence and detects an impending fault without trapping into the kernel. If a page is missing, Eden initiates the fetch from user space.

Efficient joint kernel/user-space page management is challenging to realize, as some parts of page-fault handling must occur in kernel context. For example reading the faulting address is a privileged operation on x86 processors. Similarly, mapping and unmapping pages must occur in kernel space. Finally, hints may not be perfect, so Eden's user-space runtime may not catch every fault. Thus, employing a page-based approach with today's CPUs fundamentally requires some kernel participation, whose overheads, if left unchecked, can quickly overwhelm any potential performance benefits.

Eden uses two key ideas to overcome the challenges of hybrid kernel/user-space page management. First, because the kernel retains control of page tables in Eden, syscalls are still needed for tasks such as mapping pages after they are fetched, toggling write protection, and indicating when pages can be reclaimed from a process' address space. Our design streamlines these operations by extending Linux's `userfaultfd` and `madvise()` syscalls to provide *vectorized APIs*. Using these enhanced syscalls, Eden amortizes the cost of necessary kernel traps across many pages, dramatically improving performance.

Second, Eden further uses its hints to pass additional application-specific information to guide prefetching and reclamation. As the hinted accesses cover most page faults in the application, these hints provide a great opportunity to pass data-access knowledge gained either through developer insight or offline profiling. For example, in loops or when accessing large objects, hints can provide precise read-aheads to batch page faults and amortize the page-in cost. Similarly, faulting accesses to certain data structures can be prioritized for reclaim over others by setting different priorities for different hints. We show that such *extended* hints help Eden perform on-par with app-integrated approaches that require significant developer effort. While Eden relies on developer insight to extend hints (similar to app-integrated systems), the effort is smaller and we carefully design the hint extensions to be simple enough for automatic detection and injection based on offline profiling.

We implement Eden on top of Shenango [37], a highly scalable user-level thread scheduling runtime, which Eden leverages to efficiently switch from one thread to another while a hinted fault is being resolved. We evaluate Eden across a variety of workloads both from a performance and developer-effort standpoint. We show that Eden achieves higher throughput than a recent kernel-based far memory system, Fastswap [13], by 19.4–178% on real-world applications such as DataFrame and memcached. Furthermore, Eden achieves similar throughput to an app-integrated approach, AIFM [42], on both DataFrame and synthetic Web service workloads with sufficient local memory. In terms of developer effort, we show that for several example applications, only a handful of hints (2–32) are required to handle 95% of page faults in Eden. In contrast, the AIFM authors modified 1,192 lines in the DataFrame library—108× more than Eden. Our code is openly available at `https://github.com/eden-farmem/eden`.

2 Background and Motivation

In this section we justify our key design decisions. First, we explain the issues with prior app-integrated systems that we address with our hybrid approach. We then document the overheads inherent in managing traditional, page-based virtual memory from user level and suggest how hints can be used to both communicate application-specific workload information and ameliorate the cost of user/kernel transitions. And finally, we show that there are typically only a small number of locations where such hints are needed so introducing them requires limited developer effort.

2.1 Issues with prior app-integrated systems

The original app-integrated approach to far memory, used in AIFM [42] and Carbink [53], entails significant developer effort and performance overhead due to its remotable pointers. To use these systems, the developer must identify every location where a remote pointer dereference might occur and insert a software guard at each. The guard checks that the data is in local memory, and if not, reads it from far memory. Adding these guards can involve significant modifications; for example, porting the DataFrame library to use AIFM required modifying 7.7% of the lines of code.[1] In addition, while these

[1]The AIFM authors reported modifying 1,192 lines of code [42] out of 15,525 lines of C, C++, and makefiles in the library [2].

guards are highly optimized, they still incur overhead, even if the check succeeds (i.e., the data is already in local memory).

For example, AIFM's guard contains 5 instructions in the best case, and can take up to 489 cycles at the 90th percentile even when data is in local memory. (In contrast, the hardware guards of paging-based approaches use highly optimized TLB hardware.) Unfortunately, for functional correctness, guards are needed throughout the application (anywhere a pointer to the heap may be dereferenced) resulting in a large number of guards. To avoid invoking guards on every access, AIFM employs programmer-assisted *dereference scopes*—small blocks in the program code—wherein the object is marked unevictable and guards are avoided using native pointers. Such optimizations, while helpful, are not always applicable (e.g., streaming workloads where objects experience a single access) and may even add to the programmer burden. For example, the DataFrame library above sees up to 30% slowdown with AIFM even after these guard optimizations. Eden does not need such optimizations because it uses hardware guards where accesses are likely to be local.

More recently, systems such as TrackFM [45] and Mira [26] use compiler techniques to programmatically insert software guards. While effective at reducing programmer burden, neither can eliminate the overhead of guards (e.g., TrackFM's guard contains 14 instructions). Both TrackFM and Mira try to reduce the number of guards required through static analysis, but such techniques have limits (e.g., when the compiler cannot statically resolve branching, function calls, or shared accesses from multiple threads). Ultimately, even with optimizations, TrackFM's overheads are significant: up to 40% slowdown in application performance (§5). Furthermore, for correctness, both systems require instrumenting most or all external library dependencies of an application, which may not be possible (e.g., when source code is not available). In addition, the instrumentation produces larger binaries, incurs higher compilation times—TrackFM reports 2.4× bigger binaries and 6× longer compilation times on average—and complicates the tasks of debugging and profiling.

2.2 Page management overheads

When we combine software and hardware guards, any piece of remote data may be fetched through either our user library (software guards) or page faults (hardware guards). Our library thus needs a way to track and manage page faults to ensure consistent operation: if the user library fetches a page, it should be marked as present in its page table entry, so that subsequent accesses do not cause a page fault; similarly, if the fault handler fetches a page, our software guard should know that the page is local.

The Linux kernel has a simple mechanism to manage page faults in user space called `userfaultfd` [4]. To use `userfaultfd`, a process first registers a region of virtual memory with the kernel and receives a file descriptor in return. Then, if the process faults on an address in that region, the kernel notifies the process by sending an event to the file descriptor. Typically, the process will dedicate a core to polling the file descriptor to detect page faults and resolve them by using the `UFFDIO_COPY` `ioctl()` to map the missing page in the process' address space and unblock the faulting thread. When pages are no longer needed, processes use the `madvise()` syscall to ask the kernel to unmap them, and processes use another `ioctl()`, `UFFDIO_WRITEPROTECT`, to write-protect dirty pages while they are written out.

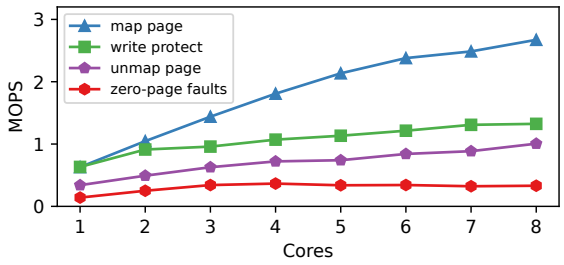

Figure 1: The maximum throughput of memory operations when performed from user space on Linux, as a function of the number of cores. Faults are serviced by four dedicated handler cores; additional cores do not improve performance.

However, we find that `userfaultfd` can entail significant overheads. Figure 1 presents a simple microbenchmark in which a variable number of application cores trigger each of the above memory-management operations as quickly as possible. (We service the zero-page faults on separate handler cores; the other three operations are performed locally at each core.) Even when faults are resolved in the simplest way possible—supplying a zeroed page with `UFFD_ZERO`—we find that the maximum rate at which (any number of) handler cores can poll for faults via a single `userfaultfd` file descriptor is 350 thousand faults per second on our hardware ("zero-page faults" plotted in red).[2] A far-memory system that handles all page faults via `userfaultfd` would only be able to handle ∼12% percent of the 3 million page transfers per second that are possible with a 100-Gbps NIC. While the other three operations are more lightweight, both unmapping (shown in purple) and write protecting pages (green) scale poorly due to the need to flush TLBs across all impacted cores.

Fortunately, our approach invokes this expensive `userfaultfd` machinery only occasionally, as hints can invoke our user-space page-management code before a page fault occurs. Moreover, we provide some simple vectorized enhancements to system calls to reduce the overheads of context switching to the kernel; with these enhancements, our library can manage multiple pages with a single system call.

2.3 Faulting locations

We validate our intuition regarding the number of different places in an application's source code that generate page faults

[2] Using additional file descriptors can improve throughput, but requires sharding far memory into one segment per `fd` (and, hence, across multiple handler cores) potentially causing load imbalance across handler cores.

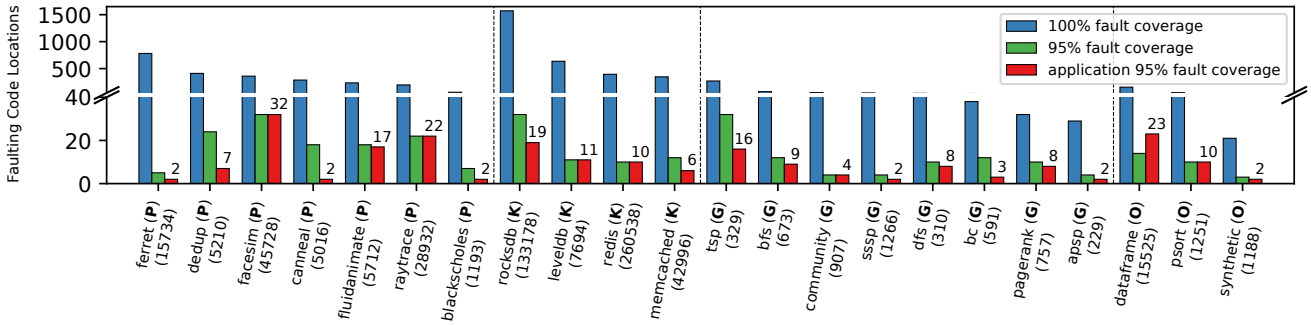

Figure 2: The number of unique lines of source code that account for 100% (blue) and 95% (green, localized to application code in red) of the page faults in 22 different applications. Local memory is configured to hold only 10% of the working set. The *x*-axis labels indicate the total number of lines of code in each application and the application's category (bolded letter).

in a far-memory context—and, therefore, require a programmer to add hints—by conducting a study across a set of 22 applications drawn from different benchmark suites to cover a range of application categories. (These results were published in a workshop paper [14]; we reproduce the high-level findings in this subsection for self-contained review.[3])

Specifically, we consider HPC applications from **P**ARSEC [15], **K**ey-value stores from LK_PROFILE [48] (e.g., LevelDB [5] and Memcached [33]), **G**raph algorithms from CRONO [11], and three **O**ther applications used in our evaluation. We run each application with its standard benchmarking workload to ensure realistic code coverage. Details about the applications and their workloads are provided as Supplementary Material (§A). Using our Eden-based fault-tracing tool (§4), we observe the behavior of each application while restricting the amount of local memory available to 10% of its maximum resident set. The tool identifies all unique fault-triggering source code locations in the application and the libraries it uses.

Figure 2 shows for each application both the total number of code locations that trigger faults and the number of code locations responsible for 95% of faults. In most cases, a small number of locations cover 95% of faults—12 locations at the median and fewer than 32 for all applications. Moreover, when we trace the faults back to the line of application code that led to the fault, even fewer unique lines of code are implicated: less than 10 in most cases. Further experimentation on these and other applications published elsewhere [14] shows that the set of locations is robust across different degrees of memory pressure. Manual analysis reveals the reason is straightforward: few code paths dominate runtime in these applications. At even 10% of the maximum resident set size, local memory is sufficiently large that each page brought in on a code path tends to remain available for later page accesses in that path. As a result, only the initial reference on a given path is likely to cause a fault.

[3]We emphasize that the workshop paper studies faulting locations in far-memory applications; neither Eden nor its evaluation have been published.

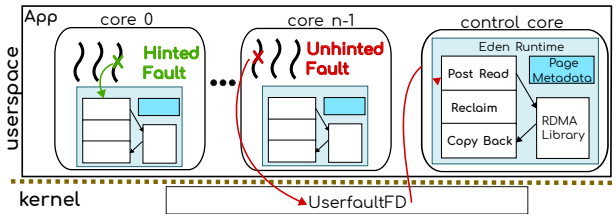

Figure 3: Eden's runtime runs on each application core and a dedicated control core. Hinted faults are handled directly by the runtime on the faulting core while unhinted faults are caught by the kernel and steered to the control core.

3 Eden Design

Eden is a far memory system that aims to achieve three goals:

1. **Low developer effort:** developers should not have to extensively modify their application to use Eden.
2. **Flexible policies:** applications should be able to specify prefetch and eviction policies, and to leverage application-specific information in these policies.
3. **High throughput:** Eden should minimize its overheads as much as possible to deliver high throughput.

Eden's key idea is to manage remote memory accesses with software guards in the common case while avoiding these guards for most local accesses. It achieves this by having the developer add (a small number of) hints to their program about locations where remote accesses are most likely to occur. Eden's runtime can then efficiently check in user space whether the needed page is present, and initiate its fetch if not. In addition, Eden's hints provide an opportunity for applications to convey additional application-specific information about their memory-access patterns to customize prefetch and reclamation policies. Finally, for operations like write-protecting and unmapping pages which require kernel privileges, Eden provides low-overhead vectorized syscalls.

Figure 3 shows Eden's overall design. Application cores run applications in lightweight, user-level threads. Eden's runtime runs on each core and provides general-purpose functionality such as threading and networking. In addition, the

```
hint_fault(
  /* basic hint */
  address, /* faulting address or page */
  mut = false, /* map read-only or writable */
  size = PAGE_SIZE, /* size of the region */
  /* extended hint */
  rdahead = 0, /* positive or negative read-ahead */
  ev_prio = 0, /* eviction priority */
  seq = false, /* sequential access */ );
```

Figure 4: Eden's hint API. Basic hints suffice to signal potential impending page faults; developers wishing to convey additional workload information can use extended hints.

runtime implements memory-management functionality such as logic for handling hints, fetching and evicting pages, and prefetch and reclaim policies. In addition to the application cores, Eden's design includes a dedicated *control core* which is responsible for proactive memory reclamation and handling any "unhinted faults", i.e., those remote accesses which are not presaged by Eden's hints and therefore trigger a hardware guard (i.e., page fault). The kernel steers these (relatively rare) faults to the control core using `userfaultfd`.

3.1 Hint API

Hints are annotations that a developer adds to their program to notify the runtime of a potential page fault and to convey application-specific information about memory access patterns. The runtime uses the information provided by hints to fetch missing pages and avoid almost all page faults, as well as to improve its policies for prefetch and memory reclaim.

3.1.1 Basic hints

Figure 4 shows Eden's hint API. It includes two types of hints: basic hints and extended hints. Eden expects applications to provide at least the basic hints; otherwise all page faults will be handled with high overhead via traditional hardware guards and `userfaultfd`. The key piece of information that each hint conveys is the upcoming memory address (or region) that, if unhinted, might trigger page fault(s), and whether the faulting pages should be mapped read-only or writable. These addresses need not be page aligned. Eden strives to make placing hints as easy as possible, both in terms of lines of code modified and time spent to identify hint locations. We provide a tool to assist in this process (§4).

3.1.2 Extended hints

Eden's extended hints allow motivated developers to pass application-specific knowledge to the runtime. For example, an application can trigger prefetching by using `rdahead` to specify a number of batched pages to read either immediately before or after the hinted address. When the `size` of the hinted region is large, read-ahead can be extremely useful as the entire region can be fetched in a few `rdahead`-size chunks, amortizing the cost of page faults. Note that unlike `size`, `rdahead` is only suggestive and does not necessitate fetching all the pages in the window (e.g., when necessary page locks cannot be obtained). Eden also lets the application specify a page's eviction priority with `ev_prio`, which enables cache separation similar to AIFM's non-temporal hints. In addition, developers can use the `seq` flag to reduce the overhead of hints for workloads that scan data sequentially (e.g., array lookup in a `for` loop). When the `seq` flag is set, the runtime saves the last page accessed by a hint and skips the hint-handling process if the next invocation of that hint points to the same page.

Extended hints enable Eden to convey far more information than what is available to existing prefetch and eviction policies that run inside the kernel. Existing prefetching policies in Linux tend to rely on detecting sequential accesses or using more sophisticated algorithms to detect more complex access patterns [12]. In contrast, when an application knows (even parts of) its memory-access pattern, it can use extended hints to directly convey this information to Eden. The API could be extended to convey access patterns as well (for example to specify non-contiguous pages to prefetch) but we defer a full exploration to future work, focusing instead on leveraging deliberately limited annotation.

3.2 Handling page faults

In Eden, there are two paths for handling page faults, depending on whether the remote access is detected by a software or hardware guard. The *hinted path* corresponds to instances where the address is signaled by a hint before the program attempts to access it—thus, the fault is detected by Eden's software guards and no trap to the kernel is required. The *unhinted path* is followed if the application actually traps to the kernel due to a hardware guard, i.e., traditional page fault.

In both cases, if the page is not present, Eden's runtime fetches the page—or pages, in the case of extended hints—from far memory via RDMA and uses the `UFFDIO_COPY ioctl` to allocate a physical page, copy the fetched data in, and map it in the process' page tables. If the fault is due to missing write privileges, the runtime uses a `UFFDIO_WRITEPROTECT ioctl` to remove write-protection on the page. (The expensive `ioctl` calls are necessary in both hinted and unhinted paths because, unlike pure app-integrated systems, Eden needs to support hardware guards as well. While Eden is in control of what pages are mapped locally, the kernel still controls the page tables and translation hardware that support the hardware guards. Hence, when evicting pages, Eden must unmap them from the page tables.) However, the two paths differ in several aspects including which core handles the fault and whether detecting the fault involves context switching to the kernel.

Hinted path. Eden expects to handle the majority of page faults via the hinted path. When an application invokes Eden's hint API (i.e., `hint_fault(...)`), it calls into Eden's runtime, which implements a software guard. The runtime computes the page-aligned address and looks up the page in its own internal data structure of page metadata. If the page re-

quires that write-protection be removed, the runtime issues a synchronous `ioctl()`. Otherwise, if the page is present, the runtime returns to the application immediately. This process completes entirely on the same core as the application.

If the page is missing, the runtime fetches it from far memory and runs another user-level thread while the page is being fetched (unless the hint specifies otherwise). First, the runtime marks the current user-level thread as blocked. Then it initiates the RDMA read for the page. While the page is being fetched, Eden's runtime can switch to a different user-level thread and run it. This enables Eden to effectively utilize CPU cycles while a page fetch is outstanding, in contrast with existing systems such as Fastswap that busy wait [13]. When control returns to the runtime (e.g., the thread yields, exits, or issues another hint), it polls for any completed RDMA operations on its local queue. On a page-fetch completion, the runtime `UFFDIO_COPY`s the page and resumes the original user-level thread. While issuing the `ioctl()` still requires a context switch to the kernel, hinted faults only require one such context switch, whereas unhinted faults (described below) require two. In addition, the copy happens on the same core, warming up the cache for the application thread, unlike in the unhinted path.

Unhinted path. Hints may not catch all page faults in Eden, so regular page faults can still occur. This can happen if a developer instruments most of—but not quite all of—the potential fault locations, or the system experiences unexpected memory pressure. Eden handles these faults in the control core. In Eden, each application's memory is registered with a single `userfaultfd` file descriptor (§4). When an unhinted fault occurs, traditional hardware guards detect the fault and trap to the kernel, which then writes an event to the `userfaultfd` file descriptor. The control core polls this descriptor and receives the event. It resolves the fault in manner similar to the hinted path with a key difference: Because the control core does not run application threads, it handles other faults or memory reclaim (§3.3) while a page fetch is outstanding. When unhinted faults are rare, the control core is not a bottleneck.

Concurrent faults. It is possible that while a fault (either hinted or unhinted) is being resolved, another user-level thread faults on the same page. The runtime must not re-execute the fault-handling logic for the second fault, because this would trigger an extra page fetch and could potentially overwrite the page of memory after the first thread had already resumed. Eden handles this by including a lock in its page metadata, which the runtime acquires when it starts working on a page fault to ensure concurrent faults are resolved exactly once. When the runtime encounters a concurrent fault, it places the fault on a local waiting queue and proceeds to do other work. When the first fault finishes, the runtime sets the page status bits in global page metadata. Whenever a core returns to the runtime, it checks for completed faults and releases the blocked threads.

Fault stealing. In the common case, Eden resolves hinted faults on the core that triggered them. However, when load is imbalanced or deadlocks occur, Eden can also resolve faults on a different core via work stealing. Load can become imbalanced if an application thread runs for a long time without yielding (Eden inherits Shenango's non-preemptive cooperative threading model [37]) while another core sits idle. Deadlocks can arise due to asynchronous page fault handling where application cores block while waiting for locked pages to be handled by other cores that in turn wait on the former cores. Eden addresses both of these challenges with fault stealing. Faults can be stolen (served) not just by other application cores, but by the runtime on the control core. This is necessary for correctness as all the application cores may block. We ensure progress because the control core never blocks, so any faults waiting past a timeout get handled.

3.3 Memory reclamation

In Eden, both the control core and application cores participate in memory reclaim; this is similar to Fastswap [13], which has a dedicated "reclaimer core". Reclaim involves evicting enough cold pages to maintain the fraction of empty page frames at a configurable threshold. (We use 1% by default.) Most memory reclamation in Eden happens on the control core, since only a small portion of its time is consumed with handling unhinted faults. In some instances, however, the control core may become overwhelmed. In this case (i.e., when there are no empty frames), a faulting core will perform its own reclamation (i.e., instead of running another user-level thread while a page fetch is outstanding).

Regardless of which core performs reclamation, the runtime first must identify which page(s) to reclaim by running a reclaim policy (§4). Once the runtime has selected a page to evict, it first locks the page to check whether it is dirty. (Eden initially write protects pages pulled in by read faults and sets the dirty bit on a write hint or a `userfaultfd` write notification.) If the page is dirty, Eden write protects it using `UFFDIO_WRITEPROTECT` so that it cannot be modified during eviction. Then it copies the page to a buffer and writes it out to far memory using RDMA. Once this is complete—or if the original page was clean to begin with—the runtime removes the page from process memory with the `madvise(MADV_DONTNEED)` syscall.

3.4 Vectorized syscalls

The Userfaultfd syscalls that Eden relies on for memory reclamation (specifically, for write-protecting and unmapping pages), scale poorly due to the need to flush TLBs across cores (§2.2). These operations limit the rate at which Eden can possibly evict pages, and therefore the rate at which Eden can fetch pages as well. As currently implemented in Linux, these operations support batching of contiguous ranges of pages, thereby amortizing the overheads of context switching in and out of the kernel and flushing TLBs. However this is not particularly helpful in our context because the set of pages to be

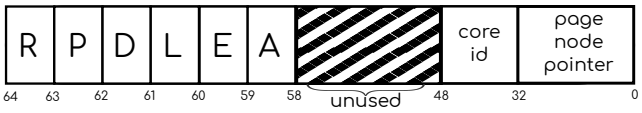

Figure 5: Eden's page metadata format. Each page has six bitflags (Registered, Present, Dirty, Locked, Evicting, Accessed), the ID of the core managing any outstanding faults, and a pointer to the page node for pages present locally.

reclaimed simultaneously is rarely contiguous. Thus Eden introduces vectorized variants of `UFFDIO_WRITEPROTECT` and `madvise(MADV_DONTNEED)`, which enable Eden to reclaim multiple non-contiguous pages in a single syscall and a TLB flush. This significantly improves the scalability of these operations, as shown in Figure 8(a) of our evaluation.

4 Implementation

Our prototype builds on Shenango [46], a user-level thread scheduler written in C/C++. The Eden runtime extends Shenango in several ways. It adds 6,296 lines of code that implement: an `LD_PRELOAD` library to provide transparent support for the standard memory allocation API; fault handling, work stealing and memory reclamation; and page management. Note that while we based Eden on Shenango, Eden can be easily extended to run with other "two-level" thread schedulers like Arachne [40] or GoLang [22]. In addition, Eden includes an RDMA network stack (605 lines) and a far-memory RDMA server (1,304 lines). Finally, we implement a stand-alone tool to identify page fault locations [14] and a patch for the Linux kernel to support vectorized syscalls.

Memory management. Eden intercepts memory allocation functions and forwards them to to `jemalloc` [18], which generates easier-to-manage batched page-sized allocations. Eden supports mapping multiple far memory segments from one or more memory servers as separate memory regions that are registered with `userfaultfd`. Eden maintains a single metadata array per segment with 64-bit per-page entries (shown in Figure 5) that hold page flags, an index to the page node in the reclaim page lists (that is valid only if the page exists locally), and a few bits to save the current application core ID when a fault is in progress. The core ID allows the control core to perform targeted stealing and resolve deadlocks (§3.2). In terms of memory overhead, Eden requires both a 64-bit entry for every mapped page and an additional 24-B page node for resident pages; e.g., supporting 256 GB of far memory with a 64-GB local cache requires 750 MB (∼1%) for Eden's bookkeeping using standard 4-KB pages.

Reclaim policies. Even Eden's basic hints enable more sophisticated reclaim policies than existing kernel-based systems. We implemented four reclaim policies; applications are free to choose the policy that provides the best trade-off for them. With *default*, Eden does not use hints for page hotness and just maintains one big page list that it pops off candidates from. *Second chance* is similar to the Linux kernel's default policy, where hints set a hot bit and Eden maintains two lists and bumps or evicts a page depending on the hot bit. With *LRU*, hints update a timestamp on the page on each access which Eden uses to either evict or bump the page to any of the top $(N-1)$ lists based on how recent the last access was, where N is the configurable number of lists. Finally, with *priority*, Eden lets applications set different priorities for pages faulted in through hints (via the `ev_prio` argument). Eden maintains a configurable number of priority levels for each eviction page list, which are appended to based on the priority set by hints (default is zero for low priority). When evicting, Eden starts with the higher priority levels. This policy generalizes AIFM's non-temporal dereferences, which reclaims an object immediately after its `DerefScope` ends [42].

Fault tracing tool. To find which source code lines should be hinted, we provide a simple tool (also used in [14]) that outputs faulting code locations and the fraction of total page faults they trigger. Like Eden, the tool registers application's memory with `userfaultfd` and records the call stacks on each page fault. While tools like `ftrace` can also be used to collect traces, our tool can run as a part of Eden and help the developer iteratively with the hinting process; when running with Eden, the tool will only record the unhinted faults, and generate flame graphs that highlight only the parts of the application that are yet to be hinted. In future work, we could extend the tool to help detect misplaced hints (e.g., by checking to see if each hint results in page fetches) and automatically suggest hint extensions like `rdahead` and `seq` based on profiled access patterns at the hinted faulting locations. The tool is openly available at `https://github.com/eden-farmem/fltrace`.

5 Evaluation

Our evaluation seeks to address the following questions:

1. How much developer effort does Eden require? (§5.2)
2. How does Eden perform for different applications, and how does it compare to Fastswap, AIFM, and TrackFM? (§5.3)
3. How much do each of Eden's individual elements contribute to its performance? (§5.4)

We answer these questions using four C/C++ far-memory applications: The synthetic Web service and DataFrame library [2] used in the AIFM paper [42], Memcached [33], and an implementation of parallel sort [44]. We use the first two to compare Eden's mechanisms for leveraging application-specific information against those of AIFM (and TrackFM in the case of DataFrame). The latter two represent common real-world workloads. (For brevity, we discuss parallel sort in the Supplementary Material (§A.4), as the results are qualitatively similar to the DataFrame benchmark.)

5.1 Experimental setup

We evaluate Eden and Fastswap on a testbed of three Linux servers, each equipped with a single 100-Gbps Mellanox

App	LoC	# Hints	Coverage	Extensions	Reclaim Policy	Max gain%	Benefits from
DataFrame [2]	15k	11	97.3%	`rdahead,seq`	Default	37%	Read ahead
Syn Web Service [42]	1.1k	4	> 99%	`ev_prio`	Priority	178%	Priority reclaim
Memcached [33]	43k	2	> 99%	-	Second-chance	104%	Latency hiding
Parallel Sort [44]	1.2k	6	> 99%	`rdahead,seq`	Default	19.4%	Read ahead

Table 1: For each application, we show the total lines of code (LoC), the number of hints we add (# Hints), the percentage of faults covered by the hints, any hint extensions employed, the reclaim policy (§4) employed, the maximum relative performance gain over Fastswap at any local memory, and the main reason for that speedup.

ConnectX-5 NIC and two 14-core Intel Xeon Gold 5120 CPUs clocked at 2.20 GHz and provisioned with 94 GB of DRAM per socket. We run on a single NUMA node and disable hyperthreading, TurboBoost, C-states, and CPU frequency scaling. One server plays the role of both the far-memory server and, for certain applications, the client traffic generator. The applications under test run on one of the other two servers: one is configured for Eden and runs Linux 5.15, the other for Fastswap which requires Linux 4.11. We disable page-table isolation (PTI) because it is not available until 4.15, although Eden's performance is similar with PTI enabled.

Both Eden and Fastswap use a dedicated core for memory reclamation, placing them on equal footing. For Eden we use the reclaim policy that worked best for each benchmark (listed in Table 1) while Fastswap uses the Linux default. We employ eviction batching (32 pages) and set the eviction threshold (the local memory usage at which the control core begins to reclaim memory) to 99% of local memory. For Fastswap, the analogous eviction batching parameter is hardwired in the kernel with the reclaim core activating when the memory is above the limit, and other cores joining in if the excess memory use exceeds 2,048 pages.

We run AIFM and TrackFM in the same configurations as their published artifacts on Cloudlab [1, 3]. AIFM requires manual porting and we use only benchmarks ported by the AIFM authors. To facilitate comparisons across all systems, we normalize the results and report the throughput (or runtime) of each system as a fraction of its performance in a fully local baseline configuration, i.e, when no page faults are required. For Eden we measure baseline performance before adding hints (so the normalized numbers incorporate any hinting overhead). In the case of AIFM and TrackFM, we normalize to the performance of versions of the application programs that do not link these libraries to account for their dereference overheads.

5.2 Developer effort

Our analysis in Section §2.3 shows that, for many applications, we can achieve good coverage of potential page faults with a small number of faulting locations. Table 1 summarizes the hinting effort for the applications we evaluate by showing the number of (single-line) hints added, the resulting page fault coverage, and the way hints are extended to benefit each application. We find that we are able to hint faults in Eden for all four of these applications with a handful of hints (at most 11). For DataFrame, the percentage of unhinted fault occurrences is at most 2.7% and for the rest of the applications it remains less than 1%. In the rest of this section, we detail the hinting process for DataFrame as it is the most complex application we consider and allows direct comparison to the effort required for an AIFM port. The process was much more straightforward for the other applications which we omit due to space constraints. (We summarize the analogous process for Memcached in the Supplementary Material (§A.2)).

DataFrame and AIFM porting. DataFrame [2] provides a Pandas-like C++ library for common data-analysis tasks like slicing, grouping, and aggregating table-based in-memory data structures. Tables are stored in columnar format with STL vectors for each column, and, as such, most data accesses occur through vector indexing. The AIFM authors report changing 1,192 lines of code, or 7.7% of the total codebase to port the library to far memory; most of these changes replace the STL vectors used to implement table columns with custom, far-memory-friendly vectors provided by AIFM's customized STL library. Instead of transforming the data structures, TrackFM [45] (like Eden) interposes on all memory allocations using a pre-defined object size for the entire program. It then uses LLVM-based compiler passes to transforms all pointers, while applying a loop-chunking optimization to reduce dereference overheads which is necessary for this heavy array-scanning application. Because NOELLE [32], TrackFM's LLVM C++ frontend, does not currently support certain C++ semantics in its loop analysis, the authors first port the application to C. (Mira's authors [26] reported a similar effort to simplify DataFrame's C++ constructor and list initializations for which their frontend [34] had limited support.)

Hinting DataFrame for Eden. For Eden, we took the original, unmodified DataFrame library [2] and traced faults when running with AIFM's analytics benchmark based on NYC Taxi trip data. 23 distinct code locations are responsible for 95% of DataFrame's faults (Figure 2) but we are able to presage two thirds of the faults by adding hints for just the top-three faulting locations. These locations are highlighted by our tool in a list of top faulting locations ordered by fault density. (Figure 10 in the Supplementary Material shows an example fault-density flame graph for DataFrame). Out of the 23 locations, 13 raise allocation faults for newly created column vectors. Because Eden controls memory allocations, we optionally support pre-faulting small allocations, i.e., those less than 100 MB, at allocation time to avoid the need to add

```
679 new_col.reserve(std::min(sel_indices.size(), vec_size));
680 hint_fault(new_col.data(),new_col.size(),mut=True,rdahead=MAX);
681 for (const auto citer : sel_indices)
682   hint_fault(&(*citer), seq=True, rdahead=MAX);
683   const size_type index =
684       citer >= 0 ? citer : static_cast<IT>(indices_size) + citer;
685   const auto citer = sel_indices[i];
686   const size_type index =
687       citer >= 0 ? citer : static_cast<IT>(indices_size) + citer;
688   if (index < vec_size) {
689       hint_fault(&vec[index], seq=True, rdahead=MAX);
690       new_col.push_back(vec[index]);
```

Listing 1: Lines 680, 682 and 689 are the hints we add to cover the two top faulting locations in DataFrame. Line 680 hints the write faults for the `new_col` vector in 690, whereas 682 and 689 hint the read faults for the lines that immediately follow them. The latter two hints are extended with `rdahead` and `seq` as they access a contiguous vector in a loop.

explicit hints. With DataFrame, this feature obviates the need to explicitly hint all but one allocation location, leaving only 11 locations to hint.

The top-three faulting locations fall in the selection operator where new columns are generated out of existing ones, and involves a lot of data copying; Listing 1 (without the highlighted green lines) shows the portion of original code where a new column is written to from an existing one (Line 690 sees two faults) based on an index vector (accessed in Line 683 that sees another fault). Unsurprisingly, this is one—and by far the most impactful (c.f. [42, Fig. 8])—of the operations that AIFM offloads to the memory server. We add two hints to read in the index and data vectors, and a third to allocate the column vector in one go.

Extended hints. Each of these hints are inside C++ vector scans, prompting us to add `rdahead` to bring in more pages and `seq` to reduce hinting overhead in each instance. (As we show in Section 5.3.1, this enables Eden to perform on par with AIFM.) Overall, our changes to the application include 11 hints, all similar to those above, each incurring an extra line of source code. With the assistance of our tracing tool, it took the first author only a couple of hours to insert the hints and no time was spent in debugging.

5.3 Performance benefits

We compare the performance of Eden to AIFM, TrackFM, and Fastswap [13], a state-of-the-art kernel-based far-memory system. We evaluate each of our four applications with Fastswap, two with AIFM, and one with TrackFM. Eden consistently outperforms Fastswap, due to the benefits enabled by its hints; for each app, a single mechanism (listed in the last column of Table 1) predominantly drives the performance improvement. Eden's hints can capture most of the benefits of AIFM with many fewer code changes. Specifically, for DataFrame, Eden's hint-level read-ahead was enough to match AIFM's data structure-specific prefetching. In AIFM's Synthetic benchmark, Eden's hint-level eviction priority matched AIFM's data structure-level cache separation. We only evaluate the Synthetic and DataFrame applications on AIFM because the effort of porting other applications to AIFM is high and out of scope given our limited expertise with AIFM. Eden bests TrackFM's DataFrame performance due to the latter's need to insert software guards around every potentially remote access as opposed to Eden's few hint locations.

5.3.1 DataFrame

We start with the performance of the DataFrame application described in §5.2. We use the benchmark provided by the AIFM authors [1], varying the local memory between 3 GB and 31 GB, the workload's full working set size. The leftmost graph of Figure 6 shows the overhead of running DataFrame on Fastswap, AIFM, TrackFM, and Eden in fully local configurations. At 100% local memory, AIFM incurs a slowdown of 30% (85 seconds normalized to the 65-second baseline on AIFM's testbed) because of overheads on pointer dereferences, while TrackFM's overhead is even higher (more so than reported in their paper [45]) because TrackFM runs a C-ported version of the application while all the other systems run the original C++ version. Eden incurs a 12% (82 seconds normalized to the 73-second baseline on Eden's testbed) overhead due to its localized hints. Fastswap incurs essentially no overhead due to its exclusive reliance on hardware guards.

The second graph of Figure 6 shows the normalized runtime of DataFrame on each system as a function of available local memory.[4] Fastswap's performance degrades significantly due to page-fault overheads whereas Eden, TrackFM, and AIFM degrade more gradually. As local memory becomes extremely constrained, Eden's performance deteriorates slightly due to an increased prevalence of unhinted faults (rising to 2.7% at 9% local memory); yet even then Eden's performance remains close to that of AIFM—achieving a normalized runtime 37% faster than Fastswap—because Eden is able to amortize page-fault costs with targeted read ahead and eviction batching. For example, with only basic hints Eden's performance at 22% (5 GB) local memory is 4× (296 secs) the baseline (not shown), compared to Fastswap's 2.7×. With eviction batching Eden improves to 2.9× (214 secs)—comparable to Fastswap—and adding targeted read ahead drops Eden's runtime to the final 1.75× (127 secs), competitive with AIFM's 1.67×.

5.3.2 Synthetic Web service front end

We demonstrate Eden's ability to perform application-informed reclaim using the Web service described in the AIFM paper [42]. This application services each client request with a series of lookups: it retrieves a 4-byte user ID by doing several lookups (32 in AIFM's benchmark) into a hash table and then an additional lookup retrieves a large (8-KB) object from a user data array. Both objects are compressed with Snappy [21] and encrypted before being sent back to the client. The workload is designed to stress the hash-table data, which is prone to cache evictions by the much larger user data

[4] This is the experiment depicted in Figure 7 of the AIFM paper [42], but we (like [45]) plot normalized runtime because the benchmark does not specify how to compute normalized throughput.

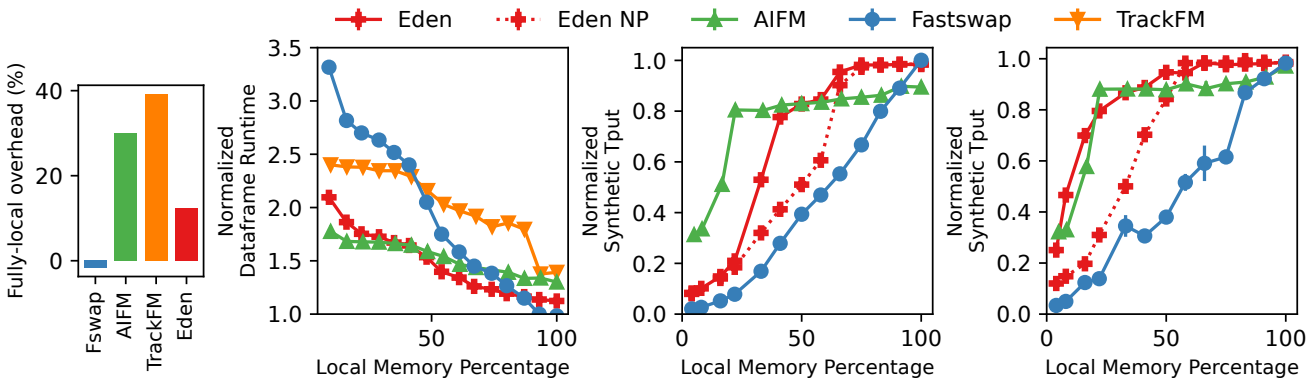

Figure 6: Performance comparison with two AIFM-ported applications. From the left, the first graph shows the performance overhead of DataFrame running on Eden, TrackFM, AIFM, and Fastswap in fully-local configurations compared to its native performance, highlighting the much higher overheads of object-based approaches. The second graph shows the runtime of DataFrame as a function of local memory normalized to the native performance. The third graph similarly shows the normalized throughput of AIFM's synthetic Web server on Eden with and without (Eden NP) priority hints, AIFM non-temporal, and Fastswap. The rightmost graph shows the same experiment with 1,600-byte hash entires.

objects, thus hurting performance under oblivious reclaim policies. AIFM's "non-temporal" feature isolates hash-table data from the user data to avoid cache evictions of the former. Eden deliver similar benefits with priority-reclaim hints (§4).

To facilitate comparison to Eden and Fastswap, we "backport" the application to transparent page-based far memory by replacing AIFM's custom far-memory data structures with standard variants, including the "local-only" hopscotch hashtable available in the AIFM repo [1]. Running the backported application through our fault-tracing tool with AIFM's workload identifies two faulting locations in the hash table and one location for the user-data array access. As a baseline (plotted as "Eden NP"), we add 2 basic hints to the Web service, one before accessing the bucket structure in the hopscotch-hash lookup, and a second ahead of accessing the object itself (the key-value objects are stored separately from the buckets). We consider the workload from the AIFM paper: 128 M hash-table entries and 2 M user objects, resulting in a ∼26-GB memory footprint. Client requests are Zipf(0.8) distributed.

The third graph of Figure 6 plots the normalized performance of Eden, Fastswap, and AIFM, each with 10 cores. At 100% local memory, both Eden and Fastswap achieve normalized throughput close to 1.0 (520 KOPS in absolute terms). However, AIFM incurs overhead due to dereferencing its smart pointers; in this workload this occurs much more frequently than hints in Eden, yielding 10.6% lower throughput for AIFM (385 KOPS normalized to 430 KOPS vanilla performance on AIFM testbed) in fully local configuration.[5] At lower local memory where paging is required, Fastswap degrades roughly linearly, down to a normalized throughput of 0.02 (10.7 KOPS) at 4% local memory. Eden's throughput degrades as well, but remains higher than Fastswap (43 KOPS). Unsurprisingly, AIFM degrades more gracefully than either page-based system, maintaining roughly stable performance until about 20% local memory, at which point almost all local memory is required for the hash table.[6]

To mimic AIFM's non-temporal feature, we prioritize reclaim of array data in the array-access hint using Eden's `ev_prio` setting (plotted as "Eden"). Under this configuration, Eden's performance remains competitive with that of AIFM down to about 40% local memory, as the cache miss rate is low (< 1 miss per request for both) and there is no I/O amplification as all the misses are for page-sized array items—hence, the network read I/O (not shown) for both systems is similar at 15 Gbps. Eden also sees the highest normalized performance gain of 0.49 (or 178%) over Fastswap at this setting. As local memory becomes further constrained, both systems begin evicting (4-B) hash-table entries, causing I/O amplification for Eden. Specifically, AIFM is able to reference far memory on a per-object basis, while Eden must pull in—and evict—entire pages at a time, resulting in less efficient local memory utilization. For example, at 8% local memory, AIFM sees an average of 13 misses per request and generates a network I/O rate of 6 Gbps. Eden sees a much higher I/O rate with 1.2 million page faults at 40 Gbps (which saturates our NIC, explaining the performance bottleneck) due to both a higher miss rate (23 per request) and page-sized I/O (i.e., amplification). Recall that each request in this benchmark can see up to 33 far memory lookups.

To isolate this effect, we re-run the experiment with larger hash-table entries. Specifically, instead of a 4-byte entry as before (for which the memory allocator uses a 32-B slab), we use a 1,600-byte entry (requiring a 2-KB slab) while maintain-

[5] Note that the original AIFM evaluation uses the far-memory-capable variant as a baseline, leading to higher normalized throughput at all local memory percentages presented in their paper [41].

[6] AIFM employs hand-crafted look-aside tables in the smallest (<20%) memory configurations to avoid spilling the hash table to far memory.

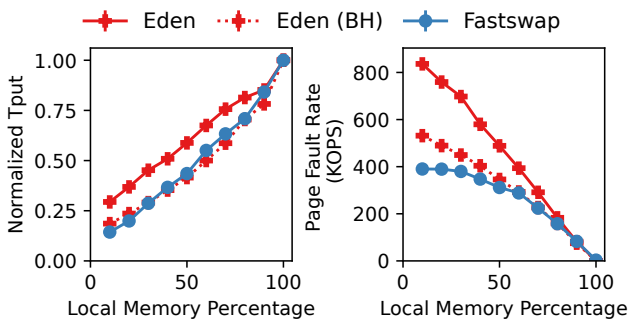

Figure 7: Memcached performance as a function of the fraction of the working set that can fit in local memory. The left-hand graph shows the maximum achievable throughput on both Eden (red; blocking hints in dashed red) and Fastswap (blue) normalized to their respective fully local configurations. The right graph shows the corresponding page fault rate for the same experiment.

ing total hash-table size by decreasing the number of entries to 2 M. In this configuration (shown in the rightmost graph of Figure 6), the normalized performance of Eden and AIFM is similar. Hence, we conclude that Eden's poor performance (relative to AIFM) on the original synthetic workload is due to the interaction of Eden's page-based granularity and the workload's lack of (spatial) locality.

5.3.3 Memcached

Next we consider an application that benefits from our user-level scheduler that hides the latencies more effectively than the kernel: memcached. We add only 4 hints using our tracing tool, 3 to cover item search in the hash table in the GET path and an extra write-fault hint in the PUT path. (More details are in the Supplementary Material (§A.2).) To maximize throughput we use a read-only workload and preload memcached with 30M (24-byte, 512-byte) key-value items, resulting in a ∼8-GB memory footprint. We issue client requests based on a Zipf(1.0) distribution.

Figure 7 shows the performance on 5 cores in comparison to Fastswap. We plot the average across multiple runs; the standard deviation is below 2% in all cases, and usually well below 1%. The leftmost graph plots the throughput of each system normalized to the performance of its fully local baseline (4.45 MOPS for Eden and 3.74 for Fastswap). Because memcached requires almost no computation to service each request, its throughput drops dramatically as memory pressure increases. Eden degrades more gracefully than Fastswap, maintaining 29.4% of its baseline performance with ony 10% local memory as compared to 14.4% for Fastswap—an improvement of 104%. (In absolute terms, the gap is even larger: Eden delivers 1.31 vs. Fastswap's 0.54 MOPS.) For this workload, Eden extracts significant additional throughput from the increased concurrency of its lightweight threads (memcached services each request with a separate thread), allowing it to process client requests in parallel on each core, resulting in a dramatically higher page-fault throughput (836 KOPS) than Fastswap (312 KOPS), as shown in the center graph. To isolate this effect from Eden's other features we also measure the performance when Eden spins during fetches ("Eden (BH)") rather than scheduling another thread.

5.4 Microbenchmarks

In this section we isolate the performance benefits of different components of Eden's design through microbenchmarks.

Vectorized operations First we evaluate the performance of Eden's vectorized operations by repeating the experiment from Section §2.2, for the write protect (`UFFDIO_WRITEPROTECT ioctl()`) and unmap (`madvise(MADV_DONTNEED)`) operations. The leftmost portion of Figure 8 shows that with a batch size of 16, Eden's vectorized operations achieve 5.4–6.6× and 3.7–5.7× as much throughput, respectively, as Linux's standard versions. This is because batching enables Eden to amortize the overhead of context switching in and out of the kernel and batch TLB flushes. Eden's vectorized operations are sufficient to sustain line rate of page operations with 100-Gbps NICs, with 1 core for write protecting and 6 for unmapping pages.

Page fetch rate Next we evaluate the maximum rate at which Eden can fetch pages, with eviction disabled. We run a simple multi-threaded benchmark that first registers a unique, large memory region on each core, then touches every page and evicts it to far memory. Next the benchmark accesses the evicted pages sequentially such that each access incurs a major page fault (but local memory is sufficient to never trigger reclaim). We evaluate three systems: Eden, Eden without hints, and Fastswap.

The second graph in Figure 8 shows that, without hints, Eden is bottlenecked by the control core (which must handle every fault), and cannot sustain high throughput. However, with hints, Eden approaches 2 MOPS, achieving 38–88% more throughput than Fastswap, with the same number of cores. This demonstrates the benefit of non-blocking hints, which allow Eden to continue the microbenchmark and initiate additional asynchronous page fetches.

Fetching and evicting Now we adapt the sequential benchmark above by restricting the amount of local memory available so that every page access triggers both a page fetch and an eviction. We evaluate the performance of two reclaim configurations: non-dirty reclaim and dirty reclaim (with write-back) by touching pages with reads and writes respectively, on initialization. Eden uses a batch size of 16. The third graph in Figure 8 shows that throughput with reclaim decreases significantly for both Eden and Fastswap compared to without reclaim (second graph), because reclaim adds more work to every page fault. Though Eden incurs additional kernel crossings during reclaim for write protecting (when the page is dirty) and unmapping, its vectorized APIs enable it to amortize these costs across several pages. In addition, Eden benefits from overlapping the eviction work with page fetches, allowing it to achieve higher throughput than Fastswap.

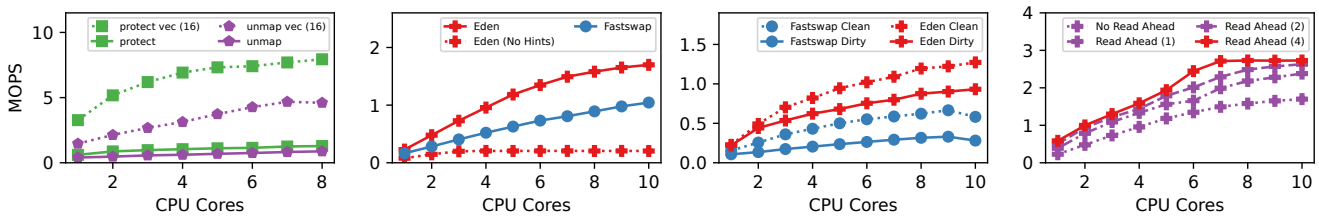

Figure 8: The performance of Eden's vectorized write protect and unmap implementations compared to default Linux (c.f. Figure 1) (a). On a sequential microbenchmark (b,c,d), Eden achieves higher throughput than Fastswap when just fetching pages (b) and both fetching and reclaiming pages (c). In addition, Eden benefits significantly from hints (b) and read ahead (d).

Read-ahead performance Finally, we evaluate the benefits of leveraging application-specific knowledge with Eden's read-ahead feature in its extended hints. We repeat the microbenchmark shown in the third graph ("Eden Clean") with varying amounts of read-ahead, so that Eden can fetch multiple pages in a single RDMA read. The right graph in Figure 8 demonstrates that, with this sequential workload, read ahead improves throughput significantly, saturating the 100-Gbps NIC at high core counts.

6 Related Work

Far memory systems vary widely in terms of programmer effort. Solutions based entirely on transparent hardware guards have been implemented at both the hardware [16, 23, 31] and kernel [9, 10, 12, 13, 19, 24, 29, 39, 43, 50, 51] level, but leave potential application and workload-specific optimizations on the table. In contrast, some app-integrated systems [8, 42, 53] eke out those gains through software guards at the cost of heavy application modifications. Other recent app-integrated systems like TrackFM [45] and Mira [26] use compiler help to automate application changes however they still suffer from significant overhead of their software guards and bring in some practicality concerns like requiring source code for all external dependencies.

Like Eden, DiLOS [52] leverages hardware guards while moving page handling into the application to enable specialized swap caching policies and app-specific optimizations; however, DiLOS employs a LibOS approach to handle hardware guards in the application and cannot run applications natively on Linux. Moreover, while DiLOS's design obviates basic hints, it can still benefit from Eden's extended hints.

Hints, whether specified by the user or a compiler, have long been used to supply prefetching information [35, 38, 47, 49]. Eden's hints go further by both preventing page faults and specifying reclaim behavior. In that way, Eden's hints are semantically analogous to some `madvise()` options. For example, Eden's read-ahead hints are similar to `madvise()` with `MADV_POPULATE` and reclaim priority hints are similar to `MADV_COLD` but with more levels. Critically, Eden's hints are much lower overhead than `madvise()` calls, allowing them to be used more generously in the code. Moreover, `madvise()` guidance is input to the kernel's fixed swap implementation whereas Eden's policies are much more flexible.

7 Conclusion

Eden represents a new point in the design space of far-memory systems: it combines software and hardware guards to intercept accesses to remote memory. Eden uses software guards at the few code locations where most of the remote accesses tend to occur, while relying on hardware guards elsewhere in the application. This approach provides good performance—better than paging-based approaches (pure hardware guards) and comparable and sometimes better than prior app-integrated systems (pure software guards).

It does not, however, tackle a few remaining limitations with page-based accesses. First, for applications that work with small objects and poor locality, managing memory at page granularity can result in overhead due to cache and I/O amplification (as we saw in § 5.3.2). While object-based designs address this issue, such benefits may be easily offset by their high guard and bookkeeping overheads (e.g., object tracking for eviction), which also grow with smaller objects [17]. Second, Eden's far memory handling (miss path) is slower than pure app-integrated systems, especially when Eden triggers a hardware guard and traps into the kernel; in fact, here Eden is even slower than other existing paging-based systems due to its use of `userfaultfd`.

On balance, we believe Eden strikes a useful middle ground between completely transparent page-based systems and existing app-integrated designs. Our approach reduces programmer effort and the overhead of software guards while still enabling application-specific optimizations, which we find more than compensate for the remaining overheads of our page-based design.

Acknowledgements

We thank our shepherd, Sam Kumar, and the anonymous reviewers for their valuable feedback. We also thank Tanvir Ahmed Khan and Baris Kasikci for sharing the dataset [48] we used in our analysis, and Zhenyuan Ruan and Brian Tauro for their help with reproducing the AIFM and TrackFM numbers respectively. This work was conducted under a sponsored research agreement between UC San Diego and VMware Research.

Table 2: Application suite for fault location analysis.

A Supplementary Material

We provide additional information about the applications used in our fault analysis (§A.1) and the hinting process for two of our evaluated applications (§A.2 and §A.3).

A.1 Applications

Table 2 lists the number of applications that we evaluate per category and the lines of code and maximum resident set size (RSS) for each.

PARSEC: PARSEC [15] is a benchmarking suite of compute-intensive applications designed to stress parallel performance on multi-core CPUs. We include a subset of these applications which are more HPC focused. We run each with 8 threads and its *native* dataset.

KVS: We evaluate four key-value store applications: two in-memory caches (Redis [6] and Memcached [33]) and two persistent data stores (Rocksdb [7] and LevelDB [5] with memory caches). We use the workloads from LK_PROFILE but increase the number of operations to at least a million, which yields a proportionally larger memory footprint.

Graph: We consider the CRONO graph benchmark [11], which consists of 10 independent multi-threaded graph algorithms. We use the inputs provided with the benchmark suite and run each program with 4 threads.

Other: Contains applications from our evaluation described in Section 5.3. Synthetic and DataFrame are ported from AIFM's evaluation [42], and psort is our own multi-threaded quicksort implementation.

A.2 Memcached hinting

Here we describe the hinting process for Memcached, a widely used in-memory key-value store. Key-value items are sorted into buckets indexed by the hash of the key, and each bucket is a linked list of items storing a key, its associated value, and other metadata like reference counts, locks, and list pointers. To look up a key, Memcached finds the bucket and walks the list until the key is found. We use a port by the authors of Shenango [46] where each request is served by a separate lightweight thread.

We run the executable on our selected workload (see Section 5.3) linked against our tracing tool. The tool produces a flame graph that visualizes the frequency and call stacks for a configurable fraction of faulting locations. Figure 9 shows the locations of 95% of all faults. The bottom-most layer corresponds to `main` and includes all faults, while the top-most layer shows the functions that include the faulting locations.

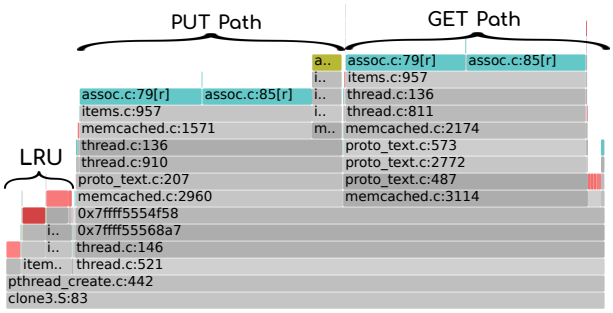

Figure 9: Output of our fault-tracing tool on Memcached.

```
82  item *ret = NULL;
83  int depth = 0;
84  while (it) {
85    hint_fault(&it->nkey);
86    if ((nkey == it->nkey) && (memcmp(key, ITEM_key(it), nkey) ==
          0)) {
87      ret = it;
88      hint_fault(&ITEM\_data(it), it->nbytes);
89      break;
90    }
91    it = it->h_next;
```

Listing 2: In Memcached we add a hint on line 85 to prevent the fault on line 86 and another hint on line 88 to indicate size of the data and ensure that all pages spanned by the item data are faulted in.

Read faults are colored blue, write faults are shown in red, and the protection faults (i.e., the page is present as read only) are greenish yellow. Based on this graph we see that there are two major faulting locations (`assoc.c:79` and `assoc.c:85`) which occur in both the PUT and GET code paths triggered by our 50:50 workload. These correspond to accesses for the bucket and the items. An additional protection fault location appears in the PUT path.

After identifying the faulting locations, Listing 2 shows how we add hints to the item access location, `assoc.c:85`. The fault occurs inside a `while` loop that traverses a linked list in a hash-table bucket: The value of the key being looked up is compared against the contents of the bucket by dereferencing a pointer (`it->nkey`); this dereference frequently causes a fault. We add a basic hint immediately beforehand to prevent this fault. The hint added for the second faulting location (`assoc.c:79`) is similar.

While these two locations cover the majority of faults, there are others. The (write-fault) locations on the far left correspond to accesses by the LRU-maintainer thread. Memcached tracks per-item access information to maintain LRU lists and evicts cold items under memory pressure, thereby dirtying memory even when serving reads. Additionally, it performs "item shuffling" between these lists and updates item pointers in the background, further dirtying memory. As a result, read-only workloads dirty pages at a rate similar to write-heavy workloads. Rather than insert (four additional) hints at these locations, we instead disable both of these unnecessary features in our tests—dramatically improving performance for both Eden and Fastswap—as the underlying far-memory sys-

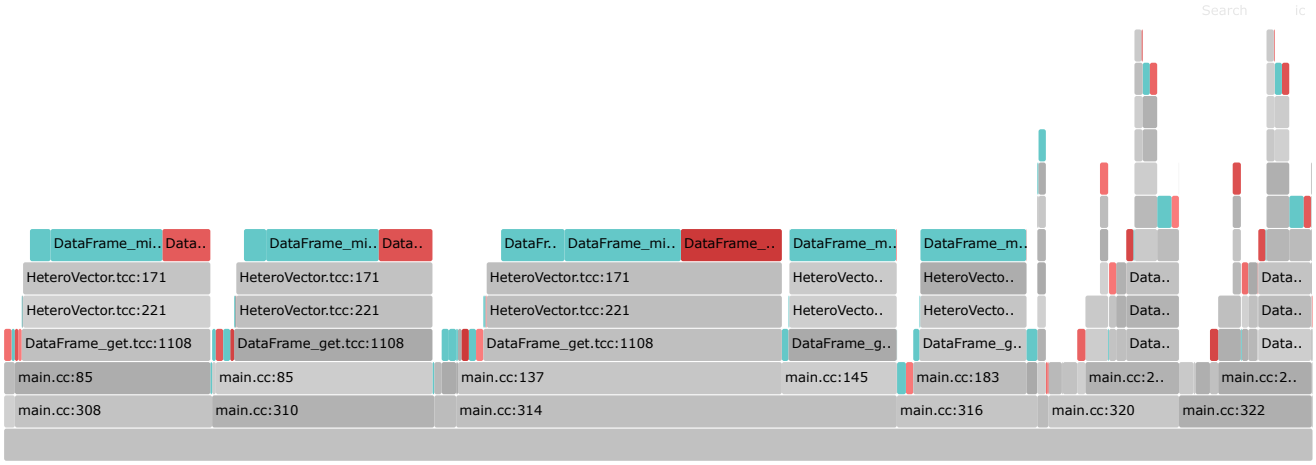

Figure 10: A flame chart for faulting code locations generated from DataFrame's entire execution.

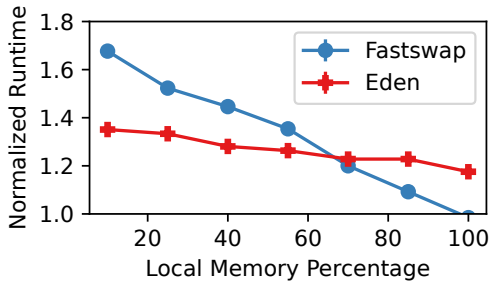

Figure 11: Performance of parallel-sort application with optimal read-ahead settings. The plot shows the run time (lower is better) normalized to the (unhinted) fully local configuration.

tem already takes care of access tracking and moving pages to and from far memory—obviating the need for such internal LRU lists. A number of other rare locations on the right happen when the item found falls across two pages and the page hint brings in only one of them, so we add an extra hint (`assoc.c:88`) for the matched item indicating the size of the item to bring in both pages in such cases.

A.3 DataFrame hinting

Figure 10 presents the fault-density flame graph for DataFrame generated by our tracing tool when running the analytics benchmark. The benchmark runs nine different analytics queries on the data, with seven segments in the flame graph showing the most time-consuming ones.

A.4 Parallel-sort evaluation

Here, we describe the evaluation of a sorting benchmark, in which, unlike the other applications we evaluated, each thread has its own distinct working set. Specifically, we implement parallel sorting with regular sampling [44]. This application first shards an input buffer to individual threads which each quicksort their shard. Then it merges the sorted shards together into an output buffer and copies it back to the input buffer. Because of the overhead of merging results, best performance is typically achieved by matching the number of threads to the number of CPU cores.

Our benchmark sorts 3B 4-byte integers (resulting in a 21-GB memory footprint). We implement two versions: one using Linux pthreads for Fastswap and another using Shenango threads for Eden. We add 6 hints (2 in quicksort, 3 in merge and 1 in copy-back stages) to the baseline code for Eden. The rightmost graph of Figure 11 presents the normalized runtime of both systems running on 10 cores, with Fastswap normalized to the fully local pthreads version and Eden normalized to the (unhinted) Shenango version. (The total runtime does not differ substantively between fully local pthreads and Shenango versions.) Eden experiences a 17.5% slowdown when fully local, most of it coming from the (unnecessary, in that configuration) hints in the partition function of quicksort. However, the (64-page) read ahead signaled through these hints starts helping as memory pressure increases. We plot Fastswap's performance with an optimal *system-wide* configuration of 7-page read ahead. Fastswap extracts less benefit from read ahead because prefetched pages are not mapped until accessed, triggering minor page faults for pages that are already present. As a result, Eden's runtime is 19.4% less than Fastswap's in the 10% local-memory case. Note that the hinting effort, hint extensions and the performance benefits are similar to those of DataFrame as both applications have similar array scanning patterns.

Achieving Wire-Latency Storage Systems by Exploiting Hardware ACKs

Qing Wang, Jiwu Shu*, Jing Wang, and Yuhao Zhang

Tsinghua University

Abstract

We present JUNEBERRY, a low-latency communication framework for storage systems. Different from existing RPC frameworks, JUNEBERRY provides a fast path for storage requests: they can be committed with *a single round trip* and *server CPU bypass*, thus delivering extremely low latency; the execution of these requests is performed asynchronously on the server CPU. JUNEBERRY achieves it by relying on our proposed Ordered Queue abstraction, which exploits NICs' hardware ACKs as commit signals of requests while ensuring linearizability of the whole system. JUNEBERRY also supports durability by placing requests in persistent memory (PM). We implement JUNEBERRY using commodity RDMA NICs and integrate it into two storage systems: Memcached (a widely used in-memory caching system) and PMemKV (a PM-based persistent key-value store). Evaluation shows that compared with RPC, JUNEBERRY can significantly lower their latency under write-intensive workloads.

1 Introduction

Fast Remote Direct Memory Access (RDMA) networks are driving us to build low-latency storage systems [1, 10, 18, 19, 42, 59]. First, RDMA NICs (RNICs) offload network protocol tasks, such as segmentation and checksum, freeing CPU cycles and thus reducing software latency. Second, the RDMA software stack bypasses the OS kernel, thus eschewing latency overhead from context switch and data copying. Finally, the latency can be further reduced by leveraging RDMA one-sided verbs (i.e., RDMA `WRITE`/`READ`) to access remote memory directly; it bypasses the remote CPU, thus detaching the remote CPU's software overhead from the critical path.

Protocol offloads and kernel bypass can bring latency reduction for *every* storage request. However, this is not the case for remote CPU bypass: it is non-trivial to commit a request using one-sided verbs *without increasing the number of round trips*. For simplicity, we term the latency of a single round trip with remote CPU bypass as **wire latency**. Currently, only two use cases can achieve wire latency: simple data access and data replication. In the first case, clients use one-sided verbs to read/write a data block whose remote address is known [18]. However, due to the limited semantics of one-sided verbs, this approach cannot be extended to complex scenarios, such as those containing index traversal and concurrency control, since it will induce excessive round trips [53, 55], offsetting the latency benefits of bypassing remote CPUs. In the data replication case, the leader appends replication requests to followers' replication logs via RDMA `WRITE`, and commits upon the completion of RDMA `WRITE` [9, 18, 58]. Followers execute replication requests lazily in the background. By doing so, the software overhead of followers is removed from the replication critical path.

In this paper, we explore how to achieve wire latency for more general storage requests (beyond simple data access and data replication mentioned before). We begin by identifying what types of storage requests semantically support wire latency. By analyzing, we find that *nil-externalizing* (nilext) requests defined by recent work [21] can meet the requirement of wire latency. Nilext requests do not return execution results or execution errors, i.e., they do not externalize its effects or system state. Hence, the execution of nilext requests can be deferred, making it possible to commit them with server CPU bypass (one requirement of wire latency). Nilext requests are common: for example, `set` requests in Memcached, and `put`/`delete`/`merge` requests in RocksDB [21]. So our goal becomes to make nilext requests wire-latency.

The challenge of achieving wire-latency nilext requests is *maintaining linearizability in the presence of multiple clients*. Specifically, we need to order (nilext and non-nilext) requests issued by different clients for linearizability, and ensure that nilext requests are committed with server CPU bypass. However, RDMA one-sided verbs lack the ability of inter-client coordination, since clients must specify the destination addresses of sent data. This restricts RDMA `WRITE` to achieve wire latency only for single-client scenarios (e.g., replication case where only one leader writes log entries to followers).

We propose Ordered Queue (OQ) abstraction to address the challenge. It is based on our new insight: *the property of remote CPU bypass results from the ability of RNICs to generate hardware ACKs, independent of the type of RDMA verbs*. Specifically, as long as the RNIC supports reliable data transfer, it will generate hardware ACKs, which we can use as the commit signals of nilext requests, to achieve remote CPU bypass. Inspired by the insight, OQ abstraction leverages receive queue, a key structure of RDMA two-sided verbs, to achieve wire-latency nilext requests. It specifies how the CPU and RNIC separately interact with the receive queue using two rules : 1) NIC rule: the server-side RNIC allocates buffers from the receive queue *in order*, accommodating incoming requests, as well as generates hardware ACKs; 2) CPU rule: the server CPU executes requests in the receive queue *in order*

*Jiwu Shu is the corresponding author (shujw@tsinghua.edu.cn)

and returns software responses for non-nilext requests. By using the OQ abstraction, storage systems will generate a linearizable history that follows the positions of buffers in the receive queue, while enabling wire-latency nilext requests.

We build JUNEBERRY, a communication framework that implements the OQ abstraction using commodity RDMA NICs. In JUNEBERRY, clients can mark a request as nilext and use the hardware ACK from server-side RNIC as its commit signal, to make nilext requests wire-latency. The OQ abstraction in JUNEBERRY is centered on an RDMA hardware component called *shared receive queue* (SRQ) [12]. SRQ inherently enforces the NIC rule: RNICs place requests from different clients in an SRQ in order [12]. To enforce the CPU rule and support multiple CPU cores, JUNEBERRY adopts a bitmap-assisted, in-order execution mechanism, and partitions requests into multiple SRQs according to data affinity.

The implementation of the OQ in JUNEBERRY brings two performance issues. First, work queue elements or WQEs (i.e., descriptors) in an SRQ are connected using a link list, not as an array as in a standard receive queue. As a result, the RNIC must fetch them in a pointer-chasing manner, inducing excessive DMA operations. Second, the JUNEBERRY server creates a large number of connections and the RNIC cannot cache their states due to its size-limited SRAM, thus leading to performance degradation. To address the first issue, JUNEBERRY allows a single buffer to accommodate multiple requests by leveraging the multi-packet features in RNICs [56]. Hence, a WQE fetched by one DMA operation can serve multiple requests. To address the second issue, we design a client-side delegation mechanism that supports connection sharing between client threads, reducing the number of connections.

To enable JUNEBERRY to be integrated into storage systems that are crash-consistent, we further add durability support for JUNEBERRY. This is achieved by leveraging emerging persistent memory (PM) technologies. Specifically, JUNEBERRY places SRQ buffers in PM and makes the hardware ACK have persistence guarantees. Moreover, we design a recovery procedure that scans PM-resident SRQs to identify valid requests and then restores storage systems to a consistent state.

We augment two storage systems with JUNEBERRY: Memcached [6], a widely used in-memory caching system, and PMemKV [7], a PM-based persistent key-value store. We evaluate them in a cluster of 9 machines. For Memcached, we run representative traces from Twitter's workloads [63]. Compared with RPC, JUNEBERRY reduces median latency and P99 latency by up to 90.70% and 45.65%, respectively. We also compare JUNEBERRY with a software approach that returns responses of nilext requests before execution: JUNEBERRY still reduces median/P99 latency by 83.77%/42.86%. This is because by leveraging hardware ACKs, JUNEBERRY eliminates any server-side software delay from the critical path of nilext requests, including software queueing. For PMemKV, we run YCSB-like workloads. Under write-intensive workloads (i.e., 50% `put`), JUNEBERRY reduces median latency by 40.83%. Under read-intensive workloads (i.e., 5% `put`), JUNEBERRY has 1.19× (1.6μs) higher median latency, which results from the overhead of supporting durability, including disabled DDIO and PM-resident SRQs (Optane PM [5] in our evaluation).

In summary, we make the following contributions.

- Ordered Queue (OQ) abstraction, which leverages RNIC hardware ACKs to enable wire-latency nilext requests while maintaining linearizability.
- JUNEBERRY, a communication framework that implements the OQ abstraction with commodity RNICs, optimizes performance using hardware/software techniques, and supports durability with persistent memory.
- A set of evaluations on Memcached and PMemKV that demonstrate the performance benefits of JUNEBERRY.

2 Background

In this section, we first provide the background of RDMA (§2.1). Then, we show how existing work utilizes RDMA one-sided verbs to achieve extremely low latency (i.e., wire latency) for storage systems (§2.2).

2.1 RDMA

As the CPU performance stagnates but the network bandwidth continues to grow, it is prevalent to offload network-related processing tasks to NICs [11, 22, 46, 48, 50], freeing valuable CPU cycles. RDMA is a typical example, which is widely deployed in data centers due to high performance and high CPU efficiency [1, 22, 23].

RDMA NICs (RNICs) execute RDMA protocol in hardware and provide queue pair (QP) abstraction to applications. A QP consists of a send queue (SQ) and a receive queue (RQ), each being associated with a completion queue (CQ). A sender submits RDMA commands (verbs), i.e., `WRITE`/`READ`/`SEND`, to the SQ. `WRITE` and `READ` are one-sided, which means that the sender can directly access remote memory without involving the receiver's CPUs. In contrast, `SEND` is two-sided, since the receiver needs to push `RECV` commands to the RQ to prepare receive buffers, which accommodate incoming `SEND` messages. Upon the completion of RDMA commands, the RNIC generates completion entries (CEs) to the associated CQs. RDMA offers several transport modes, of which the *reliable connection (RC)* mode is the most commonly used. RC mode supports 1) reliable data transfer, 2) one-sided `READ`/`WRITE`, and 3) larger-than-MTU message delivery, but it needs one-to-one QP connections.

2.2 Achieving Wire-latency via One-sided Verbs

RDMA one-sided verbs (i.e., `READ`/`WRITE`) are capable of accessing remote memory with remote CPU bypass. This enables extremely low-latency data transfer by avoiding the receiver's CPU software overhead. For simplicity, we term the latency of a single one-sided `READ`/`WRITE` (i.e., *a single round trip with remote CPU bypass*) as **wire latency**.

Researchers have leveraged one-sided verbs to achieve wire-latency replication for storage systems [9, 18, 19, 58].

For example, Mu [9] redesigns Paxos-based state machine replication (SMR): the leader appends a log entry to followers' replication logs via one-sided `WRITE` commands; once the majority of `WRITE` commands have been completed, the leader can ensure the log entry is committed. Followers execute log entries asynchronously in the background. As with the traditional RPC-based approach, Mu completes replication in a single round trip. The difference is that Mu removes the CPU overhead of followers from the replication critical path. Therefore, Mu achieves wire-latency for replication requests (i.e., 1.3μs for leader replicating small data [9]).

3 Motivation

Motivated by the one-sided replication case, we explore a more fundamental question in this work: *Can we achieve wire latency for general storage requests (not just replication requests)?* In this section, we analyze the feasibility and locate the associated technique challenges.

What types of storage requests semantically support wire latency? If a storage request can be realized in a wire-latency manner, it must meet certain requirements, such as not returning an execution result. This is because a wire-latency request is committed without waiting for the server CPU to execute. We find the *nil-externality* property defined by a recent work [21] perfectly describes the requirements.

Formally, a storage interface is nil-externalizing (nilext) if it does not externalize its effects or system state immediately [21]: it just returns an acknowledgment indicating committed, rather than returning an execution result or error. Nilext interfaces are common in storage systems: for example, in Memcached, `set` is nilext; in RocksDB, `put`, `delete`, and `merge` are nilext [21]. By exploiting nil-externality, the execution can be performed *asynchronously* on the server CPU, which makes wire-latency nilext requests possible.

What are the benefits of wire-latency nilext requests? Accelerating nilext requests will notably reduce overall latency (including tail and median) that clients perceive. First, the nilext requests are typically writes and read-modify-writes; executing them is more complicated and thus slower than executing read requests. For example, Memcached's `set` involves memory allocation and object eviction; LevelDB/RocksDB's `put` appends log entries to a write-ahead-log (WAL) file. Making them wire-latency will lower the tail in latency distribution. Second, according to recent studies, many workloads have a non-negligible write ratio [15, 54, 63]. For example, in Twitter, more than 35% cache clusters generate more than 30% `set` requests (nilext) [63]; in Meta's large-scale AI/ML services UP2X, which uses RocksDB for storage backend, about 92.53% of request are RocksDB's `merge` (nilext) [15]. Under these write-heavy workloads, wire-latency nilext requests will reduce the median latency.

Can wire-latency nilext requests be achieved via RDMA `WRITE`? Unfortunately, we give a negative answer by analyzing the limited semantics of RDMA `WRITE`. To guarantee linearizability [24] of storage systems (e.g., after a `set(k,v1)` is committed, the subsequent `get(k)` can return `v1`), we need to produce a linearizable order for requests from *different clients*. However, RDMA `WRITE` cannot achieve coordination between clients: a client must specify the destination address of the server when issuing an RDMA `WRITE`. If we use an external component like sequencer [13, 16, 38] for inter-client coordination, i.e., obtaining an increasing address from the sequencer before issuing `WRITE` and using addresses as the linearizable order, it will induce an extra round trip [13], violating the definition of wire latency, or require programmable switches [16, 38], hindering wide deployment. We also cannot use the server CPU to order requests, since wire-latency requests need to be committed with server CPU bypass. Now, we revisit why RDMA `WRITE` can achieve wire latency for replication. The reason behind it is simple: in the replication case, the server (i.e., a follower) has only a *single* client (i.e., the leader), so the leader can easily specify the order for replication requests by generating increasing destination addresses *locally*; but it does not work for the multi-sender scenario.

In summary, due to interface semantics of nilext requests, making them wire-latency is possible. If realized, we can obtain latency benefits for the upper storage systems. Yet, the challenge is how to guarantee linearizability in the presence of multiple clients, which RDMA `WRITE` cannot tackle.

4 Ordered Queue Abstraction

According to the analysis in §3, RDMA one-sided verbs are incapable of realizing wire-latency nilext requests, since they do not support inter-client coordination inherently. It seems to be in a predicament: the common view is that only one-sided verbs can transfer data in a remote-CPU-bypass manner, the requirement of wire latency.

We break the common view by reexamining what it means to bypass a remote CPU. For an RDMA `WRITE`, when the client gets a completion entry (CE) by polling the CQ, it can guarantee that the sent data will reliably reach the server memory; the entire process does not involve the server CPU. How does the client obtain the guarantee in a remote-CPU-bypass manner? By further looking at the hardware mechanism of RNICs, the answer is explicit: RNICs can generate hardware ACKs due to offloading reliability. Specifically, to support reliable data transfer (RC mode), upon receiving a packet, the receiver-side RNIC generates a hardware ACK to confirm safe delivery, or a negative ACK (NACK) to indicate out-of-order delivery[1]. The sender-side RNIC handles ACKs by generating CEs to the associated CQs; it handles NACKs by performing go-back-N retransmission or Selective Repeat (SR) retransmission (e.g., ConnectX-6 RNIC). This reveals a new insight: *the property of bypassing the remote CPU results from the ability of RNICs to generate hardware ACKs, independent of the type of RDMA verbs*.

[1] If a hardware ACK is lost, the RNIC will resend it.

Inspired by the new insight, we find that it has the potential to achieve wire-latency nilext requests by leveraging two-sided verbs (i.e., RDMA `SEND`). First, RNICs also generate hardware ACKs for RDMA `SEND`, which we can use as the commit signals of nilext requests, ensuring the property of bypassing the remote CPU. Second, unlike RDMA `WRITE`, clients do not need to specify destination addresses for RDMA `SEND`: the server-side RNIC writes the data into buffers in the receive queue (RQ); this gives the server-side RNIC a chance to order requests from different clients.

We therefore propose Ordered Queue (OQ) abstraction, which enables wire-latency nilext requests while maintaining linearizability of the whole storage system. In principle, in OQ abstraction, the server-side RNIC produces a linearizable order for requests from clients, and the server CPU executes requests according to the order. Concretely, OQ abstraction consists of two rules that define how the server-side RNIC and server CPU interact with the RQ, respectively:

Rule 1 *(NIC rule)*. The RNIC allocates receive buffers *in order*: ① the RNIC always allocates receive buffers from the head of RQ, and ② returns hardware ACKs *after* allocation.

Rule 2 *(CPU rule)*. The CPU executes requests *in order*. In other words, the CPU always fetches the first receive buffer not yet executed in the RQ, executes the associated request, and finally returns software responses for non-nilext requests.

A request is committed when the client receives hardware ACKs (for nilext requests) or software responses (for non-nilext requests). Using the above two rules, storage systems will generate a linearizable order that follows the positions of receive buffers in the RQ, even using hardware ACKs as responses of nilext requests. Here, we prove that a request (R_2) sees the effects of any request (R_1) that is committed before it invokes. There are three cases:

Case 1: R_2 is nilext. In this case, according to the definition of nilext requests, R_2 does not need to return any state of storage systems, including effects of committed R_1.

Case 2: R_1 and R_2 are both non-nilext. In this case, R_2 is invoked after the client receives the software response of R_1. According to **Rule 2**, server CPU executes R_1 before returning the software response. Thus, R_2 will reflect the result of R_1.

Case 3: R_1 is nilext but R_2 is non-nilext. In this case, R_2 is invoked after the client receives the hardware ACK of R_1. According to **Rule 1**, at the server side, R_1 has a more advanced position in RQ than R_2. Further, according to **Rule 2**, the server CPU executes R_1 before R_2, so the software response of R_2 will see the effects of R_1.

Here, we give an example of OQ using Figure 1. Suppose the back-end storage system is Memcached. **(a)** Initially, at the server side, the RQ is empty and the Memcached instance contains a KV pair ⟨k, v0⟩. **(b)** Then, a nilext request `set(k,v1)` arrives at the first buffer on the RQ; and the RNIC returns a hardware ACK indicating committed, achieving wire latency. **(c)** After that, a nilext request `set(k,v2)` experiences the same process with the second receive buffer; at the same time, the CPU asynchronously executes requests in RQ in order (i.e., executing `set(k,v1)` first). **(d)** Then, the RNIC receives a non-nilext request `get(k)` and places it in the third buffer in RQ. **(e)** After the CPU has finished executing the first two requests, it executes the `get(k)` and returns a software response containing `v2`. Receive buffers consumed by the CPU can be pushed into the RQ again.

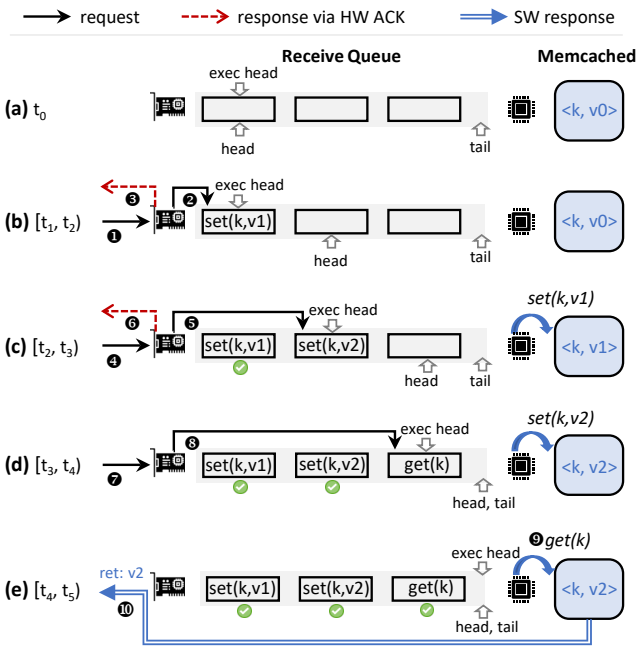

Figure 1: Memcached example with OQ. *This figure shows components at the server side, including RNIC, receive queue, CPU, and a Memcached instance.* `head` *points to the first buffer with no request;* `exec head` *points to the first buffer that is not executed by the CPU.*

Comparison with the pure software solution. One may wonder whether we can achieve the same low latency using a pure software solution that adopts deferred execution: when the server CPU meets a nilext request, it first returns a software ACK to commit, and then executes the request. However, we argue that the OQ abstraction (which achieves wire-latency nilext requests) has remarkable advantages over the pure software approach. For nilext requests, by leveraging the hardware ACKs, the OQ abstraction eliminates the server-side software delay from the critical path, not only for request execution *but also for request responses and software queuing*. In contrast, in the software approach, when the CPU is busy executing requests, the subsequent nilext requests in the RQ cannot be committed immediately and suffer from latency caused by the software queuing. We will conduct the detailed experimental comparison in §6.

Analysis of pathological access patterns. There is a pathological access pattern that makes OQ perform poorly: a client thread sends a non-nilext request *immediately after* receiving the hardware ACK of a nilext request, and both requests reach

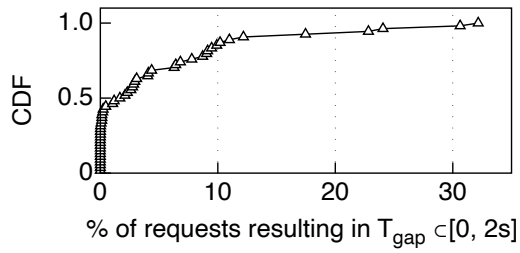

Figure 2: Analysis of 54 clusters in Twitter workloads. *For example, for a point (10, 0.852) in the figure, it means that 85.2% clusters out of 54 have less than 10% requests resulting in $T_{gap} \subset [0, 2s]$.*

the *same* RQ. In this case, the server has no chance of hiding the nilext request's execution latency to the client thread, making the non-nilext request suffer high latency.

For example, suppose the three requests in Figure 1 come from the same client thread, and the thread *immediately* sends a request when receiving the response of the previous one. We assume that the network RTT is 2μs (i.e., 1μs one-way delay), executing `set` needs 10μs, and executing `get` needs 5μs. Without the OQ, the latency of three requests are 12μs, 12μs, and 7μs, respectively. With the OQ, the latency are 2μs, 2μs, and 23μs, respectively: although the two `set` requests are fast, the `get` request has a much higher latency.

However, we argue that the above pathological access pattern is uncommon in real-world workloads. First, there are many storage servers (and each server may have multiple RQs; see §5.1), so two adjacent requests from a client often have different destinations. Second, client threads need to do computational tasks, e.g., webpage rendering (instead of sending storage requests all the time), creating time intervals between requests. As a result, client threads can easily hide the latency of executing nilext requests. Further, we analyze production traces from in-memory caching workloads of Twitter [63]. These traces contain unsampled requests that are sent to two instances (i.e., servers). We chose 1 million consecutive requests to measure the time intervals between a nilext request and the next non-nilext request issued by the same clients (called T_{gap}). Since the traces record timestamps in seconds, we can only coarsely count how many requests result in $T_{gap} \subset [0, 2s]$. Figure 2 shows the cumulative distribution across 54 clusters. In 85.2% (46) clusters, requests leading to $T_{gap} \subset [0, 2s]$ are less than 10%, which gives the OQ abstraction a great opportunity to reduce system latency.

5 Juneberry Design

Juneberry is a communication framework that implements the OQ abstraction using commodity RNICs. Juneberry provides a similar usage as RPC frameworks: The server registers request handler functions, each having a unique request type; Clients issue a request with a specified request type and parameters, to call the associated function.

Juneberry is unique in that it supports wire latency for nilext requests. Clients can mark a request as nilext. For such a request, the server CPU does not return a software response, and the client treats the hardware ACK generated by the server-side RNIC as the commit signal. In this way, the nilext request is committed with extremely low latency, removing the server CPU's overhead from the critical path.

However, when designing Juneberry, there are two obstacles that we must overcome:

- **Correct semantic with high performance**. Despite the simplicity of OQ abstraction, mapping it to the RNIC is not so straightforward. We need to carefully select hardware primitives and scrutinize them for correctness (§5.1). Moreover, while ensuring correctness, we also need to achieve high performance (§5.2).
- **Durability support with crash consistency**. The OQ abstraction lacks a description of how to handle server crashes, which is indispensable for storage systems that contain persistent states (e.g., RocksDB). Therefore, we need to augment the OQ abstraction to support durability (§5.3), including 1) making the hardware ACKs have the durability guarantee, and 2) ensuring that storage systems can recover correctly upon server crashes.

5.1 Implementing OQ Abstraction

Juneberry server leverages shared receive queues (SRQs) to implement the OQ abstraction. SRQ is a standard RDMA component supported by almost all RNICs [12]: it is proposed to reduce memory footprint by supporting multiple QPs sharing a single RQ. Juneberry exploits SRQs for another purpose: by binding multiple QPs to an SRQ, requests from different clients (i.e., QP connections) can be placed in the same queue structure, which is a basic requirement of the OQ abstraction. Juneberry runs in reliable connection (RC) mode, to enable the generation of hardware ACKs. The server pushes receive buffers to the SRQ via RDMA `RECV` commands; client threads send requests to the server's SRQ by issuing RDMA `SEND` commands.

Next, we describe how Juneberry follows the two rules of OQ (§4). In brief, SRQ naturally follows Rule 1 (i.e., NIC rule), but Juneberry relies on some software designs to follow Rule 2 (i.e., CPU rule).

According to RDMA specification [12], the receiver-side RNIC always allocates receive buffers from the head of SRQ[2]. However, if the RNIC returns hardware ACKs *before* allocation due to some radical optimizations (e.g., delayed allocation), the Rule 1 will be violated. Fortunately, by revisiting the hardware semantics of RDMA, we determine that returning ACKs before allocation is *impossible*. Concretely, in RDMA, all memory areas (including receive buffers) that can be accessed by the RNIC are registered as *memory regions* (MRs); each MR is assigned several permissions (e.g., remotely writable). Therefore, for an incoming `SEND` request,

[2] In Section 10.2.9.1 of [12]: "*When an incoming Receive Message arrives on any QP that is associated with an SRQ, the HCA uses **the next available SRQ WQE** to receive the incoming data*".

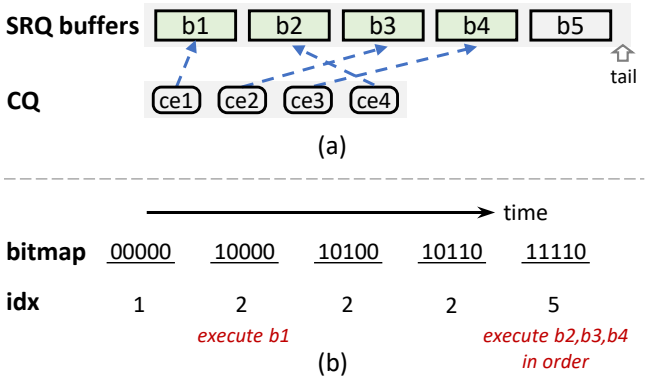

Figure 3: JUNEBERRY enforces Rule 2. ***(a)*** *The order of CEs in the CQ may not match the order of receive buffers in the SRQ.* ***(b)*** *Executing receive buffers in order with the help of the CQ and a bitmap.*

the server-side RNIC must check the permissions of the destination address before returning hardware ACKs, to enforce access control. Checking permissions indicates that the associated receive buffers have been allocated.

In existing RPC frameworks using two-sided verbs [31], the order of executing requests is the same as the order of completion entries (CEs): the server-side CPU polls the CQ to obtain CEs, then locates receive buffers using the CEs, and finally executes requests in the receive buffers. However, such a workflow (i.e., executing requests according to the order of CEs) can not enforce the Rule 2. This is because RDMA only guarantees in-order delivery for CEs generated by the *same* QP [12], but in JUNEBERRY, the SRQ's CQ accommodates CEs from different RC QPs. Hence, RDMA `RECV` commands issued to the SRQ can be completed out-of-order; in other words, when two CEs are generated by different QPs, their order in the CQ may not match the order of receive buffers (e.g., `ce3` and `ce4` in Figure 3(a)).

JUNEBERRY adopts a simple solution to enforce Rule 2, making requests in the SRQ be executed in order. As shown in Figure 3(b), JUNEBERRY maintains a bitmap and a variable `idx` for the SRQ. The bitmap tracks which receive buffers have requests; the `idx` points to the first buffer that is not executed by the CPU. CPU executes requests with the following three steps: ❶ Polls the CQ to obtain CEs and sets associated bits in the bitmap; ❷ If the `idx`-th bit is set, executes the request and advances `idx`; ❸ Repeats the step ❷ until the `idx`-th bit is clear. For example, in Figure 3(b), upon obtaining `ce4` from the CQ, the CPU executes the request in `b2` (since `idx` equals 2), and then executes the next contiguous sequence of requests in the bitmap in order (i.e., `b3` and `b4`).

Scaling to multiple CPU cores. Until now, we have assumed that there is only a single SRQ at server side. However, it is impractical when considering the multi-core architecture of servers. First, when multiple threads operate the same SRQ, the scalability issue happens. Second, when multiple threads execute requests concurrently, producing the same results as sequential execution (for Rule 2) is intricate and low-performance: it involves dependency tracking and resolution, thus inducing expensive cross-thread synchronization.

JUNEBERRY uses data partitioning to support multi-core scaling. Specifically, JUNEBERRY creates multiple SRQs at the server side, each being associated with a worker thread. Each worker thread manages an *exclusive* set of datasets. Such data partitioning is easily achieved in many storage systems [32, 33, 37, 39] such as key-value stores, since they adopt a shared-nothing architecture to improve performance. Clients in JUNEBERRY need to send requests (via RDMA `SEND`) to correct server-side worker threads according to partition scheme. For example, in the Memcached case, clients hash the target key in a `set`/`get` request, and send the request to the SRQ managed by the i-th worker thread, where i = `hash(key) % #(worker threads)`.

5.2 Optimizing Performance

JUNEBERRY materializes the OQ abstraction by leveraging SRQ and adopting software designs (§5.1). However, it poses two performance issues: 1) operating SRQs is inefficient for RNIC; 2) a large number of RC QPs harm system scalability. For each issue, this subsection first explains its causes and negative effects, and then introduces our solutions.

5.2.1 Streamlining RNIC Prefetching on SRQ

The lifecycle of work queue elements (WQEs). When creating an RQ/SRQ, the RNIC driver allocates a contiguous memory region that contains multiple WQEs, which can be accessed by RNICs (via DMA). When pushing a receive buffer to the RQ/SRQ via `RECV` commands, the CPU fills in a *free* WQE with metadata (including the address of the receive buffer), making it *valid*. A valid WQE becomes free when the CPU obtains the associated CE from CQs, which indicates that the WQE has been consumed by a `SEND` request.

The RNIC prefetches valid `RECV` WQEs via DMA and caches them in its SRAM, to accelerate the processing of incoming `SEND` requests. Such prefetching is efficient for standard RQs, since logically contiguous WQEs are also physically contiguous at memory locations, making a single prefetch operation (i.e., a DMA operation) be capable of fetching multiple valid WQEs at a time. For example, as shown in Figure 4(a), receive buffers `b1`, `b2`, `b3` are pushed into the RQ in order, and three WQEs allocated for them are memory-contiguous.

However, SRQ counteracts the benefit of RNIC prefetching due to its structure feature. Specifically, as described in §5.1, the valid WQEs in an SRQ can be completed out-of-order, thus creating fragmented free WQEs like holes. Subsequent `RECV` commands often fail to allocate WQEs in a memory-contiguous manner. As a result, valid WQEs in an SRQ are connected using a link list. For example, as shown in Figure 4(b), the SRQ organizes valid WQEs using the link list `wqe3` → `wqe1` → `wqe5`. Due to the link list structure of WQEs, the RNIC is more susceptible to cache misses (thus stalling in-

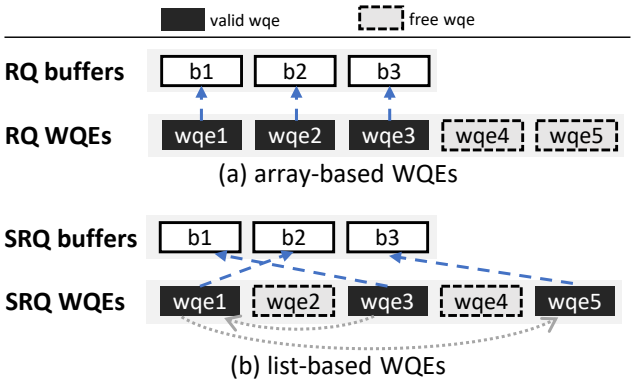

Figure 4: Array-based WQEs vs. list-based WQEs. *In these two figures, receive buffers b1, b2, and b3 are pushed into the RQ/SRQ in order, and the RNIC driver allocates WQEs for them.*

coming traffic), and needs more DMA operations to prefetch WQEs with the pointer-chasing access pattern, both degrading the network performance. We validate it using a simple experiment, where a client launches 24 threads to send 64B messages to a remote server. The remote server uses one CPU core to receive messages and respond with 64B messages; each client thread allows 4 outstanding requests. The server can deliver 2.91Mops/s when using RQ, but the performance drops to 2.24Mops/s when using SRQ. A recent work observes a similar performance degradation on Ethernet NIC that adopts list-based receive (Rx) rings [49].

JUNEBERRY improves the performance of SRQ by allowing a single WQE to accommodate multiple messages, so that a prefetch operation can serve multiple `SEND` requests. This is achieved by exploiting the multi-packet (MP) feature in advanced RNICs [20,56]. For an MP RQ/SRQ, multiple `SEND` requests can be sequentially written to the same receive buffer, and the address of each request is aligned to a k (e.g., 64) byte offset, where k is pre-defined[3]. The MP feature is proposed to reduce memory footprint, but JUNEBERRY uses it to streamline RNIC prefetching and mitigate network traffic stall. In addition, with MP SRQ, JUNEBERRY server can post a large receive buffer (e.g., 64KB) to amortize the overhead of filling in WQEs and ringing doorbells, saving CPU cycles.

5.2.2 Reducing the Number of QPs

Recall that in JUNEBERRY, a client thread can send requests to the MP SRQ of any worker thread according to partition scheme (§5.1), which indicates that there are RC connections between every client thread and every worker thread (RC QPs only support one-to-one connections). Concretely, the server maintains $C{\times}Ct{\times}St$ RC QPs in total, where `C` is the number of client machines, `Ct` is the number of client threads per client machine, and `St` is the number of worker threads in the server. However, it is well-known that RNIC cannot cache states for a large number of QPs due to its size-limited SRAM [18,31,45,57]. Upon cache misses, RNIC issues DMA operations to fetch QP states from host memory, stalling the incoming network traffic and thus degrading performance.

We reduce the number of QPs in the JUNEBERRY server to $C{\times}St$ by employing a client-side delegation mechanism. Specifically, a client machine creates St QPs, each connecting to a remote worker thread. Note that each QP uses a separate context to avoid false synchronization between client threads [58]. Each QP is managed by one client thread, which is called *owner* of the QP. When a client thread is about to send a request to a worker thread, it identifies the owner of the target QP and publishes the request in a reserved slot. The owner scans slots and emits associated requests (including requests generated by itself) to the network using the dedicated QP. The owner is also responsible for processing responses from the QP and delivering these responses to initiators.

5.2.3 Alternative Optimization Techniques

We discuss alternative optimization techniques that can address the above two performance issues.

Array-based SRQ. An alternative approach to streamlining RNIC prefetching is to make RNIC support array-based SRQ (by modifying the firmware of RNIC ASIC). This approach also requires us to modify the driver of RNIC. Compared with array-based SRQ, MP SRQ used by JUNEBERRY has an additional advantage: mitigating CPU overhead by reducing the number of doorbells.

eXtended RC (XRC). XRC [4] is an Infiniband transport service supported by Mellanox RNIC. When using XRC, an RC QP can deliver messages to multiple SRQs in a remote machine. If we adopt XRC in JUNEBERRY, the number of QPs in the server will decrease to $C{\times}Ct$, the total number of client threads in the cluster. Compared with the client-side delegation mechanism (which has $C{\times}St$ QPs at the server side), XRC has a scalability advantage when the server launches a large number of threads.

5.3 Supporting Durability

JUNEBERRY supports durability by leveraging emerging persistent memory (PM) technologies. This subsection first gives a brief background on PM, and then describes how JUNEBERRY uses it for durability and crash consistency. Here, we assume that the back-end storage systems of JUNEBERRY are crash-consistent (unlike Memcached).

A primer on persistent memory (PM). PM is a new class of storage devices that can guarantee persistence with DRAM-like features. Specifically, PM can expose its storage space as physical addresses to CPUs and other devices (e.g., RNICs). Therefore, it can be accessed by CPUs via `load/store` instructions with low latency, or other devices via DMA engines. There are two typical PM devices for datacenters: Intel's Optane PM [5] and Samsung's Memory-Semantic SSD [8]. The former sits in DIMM slots, while the latter is connected by the CXL link. The performance of Optane PM is well-known [62]: it can deliver 2GB/s writes and 6GB/s reads per DIMM, and

[3] We set k to 64, which is the minimum value that our RNICs support, thus reducing internal fragmentation caused by data alignment.

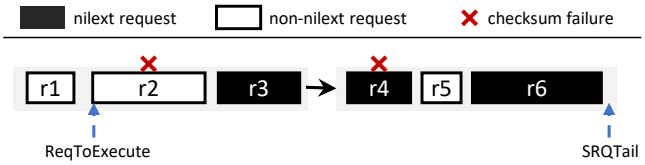

Figure 5: An example of scanning an SRQ upon recovery.

it has the same write latency and 3× higher read latency compared to DRAM. Memory-Semantic SSD is not currently available. Although the CPU cache is volatile, recent CPUs put it into the persistent domain via eADR [3,26,65] or Global Persistent Flush (GPF) in CXL [2], which simplifies the use of PM. With eADR or GPF, upon server crash, the data in the CPU cache will be flushed to PM safely.

Persistent hardware ACKs. We first place SRQ receive buffers in PM, so that requests in these buffers can survive power outages. Recall that JUNEBERRY uses hardware ACKs as commit signals of the nilext requests, to achieve wire latency. Yet, when a client receives the hardware ACK for an RDMA `SEND` command, it only ensures that the `SEND` is allocated a destination address in the SRQ; the DMA write operation in the server-side RNIC may still be in progress, i.e., the `SEND` data may not reach PM successfully. To make the hardware ACK have the persistence guarantee, JUNEBERRY drains DMA operations of `SEND` commands in the server-side RNIC. It does so by letting client threads issue an extra RDMA `READ` (with 1-byte size) to the same QP after every `SEND` command [28, 60]: the PCIe read triggered by the RDMA `READ` will flush the previous PCIe writes. In this way, the hardware ACKs of `READ` ensure the persistence of nilext requests.

In addition, JUNEBERRY performs two optimizations. First, client threads combine the `SEND` command and `READ` command in one round trip, and remove CEs of `SEND`, since the receiver-side RNIC executes these two commands in order [12]. Second, the server disables Data Direct I/O (DDIO), to let the RNIC bypass the CPU cache when performing DMA operations. It can reduce PM write amplification caused by granularity mismatch between a cache line (64B) and a PM internal write (e.g., 256B in Optane PM) [28].

Recoverable SRQ. Simply putting receive buffers in PM does not imply that we can recover requests from the SRQ after power failure. JUNEBERRY devises an identifiable request format to address it. Specifically, each request begins with a 64-bit `checksum` and a 32-bit `size`; `checksum` covers the whole request and `size` is the request length, both being filled by client threads. Moreover, each worker thread persistently maintains two variables for its SRQ in PM: `ReqToExecute` and `SRQTail`. `ReqToExecute` points to the first request not yet executed: it is updated after the worker thread executes a request. `SRQTail` records the last receive buffer in the SRQ; it is updated after the worker thread issues a `RECV` command.

Upon recovery, the server scans SRQs to identify valid requests. Recall that JUNEBERRY leverages the multi-packet feature of RNICs, so a receive buffer may contain multiple requests. Each request has a start address that is aligned to a pre-defined value (§5.2), which simplifies the scanning. For each SRQ, a recovery thread scans receive buffers from `ReqToExecute` to `SRQTail`. When an address results in checksum failure, the thread jumps to the next aligned address in the current receive buffer or the next buffer, continuing to identify valid requests. Finally, as shown in Figure 5, all valid requests (i.e., `r3`, `r5`, and `r6`) are marked. Among them, nilext requests may have returned hardware ACKs as commit signals; therefore, for crash consistency, the recovery thread executes these nilext requests in order (i.e., `r3` and `r6`). Note that we do not need to execute non-nilext request `r5`, because it is uncommitted and thus is concurrent with the subsequent requests in the SRQ (i.e., `r6` in this example).

There is a corner case: `ReqToExecute` points to a valid request that is nilext and non-idempotent (e.g., fetch-and-add without returning values). The recovery thread *cannot* determine whether this request has returned a hardware ACK. It also *cannot* determine whether this request has been executed, since executing the request and updating the `ReqToExecute` are not atomic. As a result, the recovery thread *cannot* decide whether to execute the request (may cause duplicated execution) or skip it (may miss a committed request).

To address the above issue, we make all non-idempotent requests *software controllable* (i.e., have the same workflow as non-nilext requests): the worker thread ❶ executes a request, ❷ updates `ReqToExecute`, and ❸ finally returns a software response; client threads use the software response as the commit signal. Upon recovery, the recovery thread can skip the non-idempotent (or non-nilext) request pointed by `ReqToExecute`, since the client thread has not received the request's response, according to the order of ❶ ❷ ❸.

6 Evaluation

We seek to answer the following questions in our evaluation:

- How do optimization techniques proposed in §5.2 affect JUNEBERRY's throughput? (§6.2)
- How does JUNEBERRY perform when applying to in-memory storage systems like Memcached? (§6.3)
- How does JUNEBERRY perform when applying to persistent storage systems like PMemKV? (§6.4)

6.1 Experimental Setup

We conduct experiments in a cluster having one server machine and 8 client machines. The server machine is equipped with two 18-core Intel Xeon Gold 6240M CPUs, 192GB DRAM, and 1.5TB Optane PM (three Optane DIMMs per CPU). Each client machine is equipped with two 12-core Intel Xeon E5-2650 CPUs and 128GB DRAM. Each machine installs a 100Gbps Mellanox ConnectX-5 RNIC; all RNICs are connected to a Mellanox 100Gbps IB Switch. To avoid the severe NUMA impacts on PM [35, 66], we only use one

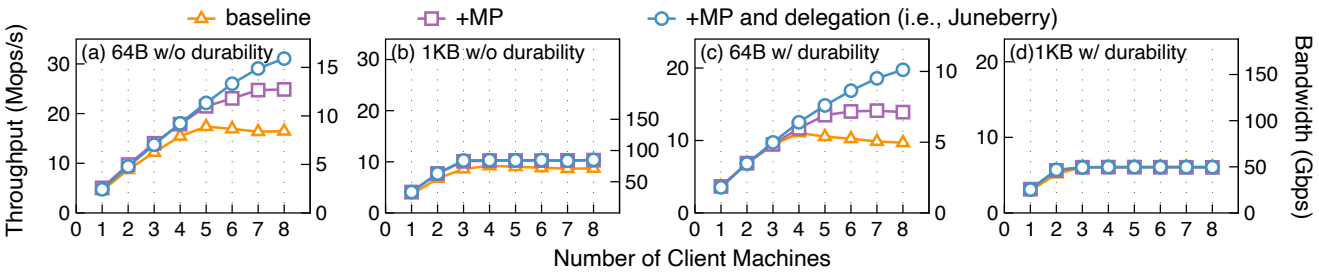

Figure 6: Throughput/Bandwidth with the varying number of client machines.

CPU and the associated DRAM/PM resources in the server.

There are two versions of our system: JUNEBERRY and JUNEBERRY-D. The latter supports durability (§5.3), so it places the server-side receive buffers in PM and disables DDIO. Without explicit mention, each MP SRQ consists of 48 receive buffers of 16KB.

Target comparisons. In §6.3 and §6.4, we will compare JUNEBERRY with three systems:

- **RawRPC.** RawRPC uses the same codebase as JUNEBERRY, including optimizations such as MP features and delegation (§5.2). Like traditional RPC frameworks, in RawRPC, the server CPU handles requests and then returns responses.
- **DeferredExec.** DeferredExec also uses the same codebase as JUNEBERRY. It optimizes nilext requests using a pure software solution: when processing a nilext request, the server CPU first returns a software ACK to commit and then executes it.
- **eRPC.** eRPC [29] is a state-of-the-art RPC framework. It uses unreliable datagrams for network communication and implements retransmission and congestion in software.

6.2 Microbenchmarks

In this experiment, we use microbenchmarks to demonstrate the efficacy of two techniques proposed to improve JUNEBERRY's performance: MP features and client-side delegation. Each client machine launches 24 threads: each client thread keeps one request in flight, and sends the request to a randomly-chosen remote worker thread. The server machine launches 18 threads: when a worker thread receives a request, it replies using the same size message. Figure 6 shows the system throughput with the varying number of client machines, under different settings (i.e., small requests vs. large requests, w/o durability vs. durability).

Small requests without durability. We make the following observations from Figure 6(a). First, with 8 client machines, MP improves the throughput of 64B requests from 16.45Mops/s to 24.86Mops/s (i.e., 1.51×). This is because by accommodating multiple requests in a single receive buffer, MP greatly mitigates the overhead of RNIC prefetching on list-based SRQ WQEs and thus lowers the probability of RNIC cache misses. Second, client-side delegation further increases throughput by 1.25×, since it reduces the number of RC QPs from 3456 (i.e., 8×24×18) to 144 (i.e., 8×18); in this way, the QP states become smaller, alleviating the cache thrash caused by RNICs' size-limited SRAM. Third, these two techniques make JUNEBERRY scale well; without them, JUNEBERRY can not scale to more than 5 client machines.

Large requests without durability. From Figure 6(b) we can see that even with large requests (i.e., 1KB), the baseline can only achieve 71Gbps due to inefficient RNIC prefetching on SRQ WQEs. When using multi-packet (MP) SRQ, the bandwidth increases to 85Gbps. What needs to be explained here is why JUNEBERRY does not reach the raw performance of RNICs (i.e., 100Gbps). We suspect the cause is the hardware limitation of the SRQ, because when we replace SRQs with standard RQs, the bandwidth can approach 100Gbps.

Small requests with durability. We make two observations from Figure 6(c). First, as with DRAM, the two techniques significantly boost the throughput of small requests when using PM: in the case of 8 client machines, MP and delegation improve throughput by 1.44× and 1.42×, respectively. Second, supporting durability brings 36.40% throughput degradation (compared with Figure 6(a)): from 31.07Mops/s to 19.76Mops/s. This is because 1) every RDMA SEND command is followed by an RDMA READ command for durability, consuming the IOPS of the server-side RNIC; 2) handling PM-resident requests consumes more CPU cycles, since PM has 3× higher read latency than DRAM.

Large requests with durability. As shown in Figure 6(d), for large requests, the limited bandwidth of PM (6GB/s for 3 Optane DIMMs) becomes the performance bottleneck.

6.3 In-Memory Caching: Memcached

In this experiment, we use Memcached (version: 1.6.19) as the back-end storage system. We remove network-related parts in Memcached's codebase and produce a local library that can be linked to JUNEBERRY server. We spawn 24 threads per client machine (8 client machines in total); client threads generate requests at a given rate with Poisson arrivals. The server machine launches 16 threads to handle requests and reserves 2 threads for background tasks (e.g., LRU maintainer).

We select four representative in-memory caching work-

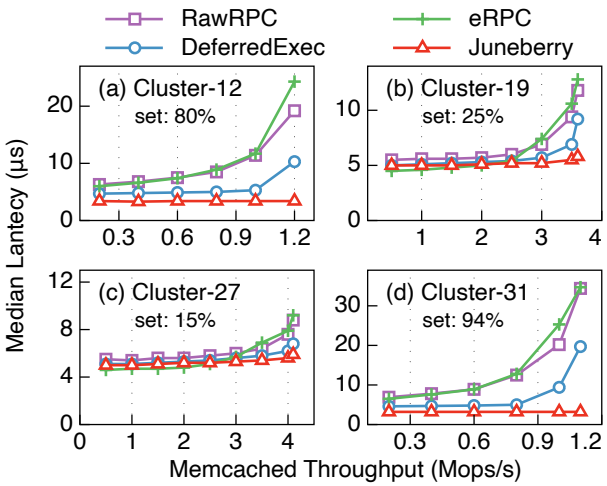

Figure 7: Median latency vs. throughput. *We use Memcached (version: 1.6.19) as the back-end storage system.*

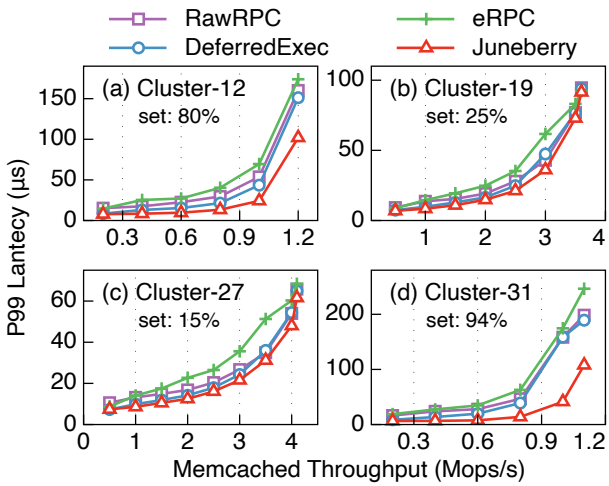

Figure 8: P99 latency vs. throughput. *We use Memcached (version: 1.6.19) as the back-end storage system.*

	ratio of `set`	key size	value size	Zipf alpha
Cluster-12	80%	44B	1030B	0.3048
Cluster-19	25%	42B	101B	0.735
Cluster-27	15%	66B	8B	1.065
Cluster-31	94%	41B	15B	0

Table 1: Settings of in-memory caching workloads.

loads from Twitter [63], as shown in Table 1. Among them, Cluster-12 and Cluster-31 are write-intensive; Cluster-19 and Cluster-27 are read-intensive.

Figure 7 shows median latency under varying throughput. All systems achieve the same peak throughput since the back-end storage engine is the throughput bottleneck. We can make the following observations.

First, under peak throughput, compared with `RawRPC`, JUNEBERRY achieves 82.30%/50.74%/32.89%/90.70% lower median latency in Cluster-12/19/27/31 workloads. This is because JUNEBERRY makes nilext requests (i.e., `set` requests) wire-latency by leveraging hardware ACKs as commit signals. For workloads containing more nilext requests (e.g., Cluster-12 and Cluster-31), the latency reduction is more pronounced.

Second, by deferring execution of nilext requests until after returning responses, `DeferredExec` reduces median latency of `RawRPC`. However, `DeferredExec` is still outperformed by JUNEBERRY: for example, when approaching peak throughput under Cluster-12, `DeferredExec` has 3.03× higher median latency compared with JUNEBERRY. This is because when worker threads of `DeferredExec` are executing requests, they cannot immediately return software responses for nilext requests residing in RQs. In contrast, JUNEBERRY offloads the task of returning nilext requests' ACKs to the RNIC hardware, avoiding software queuing caused by the busy CPU. As a result, the median latency of JUNEBERRY is not only low but also stable under different degrees of loads. This demonstrates that in the microsecond era, hardware/software co-design (e.g., the OQ abstraction) is necessary to further realize latency reduction for storage systems. It is also worth noting that compared to `DeferredExec`, JUNEBERRY reduces the number of network packets used for returning responses.

Third, `eRPC` suffers much higher latency than JUNEBERRY at peak throughput, but when workloads are read-intensive and not heavy, it median latency is slightly lower. For example, as shown in Figure 7(c), when the throughput is less than 2.5Mops/s under Cluster-27, `eRPC` has 100~400ns lower median latency than JUNEBERRY. This is because at this point, software queuing does not affect latency, but the client-side delegation in JUNEBERRY incurs extra software overhead such as cross-thread communication.

Figure 8 shows 99th percentile (P99) tail latency under varying throughput, from which we can make the following observations. First, under write-intensive workloads Cluster-12 and Cluster-31, JUNEBERRY yields a P99 latency that is up to 32.43% and 42.86% lower than the second best system (i.e., `DeferredExec`), respectively. This is because the OQ abstraction enables fast commit of nilext requests, which represent a large fraction of these two workloads.

Second, under read-intensive workloads Cluster-19 and Cluster-27, the P99 latency reduction achieved by JUNEBERRY is limited. Take Cluster-19 for example, compared with `RawRPC`, JUNEBERRY decreases P99 latency from 10.6μs to 7.4μs with 0.5Mops/s throughput, and from 65.8μs to 61.8μs with 4.1Mops/s throughput (peak throughput). This is because a small fraction of `get` requests produce pathological access patterns (recall §4), i.e., the time interval between them and previous `set` requests from the same client threads is too short to hide execution latency of `set` requests, leading to high tail latency. Therefore, the improvement from the OQ abstraction is overshadowed. This also explains why JUNEBERRY is less effective in reducing tail latency than median latency.

6.4 Persistent KV Store: PMemKV

This experiment explores the performance of persistent storage systems with JUNEBERRY-D. We select PMemKV [7] as

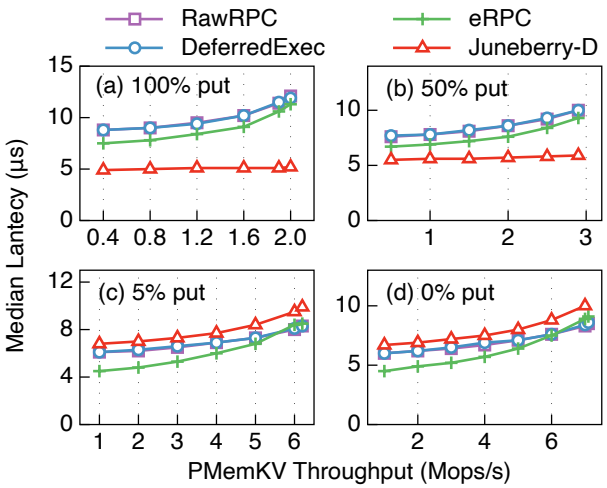

Figure 9: Median latency vs. throughput. *We use PMemKV as the back-end storage system.*

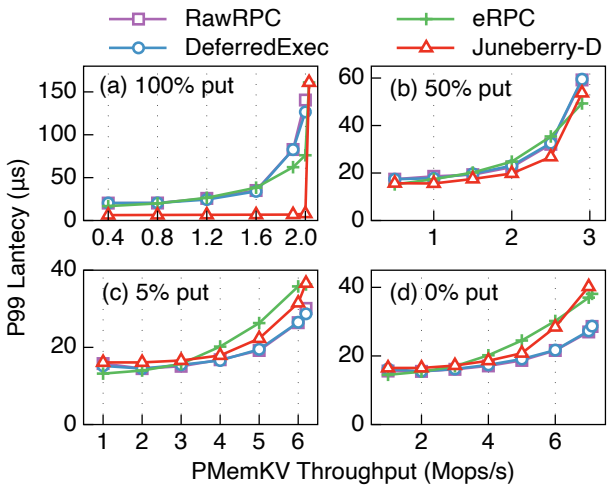

Figure 10: P99 latency vs. throughput. *We use PMemKV as the back-end storage system.*

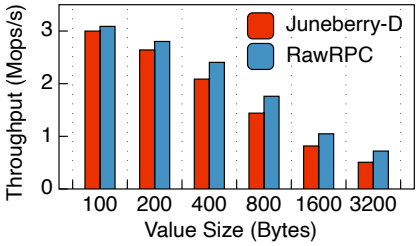

Figure 11: Throughput with different value size. *We use PMemKV as the back-end storage system. The* `put` *ratio is 50%.*

the backend; it is a persistent KV store that maintains objects in PM. The experiment setup is the same as in §6.3, except that the server launches 18 threads. We use YCSB-like workloads with four types of `put`/`get` ratio: write-only (100% `put`), read-only (100% `get`), write-intensive (50% `put` and 50% `get`), read-intensive (5% `put` and 95% `get`). We set the object size to 91-byte, which is the average object size in Meta's largest KV system, i.e., ZippyDB [15]. Workloads follow a Zipf 0.99 access distribution.

Figure 9 depicts median latency with increasing throughput, from which we make two observations. First, JUNEBERRY-D reduces median latency by 57.08%/56.33%/53.92% against `RawRPC`/`DeferredExec`/`eRPC` under write-only workloads; 40.83%/40.83%/36.71% under write-intensive workloads (i.e., 50% `put`). By leveraging persistent hardware ACKs along with PM-resident recoverable SRQ, JUNEBERRY-D can quickly commit a nilext request without sacrificing crash consistency.

Second, JUNEBERRY-D is inferior to other systems under read-intensive (i.e., 5% `put`) and read-only workloads. Specifically, compared with `RawRPC`, JUNEBERRY-D has 1.19× (1.6μs) and 1.20× (1.7μs) higher median latency. This is because in JUNEBERRY-D, the server ① disables DDIO, harming the communication latency between RNICs and host memory, and ② uses PM-resident receive buffers, leading to higher latency spent by the CPU in fetching requests. In addition, under read-only workloads, JUNEBERRY-D has about 1.5% lower peak throughput compared with other systems.

Figure 10 further shows P99 latency of PMemKV. Under write-only workloads (Figure 10(a)), when the throughput is 2.0Mops/s, JUNEBERRY-D exhibits 94.38%/93.76%/89.61% lower P99 latency against `RawRPC`/`DeferredExec`/`eRPC`. However, when the throughput offered is slightly higher than JUNEBERRY-D can handle, its tail latency increases dramatically. This is because when all requests are nilext, the server-side SRQ can easily have no free buffers, causing the server-side RNIC to generate the receive not ready (RNR) error.

When workloads are read-intensive (5% `put`) and read-only, JUNEBERRY-D has up to 1.28× and 1.49× higher P99 latency due to PM receive buffers and disabled DDIO. Combining Figure 9 and Figure 10, we can summarize that when supporting durability, the OQ abstraction brings latency benefits under write-intensive workloads, but incurs latency overhead under read-intensive workloads.

In JUNEBERRY-D, PM-resident receive buffers consume PM write bandwidth, which inevitably affects the performance of back-end storage systems using PM (recall that PM write bandwidth is limited). We conduct an experiment to show it. We use 8-byte keys and vary the value size; the ratio of `put` requests is 50%. Figure 11 presents the result. When the value size is small, the throughput degradation of JUNEBERRY-D is acceptable: only 3.0% with 100B values. However, when values become larger, the size of `put` requests increases and thus more PM write bandwidth is consumed on server-side SRQ, reducing the available PM bandwidth for the back-end storage system. As a result, with 3200B values, `RawRPC` delivers 1.42× higher throughput against JUNEBERRY-D. Fortunately, small objects are very common in real-world workloads [15, 43, 63], so JUNEBERRY-D can achieve wire-latency nilext requests at a small cost in throughput in many cases. In addition, if the back-end storage system uses a storage device that is not a PM (e.g., SSD or HDD), JUNEBERRY will not induce throughput degradation.

7 Discussion

Supporting durability without Optane PM. In our experiments, we use Optane PM to store requests for durability. However, Intel has fully killed off its Optane Memory business. Here, we provide two alternative solutions:

- **CXL-based SSD.** By attaching SSD devices on CXL links, CXL-based SSD can expose load/store interfaces to RNICs. Thus, we can place SRQ buffers on CXL-SSD and the RNIC will DMA requests to it, guaranteeing data durability. Some CXL-based SSD products (e.g., Samsung's Memory-Semantic SSD [8]) will enter the market in the near future.
- **UPS-backed DRAM.** Uninterruptible power supply (UPS) is a type of power system that makes DRAM durable. Specifically, with the help of UPS, the contents of DRAM will be written to SSD when the power fails [19]. Compared with Optane PM, USP-backed DRAM will not induce extra latency overhead to JUNEBERRY. Moreover, since the size of the SRQ buffers is small, the battery provisioning costs of UPS are limited for JUNEBERRY.

Implementing JUNEBERRY with different technologies. JUNEBERRY exploits hardware ACKs generated by RNICs to enable fast commit. It can also be implemented on other NICs supporting hardware ACKs [46, 50], such as FlexTOE [50], a TCP offload engine (TOE) on SmartNICs. Moreover, the idea of fast commits can be applied to other levels of the network stack. For example, for Linux socket-based applications, we can return a software ACK in the Linux kernel by implementing an in-kernel eBPF hook via XDP. By doing so, the latency overhead caused by the context switch can be avoided.

8 Related Work

RDMA communication. Existing works use RDMA for inter-server communication in two ways: 1) implementing RPC upon RDMA verbs [27, 29–31, 52] and 2) directly accessing remote memory via one-sided verbs [9, 18, 55, 59, 64]. RPC enables complicated server-side execution (e.g., index traversal) in one round trip. One-sided access can bypass remote CPUs and thus achieve low latency, but is restricted to simple read and write operations. Thus, retrieving data using one-sided verbs in a storage system typically involves multiple round trips due to indexing and concurrency control (e.g., Sherman [55] and CliqueMap [51]). JUNEBERRY based on the OQ abstraction provides a new way for inter-server RDMA communication: the server CPU can execute requests like RPC, supporting general operations within one round trip, and nilext requests are committed with remote CPU bypass, achieving extremely low latency.

NIC assisted systems. Recent works leverage SmartNICs and customized NICs to accelerate system software [14, 17, 25, 34, 36, 40, 41]. Among them, RPCValet [17], Dagger [36], and nanoPU [25] targets RPC systems: they offload tasks of the RPC stack to NICs, such as request scheduling and (de)serialization, and use memory interconnects (instead of PCIe) for CPU-NIC communication to lower latency. JUNEBERRY can also be viewed as leveraging NICs to accelerate RPC systems: it relies on NICs for providing a fast path to commit nilext requests. However, different from the above works, JUNEBERRY does not require hardware modification; it repurposes hardware ACKs that exist on commodity NICs supporting reliable data transfer (e.g., RNICs).

Combining RDMA and PM. RDMA and PM can offer low-latency data transfer and storage, respectively, so researchers are actively exploring how to combine them efficiently [10, 28, 42, 53, 53, 60, 61]. Kalia et al. [28] and Wei et al. [60] present a set of guidelines to optimize the interaction between RDMA and PM. Octopus [42], Orion [61], and Assise [10] are distributed file systems powered by RDMA and PM. They support one-sided RDMA access to PM-resident file data, thus mitigating CPU overhead and avoiding unnecessary data copying. Clover [53] is a PM-based key-value store that uses RDMA networks. Clients access objects in PM via RDMA `WRITE` and `READ`, and resolve concurrent conflicts via RDMA atomic verbs. JUNEBERRY adopts a different approach to combine RDMA and PM: it places receive buffers in PM to persistently store incoming RDMA `SEND` requests, rather than directly accessing PM-resident data via one-sided RDMA.

Nil-externality. Ganesan et al. identify nil-externality [21], a property for interfaces if they do not externalize effects. By exploiting nil-externality, they propose nilext-aware replication, which improves replication performance by lazily ordering and executing nilext updates. The design of OQ abstraction gets inspiration from their work. Several works on storage systems also perform early commit and asynchronous execution. Xsyncfs [47] commits a file system operation without performing disk I/O, and defers execution until external output is generated (e.g., send data to the screen or network). ScaleDB [44] commits a transaction without updating the global range index, and introduces a concurrency control mechanism for transaction serializability. JUNEBERRY is designed for networked environments and can be used for many storage systems. Moreover, JUNEBERRY's early commit is achieved by exploiting hardware ACKs, thus eliminating software delay from the critical path.

9 Conclusion

In this paper, we propose Ordered Queue (OQ) abstraction, which accelerates nilext requests by leveraging NICs's hardware ACKs for fast commit. By doing so, a nilext request can be committed in a single round trip with remote CPU bypass, achieving extremely low latency. We materialize OQ abstraction by designing JUNEBERRY, a communication framework running on commodity RDMA NICs. JUNEBERRY uses a set of techniques to improve performance and incorporates persistent memory to support durability. JUNEBERRY significantly lowers the latency of storage systems under write-intensive workloads. This work demonstrates that making storage software have visibility into network-level knowledge can bring performance benefits.

Institute of Parallel and Distributed Systems, SEIEE, Shanghai Jiao Tong University

ABSTRACT

Memory disaggregation with OS swapping is becoming popular for next-generation datacenters. RDMA is a promising technique for achieving this. However, RDMA does not support dynamic memory management in the data path. Current systems rely on RDMA's control path operations, which are designed for coarse-grained memory management. This results in a trade-off between performance and memory utilization and also requires significant CPU usage, which is a limited resource on memory nodes.

This paper introduces **O**n-**D**emand **R**emote **P**aging, the first system that smartly chains native RDMA data path primitives to offload all memory access and management operations onto the RDMA-capable NIC (RNIC). However, efficiently implementing these operations is challenging due to the limited capability of RNIC. ODRP leverages the semantics of OS swapping and adopts a client-assisted principle to address the efficiency and functionality challenges. Compared to the state-of-the-art system, ODRP can achieve significantly better memory utilization, no CPU usage while introducing only a 0.8% to 14.6% performance overhead in real-world applications.

1 INTRODUCTION

Memory-intensive applications [4, 6, 9, 44] have been widely deployed in modern datacenters. However, accurately predicting their memory requirements is challenging due to fluctuations over time [37, 27]. Over-provisioning memory for host servers would significantly decrease memory utilization. To address this issue, memory disaggregation has been proposed [32, 19, 11, 37, 21, 22, 14, 36, 29, 18, 26, 43]. This architecture separates the CPU and memory resources into CPU and memory pools. Applications running on the CPU pool (CNodes) can dynamically allocate and access memory in the memory pool (MNodes) on demand, thereby improving overall memory utilization.

RDMA is a popular interconnect for bridging CNodes and MNodes. It provides efficient data path primitives, namely one-sided RDMA, which allow RNICs to directly read and write to MNode memory without involving their CPUs. This is particularly beneficial for memory disaggregation because MNodes often have limited or no CPU resources to ensure better cost efficiency [45]. Unfortunately, RDMA is not a panacea for memory disaggregation, which requires more than simple memory access. CNodes need to dynamically allocate and deallocate remote memory during runtime, which is not supported by one-sided RDMA. Even worse, dynamic allocation necessitates registering memory to the RNIC, an RDMA control path operation that is not optimized for performance and can only be performed by the CPU. As a result, naively performing memory (de)allocation in the data path would significantly degrade application performance and overwhelm the wimpy MNode CPU (§2.3).

Due to the above limitation of RDMA, previous systems [19, 11, 40, 25] have chosen to over-provision remote memory with large memory slabs (1 GB or larger) to amortize the memory (de)allocation overhead and reduce CPU usage on MNodes. However, using large memory slabs would significantly reduce the memory utilization of MNodes due to internal fragmentation. Therefore, current RDMA-based memory disaggregation systems face a fundamental trade-off between high remote memory utilization, no MNode CPU usage and high performance.

This paper demonstrates that it is possible to achieve high memory utilization, no MNode CPU usage, and high performance on commodity RDMA hardware. It describes the design and implementation of **O**n-**D**emand **R**emote **P**aging, allowing CNodes to swap pages to the MNode with 4 KB allocation granularity—the same as Linux swapping granularity for ideal memory utilization. ODRP achieves fine-grained remote memory management in the data path by efficiently offloading memory access and (de)allocation operations to the MNode's RNIC, bypassing its CPU. Our key insight is to fully exploit a less-explored chaining feature of RDMA that allows developers to *combine various one-sided primitives to offload complex functionalities onto the RNIC* (§2.4).

Although RDMA offloading has recently been proven to be Turing complete in theory [34], meaning that it can offload arbitrary programs, efficiently offloading the complex functionalities of a swap device presents challenges due to the following three issues: First, a function may require offloading multiple RDMA work requests (WRs) for implementation. However, offloading performance decreases as the number of WRs increases. Therefore, we need to design data structures and operations that minimize the number of offloaded WRs. Second, RDMA primitives are primarily designed for networking and have limited semantics. Consequently, it is challenging or even impossible to implement certain functions efficiently with a relatively small number of WRs, such as the modulo operation. Finally, RNIC drains the offloaded WRs after execution. Re-executing them requires proactive refilling with the help of the MNode CPU. However, the MNode CPU has limited processing power and

can therefore become a performance bottleneck.

To address the aforementioned issues, first, ODRP adopts a client-assisted principle, which splits the offloaded functions and shifts part of the computation to the CNode for better performance (§4.3). Choosing how to split the functions is non-trivial, because we need to minimize the computation and storage overhead added to the CNode, as well as cope with compromised CNodes. Second, we propose utilizing the novel features offered by recent RNICs to efficiently implement several high-level primitives (referred to as meta WR) (§4.2). These include modulo and endianness conversion operators, which are critical for offloading complex functions. Finally, we discover that the RNIC only "logically" drains WRs, meaning that we can reactivate them by properly updating the RNIC's driver data structures. We are the first to propose a method to recycle executed WRs without requiring additional WRs or CPU intervention (§4.4).

We have implemented ODRP on Linux as a standard swap backend, making it transparent to applications. Compared to the state-of-the-art swap-based memory disaggregation system, namely Fastswap [11], ODRP achieves 1.72× to 12× better memory utilization with zero MNode CPU usage, and at the cost of slight performance overhead (up to 14.2%) on real-world applications including Quicksort, Kmeans, Memcached, GAPBS, and VoltDB. Moreover, it demonstrates superior performance, memory utilization, and scalability compared to other RDMA alternatives.

In summary, this paper makes the following contributions:

- We identify the issues with memory utilization and MNode CPU usage in existing RDMA alternatives for realizing swap-based memory disaggregation. (§2).
- We present a novel system design to efficiently offload memory management onto the RNIC, achieving better memory utilization and zero MNode CPU usage. (§4).
- An implementation and evaluation of ODRP to demonstrate its effectiveness and efficiency. (§5).

Although we focus on swap-based memory disaggregation, we believe that the methodology and principle summarized in our work can provide guidance for future offloading functions onto the RNIC. ODRP is available at https://github.com/SJTU-IPADS/ODRP.

2 Background and Motivation

2.1 Memory Disaggregation with RDMA

Memory disaggregation is a promising paradigm to improve overall memory utilization in datacenters [19, 11, 37, 21, 22, 14, 36, 29, 18, 26]. It separates servers into a CPU pool and a memory pool, namely CNodes and MNodes. When CNodes require additional memory, they can allocate it on MNodes and access it as needed. We focus on the asymmetric architecture, in which CNodes have powerful CPUs but limited memory, while MNodes have a large amount of memory but limited (or no) CPU power. It is worth noting that some systems adopt a symmetric architecture (i.e., a node can be both a CNode and an MNode at the same time). ODRP could be extended to support this symmetric architecture.

RDMA is a popular interconnect for CNodes to access MNode memory. One-sided primitives enable direct read, write, compare-and-swap (CAS), and fetch-and-add (FAA) operations on MNode memory, bypassing the MNode CPU. Two-sided primitives (i.e., SEND and RECV) facilitate message exchanges between CNodes and MNodes.

Our target: Swap-based memory disaggregation. We target a setup where CNodes leverage Linux's swap subsystem for memory disaggregation [19, 11, 28, 43, 39, 33, 40]. This approach offers the advantage of transparency compared to other alternatives [16, 17, 36, 21]. In this setup, if a CNode faces memory pressure, the kernel will swap out cold pages to the MNode. Likewise, if the application needs to read a swapped-out page, the kernel retrieves it from the MNode.

2.2 RDMA Alternatives to Implement Swap-based Memory Disaggregation

To support swap-based memory disaggregation, we need to implement the following functionalities on the MNode: (1) Read and write memory pages. (2) Verify the validity of the page address, i.e., whether the CNode has permission to access the page and (3) Memory allocation and deallocation. RNIC has been optimized for (1) and (2) through its data path one-sided primitives and memory region registration (MRR). However, it does not have efficient native support for (3). Specifically, MRR is a control path operation, which is inefficient and requires intensive CPU involvement. Therefore, current RDMA hardware only provides the following alternatives for existing systems to implement swap-based memory disaggregation.

- *One-sided (Static).* The MNode registers coarse-grained memory slabs (*e.g.*, 1 GB or the same size as the CNode's swap device) and allocates them to CNodes statically [11, 19, 40, 25, 33]. CNodes can directly access remote memory with one-sided primitives and require few or no memory allocation operations during runtime, making this approach highly efficient. However, this leads to poor memory utilization on the MNode due to severe internal fragmentation and the lack of elasticity.

- *One-sided (Dynamic).* To improve memory utilization and support elasticity, the MNode can register its memory as fine-grained (*e.g.*, 1 MB) memory regions (MRs) in advance and dynamically allocate them to CNodes. Specifically, if a CNode requires more (or less) remote memory, it can send an RPC message to the MNode using two-sided primitives. The MNode then allocates (or frees) an MR and returns its metadata (i.e., address and *rkey*) to the CNode. Afterwards, the CNode can use one-sided primitives to access the allocated memory like in the first approach.

Table 1: A comparison between ODRP and other RDMA alternatives. **Util**: utilization.

	Memory. Util	No CPU	Efficiency
Static	Poor	✔	Optimal
Dynamic	Medium	✘	Medium
Two-sided	Good	✘	Poor
ODRP	Good	✔	Good

Note that a freed MR must be re-registered before being allocated to other CNode for safety.

However, determining the appropriate memory allocation granularity is challenging due to the inefficiency of RDMA's control path (i.e., memory registration) and the limited CPU power of MNodes. For example, registering a 4 KB or 1 MB MR takes about 80 μs or 600 μs, respectively. Using a smaller memory slab size can improve remote memory utilization but incurs higher management overhead on MNodes and necessitates more frequent memory allocation requests from CNodes. Additionally, the limited CPU power of the MNode may become a performance bottleneck in the system.

- *Two-sided.* To minimize the cost of remote memory (de)allocation, CNodes can utilize two-sided primitives in the data path. The MNode CPU can always mediate the memory accesses from CNodes and then manage the remote memory at a fine granularity. However, this approach suffers from poor performance as two-sided primitives are less efficient than one-sided primitives [41] and requires more intensive involvement of the MNode CPU.

2.3 Issues with RDMA Alternatives for Swap-based Memory Disaggregation

This section conducts an experiment to analyze the issues of aforementioned alternatives. Detailed setup can be found in §5. Figure 1 shows the results of running increasing numbers of Quicksort tasks (each with 50% local memory) on 4 CNodes. For One-sided (dynamic), we adopt a 1 MB allocation granularity. Table 1 summarizes the comparison between ODRP and other RDMA alternatives.

Poor memory utilization of One-sided (Static). Figure 1 (a) illustrates the memory utilization of different alternatives. Memory utilization is measured as the ratio of actually used remote memory to allocated remote memory. As expected, One-sided (static) has the lowest utilization because MNode memory is pre-allocated based on the CNodes' swap space size. While One-sided (dynamic) alleviates this problem, the average remote memory utilization is still 24% lower than Two-sided due to larger allocation granularity (1 MB vs. 4 KB). It is worth noting that recent RNIC provides an on-demand-paging (ODP) MR [5] feature that provides transparent dynamic memory allocation for One-sided (static). However, this feature relies on the in-kernel driver's page fault handler for memory allocation, which is orders of magnitude slower than one-sided primitives. In our experiment, it even fails to complete the application benchmark.

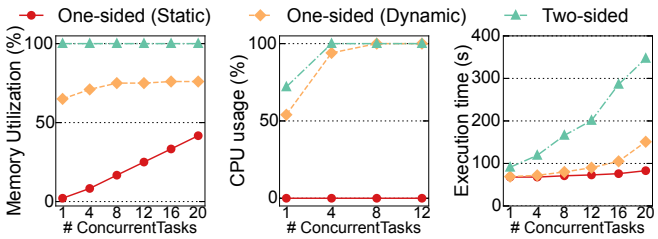

Figure 1: A comparison of RDMA alternatives in terms of (a) remote memory utilization, (b) remote CPU usage, and (c) execution time.

High MNode CPU usage of One-sided (Dynamic) and Two-sided. Figure 1(b) shows that as the number of running tasks increases, CNodes send more frequent allocation and swap requests, causing One-sided (dynamic) and Two-sided to quickly saturate the MNode CPU. As a result, the MNode CPU becomes the bottleneck and consequently slows down application performance due to request queuing.

Poor application performance of One-sided (Dynamic) and Two-sided. As shown in Figure 1(c), the average execution time for 20 Quicksort tasks in One-sided (dynamic) and Two-sided is 1.82× and 4.18× longer than One-sided (static), respectively. The performance degradation in One-sided (dynamic) can be attributed to the extra latency from waiting for memory allocation requests to complete. Moreover, Two-sided faces even more competition for the MNode CPU as every swap request needs to be queued up.

2.4 Programmable RDMA

This section presents necessary background for how to offload complex functionalities onto the RNIC.

Offloading arbitrary logic onto RNIC with WR chains. RNICs are designed to execute simple primitives posted by the CPU, known as work requests (WRs). These WRs can be linked together by recording the address of the next WR in the `next` field. When the RNIC executes the first WR, it will proceed to the next one in the chain. As a result, developers can chain multiple WRs together to offload more complex function onto the RNIC. We refer to a function offloaded to the RNIC as a *WR chain*. RDMA provides `WAIT` and `ENABLE` WRs to control execution timing. By linking a `WAIT` WR and an `ENABLE` WR after the first RECV WR in a chain, the RNIC will automatically execute the WR chain after receiving an RDMA SEND, bypassing the CPU.

An interesting property of the WR chain is its Turing completeness [34], which means we can offload arbitrary logic onto the RNIC, bypassing the CPU. Intuitively, the CAS WR provides branching, and the READ/WRITE WRs handle state reads and writes. Finally, we can implement *while* loops by reusing previously executed WR chains, i.e., after

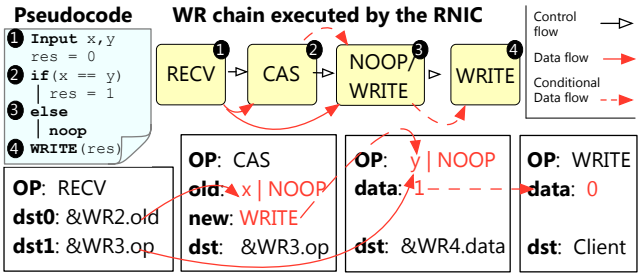

Figure 2: An illustration of how to execute the pseudocode with four RDMA WRs. For simplicity, we omit the `WAIT` and `ENABLE`.

RNIC finishes executing the last WR chain in the work queue (WQ), it wraps around to execute the first one again.

Example. Figure 2 depicts how to offload a simple conditional execution program onto the RNIC with a 4-WR chain (not counting `WAIT` and `ENABLE`). The chain checks whether x is equal to y using a CAS WR. Since the values of x and y are arguments and unknown to the WR chain before execution, the RECV WR will receive them and fill the `old` field of the CAS and the `op` field of the third WR with $x|NOOP$ and $y|NOOP$, respectively. Then, we can compare them with CAS. If x is equal to y, the CAS changes the third WR's `op` field (i.e., opcode) from NOOP to WRITE[1], causing the first branch to execute and update the final result (`WR4.data`). Otherwise, the third WR remains NOOP, and the RNIC takes no action (the second branch). Finally, the WRITE WR writes the result back to a client-side buffer.

3 ODRP Overview

Design goals. ODRP is a kernel-space swapping system that can transparently swap cold pages to the MNode. It has three main design goals: (1) *Fine-grained memory management on the MNode*, allocating and deallocating remote memory at page granularity to improve remote memory utilization; (2) *No remote CPU usage*, preventing the wimpy MNode CPU from becoming a performance bottleneck and realizing true disaggregation; (3) *Good performance*, achieving comparable performance to existing coarse-grained memory management solutions.

System architecture and high-level execution flow. Figure 3 presents the system components of ODRP. On the CNode side, ODRP provides a Linux swap backend that faithfully implements the Linux frontswap [3] API (see Table 2). On the MNode side, ODRP registers all of its provisioned memory as a large MR at initialization. The MNode maintains two types of swap metadata (detailed in §4.1): (1) it divides provisioned memory into 4 KB pages and manages them with a free page queue; (2) it maintains a translation table, initially unmapped, for each CNode that maps CNode swap addresses to page addresses. During runtime, memory

[1]Note that for the RNIC to read the updated WR, we need an `ENABLE` WR before the modified WR. For simplicity, we omit the `ENABLE` throughout the paper without losing generality.

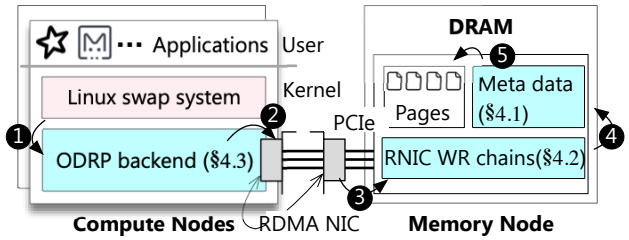

Figure 3: An overview of system components of ODRP.

pages are allocated from the free page queue and mapped in CNodes' translation tables on demand.

When the CNode's backend receives swap commands from the swap system (❶), it sends these requests to the MNode with swap addresses (❷). The MNode's RNIC then serves these requests by executing the pre-programmed logic (i.e., WR chains) stored in work queues (WQs) (❸). Each type of WR chain implements a specific high-level function (see Table 2). The WR chains leverage the swap metadata (❹) to perform address translation (swap address to page address), page access, and page (de)allocations (❺). Since all requests are handled by WR chains, there is no need for CPU intervention on the MNode.

Offloading challenges and solutions overview. While RDMA offloading presents opportunities for bypassing the CPU in fine-grained memory management, it is challenging to implement these logics efficiently and achieve full-fledged programmability due to the limited RDMA WR semantics.

C#1. Efficiency. Executing a new WR requires the RNIC to retrieve it from the work queue (WQ) in host memory via PCIe, which is relatively slow. There are two main sources of overhead that can degrade the performance of WR chains. First, more complex logic requires more WRs per chain. Second, the execution of each chain consumes all its WRs. To serve future requests, existing work [34] necessitates additional FAA and READ WRs to reactivate the executed WRs.

To minimize the number of WRs per chain, ODRP adopts a *client-assisted principle*, as detailed in §4.4. Specifically, to eliminate the need for the WR chain to calculate the address of the translation table entry (`tt_addr`) corresponding to a CNode's swap address, the MNode shares the base address of the CNode' translation table (`tt_base`) with it. Then the CNode can calculate and directly use `tt_addr` as an argument when invoking WR chains. To simplify the design of the page store WR chain, we categorize it into two cases based on whether the swap address is mapped or not (see Table 2), and have the CNode's backend determine which WR chain should be invoked. Additionally, we use the CNode as a helper to reactivate executed WR chains.

C#2. Functionality. Although RDMA offloading is theoretically Turing complete, it is non-trivial to offload complex logic onto the RNIC. First, the RNIC lacks support for the modulo operation (%), which is critical for avoiding overflow during computation. Second, the RNIC's endianness

Table 2: The CNode API and the corresponding implementation on the RNIC.

CNode frontswap API (§4.4)	RNIC Implemented Functions (§4.3)	Descriptions of the Implemented Functions
`load(swap_addr) ->page`	`load(swap_addr) ->page`	Swap in a page from the MNode with `swap_addr`.
`store(swap_addr, page)`	`mapped_store(swap_addr, page)`	Swap out a page to `swap_addr`.
	`unmapped_store(swap_addr, page)`	Allocate a page, map it to `swap_addr` and store the data in that page.
`invalidate(swap_addr)`	`invalidate(swap_addr)`	Free and unmap the page of `swap_addr` on the MNode.

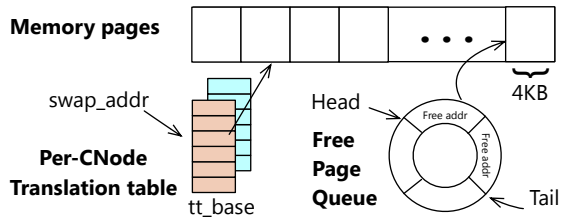

Figure 4: An illustration of the MNode-side data structures.

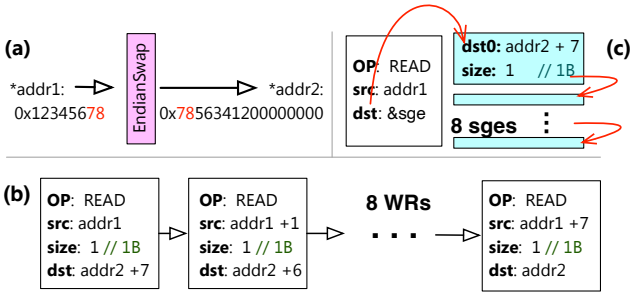

Figure 5: (a) An overview of `EndianSwap` meta WR. (b) A naive implementation using an 8 READ WRs. (c) ODRP utilizes 8 scatter/gather entries to achieve `EndianSwap` with one READ WR.

mismatches that of the host, meaning that the RNIC cannot directly use its computed value as an address to access host memory.

To address these challenges, ODRP has implemented two built-in chains as *Meta WR*s, as detailed in §4.2: one for the modulo operation and one for endianness conversion. By leveraging new RNIC features [2], we show that these operators can be supported efficiently, greatly simplifying the offloading of complex logic onto the RNIC.

4 Design and Implementation

4.1 Data Structures at the MNode

Free Page Queue. As shown in Figure 4, the MNode divides its memory into 4 KB pages and organizes them with a FIFO free page queue. During initialization, it inserts all the free pages into that queue. The queue is implemented as a fixed-sized ring buffer, determined by the number of pages the MNode can provide, and has one head pointer and one tail pointer. Each queue element is 8 bytes (8 B) in size, holding the address of a free page. When allocating a free page to a CNode, ODRP performs a dequeue operation to obtain a free page address, i.e., leverages the RDMA atomic FAA WR on the queue head pointer. When a page is freed, ODRP performs an enqueue operation, i.e., uses atomic FAA on the queue tail pointer and stores the page address in the fetched queue element.

This results in $O(1)$ complexity for (de)allocation operations, making it well-suited for the WR chain. In contrast, using other structures like bitmap to maintain free pages requires a more complex WR chain, which would harm efficiency. For example, allocating a page with a bitmap requires multiple RDMA WRs to search for a free bit and a CAS WR to update the free bit.

Translation Table (TT). ODRP provides each CNode with a swap space and maintains a TT for it, which records the mapping between swap addresses and allocated page addresses on the MNode. Each entry in the TT starts out empty. Pages are allocated from the free page queue and mapped to the TT on demand during CNode runtime. The TT is necessary to ensure memory isolation, as each WR chain can access all the MNode memory to enable fine-grained memory management and sharing (i.e., a freed page can be allocated and mapped to another CNode's swap space). Moreover, we use a single-level page table design for efficient offloading: it requires only one READ WR for address translation (see Figure 6). Finally, since the swap requests are initiated by the Linux swap subsystem in a coordinated manner (i.e., a CNode's concurrent swap requests will not target the same swap address), ODRP does not need to coordinate concurrent operations targeting the same TT entry.

4.2 Meta WRs

Before diving into the details of WR chains, we first describe the design and implementation of two meta WRs that are essential for the WR chains. Although these operations could be performed by the MNode CPU, this approach would require an interrupt from the RNIC to the CPU, which is less efficient. Therefore, we choose to implement these operations within the WR chains as meta WRs.

The modulo WR. The modulo (%) operation is crucial to prevent overflow in the enqueue and dequeue operations of ring buffer. However, without proper hardware support, it is impossible to implement the modulo operator with just a few WRs. Fortunately, recent RNICs provide an Enhanced Atomic Operations [10] feature, which includes a Masked-FAA WR that allows users to split the target value into multiple fields of selectable length for addition. By using this feature, we can mask the upper bits of the value to implement FAA with modulo support.

The endianness conversion WR (EndianSwap). Network protocols, including RDMA [1], traditionally use big-endian

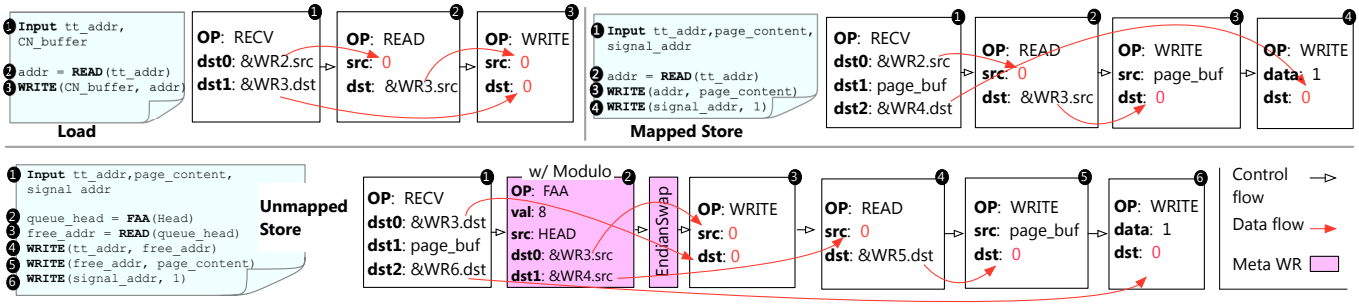

Figure 6: A simplified illustration of the WR chain design in ODRP. We omit fields like size and `WAIT` and `ENABLE` WRs. In the Load, Mapped Store, and Unmapped Store WR chains, the number of omitted `WAIT` and `ENABLE` WRs is 3, 4, and 5, respectively. The `WRITE` writes the memory from `src` to `dst`.

format, which differs from the little-endian format used by most host CPUs (*e.g.*, x86-64). This mismatch can lead to subtle issues in RDMA offloading. For example, the FAA WR performed on the host memory returns the result in little-endian format (*e.g.*, the fetched value of the queue head pointer). However, a READ WR expects its source field in big-endian format. As a result, the fetched value of the queue head pointer by FAA cannot be directly used for a subsequent READ WR without endianness conversion.

To efficiently address this issue without involving the MNode CPU, we designed an `EndianSwap` WR to simplify endianness conversion. A naive implementation would involve using N READ WRs to convert an N-bytes value. Figure 5 (b) shows an example of converting an 8-byte value from little-endian to big-endian: the first WR moves the first byte to the last byte, and so on. However, this approach is inefficient due to the excessive use of WRs. ODRP leverages the scatter-gather entry (SGE) feature provided by RNICs to reduce the number of WRs to just one. As presented in Figure 5 (c), the RNIC can scatter a continuous memory block into multiple destination buffers using SGEs. By filling the `dst` fields of multiple SGEs in reverse order, we can achieve endianness conversion with just one READ WR.

4.3 MNode-side WR Chains

Figure 6 presents the pseudocode and WR chains of offloaded functions (see Table 2). When CNodes need to swap in or out a page, they use RDMA SEND with arguments to trigger these WR chains. We assume the arguments are valid for now. Handling invalid arguments will be detailed in §4.5. Notably, instead of directly providing the swap address, we request CNodes to compute the TT entry address ($tt_base + swap_addr / PAGE_SIZE$) as an argument to all WR chains. This approach eliminates the need for an additional FAA and an EndianSwap WR in the WR chain to perform this calculation. This optimization incurs zero memory overhead for the CNode, as each CNode only needs to store its own `tt_base`.

Page load. Page load takes a TT entry address (`tt_addr`) (❶), looks up the page address stored in that entry (❷), and writes the page stored at that address back to the CNode's buffer—`CN_buffer` (❸). To look up the page address, the RECV fills the source field of the next READ with `tt_addr`. The READ then places the result of address translation (i.e., the page address on the MNode) in the source of the subsequent WRITE. Finally, the WRITE writes the page data back from the MNode memory to the destination buffer, which has been set to `CN_buffer` by the RECV.

Mapped page store. The WR chain receives a `tt_addr` and stores the received page data (`page_content`) at the address specified in that entry. The WRs used in this chain are similar to page load: the RECV (❶) fills the source field of the next READ with `tt_addr` and places the `page_content` in a temporary page buffer (`page_buf`). Then, the READ WR looks up the page address (❷) stored in the TT entry. Subsequently, the next WRITE writes the page content to that page from `page_buf` (❸). Finally, we use an additional WRITE (❹) to notify the CNode of the completion of this request by writing a magic number to a CNode-provided buffer (`signal_addr`).

Unmapped page store. This is the most complicated WR chain in ODRP, which is responsible for allocating a free page, mapping it in the TT, and storing the received page.

At a high level, this WR chain receives a `tt_addr` and allocates a page from the free page queue (❷). It then maps the allocated page address to the TT entry (❸) and stores the received page data (`page_content`) in the newly allocated page (❹–❺). To pop a free page address from the page queue, the chain uses an atomic FAA with modulo support to increment the head pointer by 8 ($head = head + 8$). The fetched old value of the head pointer (old_head) points to the allocated queue element that contains a free page address.

Note that the FAA retrieves old_head in little-endian format, which is consistent with that of a typical host CPU (e.g., x86-64). However, the subsequent WRs assume that their `src` or `dst` fields are in big-endian format. To correctly read the allocated page address ($*old_head$), we use the aforementioned EndianSwap WR to convert it to big-endian format. Given the free page address, it is straightforward to map it in the TT entry (❸) and store the `page_content` with WRITE (❹–❺). Finally, we notify the CNode with another

WRITE (❻), similar to the mapped page store WR chain.

Page invalidation. Due to space limitations, we omit this chain in Figure 6, which is similar to the unmapped page store WR chain. At a high level, we first read the address of the page to be released from the TT entry. Next, we insert the address back to the page queue by incrementing the tail pointer with FAA ($tail = tail + 8$) and using WRITE to store the freed page address to the old tail ($*old_tail = page_addr$). Finallyt, we unmap this page in the CNode's TT by setting the TT entry to zero.

Handling empty free page queue and crashed CNodes. There are two corner cases in ODRP: all memory pages on the MNode are allocated (i.e., the free page queue is empty) and a CNode crashes unexpectedly. First, we use an invalidation-based mechanism to detect the empty free page queue and abort the allocation if necessary. Specifically, after each allocation, we clear the allocated queue element ($*old_head = 0$). As a result, the first allocation attempt on the empty queue will return a null page address, causing the subsequent WRs to throw an RDMA protection error. To this end, we add a WRITE WR after the fifth WRITE WR (❺) of the unmapped store chain to set the queue element to zero. A limitation of this approach is that if such an error occurs, we need to use the MNode CPU to recover the state of the free page queue (i.e., reset the head pointer to the correct value), as page invalidation requests may continue pushing free pages into the corrupted page queue.

Second, when a CNode crashes unexpectedly, ODRP needs to recycle the resources allocated to it, including memory pages and its TT. In ODRP, the MNode detects crashed CNodes via heartbeat signals. Upon detecting a crashed CNode, the MNode scans its TT and releases the pages contained in the mapped TT entries. Then, the MNode releases the crashed CNode's TT.

4.4 CNode-side ODRP Backend

For each type of WR chain, the CNode backend has an RDMA connection to the MNode, and the MNode-side work queue (WQ) is pre-populated with corresponding WR chains to handle requests.

Swap API implementation. ODRP provides a Linux frontswap [3] backend, which operates as a swap device at the CNode. The API implementation is as follows:

- `load`: The backend calculates the `tt_addr` based on the swap address and invoke the page load WR chain by posting an RDMA SEND.
- `store`: The backend checks whether the swap address is mapped. If it is, the mapped page store chain is called; otherwise, the unmapped page store chain is invoked.
- `invalidate`: The backend invokes the page invalidation chain.

In the cases of `load` and `invalidate` operations, the swap address has a valid mapping in the TT because it must have been previously stored. However, `store` lacks this information. A naive approach would be to add extra logic in the WR chain to look up the TT and allocate a page if the target swap address is unmapped. However, it is inefficient due to the extra WRs per chain. Our observation is that a CNode's swap backend actually has full knowledge of the remote allocation status: (1) the entire swap space is unmapped initially (i.e., the whole TT starts out empty), and (2) an allocated page can only be freed by the CNode's page invalidation request, meaning the CNode controls the unmapping operation. Therefore, each CNode can maintain a bitmap to record the allocation state of each page in its swap space. With this information,`store` can determine whether the target swap address is mapped and invoke the appropriate WR chain (mapped page store or unmapped page store).

CNode-assisted MNode WR recycle. After a WR chain is executed, the WRs in it are logically dequeued from the WQ. To serve future requests, an intuitive approach is to post new WRs with the CPU. However, this would cause unexpected stalls in the RNIC's processing pipeline since the wimpy MNode CPU can only post asynchronously at a relatively low rate. To bypass the MNode CPU, ODRP makes a key observation that executed WRs are not physically erased from the WQs. Thus, by modifying the WR metadata, which is stored in WQs, we can reactivate executed WRs[2].

More specifically, to make the RNIC wrap around to the beginning of the WQ, we only need to modify the index field of the RNIC's ordering primitives, namely WAIT and ENABLE. This field indicates the index of the WR affected by these ordering primitives. Special attention needs to be paid to the RECV WR, which serves as the triggering WR of each WR chain. We discovered that to inform the RNIC that the consumed RECV is ready for re-execution, it is only necessary to modify the *doorbell record* value of the WQ.

Putting it all together, to recycle executed WRs without involving the MNode CPU, a straightforward way is to inject additional FAA and EndianSwap WRs in the chain to update the index field [34] and the doorbell record. However, this adds extra WRs to the WR chains and introduces a performance penalty. To avoid using additional WRs for index calculation and updating, we shift this calculation to CNodes. To be specific, the CNode will piggyback the calculated values with other arguments when sending requests. The RECV WR in the WR chain will use these values to update the index field and the doorbell record. As a result, no extra WR is needed for recycling.

4.5 Correctness under Benign and Malicious CNodes

We define the correctness of ODRP in two aspects. First, the TTs and the free page queue must always be consistent.

[2]RedN [34] proposed WQ recycling to implement unbounded loops. However, to the best of our knowledge, no one has found a solution to recycle RECV. RedN's open-source code also does not implement their strategy.

Specifically, these data structures are consistent if and only if (1) the free pages in the free page queue cannot be mapped to any TTs, and (2) each allocated page can only be mapped in exactly one TT. Second, requests from different CNodes must be isolated; i.e., a load or store can only access the page mapped in the CNode's own TT, even in the presence of malicious CNodes.

4.5.1 Correctness under Benign CNodes

Consistency. We informally argue that our WR chains can ensure consistency via induction. We first initialize the MNode to a consistent state by ensuring each page exists exactly once in the free page queue, and leave all the TTs empty. We then demonstrate that the execution of CNode requests will maintain the consistency of these data structures. This is straightforward when not considering concurrent requests. Executing a load or a mapped store operation, which does not modify the TT and the free page queue, naturally preserves this consistency. For the unmapped store operation, since it faithfully performs a dequeue operation, we only need to ensure that the free page address popped from the queue is consistent with the address written to the TT entry, which is obvious under our assumption of benign CNodes. Finally, page invalidation is the reverse operation of an unmapped store, so the argument is the same.

For concurrent unmapped store and invalidation operations, we use RDMA's atomic FAA to avoid race conditions, similar to other concurrent queues [31]. Concurrent load/-store operations targeted on the same `tt_addr` are inherently avoided due to the semantics of the swap subsystem. One tricky case is when the unmapped store and invalidation operations are executed concurrently. Ideally, there is no race condition between them because the ummapped store operation only modifies the queue head, while the invalidation modifies the queue tail. However, a potential race condition emerges when the queue is empty, i.e., the queue head and tail point to the same address. In this scenario, an unmapped store operation may read the queue head while an invalidation operation concurrently writes to this head. We require RDMA to provide atomic 8 B read and write for correctness, which is ensured by hardware with cache-aligned accesses [15, 16, 30, 42]. With this atomicity guarantee, the unmapped store operation will either get the latest invalidated page or a null address. Both cases are correct.

Isolation. Since all load and store requests can only access pages mapped in the CNode's own TT, requests from different CNodes are isolated as long as their TTs are consistent, which has been demonstrated above.

4.5.2 Handling Malicious CNodes

Security model. We assume MNodes are trustworthy, while CNodes can be compromised, the same as existing systems [11, 19, 22]. A malicious CNode might send illegal requests with invalid arguments (e.g., invalid `tt_addr`), or try to exhaust the memory resources of the MNode by continuously sending unmapped store requests. We show that malicious CNodes requests will be rejected by the MNode.

Correctness under illegal requests. Such requests can be categorized into two types: one with an illegal operand code (e.g., an RDMA READ instead of SEND) or one with an invalid argument. For the first one, we can configure the RDMA connection permission such that they will be rejected by the RNIC. For the latter, we only need to handle the invalid `tt_addr`, as the WRs manipulate TTs and the free page queue based on it (see Figure 6). Specifically, an invalid `tt_addr` can be (1) misaligned, (2) out-of-range and (3) being unmapped in a request that assumes mapped `tt_addr`. For (1), we can configure the RECV WR to only use the upper bits of the `tt_addr` to efficiently avoid misaligned `tt_addr`. For (2), we use RDMA's memory registration to ensure that all the WRs in WR chains can only access the CNode's own TT. For (3), we ensure the unmapped TT entries are zero through proper initialization and clean-up. As a result, such an argument will cause an RDMA protect error due to null access, which will abort execution. Additionally, we insert a conditional check similar to the one described in Figure 2 to rule out unmapped `tt_addr` in page invalidation operations.

Fairness. To ensure fairness, we follow existing works [11, 19] that set a budget for the maximum allocated memory for CNodes. If the budget is exhausted, the MNode will reject allocation requests from the CNode to maintain fairness. The challenge is how to keep track of each CNode's usage. Existing systems can leverage the CPU to actively record it before allocating memory to a CNode. However, in ODRP, we bypass the MNode CPU in memory allocation. To address this, we leverage a lazy detection method to periodically check whether a CNode exceeds its budget. Specifically, we use one CPU core at the MNode to monitor the memory usage of each CNode. The challenge is how to efficiently perform this bookkeeping. A naive solution would be scanning the TTs, which would incur significant CPU overhead. Fortunately, we can leverage the RDMA hardware counters [35] for this calculation. These counters record the completion of WRs in the unmapped store and invalidation WR chains. By comparing these counters, we can efficiently get the number of allocated pages of a CNode.

5 Evaluation

5.1 Evaluation Setup.

Testbed. Our experiments are conducted on a cluster with one MNode and up to 8 CNodes, all connected with an InfiniBand switch. Each node has a 12-core Intel Xeon E5-2650 CPU (hyper-threading is disabled), 128 GB DDR4 RAM, and a 100 Gbps Mellanox ConnectX-5 RNIC. Each node runs Mellanox OFED 4.9 and Linux 4.15. Each CNode is configured with 12 GB swap space.

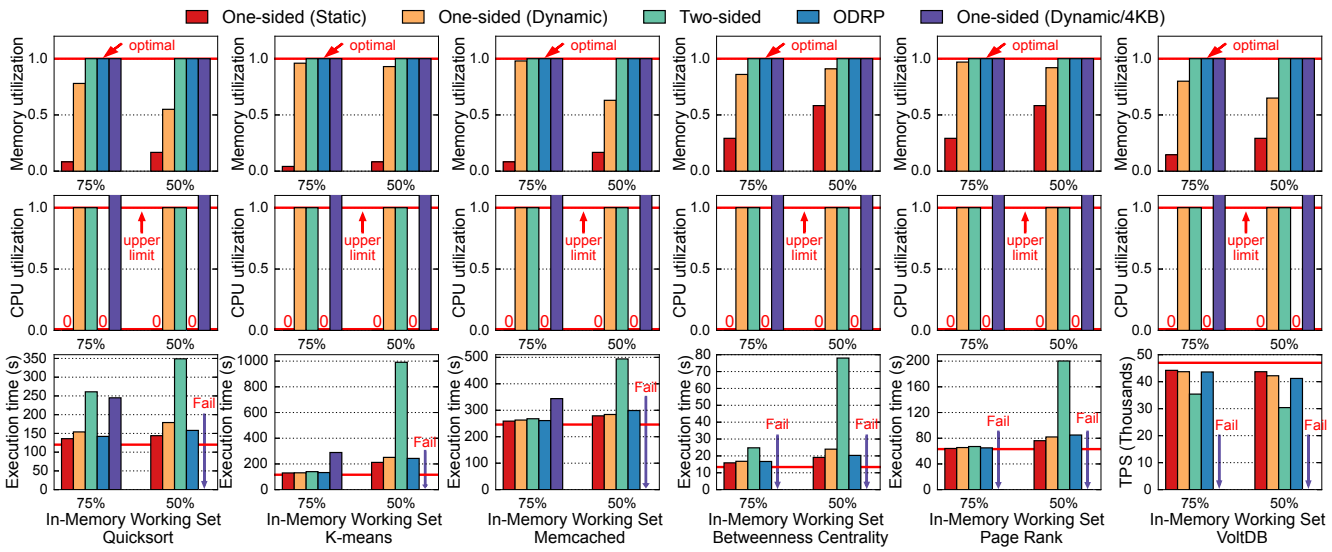

Figure 7: Remote memory utilization (higher is better), remote CPU usage (lower is better), and the execution time (throughput) of ODRP and other four baseline systems under different workloads with 8 CNodes accessing one shared MNode.

Baselines. We compare ODRP with four baselines as described in § 2.2: 1) One-sided (static), pre-registering 12 GB of remote memory for each CNode; 2) One-sided (dynamic), preparing 1 MB MRs in advance while allocating them to the CNode on-demand; 3) Two-sided, using two-sided RDMA operations in the data path to implement 4 KB-granularity memory management; 4) One-sided (dynamic/4KB), same as One-sided (dynamic) but performing 4 KB allocation. The MNode only uses one CPU core to simulate the weak processing power, unless otherwise specified. We implement all the baselines based on Fastswap [11] and compare them to ODRP, aiming to demonstrate that ODRP outperforms baselines regarding application performance, remote memory utilization, and remote CPU usage.

Evaluated applications. We evaluate the applications used in prior memory disaggregation studies [19, 11, 43]. 1) Quicksort with a 4 GB working set; 2) Kmeans with a 2 GB working set; 3) Memcached v1.4.25 with Facebook ETC workload [12] (4 GB working set), a server thread and four client threads; 4) Page rank (PR) and 5) betweenness centrality (BC) from GAPBS [13] on a Twitter dataset [24], 4 threads and a 14 GB working set; 6) VoltDB with TPC-C [8], 8 threads and a 7 GB working set.

5.2 Application Benchmarks

We run the applications on all available hardware in our cluster, which consists of 8 CNodes and one shared MNode. This cluster setup aligns with the typical deployment of memory disaggregation, such as in cloud environments [26].

Memory utilization. The first row of Figure 7 illustrates the average remote memory utilization during application runtime, which is measured as the ratio of actually used remote memory to allocated remote memory. One-sided (static) can only achieve up to 58.3% remote memory utilization because of its coarse-grained static allocation. One-sided (dynamic) can significantly improve remote memory utilization by adopting fine-grained allocation. However, it still cannot achieve ideal utilization because of the fragments within 1 MB memory slabs. It achieves about 95% remote memory utilization for workloads where internal fragmentation is not significant, such as Kmeans, betweenness centrality, and page rank. More severe internal fragmentation can lead to worse remote memory utilization. For example, One-sided (dynamic) can only achieve 55% remote memory utilization in the case of Quicksort with 50% local memory.

In contrast, thanks to the page-granularity memory management, ODRP, Two-sided, and One-sided (dynamic/4KB) can achieve ideal remote memory utilization (100%). This results in up to 1.82× improvement over One-sided (dynamic) and a 1.72× to 12× enhancement compared to One-sided (static).

Remote CPU usage. As shown in the second row of Figure 7, both One-sided (dynamic) and Two-sided reach the upper limit of one MNode CPU core in all workloads. The saturated MNode CPU turns into a performance bottleneck, as discussed in more detail in § 5.3. Some workloads even fail to complete in One-sided (dynamic/4KB). If we use a single-CNode evaluation setup, One-sided (dynamic) results in a maximum of 67% remote CPU usage because the MNode CPU needs to serve memory (de)allocation requests. Two-sided requires higher remote CPU usage because it involves the MNode CPU in every swap in/out request. In Kmeans and graph processing workloads, which involve more frequent swap operations, Two-sided leads to 86% and 99% remote CPU usage, respectively.

For One-sided (dynamic/4KB), we removed the restriction of providing only one MNode CPU core, otherwise the applications fail to complete. One-sided (dynamic/4KB) requires

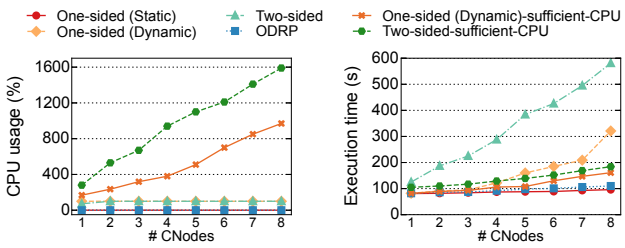

Figure 8: The impact of increasing the number of CNodes (each with 4 Quicksort tasks) on (a) Remote CPU usage and (b) Execution time

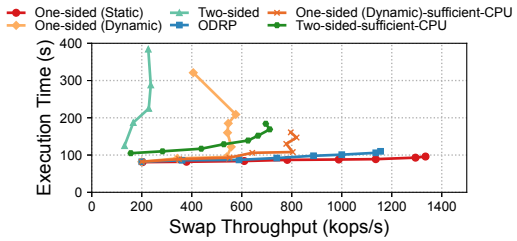

Figure 9: The average swap throughput (i.e., the number of swap in/out requests per second) and the application execution time increase as the number of CNodes (each running 4 Quicksort tasks) increases from 1 to 8.

the most intensive MNode CPU involvement and can use up to 3 MNode CPU cores in the single-CNode setup. In the 8-CNode setup, some applications even fail to complete due to poor performance.

In contrast, One-sided (static) does not require the MNode CPU during runtime due to its static allocation (i.e., all remote memory is provisioned at initialization time). ODRP implements all of its memory management logic through RDMA offloading, thereby also bypassing the MNode CPU.

Performance. The third row of Figure 7 presents the application performance (execution time or throughput). The red line indicates the performance with 100% local memory (optimal). For Quicksort, compared to One-sided (static), ODRP shows a modest performance overhead of 9.7%. In contrast, One-sided (dynamic) experiences a 24.3% performance overhead because the MNode CPU becomes saturated, causing allocation requests to queue up. Two-sided encounters substantial performance degradation, primarily due to significantly slower remote access and swap request queuing. resulting in a 142.4% overhead. One-sided (dynamic/4KB) shows the worst performance due to frequent MR registering. It introduces an 80.1% performance overhead with 75% local memory, and the application fails to complete with 50% local memory.

For Kmeans, reducing the in-memory working set has a more severe impact on its execution time because it triggers the most frequent major page faults that need swap operations in all evaluated workloads, averaging 6,400 times per second (46.7% higher than Quicksort). Compared to One-sided (static), ODRP experiences slightly higher swapping latency due to more frequent swap requests, as detailed in § 5.4. In this swapping-intensive workload, ODRP introduces a 14.2% performance overhead compared to One-sided (static).

For Memcached, both ODRP and One-sided (dynamic) demonstrate negligible performance overhead when local memory is decreased, because the swap operations are less frequent. ODRP incurs a 7.2% performance overhead compared with One-sided (static). Additionally, in terms of the query latency, the average and maximum latency increases introduced by ODRP always remain below 2%.

For BC and PR, ODRP's performance overhead is 6.3% and 11.5% compared to One-sided (static), respectively. It can outperform One-sided (dynamic) by up to 15.4%. For VoltDB, ODRP reduces throughput by 4.1% compared to One-sided (static). Regarding transaction latency, ODRP modestly elevates both the average and maximum latencies by less than 1% and 4.9%, respectively.

5.3 Scalability Analysis

In this section, we analyze the scalability of ODRP by increasing the number of CNodes and compare it to other baselines. We choose Quicksort because its swap frequency is relatively high, which can more effectively demonstrate the sensitivity of ODRP under different scales of swap frequency.

Scalability with the increasing number of CNodes. Figure 8 shows the average execution time and remote CPU usage as we increase the number of CNodes from 1 to 8, each running four Quicksort tasks (50% local memory). Despite achieving ideal remote memory utilization, Two-sided exhibits the poorest performance and scalability. The MNode CPU has been saturated with just one CNode. With 8 CNodes (i.e., 32 Quicksort tasks), it results in a 505% performance overhead compared to One-sided (static). Although One-sided (dynamic) can attain up to 77% remote memory utilization, it also overwhelms the MNode CPU with just one CNode and introduces a 234% performance overhead at 8 CNodes compared to One-sided (static). In contrast, ODRP offloads all memory management operations to the RNIC and is not limited by the wimpy MNode CPU. Consequently, ODRP demonstrates superior performance and scalability compared to Two-sided and One-sided (dynamic).

Throughput-latency. To demonstrate that ODRP can scale, we measure the overall swap throughput with respect to the application execution time. As shown in Figure 9, both One-sided (static) and ODRP reach a saturation point for the swap throughput at 8 CNodes, with ODRP achieving 87.3% of the swap throughput of One-sided (static). Consequently, ODRP incurs performance overheads of 5.7% and 14.6% at 4 and 8 CNodes, respectively. Nevertheless, ODRP significantly improves remote memory utilization, achieving 3 × better utilization than One-sided (static).

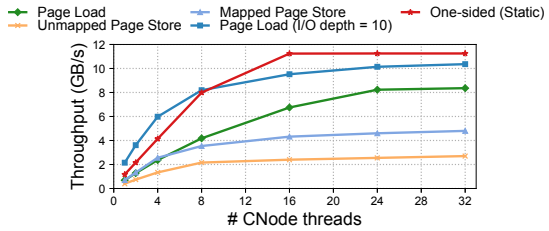

Figure 10: The throughput of different data path operations in ODRP and One-sided (static).

Microbenchmark analysis. To further analyze the scalability of ODRP, we evaluate the throughput of various data path operations in ODRP and One-sided (static). As shown in Figure 10, the throughput of page load operation with high I/O depth reaches 92.1% of the throughput achieved by RDMA READ/WRITE operations, i.e., data path operations in One-sided (static). The unmapped page store operation exhibits the lowest throughput because the throughput of RDMA atomic FAA, which is required by it, is an order of magnitude lower than that of RDMA READ/WRITE [34].

Even though ODRP introduces overhead to swap requests, application performance in ODRP is still on par with that in One-sided (static). This can be attributed to two reasons. First, page load requests account for the majority of all requests (more than 60% of the swap requests are page load) and they are sent by the CNode's swap backend in a batched manner due to page prefetching, where the performance of ODRP and One-sided (static) is similar. Meanwhile, the least efficient unmapped page store operation only accounts for approximately 10% of the requests. Second, the RNIC supports a high throughput of RDMA requests, such that even applications with high swap frequency can barely saturate it (see Figure 9).

Comparisons with baselines with sufficient MNode CPU. We further include two baselines where enough MNode CPU cores are provisioned to One-sided (dynamic) and Two-sided. As shown in Figure 8, Two-sided costs up to 16 MNode CPU cores, but it still cannot achieve the throughput of ODRP and incurs up to a 67.3% performance overhead compared to ODRP. One-sided (dynamic), being less demanding on the MNode CPU, can achieve higher throughput with up to 10 MNode CPU cores. Nevertheless, it remains 46.4% slower compared to ODRP at 8 CNodes due to additional time spent on memory (de)allocation. This is because the (de)allocation operations are costly when executed with the MNode CPU, and they are not rare during execution, occurring on average 3,000 times per second.

5.4 Factor Analysis

Figure 11 shows the latency of various data path operations in ODRP and baseline systems. When there is only one worker issuing requests (without resource competition), the one-sided RDMA READ/WRITE in One-sided (static) exhibits the lowest latency, measuring at 2.9 μs. In ODRP, the most frequent operations, namely load and mapped store, have latencies of 5.5 μs and 4.6 μs, respectively. Note that such an increase in latency can be mitigated by the swap system, e.g., with page prefetching and asynchronous page store. In comparison, the data path operations in Two-sided have significantly higher latency, 3.8× than that of the native one-sided operations. Note that One-sided (dynamic) also utilizes native one-sided operations in the data path, and the latency of `Allocation` is not excessive. This explains why One-sided (dynamic) does not introduce substantial performance overhead when the MNode CPU is not overly overwhelmed.

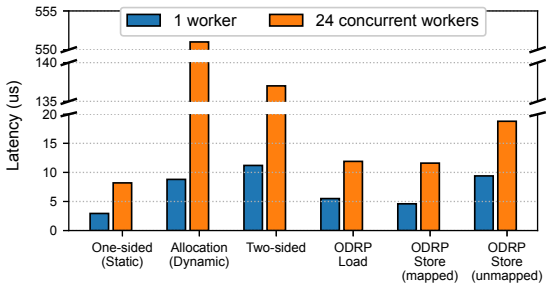

Figure 11: Latency of various data path operations. `Allocation` refers to acquiring a 1 MB memory slab (i.e., MR) in One-sided (dynamic).

When there are 24 concurrent workers issuing requests, there is an order of magnitude increase in the latency of `Allocation` and Two-sided data path operations due to the overloaded MNode CPU. This explains why both One-sided (static) and Two-sided experience a sharp decrease in performance as the number of CNode rises (see Figure 8).

The effect of ODRP optimizations. To quantify ODRP's optimizations for WR chains, we break down the execution time of the unmapped page store WR chain. The naive unmapped page store exhibits an unacceptable latency of 35.9 μs. `StoreDecision` (§ 4.4) splits the page store operation into mapped page store and unmapped page store to avoid an `if` statement in the WR chain, saving one CAS and one WRITE and reducing the latency by 1.9 μs. `CalcTTAddr` (§ 4.3) avoids calculating `tt_addr` in the WR chain, saving one FAA WR and one EndianSwap WR and reducing latency the by 2.4 μs. `RecycleHelper` (§ 4.4) prevents the use of additional FAA and EndianSwap WRs for reactivating WR chains, reducing the latency by 16 μs. Finally, `EndianSwap` (§ 4.2) reduces the number of WRs needed for the endian conversion from 8 READ to 1 READ with 8 SGEs, further reducing the latency by 6.2 μs.

6 Discussion

Extensibility. We implemented ODRP's CNode backend and the WR chain offloading (based on the RedN framework [34]) with about 1,300 and 2,400 lines of C code, respectively. Our prototype implementation only considers a setup where multiple CNodes share one MNode. However,

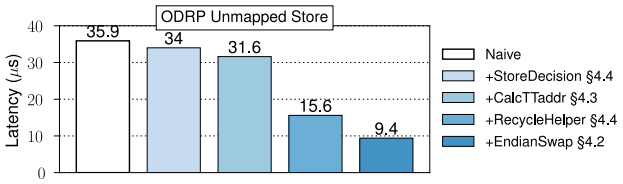

Figure 12: Analysis of ODRP optimizations to the average latency of unmapped store.

ODRP can be easily extended to support a multi-CNode-multi-MNode setup. To achieve this, a CNode only needs to partition its swap space across different MNodes and then locates the respective MNodes accordingly during runtime.

Furthermore, ODRP supports configurable allocation and access granularity, making it compatible for integration with other memory disaggregation systems [36, 43, 20, 33] that focus on optimizing CNode runtime. ODRP can improve their remote memory utilization while preserving the benefits of an optimized CNode runtime.

Memory Overhead of Translation Table. In ODRP, the MNode maintains a TT for each CNode that connects to it. The TT size depends on the size of the swap space provisioned to CNodes. Each TT entry stores an 8 B free page address. For a 32 GB swap space, the TT only occupies 64 MB of memory (0.2% memory overhead). Furthermore, this memory overhead can be alleviated by registering TTs as On-Demand-Paging MRs [5].

Suggestions to Future RNIC Vendors. Currently, the RNIC can only fetch and execute WRs one-by-one from the WQ in host memory if preceding WRs need to update subsequent WRs. This hampers efficiency when offloading complex functionalities. In the future, RNICs could incorporate a prefetching mechanism to speed up the execution of the self-modifying WR chains. Additionally, we encourage RNIC vendors to provide primitives with richer semantics. We have demonstrated that implementing this would not be overly challenging based on the current RNIC hardware. By introducing more powerful WRs, the length of WR chain can be reduced, and the development effort can be saved.

7 Related Work

RDMA-based Remote Swapping. Previous research studies have adopted RDMA remote memory as a swap backend [19, 11, 33, 28, 43, 40]. Infiniswap [19] places frequently accessed area of its swap space in remote memory to boost performance. Fastswap [11] further improves swapping performance by utilizing frontswap [3] interfaces. It makes non-critical operations asynchronous and creates a dedicated thread for asynchronous page reclamation. Leap [28] designs a more efficient page prefetching policy suited for remote memory, which is based on majority-based pattern detection. DiLOS [43] proposes to use a single address space operating system (SASOS) to reduce kernel-user switching overhead and improve performance with user-space semantics. However, none of these studies fully utilize remote memory due to their static and coarse-grained remote memory management. ODRP focuses on providing fine-grained memory management with RDMA offloading.

Fine-grained Remote Memory Management. CoRM [38] reduces memory fragmentation by leveraging Mellanox's ODP feature [5] to achieve remote memory compaction. However, CoRM requires intensive CPU involvement to compact memory, which is not suitable for wimpy MNode CPU cores. Programmable hardware devices have also been adopted to support complex computation offloading, such as SmartNICs and FPGAs. Clio [21] relies on dedicated FPGAs and network to virtualize and manage remote memory at a 4 MB granularity. TDMem [22] also utilizes specialized FPGAs and backbone network to support fine-grained and secure memory disaggregation. However, utilizing such specialized programmable hardware comes with higher costs, additional maintenance burdens, and longer deployment cycles [7]. ODRP aims to provide fine-grained memory management on commodity RNICs.

RDMA Offloading. Hyperloop [23] was the first to demonstrate that offloading complex functionality to RNICs can be achieved by combining native RDMA WRs. It leverages this offloading capability to eliminate CPU's involvement from the critical path of replicated transactions in storage systems. Furthermore, RedN [34] has recently proven that RDMA is actually Turing-complete by carefully chaining self-modifying and data-dependent RDMA WRs. RedN provides a blueprint for offloading arbitrary computation logic onto RNICs, and demonstrates its effectiveness and efficiency with two simple use cases: hash lookup and list traversal. ODRP utilizes RDMA offloading to provide fine-grained and efficient remote memory management, bringing ideal remote memory utilization.

8 Conclusion

ODRP demonstrates the viability of fully offloading a complex system (remote swap device) to RNIC, which achieves nearly zero remote CPU usage, high remote memory utilization, and low performance overhead. We highlight the advantages and limitations of RDMA offloading and, more importantly, we propose the use of client-assisted principle to mitigate many of the limitations.

Understanding and Profiling NVMe-over-TCP Using `ntprof`

Yuyuan Kang and Ming Liu

University of Wisconsin-Madison

Abstract

NVMe-over-TCP (NVMe/TCP) is an emerging remote storage protocol, increasingly adopted in enterprises and clouds. It establishes a high-performance reliable data channel between clients and storage targets to deliver block I/Os. Understanding and analyzing the protocol execution details and how well storage workloads run atop are pivotal for system developers and infrastructure engineers. However, our community lacks such a profiling utility, whereas existing solutions are ad-hoc, tedious, and heuristic-driven. Realizing it is challenging due to the unpredictable I/O workload profile, intricate system layer interaction, and deep execution pipeline.

This paper presents `ntprof`, a systematic, informative, and lightweight NVMe/TCP profiler. Our key idea is to view the NVMe/TCP storage substrate as a lossless switched network and apply network monitoring techniques. We model each on-path system module as a software switch, equip it with a programmable profiling agent on the data plane, and develop a proactive query interface for statistics collection and analysis. `ntprof`, comprising a kernel module and a user-space utility, allows developers to define various profiling tasks, incurs marginal overhead when co-locating with applications, and generates performance reports based on prescribed specifications. We build `ntprof` atop Linux kernel 5.15.143 and apply it in six cases, i.e., end-to-end latency breakdown, interference analysis, SW/HW bottleneck localization, and application performance diagnostic. `ntprof` is available at https://github.com/netlab-wisconsin/ntprof.

1 Introduction

Storage disaggregation [31, 76, 77, 92, 98] has gained significant traction recently due to independent resource scaling, high utilization, and cost efficiency. It has been increasingly deployed in data centers, enterprise on-premise clusters, and edge clouds. With the rising networking speed and emerging high performance of NVMe drives, a disaggregated SSD can deliver millions of IOPS at tens of microseconds.

The key technology enabler is an NVMe-over-Fabric (NVMe-oF) protocol [43] that delivers high-performance storage accesses between clients (*initiators*) and remote NVMe subsystems (*targets*). An initiator submits block I/O requests–encapsulated into specialized fabric packets–and delivers them to the remote side through an established protocol channel. A target receives packets from the network transport, converts them to NVMe commands, reads/writes from the SSD, and sends the response back. NVMe/TCP is one such networking fabric, which is increasingly adopted and has enabled many real-world deployments [2, 3, 12, 25, 27, 28].

However, our community lacks a system profiling tool to understand and analyze the execution characteristics of the NVMe/TCP protocol. This makes answering many design, operation, testing, and deployment questions impractical. For example, how well do the storage applications run over NVMe/TCP? How should we design the I/O merging and pacing policies of the block layer? What are the system bottlenecks along the protocol pipeline? How should we reconfigure the NVMe/TCP configurations if the initiator/target processors, networks, or NVMe drives are congested?

Building such a utility is non-trivial due to the workload non-determinism, intricate system layer interaction, and deep execution pipeline. First, storage workloads embody diverse I/O profiles, including block size distribution, read-/write mix ratio, sequential/random access pattern, and I/O concurrency. This issue is further exacerbated by (a) emerging NVMe drives with high queue depth; and (b) dense storage appliances, equipped with dozens of SSDs, cumulatively offering large data volumes (10+ terabytes) and massive bandwidth (100+ GB/s). Second, the NVMe/TCP layer closely interacts with other system modules, including the block layer, TCP/IP networking stack, and NVMe subsystem. Each presents certain execution parallelism (e.g., multi-queue, multi-connection, and multi-data path) with flexible load-balancing policies (to maximize throughput and mitigate superfluous I/O stalls). Third, an I/O has a deep pipeline with processing stages spreading two physical hosts across the CPU core, networking, and NVMe drive (Figure 2).

Developers thus resort to a heuristic top-down analysis strategy to diagnose performance anomalies, dissect

overheads, and explore optimization opportunities in an NVMe/TCP-based disaggregated storage. They combine a sequence of development utilities (from the application and system layer [11, 16, 17, 23, 37, 38, 44, 45, 94] to the infrastructure level [18, 39, 51, 66, 67, 85, 86]), embarrassingly combine them based on empirical observations, and manually synthesize isolated profiling reports from different tools to infer the root causes. The entire synthesis process is tedious and inefficient, driven by a vertical view of experimental results, requiring an esoteric understanding of the system and lots of back-and-force test/verification. More importantly, it is generally challenging to reproduce online interleaved I/O scenarios, which are common in a multi-tenant environment, rendering existing approaches futile for root cause exploration.

In this paper, we design and implement `ntprof` to enable systematic tracing and analyzing of the NVMe/TCP. *Our key insight is viewing the NVMe/TCP subsystem as a lossless switched network–an initiator sends I/O requests, a target returns the responses, and I/O blocks encapsulated as TCP packets are forwarded by different system entities along the I/O path–and apply network monitoring techniques.* Essentially, we make each on-path system component a multi-queue software switch, equip it with a programmable profiling agent on the data plane, and develop a proactive query interface for data collection and analysis. As such, our design resembles prior active network-based profiling systems (like TPP [57, 58]).

`ntprof` consists of four system components. First, it provides a profiling task specification template that allows developers to prescribe targeted I/O workloads, deployment environments, profiler configurations, and reporting statistics, enriching profiling functionalities. Second, we develop a lightweight programmable profiling agent based on the Linux tracepoint mechanism, co-locate with each modeled software switch for statistics monitoring, and take translated specifications as predicates. Third, we introduce an in-band TPP-like profiling query protocol, which injects a special NVMe/TCP command capsule to query and collect statistics periodically. Last, `ntprof` produces an informative performance report (including end-to-end application I/O performance, latency breakdown, throughput bottleneck, protocol running details, etc.) either online or offline through a sequence of steps (such as serialization, calibration, and MapReduce-like processing).

`ntprof`, built atop Linux kernel 5.15.143, comprises a kernel model and a user-space utility at the NVMe/TCP initiator and target sides. We evaluate it in a typical NVMe/TCP setup in CloudLab [40] and demonstrate its effectiveness via six case studies. Specifically, `ntprof` can report the I/O latency breakdown of the deep NVMe/TCP pipeline (§4.2) and dissect the I/O interference issue under mixed workload profiles (§4.5). Next, `ntprof` enables developers to locate the system bottlenecks at both software processing pipelines (§4.3) and the underlying I/O substrate (§4.4). Further, `ntprof` can help with application performance diagnostic when deployed in an NVMe/TCP setting (§4.6 and §4.7). `ntprof` is open-source

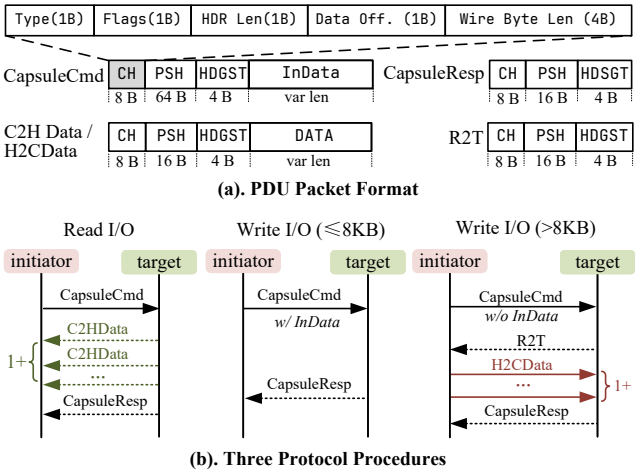

Figure 1: NVMe/TCP protocol details. (a) presents the packet format of five types of PDUs. (b) depicts the protocol procedure of an I/O read and write. InData=In-Capsule Data.

and we will keep working with the community to improve it.

2 Background and Motivation

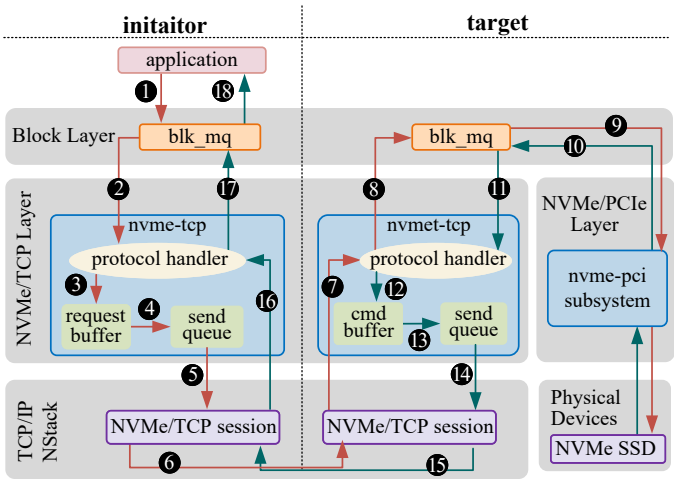
This section provides some background on the NVMe-over-TCP protocol and its Linux implementation. We then discuss the challenges and limitations of existing profiling solutions.

2.1 NVMe-over-TCP Protocol

NVMe-over-TCP (NVMe/TCP) [43] is a high-performance data transfer protocol that defines block-level storage accesses between clients (*initiators*) and remote NVMe subsystems (*targets*) via TCP/IP. An initiator submits block I/O requests–encapsulated into specialized NVMe/TCP packets–and delivers them to the remote side through an established protocol channel. A target receives packets from the network transport, converts them to NVMe commands, reads/writes from the SSD, and sends the response back. NVMe/TCP makes the remote NVMe subsystem behave similarly to a local one.

NVMe/TCP, inherited from the NVMe base protocol [41, 42], constructs reliable bidirectional communication channels (also called NVMe/TCP session) between two sides, where each comprises an initiator-side submission-completion queue pair, a TCP connection, and a target-side NVMe queue pair. The number of channels can be configured to the number of cores of an initiator's processor, which also benefits the multi-queue architecture of an NVMe drive. There is a specialized channel to deliver I/O admission commands.

Protocol Data Unit (PDU) is the basic communication granularity in NVMe/TCP that carries I/O command, data, and control status. As shown in Figure 1-a, it begins with an 8-byte Common Header (CH), followed by a 16 or 64-byte PDU Specific Header (PSH), a 4-byte header digest (HDGST) for cache alignment and integrity check, and variable length in-capsule data (optional). CH defines the PDU type, special flags (e.g., whether digest is present in the header and data), header length, data offset, and the total PDU transmission



Step	Description
❶	Submit a read/write I/O via system calls
❷	Forward the request to NVMe/TCP protocol handler
❸	Generate a CapsuleCmd PDU and insert it into the request buffer
❹	Pop the request from the request buffer and enqueue it to sending queue
❺	Copy the CapsuleCmd or H2CData PDU to the TCP socket buffer
❻	Transmit over the NVMe/TCP session
❼	Read PDUs from the TCP socket buffer
❽	Proccess the PDU, extract an NVMe command, and submit it to the blk_mq
❾	Submit the NVMe command to local NVMe subsystem
❿	Receive the I/O completion from the NVMe subsystem
⓫	Send the block layer response to the protocol handler
⓬	Produce the R2H/C2HData PDU and then insert it into the command buffer
⓭	Pop the response from the command buffer and enqueue it to sending queue
⓮	Dequeue PDUs from the sending queue and copy it to the TCP socket buffer
⓯	Reply over the NVMe/TCP session
⓰	Read a C2HData/R2T/CapsuleResp PDU from the TCP socket buffer
⓱	Perform PDU protocol processing and then produce a block I/O response
⓲	Return an I/O response to the application

Figure 2: The left side depicts the NVMe/TCP system architecture and I/O data path. The right side lists detailed processing stages.

byte. There are five types of PDUs defined in NVMe/TCP for I/O: (a) *CapsuleCmd PDU*, issued from the initiator and transmitting a command capsule that encodes a read/write request in the PSH; (b) *CapsuleResp PDU*, replied from the target and carrying a completion response capsule; (c) *H2CData PDU*(*C2HData PDU*), used for transfer I/O data from an initiator (target) to a target (initiator); (d) *R2T PDU*, a control signal from the target to notify when it is able to accept data from the initiator. The PSH header is not consistent across different PDUs. It encodes the NVMe-oF command capsule submission/completion Queue Entry in CapsuleCmd PDU/-CapsuleResp PDU, carries data in H2CData PDU/C2HData PDU, and stores the R2T PDU's metadata.

NVMe/TCP has three protocol procedures (Figure 1-b). An I/O read sends a CapsuleCmd PDU and receives one or more C2HData PDUs, ending with a CapsuleResp PDU for completion notification. A small write (less than or equal to 8KB) uses CapsuleCmd PDU with the command and data inlined, resulting in a CapsuleResp PDU response from the target, which entails only one round-trip. Large writes require one more admission control phase. First, the initiator submits the write I/O request without data. Upon receiving an R2T PDU, it sends multiple H2CData data transfer PDUs and waits for a CapsuleResp PDU as an acknowledgment. Note that all PDUs are encapsulated as TCP packets and traverse through the corresponding TCP connection.

2.2 NVMe-over-TCP in Linux

NVMe/TCP is first officially released in Linux Kernel 5.0 [1] by Lightbits Labs [26] with host and target drivers, conforming to NVMe over Fabrics 1.1 specifications [43]. It is divided into two kernel modules. One is `nvme-tcp`, staying at the initiator, which (a) instantiates and manages the NVMe/TCP session; and (b) accepts block I/O requests, translates them to NVMe/TCP PDU capsules, and delivers these TCP packets to the remote storage. The other is target-side `nvmet-tcp`, which (a) manages NVMe subsystems of the storage appliance; and (b) executes the NVMe/TCP protocol to facilitate I/O handling. This section describes their system architecture and I/O path based on Linux Kernel 5.15.143 (Figure 2).

`nvme-tcp` (Initiator). Here's its workflow on the submission path of a session. First, applications issue I/O requests via system calls and insert them into the `blk-mq` of the block layer (❶). Next, `nvme-tcp` dequeues a request (❷), traverses the protocol handling, constructs an NVMe/TCP PDU capsule (`struct nvme_tcp_request`), and pushes it into a per-session request buffer (❸). It is a LIFO (Last-In-First-Out) lockless linked list (`struct llist_head req_list`) that accepts block I/Os from all CPU cores. After that, the `nvme-tcp` kernel thread pops a ready-to-transmit request and enqueues it into a per-session LIFO sending queue (`struct list_head send_list`) (❹). Last, these ready capsules are dequeued (❺) and delivered to the corresponding NVMe/TCP session (❻) for transmission via the TCP/IP networking stack. A session is represented as a transport queue (part of `struct nvme_tcp_queue`), associated with a dedicated TCP socket handler and assigned to a specific CPU core. This is realized via either (i) the current kernel thread when the queue occupancy is low (e.g., only one outstanding I/O) or (ii) a deferred tasklet (`nvme_tcp_io_work`) that interleaves the sending and receiving PDU processing to optimize throughput.

The completion path is completely handled by the `nvme_tcp_io_work` routine after the networking stack processing. It reads data from the TCP socket buffer and constructs an NVMe/TCP capsule (⓰). A corresponding PDU handler is triggered based on the PDU type (i.e., C2HData, CapsuleResp, or R2T), which produces a block layer response and returns it to the block layer (⓱) and applications (⓲), or sends an H2CData PDU for data transmission (❸).

`nvmet-tcp` (Target). Storage traffic arrives at the NVMe/TCP session socket, stored in the `nvmet-tcp` transport queue (`struct nvmet_tcp_queue`). Akin to the `nvme-tcp` module, there is a per-session LIFO-based response command buffer (`struct llist_head resp_list`) and a per-session

LIFO-based response sending queue (`struct list_head resp_send_list`). The target workflow is as follows. First, the `nvmet-tcp` kernel thread (`nvmet_tcp_io_work`) reads a batch (up to 64) of PDUs from the TCP socket buffer and activates the PDU handler (❼). As shown in Figure 1-b, a large write without in-capsule data triggers the R2T PDU processing, produces a corresponding response (`struct nvmet_tcp_cmd`), and inserts it into the command buffer (⓬). Otherwise, it processes data payload, extracts the NVMe command (`struct nvme_command`), and delivers it to `blk_mq` (❽). Second, the block layer then interacts with its local NVMe system, submits an IO read/write (❾), accesses the SSD drive, and waits for an I/O completion (❿). Next, similar to Steps 2–4, block I/Os traverse target-side PDU handling (⓫), where the fabricated response capsules are inserted into the command buffer (⓬) and delivered to the send queue (⓭). Finally, the NVMe/TCP session takes response PDUs from the send queue (⓮), performs TCP/IP protocol processing, and sends data back to the initiator (⓯).

2.3 Challenges and Existing Solutions

Challenges. Profiling storage applications running over Linux NVMe/TCP is non-trivial. First, applications exhibit diverse I/O profiles regarding block size, access pattern, and I/O concurrency. Second, the NVMe/TCP layer closely interacts with other system modules on both control and data planes. As shown in Figure 2, it takes I/Os from the block layer, transmits requests/responses via the TCP/IP networking stack, and submits (accepts) NVMe commands to (from) the SSD through the NVMe subsystem. All layers have certain execution parallelism with flexible load-balancing support. Third, each request traverses a long data path between two physical hosts (Figure 2). An I/O can be queued at several locations in a NVMe/TCP setting. There is the block layer [33], where (a) a software staging queue buffers I/Os for flexible scheduling; and (b) a hardware dispatch queue controls the submission rate. Within the TCP/IP networking stack, we have (a) packet pending queue (`sk_write_queue`) to buffer in-network data, (b) traffic control (i.e., `qdisc`), e.g., the TCP Small Queues mechanism (TSQ) limiting the number of transmitted packets to reduce RTT and avoid bufferbloat [80]; (c) driver RX/TX queue, i.e., fixed-sized ring buffer. Further, NVMe employs the multi-queue interface between a host driver and an NVMe controller to carry submitted and completed I/O commands.

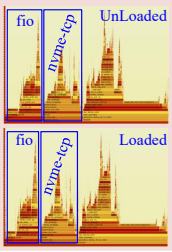
Existing Solutions. There are no structured and systematic profiling utilities in the Linux NVMe/TCP domain for performance diagnostic, overhead analysis, and optimization exploration. Developers today leverage a sequence of development utilities, embarrassingly combine them based on empirical observations, and manually synthesize isolated profiling reports from different tools to infer the root causes.

People usually take a top-down strategy and gradually apply tools from the application layer to the system stack, down to the infrastructure level. For example, one would first

Application Layer *fio*

Metrics	Unloaded	Loaded
Latency (usec)	867.1	1999.6
Throughput (MB/s)	1441.0	625.0

Hot System Layer *Perf*



Top-6 Function Calls Breakdown Sorted by Overhead(%)

Rank	UnLoaded Function Name	%	Loaded Function Name	%
1	get_io_u	24.6	get_io_u	22.7
2	internal_get_*	7.6	__blk_queue*	6.5
3	__blk_queue*	5.9	internal_get_*	6.2
4	try_grab_*	4.1	try_grab_*	3.7
5	__bio_try_*	2.2	bio_iov_iter_*	2.6
6	bio_iov_iter_*	1.9	__bio_try_*	2.5

Infrastructure Layer *iperf3, qperf*

Metrics	Unloaded	Loaded
Latency (usec)	11.6	11.4
Throughput (Gb/s)	88.5	93.8

Figure 3: Analyzing NVMe/TCP via existing solutions. We set up the unloaded and loaded cases on the NVMe/TCP target, where the latter has background I/O streams contending the SSD. In both scenarios, we run the `fio` workload (128KB write, iodepth=10) and show how existing tools from different system layers (`Perf`, `iperf3`, and `qperf`) fail to diagnose the issue.

use application-provided microbenchmarks (like RocksDB's `db_bench` [16] and Lustre's `lnet_selftest` [11]) and tracing utilities to characterize the basic I/O performance and collect running logs. Next, after figuring out anomaly/unexpected execution, she would use system tools (such as `gprof` [45], `JProfiler` [94], `cProfile` [44], `Valgrind` [23], `blktrace` [17], `Oprofile` [37] and `Perf` [38]) to examine CPU usage, memory footprint, thread hotspot, or even some hardware architectural events (like L2/L3 cache misses and retired instructions per cycle) and debug the issue. Last, she might also need to employ low-level infrastructure utilities, e.g., `iperf3` [39], `qperf` [85], `iostat` [18], and `iometer` [66], to validate if the underlying networking fabric and I/O substrate satisfy the deployment assumption. This process is tedious and requires lots of expertise and trials. Worse yet, it is hard to reproduce some interleaved I/O scenarios, especially in a multi-tenant disaggregated storage environment.

We configure an unloaded and loaded NVMe/TCP target and run the same `fio` workload atop (Figure 3). When the SSD is congested (loaded scenario), its I/O throughput drops from 1441.0 MB/s to 625.0 MB/s with average latency increasing from 867.1 µs to 1999.6 µs. However, when using `Perf` to locate the issue, it reports nearly no difference in both cases. For example, the user-space function `get_io_u` consumes the most CPU cycles, i.e., 24.6% and 22.7%, respectively. Kernel functions `__blk_queue_split` and `internal_get_user_pages_fast` rank second and third. When using networking utilities (like `iperf3` and `qperf`), we find that the network pipe between the initiator and target provides enough bandwidth (i.e., 88.5 GB/s and 93.8 GB/s), ruling out the network bottleneck. Thus, using existing tools to pinpoint the root cause is not straightforward.

Therefore, an adequate NVMe/TCP profiling utility should (a) generate different kinds of performance reports for ar-

bitrary I/O workloads (like average/tail latency, throughput, queueing delay); (b) capture I/O data path execution horizontally between distributed hosts and vertically through the system stack; (c) provide diverse and efficient analysis capabilities that serve either online/offline scenarios, identify ephemeral/persistent I/O behaviors, and incur marginal overheads for co-located applications. We target NVMe/TCP-based storage disaggregation due to its wide adoption [2, 3, 12, 25, 27, 28].

3 `ntprof`: An NVMe-over-TCP Profiler

This section describes the design and implementation of `ntprof`. Our system design goals are as follows:

- **Informative.** `ntprof` should provide adequate running statistics about NVMe/TCP processing at the prescribed I/O granularity and profiling scope for protocol understanding, performance diagnostic, and bottleneck localization;
- **Profiling rich.** `ntprof` should provide diverse end-to-end profiling capabilities, accommodating various storage workload profiles (e.g., IO sizes, read/write ratio, access pattern, and concurrency), dissecting deep and pipelined protocol handling, analyzing inter-layer interaction, and reporting characteristics based on the task specification;
- **Lightweight.** `ntprof` should allow online and offline profiling based on the developer's need. Since `ntprof` operates at the data plane and interacts with crucial system components (§ 2.2), it is pivotal to ensure `ntprof` incurs minimal system overheads in terms of memory footprint and CPU cycles with a marginal impact on running I/O applications.

3.1 Key Idea: NVMe/TCP as a Network

`ntprof` treats the NVMe/TCP subsystem as a lossless data network–an initiator sends I/O requests, a target returns the responses, and PDUs encapsulated as TCP packets are forwarded by different system entities along the I/O path. Inspired by the efficacy of network telemetry systems [32, 48, 54, 103], we model the NVMe/TCP setup as a switched networking system and apply network monitoring techniques. Essentially, we make each on-path system component a multi-queue software switch, equip it with a programmable profiling agent on the data plane, and develop a proactive query interface for data collection and analysis. As such, our design behaves similarly to active network-based profiling [57, 58].

In active networks [95, 96], switches, routers, and gateways employ a programmable architecture, and can execute mini-programs (also called "active capsule") carried by network packets. This enables several in-network capabilities, such as application-specific multicast, information fusion, monitoring, and middlebox functionalities (like address translation, load balancing, monitoring, deep packet inspection, and intrusion detection). TPP (tiny packet program) [57, 58] is an active network-based monitoring system. An Ethernet packet, embedding a TPP code segment (based on six load/store instructions), can execute the TPP program on the switch to collect runtime statistics when forwarded. The endhost then develops the data-plane network telemetry using the TPP execution results. `ntprof` employs the same approach to the NVMe/TCP context. We use a special TPP-like I/O request to collect statistics from each on-path system module and reconstruct the profiling report at the end.

Figure 4 presents the overall system architecture of `ntprof`. Programmers define the profiling task and specify its configuration (§3.3). We then translate these specifications into different profiling rules and install them into the corresponding profiling agents (§3.4), co-located with modeled switching components (§3.2). After launching the application, `ntprof` (a) bookkeeps prescribed execution statistics of traversed I/Os at all active entities on the data plane (§3.4); (b) issues a special query command periodically to collect temporary and isolated profiling summary from individual layers (§3.5); (c) reconstructs the entire I/O running profile and performs stipulated analyses (§3.6). `ntprof` works in both offline and online modes. The former targets in-depth analysis and diagnosis based on full profiling data sets, whereas the latter aims for real-time running insights through window-based monitoring.

3.2 Modeling the I/O Path

We model the NVMe/TCP-based storage substrate as a multi-stage Clos network [36, 88], where senders (initiators) and receivers (targets) communicate via a sequence of buffered software switches (Figure 4). Thus, the I/O path of an NVMe/TCP submission request (completion response) consists of a chain of switching queues. We then categorize the queueing model of different software layers using Kendall's notation [60]. In the following expression `A/S/c/K/N/D`, `A` is the arrival process, `S` is the service time distribution, `c` is the number of workers (consumers), `K` is the queueing capacity, `N` is the number of customers (producers), and `D` is the queueing discipline. We summarize three models based on the execution characteristics of different on-path software components.

- The *Central-FCFS* model (formally $G/G/1/Q/X/FCFS$) takes requests from one or several producers ($X \geq 1$) and processes them in the first-come-first-serve (FCFS) order. The per-core software staging queue of the `blk-mq` layer, the initiator-side per-session NVMe/TCP transport queue, and `nvme-pcie` submission queue belong to this;
- The *Split-FCFS* model (formally $G/G/X/Q/1/FCFS$) partitions I/Os to multiple FCFS workers ($X \geq 1$) based on the execution mapping, such as a target-side session transport queue and a `nvme-pcie` completion queue;
- The *Central-PS* model (formally $G/G/1/Q/X/PS$) is a little complex, used to describe the networking stack handling [34]. Even though NVMe/TCP packets traverse each connection in order, the connection-core mapping happens differently, depending on the system setup. For example, one core could concurrently take several sessions ($X \geq 1$)

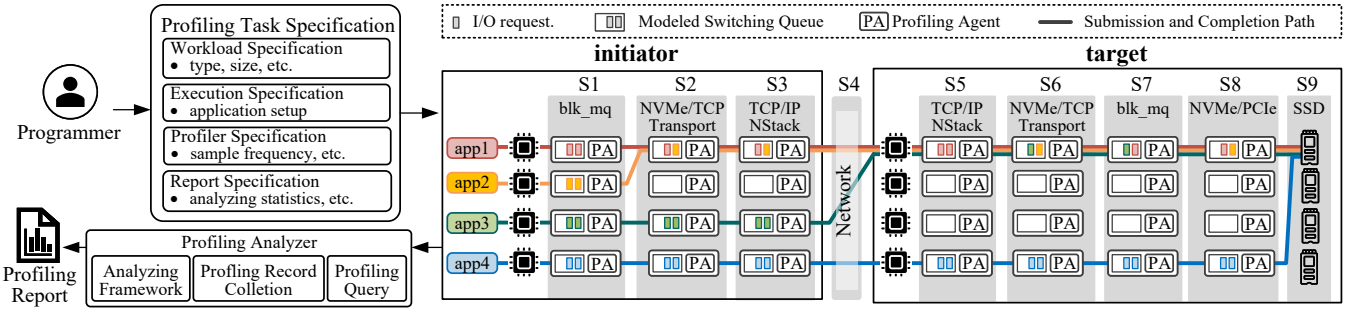


Figure 4: System overview of `ntprof`. PA refers to the Programmable Profiling Agent, attached to each switching queue. "S" refers to a processing stage. The right side of the figure illustrates four example applications. The I/O paths of app1 and app2 overlap at Stage 2 because both are mapped to the same NVMe/TCP queue. App3 shares the same I/O path as app1 at Stage 4, as their TCP connections are handled by the same core on the target side. The I/O path of app4 overlaps with app1 at Stage 8 as both mount the same SSD drive.

and load balances CPU cycles following some processor sharing (PS) discipline. One session usually can not be touched by more than one core at any given time.

These models allow us to abstract the software switch accurately, effectively integrate profiling agents into each layer, and enable more accurate queueing stall estimation.

3.3 Profiling Task Specification

`ntprof` requires a specification template (Figure 4) to define the profiling task, including I/O workloads, running environment setup, profiler configuration, and profiling statistics.

- **Workload Specification** prescribes what I/Os to profile. It tells `ntprof` (a) which NVMe/TCP sessions (i.e., name and mounted address) and (b) what types of I/Os (e.g., I/O read-/write type and I/O sizes) to trace and analyze. We support exact match (size=4KB) and range match (size≥32KB);
- **Execution Specification** defines how the application is deployed and run. This includes (a) application setup, e.g., whether application threads are pinned; (b) NVMe/TCP configuration, e.g., the number and core mapping of transport queues, connections, and NVMe queues; (c) hardware limits of network and storage substrates, e.g., maximum bandwidth of network links and NVMe drives;
- **Profiler Specification** determines the workflow of `ntprof`. First, we support both online and offline modes, where the former reports runtime statistics (like PAPI [19]), and the latter provides an execution summary based on entire tracing. Second, we allow users to specify the sampling frequency (in terms of time epoch or the number of I/Os) and profiling time window, e.g., the start and end time pair being the conventional `YYYY-MM-DD hh:mm:ss` format. Third, `ntprof` requires setting the maximum in-memory buffer size to store the profiling record. When exceeded, it either overwrites the old ones or dumps them on the local drive based on user preference. Last, in the online mode, we provide several programmable primitives to enable more advanced statistical reporting. For example, `MIN|MAX|AVG|DIST` computes the min, max, average, and distinct value of a given profiling range or time window;

Tracepoint	Triggered Condition
`_queue_rq`	When a block I/O enters the NVMe/TCP layer
`_queue_request`	After a block I/O is converted to a CapsuleCmd PDU
`_try_send_cmd_pdu`	When a CapsuleCmd PDU is copied to the TCP skbuff
`_try_send_data_pdu`	When a H2C Data PDU is copied to the TCP skbuff
`_try_send_data`	When a chunk of data is copied to the TCP skbuff
`_done_send_req`	When the entire PDU is copied to the TCP skbuff
`_handle_c2h_data`	After parsing the header of a C2HData PDU
`_recv_data`	After receiving a chunk of C2HData PDUs
`_process_nvme_cqe`	After receiving a CapsuleResp PDU
`_handle_r2t`	When parsing the header of an R2T PDU

Table 1: Tracepoints added in the `nvme-tcp` (initiator) module.

- **Report Specification** lists the format of profiling results. There are two aspects. One is analyzing statistics, including (a) I/O latency distribution, (b) end-to-end throughput, (c) latency breakdown of different layers across the I/O path, and (d) queueing occupancy. The other one is data presentation. `ntprof` allows users to stipulate grouper and aggregator functions to organize execution statistics, such as grouped by the I/O type, size, and session.

3.4 Programmable Profiling Agent

We equip each modeled software switch with a profiling agent that includes a collector capable of gathering I/O running characteristics, and predicates to filter out irrelevant ones.

Statistics collector. We build the collector based on the Linux tracepoint mechanism [10]. A tracepoint is a static instrumentation point in the kernel and exposes a hook to call a function provided by the developers. It can take parameters (Appendix A.1) and enrich the execution logic. This makes collecting detailed low-level statistics at specific points of interest possible. We add tracepoints when a request (a) enters/leaves a software module; (b) traverses essential processing stages (Figure 2). Tables 1/2 list the tracepoints that `ntprof` introduces into the `nvme-tcp` and `nvmet-tcp` modules.

Upon triggering a tracepoint, `ntprof` creates, updates, and seals a profiling record based on the registered function. Each I/O is associated with one record, consisting of request metadata (such as type, size, tag, and command/session ID) and time-series triggered events throughout the lifetime of an I/O (Figure 5). An event log is a 12-byte tuple, including the event name and activating time, which is appended to the profiling

Tracepoint	Triggered Condition
_try_recv_pdu	When nvmet-tcp tries to read data from a skbuff
_done_recv_pdu	After reading the header of a received PDU
_exec_read_req	After receiving a complete read request
_exec_write_req	After receiving a complete write request
_queue_response	When inserting an element into the response queue
_setup_c2h_data_pdu	When starting to make a C2HData PDU
_setup_r2t_pdu	When starting to make an R2T PDU
_setup_response_pdu	When starting to make a CapsuleResp PDU
_try_send_data_pdu	After copying the header of the C2HData PDU
_try_send_r2t	After copying an R2T PDU to the TCP skbuff
_try_send_response	After copying a CapsuleResp PDU to the TCP skbuff
_try_send_data	After copying a chunk of data to the TCP skbuff
_handle_h2c_data_pdu	After reading the header of an H2CData PDU
_try_recv_data	After reading a chunk of data from the TCP skbuff

Table 2: Tracepoints added in the `nvmet-tcp` (target) module.

record. Generally, a record is initialized when the tracepoint `nvme_tcp_queue_rq` happens and completed upon triggering `nvme_tcp_process_ncme_cqe`. The size of a record is I/O-dependent. For example, a read I/O, a write I/O without inline data, and a write I/O with inline data consume at least 207, 183, and 303 bytes, respectively. Appendix A.2 presents the event list of these three cases. In `ntprof`, a profiling record is pinned to a dedicated session that handles the I/O. The collection of records from all sessions forms the entire profiling statistics. Relating to Figure 4, `ntprof` collects the ingress and egress times of the profiled I/O, except for Stage 3-5 and Stage 9, as in the network stack, PDUs are flattened and packed into binary data inside TCP packets. Additionally, `ntprof` also collects the length of the PDU sending queues at Stage 2 and Stage 6. `ntprof` follows the kernel log design and uses an in-memory ring buffer to store records, whose size is configured during initialization.

Predicate. `ntprof` translates profiling specifications (§3.3) into predicates to filter out uninterested I/Os, improving the profiling efficiency. A predicate is a logical expression composed of one or more conditions, often connected by logical operators such as "and". For example, if the programmer specifies capturing 4K read I/Os, the predicate would be: $type = read \wedge size = 4KB$. When a tracepoint is active, the I/O is checked by one or several predicates to determine whether a record update is needed. `ntprof` merges predicates from one I/O stream and allows online editing.

3.5 Profiling Query Protocol

`ntprof` views the NVMe/TCP-based storage substrate as a networking system and develops an in-bind query protocol to obtain statistics at runtime. Akin to TPP [58], we design a special NVMe/TCP command capsule (called `ProbCmd`), carrying a small program segment that states what and where to query via basic load/store/reset primitives. We then introduce a response capsule (`ProbResp`) to return the results. `ProbCmd` and `ProbResp` follow the existing PDU format (Figure 1), consisting of an 8-byte command header and other corresponding headers. The data fields are restructured as a sequence of "query instructions" in the format of `[Query_Opcode] [Software_Switch_ID] [Statistics_Type] [Parameters]`. These two commands

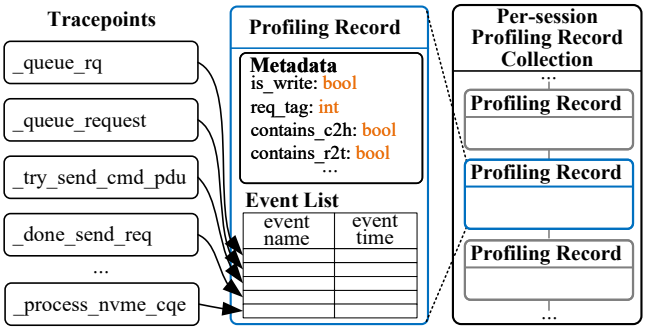

Figure 5: Tracepoints, profiling records, and per-session profiling record collection in the `nvme-tcp` layer.

specify the NVMe/TCP session, not the actual logical block address (LBA), and traverse the same path as read/write I/Os. Our protocol works as follows across different entities:

- **Requester.** The `ntprof` host utility, co-located with storage applications, fabricates the query request and submits it to the block layer. We support both frequency-based (per X I/Os) and time-based operating modes (per Y seconds). Upon receiving the responses, it then extracts the query results and delivers them to the profiling analyzer;
- **Executor.** When receiving the probe command, the software switch extracts the embedded program, teases out belonging instructions (based on the switch ID), and executes them sequentially. It blocks the profiling agent temporarily, collects all profiling records associated with the NVMe/TCP session, and manipulates their profiling records based on the statistic type field. For a load primitive, we copy the statistics, build the response capsule, and then directly push it to the completion path. A store/reset opcode causes updating/clearing up the profiling record and sending an acknowledgment back. Since there might be multiple I/O paths for one session, when forwarding a probe request, our switch would duplicate the special command and submit them to all traversed egressed paths, resembling the switch port mirroring technique [14];
- **Responder.** Unlike TPP which relies on the destination node to construct a reply packet and piggyback queried results, `ntprof` allows each software switch to reply directly due to the large memory usage of profiling records. This indicates that one `ProbCmd` capsule incurs `ProbResp` capsules back. Further, when the probing request reaches the NVMe/PCIe layer at the target side (Figure 2), we send back a probing completion response to notify the controller.

3.6 Profiling Analyzer

During the querying phase, the host sends profiling queries and buffers the received results. `ntprof` then processes and analyzes the data. The analysis involves four steps:

First, `ntprof` provides different ways to organize profiling records, such as by NVMe/TCP session, I/O path, issuing core, target NVMe drive, or request category. We first categorize

these records based on the prescribed criteria (defined in the report specification), wherein each is further serialized based on the I/O submission timestamp (tagged when entering the block layer). Second, `ntprof` performs statistics calibration. End-to-end profiling results are obtained directly at the initiator host. The latency breakdown gathers statistics from all on-path agents which contain event processing time and queueing delay. We timestamp the enqueue and dequeue events whenever possible and use our abstracted queueing model (§3.2) with the queueing occupancy and I/O concurrency distribution for validation. Third, `ntprof` encodes grouper/aggregator functions into a multi-threaded map-reduce framework. We spawn several mappers based on the profiling data volume and group records based on the mapper keys (e.g., 4KB I/O). Intermediate results are shuffled to a couple of reducers that perform the aggregation; Fourth, we output profiling results in the JSON format, which could also be visualized.

3.7 Implementation

`ntprof` requires kernel patches, adds a new kernel module, and provides a user utility, ∼10K LOCs in total.

Kernel Modifications. Tracepoints are the key approach enabling our programmable profiling agent. Here is an example showing how we track the enqueue event at the NVMe/TCP transport layer. It defines three parameters: a pointer to a request struct, the NVMe command, and the queue id.

```
/* TRACE_EVENT Example */
TRACE_EVENT(nvme_tcp_queue_request,
    TP_PROTO(struct request *req,
             struct nvme_command* cmd,
             int qid),
    TP_ARGS(req, cmd, qid),
    TP_STRUCT__entry(...),
    TP_fast_assign(...),
    TP_printk(...));
```

We insert this tracepoint into the `nvme-tcp` module when `trace_nvme_tcp_queue_request` function is called.

```
trace_nvme_tcp_queue_request(
    blk_mq_rq_from_pdu(req),
    req->req.cmd,
    nvme_tcp_queue_id(queue));
```

Kernel Module and User-space Utility. `ntprof` introduce new kernel modules at the initiator and target side. Here is an example of the callback function for the above tracepoint. It is registered during the module initialization, and it will be executed once the tracepoint is triggered. The user-space utility provides a CLI interface, and it takes the developer's inputs, interacts with kernel modules, and reports profiling results.

```
void on_nvme_tcp_queue_request(
    void* ignore, struct request* req,
    struct nvme_command* cmd, int qid) {...}
```

Implementation Alternative. `ntprof` might also be implemented using eBPF [6] instead of a standalone kernel module. One could (1) define and insert the tracepoints to the kernel as described earlier; (2) define eBPF programs, which are functions attached to the predefined tracepoints using the `SEC` macro; (3) implement a user-space analyzer to read profiling records through the eBPF maps and generate the final profiling results. The eBPF programs can retrieve the tracepoint's parameters and store profiling records in eBPF maps [7].

Extension. One could also extend `ntprof` to support the kernel-bypass storage stack. For example, over SPDK NVMe-oF, we can use its tracing framework to define corresponding tracepoints [5, 21, 22], capture them via the eBPF mechanism, and reuse some of `ntprof`'s building blocks, like profiling agent, query protocol, and profiling analyzer.

4 Case Studies

4.1 Experimental Methodology

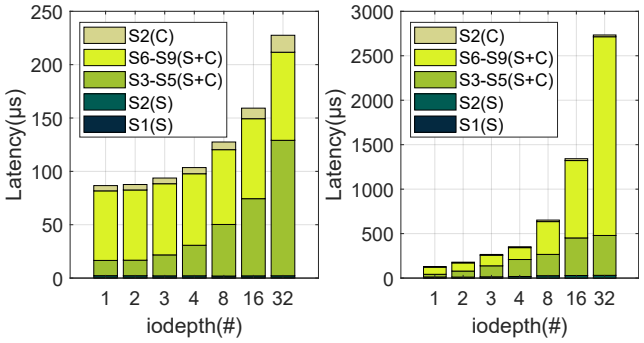
Testbed. We use two hardware setups. The first (testbed-1) consists of 2 sm110p servers from CloudLab [40]. Each node has a 32-core Intel Xeon Silver 4314 CPU, 128 GB DDR4, 1 NVIDIA/Mellanox CX6 25GbE NIC, 1 NVIDIA/Mellanox CX6 100GbE NIC, 1 Intel SATA SSD, and 4 Samsung (MZQL2960HCJR-00A07) 960GB NVMe SSDs. We configure its network MTU to 9KB. The second (testbed-2) includes 2 m510 servers from Cloudlab. Each node has a 16-core Intel Xeon D-1548 CPU, 64 GB of DDR4 memory, 1 Mellanox CX3 10 GbE NIC, 1 TOSHIBA (THNSN5256GPU7) 256 GB NVMe SSD. We disable the turbo boost and set the CPU frequency governor to "performance" in both cases. All nodes run Ubuntu 20.04 with kernel v5.15.143.

Workloads. Case studies 1–4 use synthetic workloads generated by `fio` v3.36. Case 5 runs the TSBS benchmark [20] over Apache IoTDB [4, 99] v1.2.0 in a write-heavy scenario. Case 6 runs the Filebench's [75] videoserver workload over F2FS [65] issuing read-heavy I/Os. We mainly examine I/O latency and throughput in each case. To demonstrate how `ntprof` reacts to different hardware settings, we conduct use case 1 on both testbeds. Due to space limitations, the results for the remaining use cases are presented only for testbed-1. The results for testbed-2 are presented in the Appendix A.3.

4.2 Use Case 1: Latency Breakdown

Description. `ntprof` can break down the end-to-end I/O latency into different stages (Figure 4) and provide useful system execution insights. Developers often complain about the unexpected poor performance in NVMe/TCP [15, 24], but the issue is sometimes unrelated to the protocol. More often, it's due to misconfigurations, such as having insufficient parallelism in the NVMe subsystem or mismounting a hard drive. Latency breakdown is helpful in these scenarios to pinpoint the root cause. Further, when introducing new software layers in the I/O path [55, 56, 77] or upgrading hardware, latency breakdown can help assess the impact of these changes.

Experimental Setup. On testbed-1, we break down the latency of a 4KB random read and 128KB sequential write



(a) 4K Random Read. **(b) 128K Sequential Write.**

Figure 6: Latency breakdown for the 4K random read and 128K sequential write as increasing the IO depth on testbed-1. We report the five most time-consuming parts. S1(S) refers to the time an I/O stays at the S1 stage on the submission path. S2(C) captures the time spent at the S2 stage on the completion path. S3–S5(S+C) aggregates the time spent in the S3, S4, and S5 stages across the submission and completion paths.

while increasing the iodepth from 1 to 32. We configure `fio` to run 1 job and issue requests to the Samsung drive in a direct I/O mode. The I/O engine is set to `libaio` for asynchronous operations. On testbed-2, we set the iodepth to 1, but increase the number of jobs from 1 to 32. We define the profiling task specification as follows: read(write) type, 4KB(128KB) block size, NVMe session named "nvme4n1" (the remote storage subsystem), a maximum of 10,000 profiling records, sampling frequency=1 per 1,000, grouping by NVMe session (all I/O sent to "nvme4n1" treated as one group), and `AVERAGE` as the aggregator. We launch the `fio` job with `ntprof`, which collects and analyzes profiling records and generates the report.

Result Analyses. Figure 6a illustrates the latency breakdown for 4K random read requests. As the iodepth varies from 1 to 32, "S3-S5(S+C)" increases the most, from 14.3 µs to 127.0 µs, indicating that queue is built up the networking substrate at both the initiator and target side. For example, when the iodepth equals 32, the above aggregated stages account for 92.2% of the total latency. The reason why `ntprof` can capture it is because our installed profiling agent takes timestamps at two tracepoints at the NVMe/TCP initiator (`_try_send_data` and `_handle_c2h_data`) and two tracepoints (`_done_recv_pdu` and `_try_send_reponse`) at the target, which allows the profiling agent to dissect the latency contribution from one or several stages (Figure 4). Figure 6b shows the latency breakdown for 128K sequential writes. "S6-S9(S+C)" becomes the most time-consuming part, rising from 79.2 µs to 2234.9 µs, as the iodepth increases from 1 to 32. `ntprof` is capable to further break down "S6-S9(S+C)" and reveal that the "S5-S9(S+C)" on the target side takes 95.9% of the time when iodepth is 32. Similarly, such capability comes from the fact that `ntprof` records the triggering time of the two key tracepoints (`_exec_write_req` and `_queue_response`) at the target side. Figure 11a (Appendix A.3) presents the I/O latency breakdown on testbed-2.

Takeaways. `ntprof` models the NVMe/TCP data path as a chain of software switches, where each can be equipped with a programmable profiling agent that uses tracepoints to collect statistics. This allows us to dissect the path segment and perform time accounting in a fine-grained way, and makes `ntprof` to operate across a wide range of hardware models.

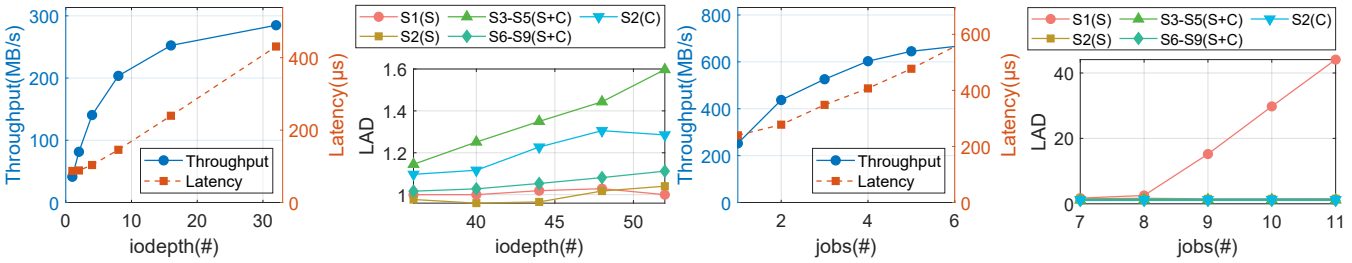
4.3 Use Case 2: Software Bottleneck Localization

Description. NVMe/TCP interacts with several vital OS kernel modules (e.g., block layer, TCP/IP networking stack, and NVMe subsystem). Any system bottleneck from multi-core execution, TCP connection, or NVMe submission/completion command delivery could throttle the achieved I/O throughput, yielding a drastic latency increase. These issues are sometimes subtle, but hard to detect and reproduce, especially given that (a) application I/O ordering is not preserved; (b) multi-tenant deployments are common. Accurate software stack bottleneck localization is a demanding feature for developers.

Experimental Setup. We configure two bottleneck scenarios. One is at the NVMe/TCP target core, where each NVMe drive is provisioned with one target core regardless of the I/O load. We launch a 4KB random read stream and gradually increase the iodepth. The other is at the TCP connection, which carries an increasing number of I/O streams. We spawn multiple `fio` jobs (iodepth=16) and make sure they are pinned to different cores on the initiator side. Both cases are common in an enterprise/cloud disaggregated setting for cost efficiency. The profiling task specification is similar to the first case (§4.2), except for the generated report format.

Result Analyses. Figure 7a depicts the performance when iodepth varies from 1 to 32. We observe a marginal throughput increase (from 252.4 MB/s to 284.9 MB/s) when the iodepth is beyond 16, while latency rises significantly, from 238.7 µs to 431.0 µs, indicating that a system bottleneck occurs. `ntprof` introduces a new metric called *Latency Amplification Degree (LAD)*–defined as T_{cong}/T_{base}, where T_{cong} and T_{base} refer to processing latency at the overloaded and unloaded scenarios–to localize the bottleneck. As shown in Figure 7b, when iodepth is 52, the "S3-S5(S+C)" sees a 1.6 LAD, dominating other parts. `ntprof` can capture this because our profiling agent records timestamps at two tracepoints on the NVMe/TCP target (`_try_send_data` and `_try_send_response`), allowing it to report the time spent in these combined stages. Further LAD analysis shows that "S6(C)" latency increases from 26.38 µs to 47.14 µs (LAD=1.8). This happens because, for the switching queue of S6, the target is not fast enough to send the I/O completion, causing queue buildup and latency increase, indicating the target core becomes the bottleneck. `ntprof` uses the `_done_recv_pdu` tracepoint on the target side to achieve this.

Figure 7c shows that when the number of `fio` jobs increases from 5 to 6, throughput only rises by 3.1%, from 645.2 MB/s to 665.5 MB/s, while latency rises from 477.3 µs to 556.7 µs. As we consolidate jobs from 6 to 11, as shown



(a) Throughput and Latency. (b) LAD. (c) Throughput and Latency. (d) LAD.

Figure 7: Software bottleneck localization. (a) and (b) depict the target core bottleneck case, where we run one `fio` job and increase its iodepth from 1 to 64. (c) and (d) shows the TCP connection bottleneck case, where we increase the number of consolidated `fio` jobs (with iodepth=16) from 1 to 11. LAD=Latency Amplification Degree.

in Figure 7d, the LAD of "S1" rises to 51. Such a latency increase indicates that there are inadequate TCP connections to deliver I/Os from the initiator to the target. `ntprof` locates this through a key tracepoint on the initiator (`_queue_rq`).

Takeaways. `ntprof` views each system component as a buffered software switch. A system bottleneck causes queueing buildup at one or several molded queues (§3.2). `ntprof` thus dissects the queueing delay and introduces a new metric (latency amplification degree) for bottleneck localization.

4.4 Use Case 3: Hardware Bottleneck Localization

Description. The underlying hardware infrastructure can also be a system bottleneck. For example, people find that a malfunctioned NIC [31,64,67] can reduce its bandwidth capacity dramatically. A fragmented NVMe SSD would deliver much lower throughput in a read/write or write-only workload. Further, hardware heterogeneity has become common in the data center, which can also cause hardware bottlenecks.

Experimental Setup. First, we create a "slow" SSD. On the initiator side, we run 1 `fio` job (referred to as "remote `fio`") issuing 128K sequential writes with an iodepth of 10. Simultaneously, we run 1 `fio` job on the target side (referred to as "local `fio`") also performing 128K sequential write workloads to the same drive. Second, we create a "slow" NIC. We run two `fio` instances on the initiator side, each targeting a different remote SSD. Both `fio` instances issue 128K random reads with 8 jobs and an iodepth of 5. Additionally, we run `iperf3` clients on the target side, sending data to the initiator at 100Gbps. The profiling spec is the same as before.

Result Analyses. Figure 12a (Appendix A.3) shows the performance when local `fio` iodepth increases from 2 to 8. The aggregated throughput reaches 1440.0 MB/s, maxing out the SSD bandwidth limit. Compared to no local `fio` jobs, the bandwidth shared by remote `fio` decreases to 627.2 MB/s, while the latency increases from 859.7 µs to 1984.6 µs. Figure 12b shows when local `fio` iodepth is 8, "S6-S9(S+C)" sees a 3.6 LAD, significantly higher than the other parts. `ntprof` can locate this because the profiling agent uses 2 tracepoints on the target (`_don_recv_pdu` and `_try_send_response`). A further drill-down shows that "S7-9(S+C)" is the primary contributor, with its latency increased from 303.8 µs to 1729.2 µs (LAD=5.7). This occurs because the local `fio` pushes more I/Os into the "S7-9(S+C)" stage while the SSD is already operating at its maximum speed, causing the queue to build up and latency to rise. `ntprof` is capable of capturing this because it records timestamps of `_exec_eritw_req` and `_queue_response` on the target.

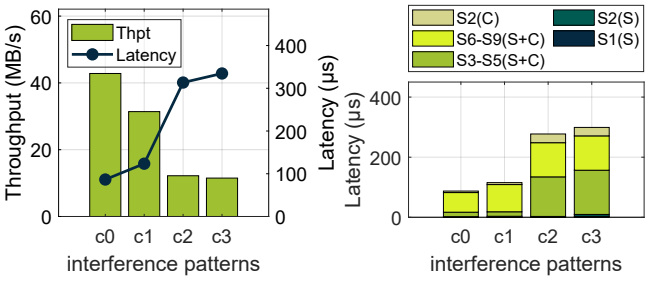
Figure 12c shows the aggregated throughput of `fio` and `iperf3` approaches 100 Gb/s, indicating the NIC is the bottleneck. The latency of `fio` I/O rises from 834.9 µs to 2803.5 µs when there are 16 `iperf3` clients, compared to when there are none. Figure 12d shows "S3-S5(S+C)" increases most significantly when increasing `iperf3` clients. It sees a 4.5 LAD when there are 16 clients. That is because on the completion path, the NVMe/TCP network flows share less bandwidth when there are more `iperf3` clients, leading to queue buildup. `ntprof` can capture it because we take timestamps at two tracepoints (`_try_send_data` and `_handle_c2h_data`) at the NVMe/TCP initiator and two tracepoints (`_done_recv_pdu` and `_try_send_reponse`) at the target.

Takeaways. `ntprof` views the SSD or NIC as one stage. Its queueing model is inherent from the upstream storage, making `ntprof` capable of localizing the hardware bottleneck.

4.5 Use Case 4: Interference Analysis

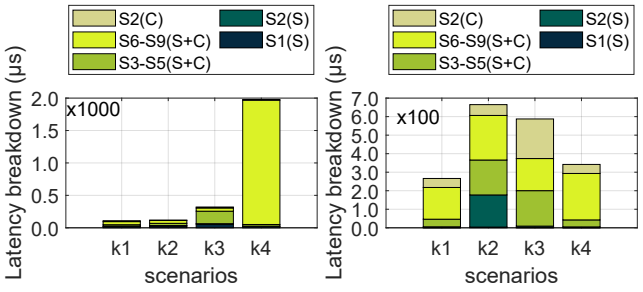
Description. Multi-tenancy is a pressing concern for storage disaggregation. When latency-sensitive I/O streams co-locate with throughput-oriented ones, one would observe significant head-of-line blocking and unfair bandwidth partition [56,77].

Experimental Setup. We run 2 `fio` instances on the target side. The latency-sensitive workload is configured to issue 4K random read requests with 1 job (iodepth=1). The throughput-sensitive one issues 128K random read requests to the same NVMe drive. We design 3 interference patterns. For case "c1", the two I/O flows are pinned to different cores on the initiator side, each using a separate NVMe/TCP session. For case "c2", they are pinned to the same core and therefore share the same NVMe/TCP session. For case "c3", they are pinned to different cores but share the same NVMe/TCP session. We define the profiling task specification as follows: read type, 4KB block size, NVMe session named "nvme4n1", a maximum of 10,000 profiling records, sampling frequency=1 per 1,000, grouping by NVMe session, and `AVERAGE` as the aggregator. We launch the `fio` job with `ntprof`, which collects



(a) Throughput and Average Latency. (b) Latency Breakdown.

Figure 8: Latency breakdown and throughput analysis of the 4K random read I/O flow when introducing a 128K random read I/O in different scenarios. There is only the 4K read I/O flow running in "c0". "c1" Two I/O flows are pinned to different cores and using different NVMe/TCP sessions in "c1". Both flows are pinned to the same core, sharing the same NVMe/TCP session in "c2". Both flows are pinned to different cores but share the same NVMe/TCP sessions in "c3".



(a) Use case: IoTDB. (b) Use case: F2FS.

Figure 9: I/O Latency breakdowns for real-world applications under different scenarios. k1 is the baseline, where there are 32 NVMe/TCP sessions. The number is reduced to 1 in k2. 8 `iperf3` clients are running in k3, and `fio` workload is running on the target side in k4. The IoTDB and F2FS show the latency breakdown for 4KB writes and 128KB reads.

and analyzes profiling records and generates the report.

Result Analyses. Figure 8a shows the latency of 4KB reads is increased in all interference cases, with a 26.7%, 71.5%, and 73.1% throughput degradation in "c1", "c2", and "c3", respectively. Figure 8 shows the latency breakdown of the 4KB read requests. In "c1", the "S6-S9(S+C)" latency rises the most, from 65.4 µs to 90.6 µs. A further breakdown reveals that the majority of this increase, 25.2 µs, comes from the "S7-S9(S+C)". A queue is built up at the NVMe/TCP session at the target due to the increasing I/O load. `ntprof` captures this because it utilizes the timestamp when the 2 tracepoints on the target are triggered (`_exec_read_req` and `_queue_response`). In "c2", "S3-S5(S+C)" increases the most, from 14.9 to 131.6 µs, also due to "S6-S9(S+C)". The impact of latency in "c3" is similar to "c2", where "S3-S5(S+C)" is increased to 114.2 µs.

Takeaways. `ntprof` enables profiling at different I/O granularities with separated profiling paths. Under mixed I/O traffic, `ntprof` generates different profiling records to collect statistics, making interference analysis possible.

4.6 Use Case 5: Apache IoTDB

Description. Apache IoTDB [4, 59, 99] is an LSM-tree-based high-performance time-series database designed for IoT scenarios. Storage disaggregation gains significant traction in such settings given that edge computing nodes have limited storage resources. We used the Time Series Benchmark Suite (TSBS) [20, 89] to generate DevOps workloads to evaluate the performance of time-series databases. By using the default parameters, the workload is set to contain 4000 devices' information running for 3 days, with each device generating multiple time-series metrics, such as CPU utilization, memory usage, disk I/O, and network activity, respectively.

Experimental Setup. Both the Apache IoTDB server and client run on the initiator node, with IoTDB's data directory mounted to a remote Samsung SSD. Using the default configuration of TSBS, we run 32 workers to write data into the database. We analyze the latency breakdown of all write I/Os under the following scenarios: (1) "k1" uses 32 NVMe-TCP sessions, (2) "k2" pins all I/O to a single NVMe/TCP session, (3) in "k3", there are 8 `iperf3` clients on the initiator side, each sending data to one of 8 servers on the target side, emulating a NIC bottleneck, and (4) in "k4" two `fio` jobs run on the target side, issuing 128 KB sequential writes to the same SSD (iodepth=10), creating an SSD bottleneck. We configure `ntprof` similarly to §4.2, except that we monitor ANY types of write I/Os, and results are grouped by I/O type/size.

Result Analysis. The TSBS benchmark reports the throughput of IoTDB as follows: 10.6M matrices/s in k1, 10.4M in k2, 8.7M in k3, and 9.6M in k4. `ntprof` shows different sized writes are issued, ranging from 4KB to several MB. `ntprof` reports this because it generates different profiling records of different types of I/O. Across all scenarios, 4 KB write requests constitute the majority, 80.9% in scenario k1, 80.2% in k2, 77.5% in k3, and 80.1% in k4. Figure 9a shows the latency breakdown for 4KB writes (since it dominates the write traffic). k3 sees a drastic increase in "S3-S5(S+C)". That is because NVMe/TCP sessions are competing with `iperf3` flows. The queue is built up in stage S3. In k4, "S6-S9(S+C)" increases most significantly, from 47.8 µs to 1917.3 µs. A further breakdown shows an 1859.7 µs increase in "S7-S9(S+C)" is the primary contributor, indicating that the background I/O streams consume bandwidth and make SSD a bottleneck.

Takeaways. Real-world applications exhibit diverse I/O profiles. `ntprof` exposes a rich task specification interface for developers, translates these profiling requirements into predicates, and installs them into the modeled software switch. As such, it enables concurrent heterogeneous I/O profiling.

4.7 Use Case 6: F2FS

Description. F2FS [65] is a Linux file system designed for modern flash storage devices. F2FS performs exceptionally well with NVMe SSDs, as it efficiently handles the inherent characteristics of flash memory, such as wear-leveling and

garbage collection. In this case study, we focus on analyzing how file I/Os traverse the NVMe/TCP. We take Filebench [75] and run the 'videoserver" workload, which emulates a video streaming server managing multiple concurrent streams.

Experimental Setup. We configure the "videoserver" to run 32 threads issuing 128KB read requests to the active videos, while there is another thread issuing 1MB write requests to the passive videos. The video size is set to 10 GB. Direct I/O is enabled. We also run the application under the 4 scenarios as described in §4.6, except in k3, the `iperf3` clients are on the target side, while the servers are on the initiator side. We use the same profiling task specification and focus on reads.

Result Analysis. Filebench reports 117µs per operation in k1, 319 µs in k2, 235 µs in k3 and 114 µs in k4. Figure 9b shows the latency breakdown for 128KB read I/O. Comparing to k1, "S2(S)" in k2 increases significantly, from 4.6 µs to 173.5 µs. This is because a single TCP connection in the nvme-tcp queue struggles to handle the read I/Os submitted by all the cores, indicating the need to increase the number of NVMe/TCP queues. Akin to §4.2, `ntprof` locates this via two tracepoints (`_queue_request` and `_try_send_cmd_pdu`). "S6-S9(S+C)" is increased from 171.3 µs to 240.6 µs. A further breakdown shows that "S6(C)" is increased by 55.2 µs, dominating the entire latency. That is because by reducing NVMe/TCP sessions we also reduce the dequeuing rate in S6 on the completion path. `ntprof` uses two tracepoints (`_queue_response` and `_setup_response_pdu`) on the target side for analysis. In k3, "S3-S5(S+C)" is increased from 41.0 µs to 191.1 µs. The reason is similar to the case in §4.6. In addition, "S2(C)" is increased from 48.7 µs to 213.8 µs, shown via 2 tracepoints on the initiator side (`_handle_c2h_data` and `_process_nvme_cqe`). In k4, "S6-S9(S+C)" is increased from 171.3 µs to 250.8 µs, aligning with our scenario design.

Takeaways. `ntprof` enables hierarchical I/O path analysis due to our Clos network view. Similar to the Flame Graph [8], one can gradually drill the I/O path segment using different metrics and locate the system bottleneck.

4.8 Overhead Analysis

`ntprof` operates at the data plane and interacts with critical system components. It is important to minimize overhead, including memory and CPU usage. We configure four sets of `fio` experiments (Appendix A.3) and measure the application performance, CPU usage, and memory usage when enabling and disabling (Table 5). Across all workloads, the overhead introduced by `ntprof` is marginal. The CPU usage increases by 0.6% and 2.9% for the read and write cases. We observe up to 17MB more memory usage during the profiling.

5 Related Work

Network Telemetry. `ntprof` benefits from prior network telemetry systems [32, 48, 54, 74, 81, 93, 101, 103, 104, 106]. For example, Sonata [48] develops a declarative interface to express telemetry tasks and partitions query execution to streaming processors and switches. [32, 68, 72, 74, 81, 90, 91, 101, 104, 106] introduce probabilistic data structures (like Sketch) to capture high-volume data streams with low storage on the programmable data plane, i.e., in-network telemetry.

Profiling Systems. Many software utilities are developed to identify code hotspots, analyze concurrency dependency, and break down stalled cycles [9, 13, 18, 19, 38, 45, 66, 102]. For example, Linux `perf` [38] is a widely used tool to instrument CPU performance counters, tracepoints, and probes and reports application execution statistics. Intel VTune [9] takes a top-down analysis strategy [102] and drills down the performance analysis mostly using architectural counters. Some are also integrated into the language system facilitating application development [13, 35, 46, 61, 70, 73, 82–84, 87, 100]. We focus on profiling and analyzing the NVMe/TCP protocol.

Storage Disaggregation. People have explored disaggregated storage extensively given the rising networking bandwidth and fast remote storage protocol [47, 49, 50, 52, 55, 62, 63, 71, 77–79, 105]. Ana Klimovic *et al.* characterize the performance of iSCSI-based disaggregated storage [62]. i10 [55] develops an efficient in-kernel TCP/IP remote storage based on dedicated end-to-end IO paths and delayed doorbell notifications. Researchers [49] also report the performance characteristics of server-based NVMe-oF boxes.

Intra-host Diagnosis. The host interconnect is becoming a bottleneck under high-bandwidth networks. Researchers have developed benchmarking frameworks and diagnostic tools to analyze it [29, 30, 51, 53, 67, 69, 97]. For example, Saksham Agarwal et al. [29, 30] analyze the host congestion issues and build the host congestion control protocol. NSight [51], leveraging CPU profilers, captures sources of overheads in the end-host stack at the nanosecond scale. Hostping [67] monitors and diagnoses intra-host bottlenecks in RDMA networks. `ntprof` can use them to improve its efficiency.

6 Conclusion

This paper presents a profiling and development utility for NVMe/TCP. It enables developers to understand and analyze the execution characteristics of the NVMe/TCP systematically. The key idea is to view the NVMe/TCP storage substrate as a lossless switched network and apply network monitoring techniques. `ntprof` models each on-path system module as a software switch, integrates a programmable profiling agent on the data plane, and introduces a proactive query interface for statistics collection and analysis. We build `ntprof` over Linux kernel and apply it for six case studies.

A Appendix

A.1 Tracepoint Parameters

Table 3 and Table 4 show the parameters of our added tracepoints in the `nvme-tcp` and `nvmet-tcp` module, respectively.

Tracepoint	Parameters
_queue_rq	struct request *req, void *pdu, int qid, struct llist_head *req_list, struct list_head *send_list, struct mutex *send_mutex
_queue_request	struct request *req, struct nvme_command* cmd, int qid
_try_send_cmd_pdu	struct request *rq, struct socket *sock, int qid, int len
_try_send_data_pdu	struct request *rq, void *pdu, int qid
_try_send_data	struct request *rq, void *pdu, int qid
_done_send_req	struct request *rq, int qid
_handle_c2h_data	struct request* rq, int qid, int data_remain, u64 recv_time
_recv_data	struct request* rq, int qid, int len
_process_nvme_cqe	struct request *rq, void* pdu, int qid, u64 recv_time
_handle_r2t	struct request *rq, void* pdu, int qid, u64 recv_time
_try_send	struct request *rq, int qid

Table 3: Parameters of tracepoints in the module `nvme-tcp` (initiator).

Tracepoint	Parameters
_done_recv_pdu	struct nvme_tcp_cmd_pdu *pdu, int qid, long long recv_time
_exec_read_req	struct nvme_command *cmd, int qid
_exec_write_req	struct nvme_command *cmd, int qid, int size
_queue_response	struct nvme_command *cmd, int qid
_setup_c2h_data_pdu	struct nvme_completion *cqe, int qid
_setup_r2t_pdu	struct nvme_command *cmd, int qid
_setup_response_pdu	struct nvme_completion *cqe, int qid
_try_send_data_pdu	struct nvme_completion *cqe, void *pdu, int qid, int size
_try_send_r2t	struct nvme_command *cmd, void *pdu, int qid, int size
_try_send_response	struct nvme_completion *cqe,void *pdu, int qid, int size
_try_send_data	struct nvme_completion *cqe, int qid, int size
_handle_h2c_data_pdu	struct nvme_tcp_data_pdu *pdu, struct nvme_command *cmd, int qid, int size, long long recv_time
_try_recv_data	struct nvme_command *cmd, int qid, int size, long long recv_time

Table 4: Parameters of tracepoints in the module `nvmet-tcp` (target).

A.2 Triggered Events of an NVMe/TCP I/O

Figure 10 enumerates the ordered list of events that an I/O may experience throughout its lifetime in the `nvme-tcp` layer. Some events may occur multiple times, indicated by "1+". Generally, all types of I/O begin with `QUEUE_RQ` and end with `PROCESS_NVME_CQE`.

A.3 More Evaluation

Latency Breakdown on Testbed-2. In Figure 11a, we observe similar breakdown results as in Figure 6a when the number of jobs increases in testbed-2. As shown in Figure 11b, for 128KB sequential writes, "S3-S5(S+C)" becomes the dominant component when the job count exceeds 16, indicating

read I/O

Event Name	Num
QUEUE_RQ	1
QUEUE_REQUEST	1
TRY_SEND	1
TRY_SEND_CMD_PDU	1
DONE_SEND_REQ	1
HANDLE_C2H_DATA	1
RECV_DATA	1+
PROCESS_NVME_CQE	1

write I/O without inline data

Event Name	Num
QUEUE_RQ	1

DONE_SEND_REQ	1
PROCESS_NVME_CQE	1

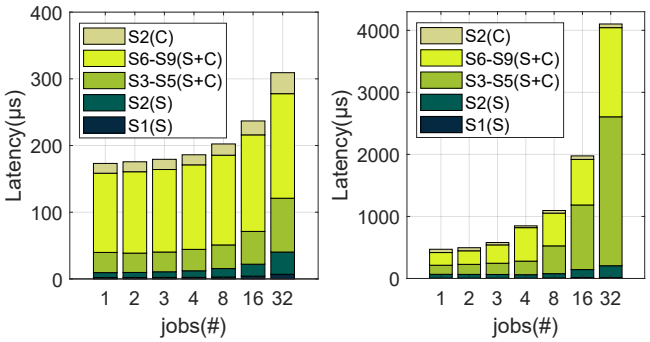
Figure 10: Event series of different types of I/O in the `nvme-tcp` layer. The event name corresponds to the tracepoint name, omitting the "nvme_tcp_" prefix.



(a) 4K Random Read. **(b) 128K Sequential Write.**

Figure 11: Latency breakdown for the 4K random read and 128K sequential write as increasing the number of jobs on testbed-2. We report the five most time-consuming parts. S1(S) refers to the time an I/O stays at the S1 stage on the submission path. S2(C) captures the time spent at the S2 stage on the completion path. S3–S5(S+C) aggregates the time spent in the S3, S4, and S5 stages across the submission and completion paths.

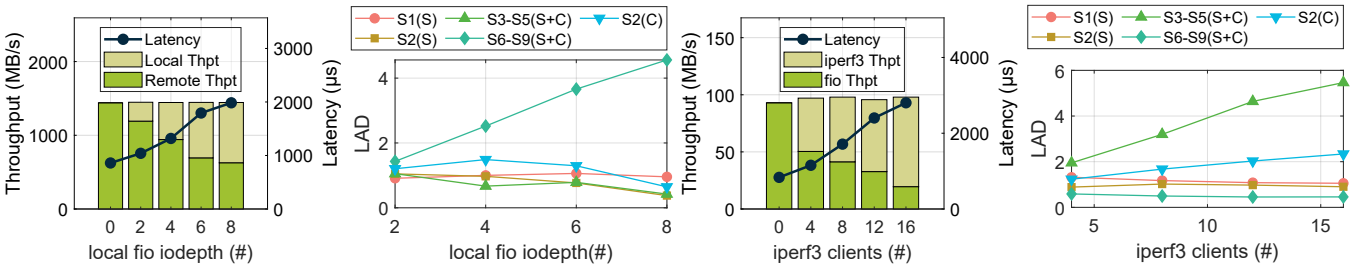
workload	without `ntprof`		with `ntprof`			
	lat(µs)	bw(MB/s)	lat(µs)	bw(MB/s)	imem(MB)	tmem(MB)
4k read	449.26	2202.91	460.57	2099.11	12	10
4k write	66.75	883.91	69.47	835.86	1	7
128k read	1136.72	3493.03	1136.24	3491.88	13	3
128k write	338.75	1439.89	337.44	1439.17	1	17

Table 5: Performance comparison with and without `ntprof`. imem represents the memory usage increase on the initiator side, while tmem indicates the increase on the target side. lat and bw denote the average latency and bandwidth, respectively.

that the queue builds up during data transmission through the network stack. When there are 32 jobs, 2400.4µs is spent out of 4102.2µs of end-to-end latency.

Use Case 3 Results. Figure 12 presents our hardware bottleneck localization results.

Experimental setup for `ntprof` overhead analysis. We configure four sets of `fio` experiments to analyze the `ntprof` overheads: (a) 4K random read, with 16 jobs and an iodepth of 16; (b) 4K sequential write, 4 jobs and an iodepth of 4; (c) 128K sequential read, with 4 jobs and an iodepth of 8; (d) 128K sequential write, with 2 jobs and an iodepth of 2. Each job is assigned to a different core. These parameters were selected based on experiments designed to prevent any



(a) Throughput and Latency. **(b) LAD.** **(c) Throughput and Latency.** **(d) LAD.**

Figure 12: Hardware bottleneck localization. (a) and (b) depict the "slow SSD" case, where we run one extra `fio` job on the target and increases the iodepth from 2 to 8. (c) and (d) show the "slow NIC" case, where we run `iperf3` server on the initiator side and clients on the target sides, and we increase the TCP flows from 4 to 16. LAD=Latency Amplification Degree.

component in the I/O path from becoming a bottleneck, while applying sufficient load to stress the system. The `fio` tests ran for 60 seconds, during which total memory consumption was recorded every second, and an average was calculated at the end of each run.

Building an Elastic Block Storage over EBOFs Using Shadow Views

Sheng Jiang[1] and Ming Liu[2]

[1]Carnegie Mellon University [2]University of Wisconsin-Madison

Abstract

The EBOF (Ethernet-Bunch-Of-Flash) has emerged as an enticing and promising disaggregated storage platform due to its streamlined I/O processing, high scalability, and substantial energy/cost-efficiency improvement. An EBOF applies a smart-sender dumb-receiver design philosophy and provides backward-compatible storage volumes to expedite system deployment. Yet, the static and opaque internal I/O processing pipeline lacks resource allocation, I/O scheduling, and traffic orchestration capabilities, entailing bandwidth waste, workload non-adaptiveness, and performance interference.

This paper presents the design and implementation of a distributed telemetry system (called **shadow view**) to tackle the above challenges and facilitate the effective use of an EBOF. We model an EBOF as a two-layer multi-switch architecture and develop a view development protocol to construct the EBOF running snapshot and expose internal execution statistics at runtime. Our design is motivated by the observation that fast data center networks make the overheads of inter-server communication and synchronization negligible. We demonstrate the effectiveness of shadow view by building a block storage (dubbed **Flint**[1]) atop EBOFs. The enhanced I/O data plane allows us to develop new three techniques–an elastic volume manager, an eIO scheduler, and a view-enabled bandwidth auction mechanism. Our evaluations using the Fungible FS1600 EBOF show that a Flint volume achieves 9.3/9.2 GB/s read/write bandwidth with no latency degradation, significantly outperforming the defacto EBOF volume. It achieves up to 2.9× throughput improvements when running an object store. Flint is tenant-aware and remote target-aware, delivering efficient multi-tenancy and workload adaptiveness.

1 Introduction

Storage disaggregation has gained increasing attraction in the past few years because of its independent scaling, high utilization, and cost-efficiency improvement. With the advent of 400+GbE network and fast remote storage protocols, a remote storage server can deliver millions of IOPS at tens to hundreds of microseconds, approaching the performance of a direct-attached storage system. We have seen a rising number of deployments [15, 52, 72, 76] at public clouds, enterprise on-premise clusters, and edge data centers.

Ethernet-Bunch-Of-Flash (EBOF) is an emerging disaggregated storage solution that packs an Ethernet switch with NVMe drives into one system SoC (System-on-a-Chip). Compared with today's server JBOFs (Just-a-Bunch-Of-Flash), an EBOF implements hardware-assisted remote I/O processing pipelines, elides the power-hungry general-purpose CPUs on the I/O path, and increases the I/O scalability by eliminating the DRAM and PCIe subsystems, significantly improving the system energy efficiency. For example, the Fungible FS1600 (our evaluation target) achieves 200K and 5.9K IOPS per Joule for reads and writes, nearly outperforming existing server storage appliances by one order of magnitude!

However, there is no well-trodden understanding of the EBOF capabilities and limitations, hindering deploying this new storage platform. An EBOF applies the *smart-sender dumb-receiver* design philosophy and provides backward-compatible volume-oriented storage functionalities. This simplifies the system integration and expedites platform deployment but imposes several inefficiencies (§2.2). First, an EBOF volume is statically mapped to an NVMe drive and embodies location oblivious block placement, failing to harness the massive internal I/O bandwidth. Second, an EBOF volume employs size-dependent bandwidth allocation, whose performance only scales with the volume capacity, unadapted to what the actual workload I/O needs. Third, an EBOF is tenant-unconscious, unaware of the device condition, and incurs substantial interference among concurrent I/O streams.

The root cause is that its static I/O processing pipelines only expose block read/write access interfaces, but lack resource allocation, I/O scheduling, and traffic orchestration capabilities. To address this, our idea is to develop a distributed telemetry system (dubbed **shadow view**) that continuously monitors the EBOF running condition. The shadow view serves as the intermediate layer between an EBOF and storage clients,

[1]Flint is available at https://github.com/netlab-wisconsin/Flint.

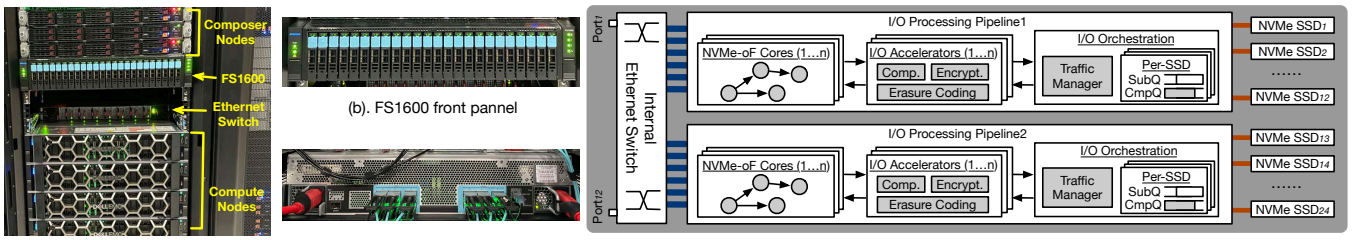


Figure 1: The system deployment and internal architecture of the Fungible FS1600 EBOF platform. (a) depicts our evaluation testbed. (b)/(c) show the front/back panels of the chassis. (d) details the internal architecture of an FS1600.

which exposes the EBOF's internal execution characteristics and assists clients in making efficient I/O execution (such as block placement, bandwidth allocation, and scheduling). The key observation behind this is that the rising data center network speeds make fast (single-digit microsecond) inter-server communication and data synchronization possible. Such a marginal latency to develop the shadow view will then have a negligible impact on the storage applications.

Realizing this vision is non-trivial due to the inherent opaqueness and non-programmable interface of EBOF internals. Towards this, we model an EBOF as a *two-layer multi-switch architecture* that bridges frontend Ethernet ports and backend NVMe drives. Based on the model, we develop a view construction scheme by enabling performance monitoring at multiple vantage points along the I/O path, tracing I/O execution from storage clients, and collectively analyzing the performance characteristics of different components. Our shadow view service runs at view agents (co-located with clients) and a view controller, continuously synchronized via a managed protocol to ensure an up-to-date view is shared among clients. The view controller employs a back-propagation bottleneck analysis mechanism to detect internal EBOF congestions and affected storage streams.

We then build **Flint**–an elastic block storage for an EBOF–atop the shadow view to demonstrate its effectiveness. With the enhanced EBOF I/O data plane, Flint develops three techniques leveraging the shadow view's capabilities. The first one is an elastic volume manager that places storage blocks across all internal NVMe drives on-demand, guided by a runtime EBOF execution profile. The second one is an eIO scheduler that dynamically computes per-IO priority as rank and uses it to orchestrate concurrent I/O submission. The third one is a view-enabled bandwidth auction mechanism, which partitions available bandwidth among competing volumes in a max-min fairness manner at fine granularity. In tandem, Flint achieves high throughput with tolerable latency cost, maximizes device utilization, and ensures efficient multi-tenancy.

We evaluate Flint on a real-system testbed comprising commodity Dell servers and Fungible FS1600 EBOFs. Using FIO-based synthetic micro-benchmarks, we show that one elastic volume over Flint achieves up to 9.3/9.2 GB/s read/write bandwidth, outperforming the defacto EBOF volume by 14.5/13.6×, whose I/O latencies are similar. We further configure various experiments and demonstrate that Flint is tenant-aware and remote target-aware, which can mitigate I/O interference, deliver fair bandwidth allocation, and offer workload adaptiveness. When deploying an object store over Flint, one can achieve up to 2.9× throughput improvements with 66.4%/74.6% average read/write latency savings.

2 Understanding EBOF

This section provides some necessary background about EBOFs and presents a characterization study.

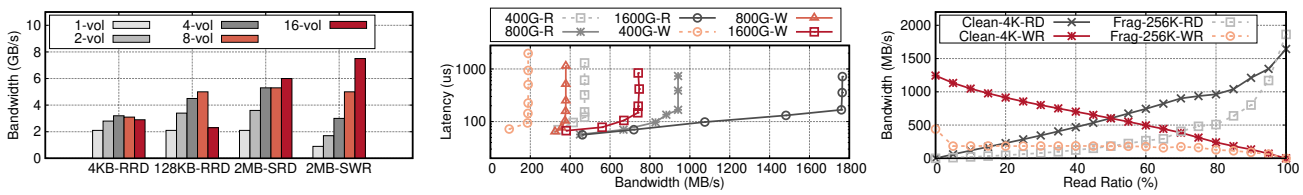
2.1 Ethernet Bunch of Flash (EBOF)

EBOFs are an emerging disaggregated storage solution that holds a number of NVMe drives using an Ethernet switch-integrated SoC (System-on-a-Chip). Compared with today's server/SmartNIC-based JBOFs (Just-A-Bunch-Of-Flash), an EBOF (a) increases the I/O scalability since it elides system-level bottlenecks due to the constrained CPU processing speeds and DRAM/PCIe bandwidths; (b) improves the overall resource utilization and mitigates the resource stranding issue as it eschews the fixed ratio between CPU and SSDs induced by the number of PCIe lanes; (c) achieves high energy/cost-efficiency because it eradicates the hefty computational resources at the storage target. There are some early engineering prototypes being developed, tested, and sampled, such as Ingrasys ES2000 [7] and Fungible FS1600 [5].

FS1600 EBOF. An EBOF is a standalone 2U chassis resembling commodity servers in physical appearance (Figure 1-a). Take the Fungible FS1600 EBOF as an example (which is our development and evaluation target). It encloses 12× 100GbE ports (Figure 1-c) and 24 NVMe drives (Figure 1-b), capable of processing 1.2Tbps storage traffic, sustaining 15M IOPS small random reads and 4.4M IOPS large sequential writes at most, aggregated across all the drives. The typical active power consumption is 750W (850W peak), translating to 200K and 5.9K IOPS per Joule for reads and writes, respectively, significantly outperforming existing JBOF boxes.

Figure 1-d presents the FS1600's internal architecture, consisting of an integrated Ethernet switch, two I/O processing pipelines, and 24 NVMe SSDs. First, the internal switch has 12 ports for external connectivity and delivers network traffic to two pipelines based on the storage targets. Next, packets undergo a sequence of processing stages along the pipeline:

- *Stage 1: NVMe-oF protocol processing.* This includes (i)



(a) Static mapping and location oblivious. **(b) Size-dependent and workload-agnostic.** **(c) Tenant-unconscious and device unaware.**

Figure 2: Performance characteristics of EBOF volumes on FS1600. (a) compares the throughput of four I/O workloads under five logical volume configurations. Physical volumes are from different SSDs. A logical volume uses the striped type (with the 128KB stripe size) where the striping width equals the number of physical volumes. We max out the bandwidth using multiple I/O streams with adequate queue depth. RRD=Random Read. SRD=Sequential read. SWR=Sequential Write. (b) presents the latency-throughput of 4KB random reads and 4KB sequential writes for 400GB, 800GB, and 1600GB volumes, respectively. The y-axis is log scale. (c) shows read/write throughput varying with the read ratio of a mixed workload. The 4KB I/O runs over a clean drive, while the 256KB one runs on a fragmented SSD (preconditioned with 128KB random writes).

networking stack handling and (ii) NVMe-oF capsules and NVMe I/O commands conversion, which are executed over a chain of specialized NVMe-oF cores;

- *Stage 2: Per-IO acceleration.* An EBOF is equipped with several domain-specific accelerators for compute-intensive tasks, such as compression, encryption, and erasure coding;
- *Stage 3: I/O orchestration.* It delivers I/O commands to each SSD via a traffic control module. Akin to an Ethernet switch, there is a traffic manager and a queueing subsystem for both submission and completion.

Last, an EBOF usually supports NVMe drives in U.2 and the emerging compacted EDSFF form factors [3].

EBOF Deployment. An EBOF imposes two differences compared with deploying a traditional JBOF. First, it requires several redundant dedicated servers (called composer nodes in Figure 1-a) to hold the management plane, which (a) configures the EBOF system (e.g., adding/removing forwarding rules for the internal switch, formatting the hot-plugged NVMe drives); and (b) provides a remote control panel for users. Clients interact with these composers on creating/deleting/modifying volumes, monitoring the EBOF running status, and alerting the health condition. Second, each pipeline of an EBOF organizes its Ethernet ports (6 in our case) as one trunk port, with a L3 IP address assigned. The ToR switch, connecting to the EBOF, should then create LACP (Link Aggregation Control Protocol) [6] trunk groups for the corresponding ports, and configure the fallback mode.

An EBOF system provides the physical volume abstraction as today's storage disaggregation solutions. To use it, one should first create a fixed-sized physical volume, which is mapped to one specific SSD. Clients then instantiate an NVMe-oF session, mount the remote volume locally, and make it an NVMe block device. Users can further create logical volumes for capacity/bandwidth expansion and fault tolerance. On our FS1600 testbed, a physical volume, consisting of a sequence of extents, can also be compressed and encrypted if enabled during the volume initialization phase. It primarily supports the NVMe-over-TCP protocol [8].

2.2 Characterizing an EBOF

An EBOF system applies the *smart-sender dumb-receiver* design philosophy and provides backward-compatible volume-oriented storage functionalities. It exposes physical volumes with basic block I/O read/write capabilities, and delegates advanced storage support (such as load balancing and replication) to clients. This drastically expedites the system integration and platform deployment because one can seamlessly transition to an EBOF setup from traditional server-based storage appliances. However, such simplicity comes at a cost. Below we empirically characterize an EBOF and identify several limitations that hinder its performance and efficacy.

Issue #1: Location oblivious block placement. An EBOF volume is statically mapped to an NVMe drive and cannot harness the massive internal I/O bandwidth. Its data placement strategy is straightforward: (i) a newly created volume is placed at one SSD with enough available space; (2) when there are multiple candidates, it chooses one randomly. This simplifies the hardware logic and reduces the in-memory metadata footprint, but bounds the maximum performance of a volume to just one drive, far below the bandwidth capacity of an EBOF. As shown in Figure 2-a, the bandwidth of random reads and sequential writes under large blocks of a physical volume is capped at 2.1GB/s and 0.9GB/s, respectively, approaching the NVMe SSD device limit.

A workaround solution is to create multiple physical volumes (from different SSDs), combine them as a logical volume, and format it into the striped type. This could benefit large sequential I/Os. For example, the 2MB sequential write (Figure 2-a) achieves nearly twice the bandwidth when doubling the number of physical volumes because each I/O hits the strip group, yielding multiple concurrent I/Os to different SSDs. However, for many other I/O profiles, one would observe marginal benefits because the inherent extent layout of a logical volume is location oblivious, unable to harness the parallel I/O paths. As depicted in Figure 2-a, the 4KB/128KB random read maxes out with 4/8 physical volumes, achieving 3.2GB/s and 5.0GB/s. Similarly, the 2MB sequential read shows inferior performance and only sustains 6.0GB/s, less

than one-fifth of the throughput in the 16-vol case.

Takeaways. Flexible and location-aware data placement is essential to unleash the EBOF bandwidth capacity. Ideally, a volume can distribute its extents to one or several bandwidth-capable drives based on online profiling.

Issue #2: Size-dependent bandwidth allocation. The performance of an EBOF volume only scales its capacity and is inadaptable to the actual workload requirements. An EBOF takes the *IOPS/GB* as the key metric when reserving per-volume bandwidth on the control plane upon initialization. The data plane then ensures that the actual bandwidth usage doesn't exceed its allocated share. Such a design only requires a static traffic policer installed at the processing pipeline without employing some dynamic mechanisms like the water-filling algorithm [66]. This completely moves the I/O resource allocation and scheduling out of the performance path, entailing a streamlined I/O pipeline. Take the FS1600 as an example. It configures the QoS upper bound of a volume via $\frac{EBOF\ Read/Write\ IOPS}{EBOF\ Capacity} \times Volume_{size}$.

Figure 2-b depicts the latency-throughput of two workloads running under different-sized volumes. The latency of 4KB random reads (sequential writes) rises drastically when the bandwidth approaches 472 (188) MB/s, 941 (378) MB/s, and 1760 (741) MB/s for 400GB, 800GB, and 1600GB volumes, respectively. This matches the bandwidth upper bound prescribed as above. Such a size-dependent EBOF volume, benefits workloads embodying the same requirements on capacity and throughput, but conversely, contradicts many other application usage patterns. For example, a throughput-oriented workload with a small size requirement, like a metadata service in a distributed blob store [38, 57, 59], has to request a large volume to ensure enough bandwidth is provisioned, entailing storage capacity waste. Similarly, a capacity-oriented application with low throughput needs, like a logging service, allocates a high-capacity volume with excessive throughput reserved implicitly, causing bandwidth waste.

Takeaways. Decoupling capacity allocation and bandwidth reservation functionalities of an EBOF helps improve its efficiency when holding I/O workloads with incongruent size and throughput requirements. This necessitates the I/O processing pipeline to control bandwidth on-demand at the data plane.

Issue #3: Interference heavy. An EBOF volume is tenant-unconscious and device condition unaware, entailing great interference among concurrent I/O streams. An EBOF system enforces performance isolation at the volume granularity. There is a per-volume rate limiter inside the traffic manager that ensures a busy or noisy volume cannot exceed its bandwidth share. This mechanism mitigates inter-volume I/O interference when requests transmit within the pipeline, but completely ignores interference at the NVMe drive. As an example, we co-locate one victim volume with four adversarial volumes on one SSD. The victim volume runs a 4KB random read with QD (queue depth) =1, and we measure its latency. The rest volumes run other throughput-intensive read/write streams. We observe that the P999 latency of the victim volume increases from 169us to several milliseconds!

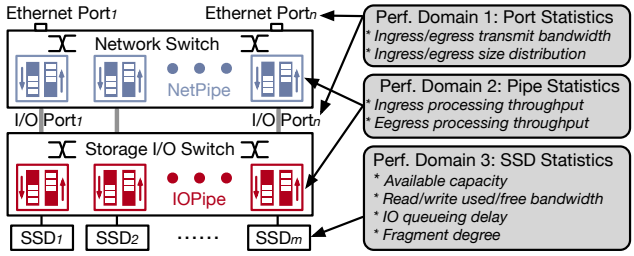


Figure 3: The hardware model of an EBOF and the performance monitor domains of the shadow view.

Further, intra-volume performance isolation is not supported on the EBOF. As shown in Figure 2-c, a 4KB read-only stream achieves 439.0 MB/s higher bandwidth than the mixed case with a 50/50 read/write ratio on a clean SSD. When the drive becomes fragmented, even with a large 256KB block size, it sustains 59.5% and 63.4% less read and write throughput on average across all scenarios. The fundamental issue is that an EBOF schedules I/Os without considering the request cost and SSD condition, yielding inefficient multi-tenancy. As shown in prior studies [11, 37, 50, 54, 74], the per-I/O execution cost is determined by read/write mix ratio, I/O block size, and I/O concurrency. When contention happens at the SSD controller, the device queue, or NAND channels/chips/dies, an I/O would be stalled and incur a high execution cost. Capturing the SSD condition is non-trivial because (a) the number of clean flash pages and their location distribution hinge on the previous write history, which is not exposed; (b) the SSD internal parallelism is unknown due to the FTL mapping and private proprietary internal architecture; (c) housekeeping operations (like garbage collection and wear leveling) are unpredictable and thereby consume a non-deterministic amount of internal bandwidth when triggered.

Takeaways. Mitigating I/O interference requires an EBOF to monitor its end-to-end bandwidth availability (including network, I/O pipeline, and SSD) at the runtime and prudently schedule individual IO in a tenant-aware manner.

3 Shadow View: A EBOF Telemetry System

This section introduces the shadow view, a distributed telemetry system that enhances the EBOF data-plane capabilities.

3.1 Key Idea

The root cause that yields EBOF inefficiencies is the static I/O processing pipelines that only provide block read/write access functionalities, but lack resource allocation, I/O scheduling, and traffic orchestration capabilities. Our key observation is that the rising data center network speeds make fast (single-digit microsecond) inter-server communication and data synchronization possible. Such a marginal latency overhead will have a negligible impact on the storage applications

because the per-I/O latency is in the order of tens to hundreds of microseconds. Therefore, our idea is to develop a software-based telemetry system (called **shadow view**) that continuously monitors the EBOF running condition. It serves as an intermediate layer between an EBOF and storage clients, which exposes EBOF runtime internal statistics and assists clients in efficient I/O execution (including block placement, bandwidth allocation, and scheduling).

3.2 Definition and Capabilities

The shadow view is a software-managed distributed telemetry system that profiles and reports the computation and I/O resource availability of an EBOF at runtime. It decouples from the EBOF hardware box and works as a standalone distributed service, deployed over a bunch of general server hosts. The key challenge to realizing it is the black box nature of EBOF internals that exposes little interaction and programmable interfaces. Hence, we develop a reactive approach that tracks, collects, and analyzes the end-to-end per-I/O statistics from all mounted volumes to construct an EBOF running snapshot.

To facilitate the view development, we model an EBOF as a two-layer multi-switch architecture (Figure 3) that bridges frontend Ethernet ports and backend NVMe drives.

- The **upper half** is a network switch, connecting N Ethernet ports on one side and an equal amount of I/O backplane ports on the other side, which forwards incoming/outgoing Ethernet packets. The switch internally comprises N bidirectional *NetPipe*s. For each pipe, we associate a virtual packet queue with each direction;
- The **bottom half** is a storage I/O switch that connects N I/O ports and M NVMe drives. Except for the basic forwarding functionality, it converts between NVMe-oF capsules and NVMe commands and accesses the SSD drive. Similarly, we model the switch as M bidirectional *IOPipe*s, staying close to the SSD, where each is equipped with a virtual I/O queue on the submission and completion paths.

Note that (a) unlike traditional Ethernet switches, both switches are asymmetric with two distinct sets of operating ports; (b) our hardware model is generic, only requiring minimal knowledge (like port #) of the EBOF specification.

Based on the proposed hardware model, we then organize the shadow view into three performance monitoring domains. The first one is port statistics, where we capture the traffic usage of Ethernet/IO backplane ports at packet/flow/session granularities, including used/available bandwidth and size distribution. The second one is pipe statistics that focus on reporting the processing throughput and queueing delay of *NetPipe*s and *IOPipe*s. We separate ingress and egress metrics to capture I/O submission and completion paths. The last one is SSD statistics. Due to the inherent opaqueness, except for the SSD's available space, we estimate the available read/write bandwidth headroom, I/O delay, and NAND fragment degree (an indicator to determine the I/O write cost) following prior studies [11, 37, 50, 54].

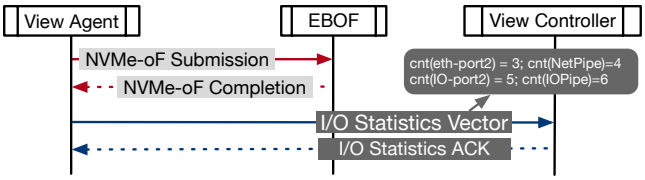

Figure 4: The view construction procedure.

Akin to other telemetry systems, our shadow view behaves as a database for an EBOF. It imposes two main capabilities. One is the runtime statistics query in which one can flexibly integrate the shadow view into a system and explore EBOF-conscious optimizations. The other is event notification, where applications can register callbacks to trigger proactive resource management. We will show how to use the shadow view to develop a block storage (§4).

3.3 View Construction

We construct the shadow view by tracing I/O execution from storage clients, collectively analyzing the performance characteristics of different components, and mapping them to the underlying hardware model. Our shadow view service is distributed across two entities: view controller and view agent. The view controller is integrated into the central arbiter and maintains the entire picture of an EBOF. It receives the per-I/O running statistics from view agents, performs collaborative analyses, and exposes RPC interfaces for interaction. The view agent, colocated with storage clients, monitors the I/O execution of its mounted block devices and only holds a partial view of an EBOF. We employ a hybrid pull/push approach to synchronize the view between these two (§3.4).

An EBOF embodies two types of execution paths, described as follows: (a) NVMe-oF submission: $\textit{Ethernet Port} \Rightarrow \textit{NetPipe}_{ingress} \Rightarrow \textit{I/O Port} \Rightarrow \textit{IOPipe}_{ingress} \Rightarrow \textit{SSD}$; (b) NVMe-oF completion: $\textit{SSD} \Rightarrow \textit{IOPipe}_{egress} \Rightarrow \textit{I/O Port} \Rightarrow \textit{NetPipe}_{egress} \Rightarrow \textit{Ethernet Port}$. Based on this, we show how the view is developed across the following two entities:

- **View Agent.** It takes the timestamp when submitting the I/O request and receiving the response. By subtracting these two, we know the end-to-end round-trip time (RTT), i.e., the sum of NVMe-oF submission and NVMe-oF completion. Upon completion (Figure 4), the agent (a) forwards the I/O statistic vector–<NVMe-oF session, target SSD, I/O type, I/O size, RTT>–to the controller; (b) updates corresponding metrics for its partial view. The I/O statistics vectors are batched before sending to the controller to reduce network communications. This indicates that the view development process is out of the system's performance path;
- **View Controller.** We maintain an in-memory representation of the hardware model (Figure 3) at the controller. It covers all system components from three performance domains. We employ a window-based approach to profile each metric to report the current and EWMA (exponentially

weighted moving average) value. Upon receiving an I/O vector message, the controller first dissects its traversed path within an EBOF based on the NVMe-oF session and target SSD, including *NetPipe*, *IOPipe*, and $I/O\ Port$. It then updates the corresponding metrics of the full view.

Bookkeeping Statistics. Our agent and controller use the same methods for aggregating running statistics. The packet and I/O distribution are captured via a typical counting array. Regarding bandwidth and throughput, we consider both bit-per-second and packet (I/O)-per-second because the processing capacity of an EBOF is size-dependent. Except for the available capacity, SSD statistics are generally challenging to obtain due to the opaqueness. Following prior work [37, 54, 70], we combine an offline profiling and an online estimation strategy that uses the end-to-end I/O delay as an indicator to decide the queueing delay at the controller and bandwidth headroom. The fragment degree is approximated using the dynamic write cost [54]. Due to the window-based profiling scheme, the view service supports aging automatically. Future commodity EBOFs could do fine-grained timestamping at different stages across the pipeline, which would give us more internal execution visibility. Our shadow view leaves the extension interface to integrate them later.

3.4 View Synchronization

The shadow view is collaboratively built by the view controller and view agents. We develop a view synchronization protocol to update and synchronize the view. Our design is inspired by prior distributed cache-coherence protocols [40, 42]. The key idea is to use a monotonically increasing counter to represent the view recency. Thus, each entity of the hardware model (like port, pipe, and SSD) is assigned a dedicated counter at both agent and controller. We don't use a shared counter because the view can be updated partially, i.e., an I/O request only traverses a subset of an EBOF.

The view controller works as a serialization point of an EBOF to order all issued I/Os. Upon receiving the statistic vector of a completed I/O request, it performs three operations atomically: updates the corresponding view entries, increments their counters by one, and returns an acknowledgment message that attaches the changed counters for the agent's partial view (Figure 4). The controller also maintains a directory of mounting storage clients who hold the partial view. Next, when the view agent receives the response, it first compares the attached counter (X') with the previously held one (X) to decide if the view is obsolete as follows:

- If |X'-X| = 1, this indicates the client is the latest EBOF user and its partial view is update-to-date;
- If |X'-X| > 1, it means there are multiple concurrent storage clients issue I/Os and its partial view is outdated;

The view agent always overwrites the counter with the newly received value because only the controller can update the counter. A careful reader might notice that the message order of the I/O statistics vector received by the controller might be different from the I/O completion order of an EBOF. For example, a client might complete an I/O request earlier than another one, while its statistics update message comes late. We resort to the EBOF timestamp information of the statistics message to resolve the issue. Our controller connects to EBOF composer nodes (§ 2.1) via the management network and has time synchronized. When updating each component of the shadow view, it uses the timestamp to decide if the statistics stay within the profiling window.

Algorithm 1 Back-propagation Bottleneck Analysis.

```
1:  procedure ANALYZE_BOTTLENECK                ▷ Executed per-epoch
2:      for SSD in all_SSDs do
3:          if SSD.avail_bw ≤ Threshold then
4:              Congested_SSDs.add(SSD);
5:              Congested_IOPipes.add(SSD.IOPipe);
6:      for Session in all_NVMeoF_Sessions do
7:          if Session.target_SSD in Congested_SSDs then
8:              Congested_NetPipes.add(Session.NetPipe);
9:              Victim_Sessions.add(Session);
10:     for Session in all_NVMeoF_Sessions do
11:         if Session.NetPipe in Congested_NetPipes then
12:             if Session not in Victim_Sessions then
13:                 Victim_Sessions.add(Session);
```

Based on the above support, our shadow view service provides two types of synchronization. In the *PUSH* mode, the view controller periodically publishes its latest shadow view to its view agents. If a client registers a particular callback function to monitor an event (such as if the SSD available bandwidth has dropped to a threshold), the controller then copies the view proactively. In the *PULL* model, the view agent eagerly fetches its accessed partial view if its own is obsolete. This is realized via the controller RPC.

3.5 Bottleneck Analysis

When an internal component of an EBOF reaches its processing limit, one would observe queue buildup along the EBOF I/O processing pipeline, entailing head-of-line blocking and jeopardizing I/O latency. The shadow view offers two possible solutions to identify the bottleneck: one is examining the queueing delay at the *NetPipe*, *IOPipe*, and *SSD*; another one is comparing the achieved bandwidth with the device limit (obtained from the EBOF specification). Based on our operating and development experience, we find that (a) *SSD*s are always the first to hit the system bottleneck; (b) the processing capability of the *NetPipe* and *IOPipe* is generally over-provisioned. Because of the path symmetry between I/O submission and completion within an EBOF, congestion only happens at the ingress path, not egress.

The shadow view employs a back-propagation analysis scheme to dissect the congestion region and identify victim NVMe-oF sessions (ALG1). When an NVMe drive becomes over-subscribed, the shadow view can quickly locate the affected *IOPipe* because there is a 1-to-1 mapping between

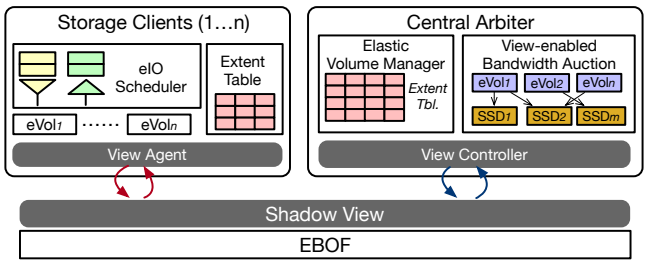

Figure 5: The system architecture of Flint.

IOPipe and *SSD* (ALG1 L1-5). Next, since the mapping between *NetPipe* and *IOPipe* is n-to-m, to identify victim *NetPipe*s, we scan through active NVMe-oF sessions whose destination is the congested SSD (ALG1 L6-9). Last, for each victim *NetPipe*, the algorithm reexamines all other NVMe-oF sessions and finds out the ones that share the congested pipe (ALG1 L10-13). The bottleneck analysis process is launched periodically at the end of each profiling epoch.

4 Flint: an Elastic Block Storage

This section presents Flint that overcomes the drawbacks (§2.2) of existing EBOF volumes. Our design goals are:

- **High throughput with tolerable latency cost.** Massive I/O bandwidth is the crucial capability of an EBOF compared with conventional JBOFs. Flint aims to fully utilize the storage bandwidth across all NVMe drives and eliminate any potential I/O stalls along the pipeline;
- **High utilization and deployment flexibility.** The volume provided by Flint should use any available space from any SSDs, regardless of whether the storage blocks are continuous on one SSD or fragmented across multiple drives. Its performance should scale with the application demands instead of being determined by volume sizes;
- **Efficient multi-tenancy.** Flint should provide the max-min fairness guarantee when partitioning bandwidth among co-located volumes. It should estimate the device bandwidth availability at runtime and admit the right amount of I/Os to avoid oversubscription. The head-of-line blocking issue should be tackled in an end-to-end fashion.

4.1 Overview

Flint comprises two types of nodes (Figure 5): storage client and central arbiter, running atop the shadow view. The client, co-locating with a view agent, allocates/deletes/manipulates volumes, submits read/write I/Os, and orchestrates requests through **an eIO scheduler** (§4.3 and §4.5) to mitigate the head-of-line blocking. The central arbiter, cooperating with a view controller, acts as the EBOF resource manager. It encloses two key system components: (1) **an elastic volume manager** (§4.2), which places data blocks, maintains an extent mapping table, and serves volume management requests; (2) **a view-enabled bandwidth auction mechanism** (§4.6), partitioning available bandwidth among competing volumes in a max-min fairness manner at the fine granularity. A volume

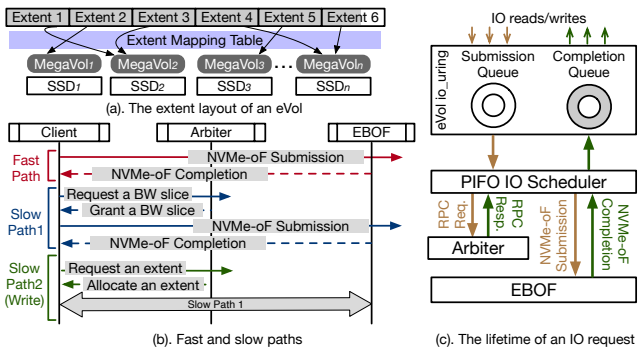

Figure 6: *eVol* extent layout, I/O lifetime and I/O path.

can be replicated using chain replication for high availability (§4.4). The arbiter is not replicated because it is not in the data path and clients can continue performing I/Os on an open volume even if the arbiter is down, although it can be made reliable. All the cross-node communications are realized via RPCs, and we implement them atop eRPC [35].

4.2 Elastic Volume and Volume Manager

Flint provides an elastic volume (*eVol*) to address the limitations of the defacto EBOF volume. An *eVol* consists of a sequence of fixed-sized extents (2MB in our case), spreading across more than one SSD. To enable flexible data placement over all EBOF drives, Flint employs a two-level hierarchical volume manager at the arbiter. As depicted in Figure 6-a, the bottom layer creates one mega-volume (*MegaVol*) for each SSD covering the entire storage space through the default EBOF control plane. The upper layer then performs block allocation and places extents to different mega-volumes based on the given policy. Each *eVol* has an extent mapping table, where our volume manager uses an aggregated one for the whole EBOF. Each mapping entry has 16 bytes with the following format: SSD index, physical extent number, and replication node. We implement the extent table using an in-memory hashtable. It takes only 8MB to address a 1TB *eVol*, which is feasible on commodity servers.

A storage client requests a new volume via the `create_vol` API. It takes the volume size and allocation policies as parameters. We apply a lazy allocation scheme. Upon the `create_vol` request, the volume manager only checks whether there is enough capacity to hold the volume, reserves the space, and sends back the acknowledgment. A successful return doesn't indicate the actual data placement is done. When an I/O write happens and there is no corresponding mapping entry in the local extent table, clients would interact with our volume manager to allocate a new extent from one SSD (mega-volume), and then update extent tables on both sides. The extent tables are stored in RocksDB [1] backed by a replicated file system (such as Ceph [77]), and all updates are executed in a transactional manner.

We use a weighted score function to realize different data placement policies. Under the extent allocation request from an *eVol*, our volume manager calculates the intended score

for each SSD and chooses the one with the lowest score. The function (shown below) balances a slew of factors: (a) prior allocation history, i.e., how many extents have been placed; (b) available capacity, where we aim to balance the SSD utilization; (c) recent busy status from the bandwidth perspective; (d) fragment (or wear-leveling) degree of the SSD; (e) user-defined preferences. We obtain the parameters of (c) and (d) from the shadow view.

$$Score(eVol_i, SSD_j) = \alpha \times Extent_{\#} + \beta \times Capacity_{used} + \gamma \times Busy_{degree} + \delta \times Fragment_{degree} + \eta \times Preference$$

The volume manager maintains a score matrix for each *eVol* and updates it periodically. Clients set the initial placement policy in `create_vol` and can alter the strategy on the fly via `update_vol`. When a volume is destroyed (`destroy_vol`), the volume manager frees the space, updates the metadata from the extent table, and deletes the related score matrix.

4.3 I/O Path

In Flint, a storage client submits I/O requests first to a co-located block I/O scheduler, then to a per-thread `io_uring` engine. We choose the `io_uring` interface [2, 10, 22] due to its efficient asynchronous support, rich feature set, and high scalability. The I/O scheduler (§4.5) leverages the shadow view to determine the I/O issuing order, mitigating the head-of-line blocking. Finally, Flint uses the NVMe-over-TCP protocol [8] to carry I/O reads/writes between clients and an EBOF. Figure 6-c depicts the lifetime of an I/O.

Flint introduces fast and slow paths when accessing the EBOF because its bandwidth resources are managed by the central arbiter (Figure 6-b). A read can be issued to the EBOF directly only if the allocated bandwidth slice (§4.6) can hold the request size (fast path). Otherwise, it should request a new slice from the arbiter and then submit the I/O (slow path1). A write behaves similarly except that it may introduce one more slow path–asking the arbiter to allocate a new extent. However, in practice, we noticed that this extra RPC call takes only a few hundred microseconds and incurs negligible performance overhead, given that: 1) a typical write I/O to consume an extent (2MB) takes thousands of microseconds; 2) this slow path can only happen for write I/Os; 3) write I/Os are directed to the most performance-capable extent that is dynamically allocated based on the current system condition.

4.4 Replication

Flint employs the chain replication [65] as an optional configuration to improve system availability. It replicates data blocks at the extent granularity. When enabled, given an extent allocation, the volume manager chooses three different SSDs with the lowest scores for placement. Then in the extent mapping table, each entry records all the replicas along with the ordering in the replication chain.

Flint follows standard protocol execution logics as chain replication prescribes. I/O writes are issued to the head, which are then passed along the chain. We pass down commands instead of actual updates because the target LBAs (logical block addresses) are different. I/O reads are handled by the tail of the chain. Chain replication achieves strong consistency naturally because requests are ordered by the tail, which operates as the primary in a traditional primary-backup system. There are two ways to facilitate request passing over the chain. One is using the EBOF's recirculation capability, where a completed I/O can be reinserted into the I/O processing pipeline with some modifications. Such an intra-EBOF coordination is an ideal solution, reducing the replication latency and saving external network bandwidth. The other one is implementing the chain replication coordinator at the client host. Essentially, after receiving the I/O completion from the predecessor, it refabricates the I/O submission request and sends it to the successor. This incurs multiple round trips between the client and EBOF. Flint takes the latter approach because our FS1600 box doesn't expose the recirculation directly. We are currently working with the vendor on realizing the former approach.

Algorithm 2 eIO Scheduler.

```
1:  procedure EIO_ENQUEUE
2:      io = pending_queue.poll();
3:      compute_rank(io);
4:      sort_window.binary_insert(io);
5:  procedure EIO_DEQUEUE
6:      for io IN sort_window do
7:          if io.id == io.stream.sq.front().id then
8:              io.admit();
9:              sort_window.remove(i);
10:             io.stream.sq.pop();
11:             aging(); break;
```

4.5 eIO PIFO Scheduler

Flint runs an I/O scheduler at each client to improve the *eVol* performance. To capture the dynamic I/O execution cost and mitigate the resulting head-of-line blocking, Flint develops a priority-based I/O scheduler based on the ranking concept. The rank of an I/O determines its issuing order.

Our eIO PIFO scheduler uses a scheduling tree for the implementation. It encompasses a priority queue for submission and a FIFO queue for completion. Upon an incoming I/O, the scheduler computes its rank and inserts it into the corresponding location. Rank, representing the I/O cost, takes I/O characteristics (size and type), queueing time, and allocated bandwidth into account. A lower-ranked I/O would be dequeued first. The completion side delivers I/O simply following the arrival order. When the client receives a bottleneck report (§3.5), all victim I/Os will experience a rank increase due to the rising cost, thereby hedged from submission.

Algorirthm 2 presents the pseudo-code of our eIO scheduler. It polls I/Os issued from different threads, calculates their ranks based on the current shadow view, and inserts them into a binary search tree that is sorted using the rank value. The *sort_window* uses binary search since requests

Algorithm 3 Client-Side Bandwidth Auction.

```
1:  procedure IO_SUBMISSION(io)
2:      ssd_nqn = io.ssd_nqn;
3:      avail_slices = shadow_view[ssd_nqn].avail_slices;
4:      slice = avail_slices.back();
5:      if slice.is_full() then
6:          slot = RPC_request_slice(avail_slice);
7:      slice.consume_io(io);
8:      io.admit();
9:  procedure IO_COMPLETION
10:     slice = io.slice
11:     slice.completes += 1;
12:     if slice.is_full() AND slice.submits = slice.completes then
13:         slice.close();
14:     RPC_report_completion();
```

Algorithm 4 Arbiter-Side Bandwidth Auction.

```
1:  procedure ARBITER_BW_AUCT
2:      while true do
3:          epoch_advance(); estimate_avail_bw();
4:          reassign_quota();
5:          while not epoch_expired() do
6:              refresh_drr_lists();
7:              for tenant in active_list do
8:                  tenant.deficit += Quantum;
9:                  if tenant.deficit > DEF_THRESHOLD then
10:                     tenant.state = Idle; tenant.deficit = 0;
11:                     idle_list.add(tenant);
12:                     active_list.remove(tenant);
13:                     reassign_quota();
```

are sorted by their ranks. During dequeue, Flint iterates over the *sort_window* until an I/O is in the front of the submission queue of an I/O stream and admits it. Hence, Flint ensures: (1) no I/O reordering happens within a stream, therefore following their submission order; (2) requests belonging to different streams are submitted following their ranks. Finally, we apply aging for the pending requests to prevent starvation.

4.6 Bandwidth Auction

Flint allocates bandwidth fairly among competing storage streams using an RTS/CTS-like mechanism [17]. An NVMe-oF client can only issue an I/O when granted enough bandwidth slices. Hence, each active client periodically asks the arbiter for available bandwidth, and the arbiter sends back grant messages after the auction. The challenge to realizing it is that the bandwidth allocation of an EBOF should holistically consider each component between Ethernet ports and SSDs, instead of only targeting one entity. For example, a storage stream might receive adequate bandwidth from an SSD but then be bottlenecked by the I/O processing pipeline (like *NetPipe*), causing bandwidth waste.

Our arbiter combines deficit round-robin (DRR) [71] and gang scheduling [23,24] techniques to address the issue. Each active NVMe-oF session–that has issued a bandwidth allocation request–is assigned a three-tuple deficit counter vector, representing resource requirements for *NetPipe*, *IOPipe*, and *SSD*. We then divide all sessions into different groups based on their target SSD. The shadow view reports the bandwidth headroom of each component, which we translate to the total amount of I/Os that can be admitted. For each group, the arbiter walks through its associated sessions whose deficit counter vector is accumulated with a prescribed quantum (whose value is in proportion to the session's priority) at each round. A bandwidth slice is granted when (a) all the deficit counters of a session have reached their target thresholds, and (b) there are adequate resources indicated by the shadow view. After that, the deficit counter vector is reset and the session waits for the next allocation. Users can specify their performance targets and Flint will then calculate the quantum to ensure the total bandwidth of a SSD is partitioned accordingly. By default the bandwidth is equally shared.

Algorithms 3 and 4 detail the bandwidth auction mechanism on the client and arbiter sides. When a client issues an I/O, it looks up the current bandwidth slice from the local shadow view and checks its availability. If the slice has no room, it asks for a new one from the arbiter. The slice consumes an I/O based on its weighted cost (profiled by the shadow view) and then calls *admit*() to notify the I/O executors for submission (through the `io_uring`). Upon completion, the client reports the I/O latency to the arbiter. If the slice becomes empty and there are no outstanding I/Os, it requests for a new bandwidth slice, which is piggybacked through the report RPC (ALG 3 L12–14).

On the arbiter's side, there is a DRR routine running for each SSD device. Each DRR routine maintains three different lists: (a) an active list containing tenants that are actively issuing I/Os, (b) a deferred list containing tenants that have run out of the virtual slice quota, and (c) an idle list that includes tenants that do not issue I/Os within a time window. At the beginning of a new epoch, Flint estimates the available bandwidth of the device and reassigns the bandwidth slices to each tenant. Flint then runs the DRR loop until the current epoch expires. In each loop, we refresh the lists in case their states have changed and iterate tenants over the *active_list* to increase their deficit value. If the deficit exceeds a threshold, we set its state to *Idle*, update the corresponding lists, and reassign quotas (ALG 4 L10–L13).

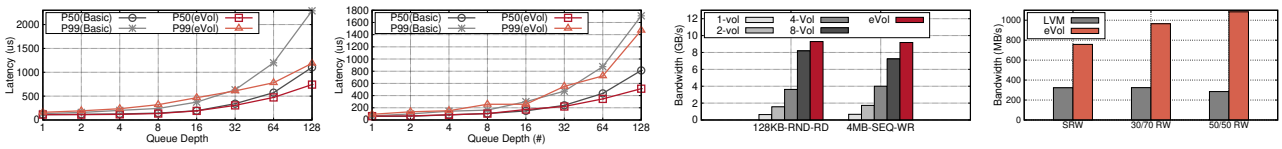
5 Evaluation

Our evaluations aim to answer the following questions:

- How does Flint perform compared with the default EBOF block storage in terms of latency and throughput? (§5.2)
- How does Flint address the three performance inefficiencies of an EBOF volume? (§5.3, §5.4, §5.5)
- What are the considerations when deploying Flint? (§5.6)

5.1 Experimental Methodology

Testbed. We evaluated Flint using a small-scale rack cluster, comprising 2U commodity servers as storage clients, a Dell



(a) 4KB Random Read. **(b) 4KB Sequential Write.** **(c) Bandwidth.** **(d) Congested Bandwidth.**

Figure 7: Performance comparison between eVol and the defacto physical/logical volume on EBOF and LVM. (a)/(b) report the P50 and P99 latency of 4KB random read and 4KB sequential write when increasing the queue depth. (c) shows the maximum bandwidth of 128KB random read and 4MB sequential write comparing eVol and different types of logical volumes. (d) shows the bandwidth of LVM and eVol of 1MB sequential write, 30/70 mixed read/write, and 50/50 mixed read/write, where certain drives are congested.

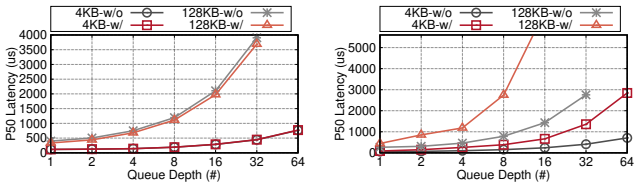
Z9264F-ON ToR switch (w/ 64× 100GbE ports), and the Fungible FS1600 EBOF. Each server is a Dell R7525 box, enclosing two AMD 7302 processors (running at 3.0GHz), 256GB DDR4 memory, a Broadcom 25GbE dual-port NIC, a Mellanox 100GbE dual-port CX6 NIC, and two Samsung NVMe SSDs. All clients run Ubuntu 22.04.

Experiment setup. We build Flint from scratch in about 7600 lines of C++ code. Flint provides eVol management and both sync/async I/O interfaces to the client. We primarily compared with the defacto volume service provided by EBOF. Our experiments first use FIO-based synthetic workloads [4] to explore the benefits of Flint proposed techniques and the capabilities of the shadow view. We then take an object store as a storage application to showcase the overall benefits. We use the YCSB benchmark [20] in this case. We report throughput and average/tail per-I/O latencies as the performance metrics.

5.2 eVol Performance

We first examine the basic performance of an eVol. In terms of small I/Os, when we increase the same queue depth for an I/O stream, eVol achieves the same P50 latency as a physical volume (Figures 7-a and b). This is because the majority of I/Os traverse the fast path (§4.3), yielding one RTT between the client and an EBOF. An eVol places data blocks over all the SSDs in an EBOF. As a result, given the same queue depth, each SSD will receive less amount of I/Os than the physical volume. Thus, the eVol reduces the P99 latency by 48.1% and 13.4% in terms of 4KB random read and 4KB sequential write, respectively. Regarding large I/Os, eVol can harness the massive I/O bandwidth of an EBOF easily because of its flexible data layout (Issue #1 in §2.2). As shown in Figure 7-c, it achieves 9.3/9.2 GB/s when running 128KB random read/4KB sequential write, outperforming a logical volume with 1, 2, 4, and 8 physical volumes by 14.5/13.6×, 5.9/5.3×, 2.6/2.3×, 1.2/1.3×, respectively.

Replication. Flint uses chain replication (§4.4) to achieve high availability. Figure 8 reports the P50 latency of I/O reads and writes with the replication enabled/disabled. We use three replicas in this experiment. For 4KB and 128KB random reads, with replication, they achieve the same performance as the disabled case when varying the queue depth because requests are served by the tail node. However, in terms of writes, since an I/O should pass through the chain from the



(a) I/O read under replication **(b) I/O write under replication**

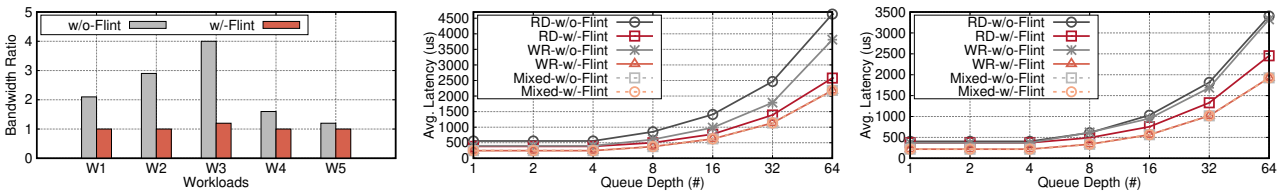
Figure 8: Latency varying the I/O queue depth when enabling and disabling the replication.

head to the tail, one would experience a considerable latency increase. For example, on average across all cases, the P50 latency of a 4KB and 128KB write is worsened by 2.9× and 3.5×, respectively. With future EBOF recirculation support (where a request can be reinjected into the I/O processing pipeline), we expect the latency can be further reduced.

5.3 Flint Decouples Capacity and Bandwidth Allocation

Next, we evaluate how Flint addresses the second issue (§2.2) via the bandwidth auction technique. We configure five scenarios with two types of contending random I/O streams, where each is issued from different-sized volumes: W1 (16× 4KB reads *v.s.* 8× 128KB reads), W2 (8× 4KB reads *v.s.* 8× 4KB writes), W3 (8× 4KB writes *v.s.* 8× 128KB reads), W3 (8× 4KB reads *v.s.* 8× 4KB writes), W4 (8× 128KB reads *v.s.* 8× 128KB writes), and W5 (8× 4KB 70/30 reads/writes *v.s.* 8× 4KB 30/70 reads/writes). We max out the bandwidth of each stream using a large queue depth (QD).

Figure 9-a reports their aggregated relative bandwidth ratio. For all scenarios, Flint ensures I/O streams with the same demand receive similar bandwidth regardless of their capacity. This is because (a) our arbiter distributes equal bandwidth slices to each active tenant in a deficit round-robin manner; (b) a client can only submit an I/O when its granted slice still has room. Thus, a small volume can still receive more bandwidth if it has more pending I/Os, whereas a large volume cannot take more than its (weighted) equal share. Under contention, no matter how many outstanding I/Os a stream issued, it can only receive more bandwidth when all contending streams operate in a similar phase. When disabling our mechanism, one can observe great unfair allocation. For example, in W3, the 128KB read ones take 4× more than the 4KB write ones.



(a) Bandwidth Allocation. (b) Perf. under a read-congested SSD. (c) Perf. under a write-congested SSD.

Figure 9: We compare two cases that enable (w/) and disable (w/o) the proposed Flint technique to evaluate the multi-tenancy support. (a) presents the achieved bandwidth ratio between two categories of contending I/O streams. (b) and (c) show the average latency of a 32KB read, write, mixed (70% read) I/O stream when running under a read/write-congested SSD.

5.4 Flint Mitigates I/O Interference

This experiment demonstrates the effectiveness of the Flint I/O scheduler. We set up two categories of I/O streams on one SSD: the victim ones that issue 4KB read/write I/Os with a small QD; and the background ones that send different types of I/Os with a large QD. Because Flint computes the I/O rank (priority) on the fly and dynamically determines the request issuing order, a low-ranked I/O would then be inserted in the front of the queue, which is dequeued first, mitigating the head-of-line blocking issue. Figure 10 reports the average P50/P99/P999 latency of the victim streams. When 4KB random read co-locating with 128KB random read (Figure 10), Flint helps reduce the P50, P99, and P99 latencies by 4.8×, 2.6×, and 7.5×, respectively. We observe similar trends in the other three cases. Under read/write mixed cases, the latency savings are related to the write cost estimation, which determines the accuracy of computing the write I/O rank. For example, when 4KB writes interleave with 128KB writes, one can achieve 36.4%, 17.7%, and 18.9% lower P50, P99, and P999 latency when enabling Flint, respectively.

5.5 Flint Avoids Busy EBOF SSDs

Flint is conscious of the device running condition due to the shadow view's capabilities. To demonstrate this, we set up an experiment that pollutes an EBOF SSD using 4 128KB random reads/writes. We then create an eVol over the SSD and launch a 32KB read, write, and mixed (70% read) stream. We disable/enable the dynamic extent remapping technique and I/O scheduler and measure the average latency when increasing the QD. As shown in Figures 9-b and c, Flint consistently reduces latency for scenarios because it eschews the congested SSD and directs I/Os to others. For example, under the read/write congestion, it reduces the average latency by 40.1%/29.8%. Therefore, based on §5.4 and §5.5, one can see that Flint is capable of tackling the third issue (§2.2) and achieves effective multi-tenancy.

We also compare the performance of eVol and Logical Volume Management (LVM). Figure 7-d shows their bandwidth under three different workloads, where some SSDs are congested. Compared with the workload oblivious placement in LVM, eVol is aware of the device's runtime condition and places extents in a less-loaded drive, yielding 2.3×, 3.0×, 3.8× throughput improvement, respectively.

Primitive	Throughput (MRPS)	P50 (us)	P99 (us)
`view_query`	21.5	24	31
`view_sync`	5.8	38	67

Table 1: The shadow view performance on a storage client.

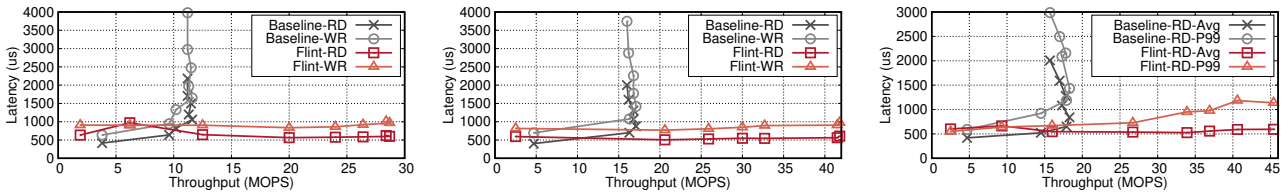
5.6 System deployment

Application integration. Flint is backward-compatible, provides the volume interface, and supports different storage workloads. As a case study, we deploy an object store [12,29] over Flint and see how much benefits it can bring to the application. We use one storage client in this experiment. Figure 11 presents the latency v.s. throughput when running YCSB workloads. When running over an eVol, one can achieve 2.8×, 2.8×, 2.9× throughput improvements, with 66.4(74.6)%, 63.7(73.8%), and 61.9% read(write) latency reduction for YCSB-A, YCSB-B, and YCSB-C, respectively.

Shadow view. `view_query` and `view_sync` are the two major RPC primitives provided by our shadow view service. Flint uses the Protobuf [9] for serialization, incurring some data processing overheads on both the client and arbiter sides. For example, as shown in Table 1, the average/tail latency of a `view_query` is 24/31us, which could be optimized using hardware-assisted serialization techniques [63].

6 Related Work

Block Storage. Researchers have built a plethora of distributed block storage systems in different settings. For example, Petal [41] realizes an early vision of network-attached disks through ATM networks that enable adaptive capac-



(a) YCSB-A. (b) YCSB-B. (c) YCSB-C.

Figure 11: Performance comparison between the EBOF volume (Baseline) and Flint when holding an object store. We use the YCSB benchmark [20] with the default parameters. We report the average latency for A/B and average/P99 latency for C.

ity/bandwidth scaling. Parallax [51] harnesses the characteristics of a virtualized environment to implement advanced storage features and provides a block interface over storage VMs. Strata [21] develops a scalable storage system over network-attached flash using global data address translation and SDN-assisted storage protocol virtualization. Blizzard [53], built atop FDS [59], provides a cloud-scale virtual drive with some optimizations, such as nested striping and out-of-order write commits. Decibel [58] exposes the *dVols* abstraction and employs a shared-nothing data-plane design, allowing efficient sharing of disaggregated storage class memories (SCMs).

Object Storage. It organizes data as objects and uses a global identifier for addressing. NASD (network-attached secure disks) [27] builds an early version of object store and enables scalable disk bandwidth. OceanStore [39] develops a data object infrastructure that spans the globe and provides continuous access to persistent information. Ceph [77] distributes data replication, failure detection, and recovery to semi-autonomous object storage devices that run a specialized local object file system. Haystack [16] is an object store for the Facebook's photos application and changes costly disk metadata operations into in-memory ones. FDS [59] proposes locality-oblivious blobs over full bisection CLOS networks. F4 [57] designs a hierarchical tier architecture and improves the warm object access performance. Pocket [38] is a distributed object store for serverless applications with fast response, auto-scaling, and smart data placement capabilities.

Distributed File Systems. There is a long history of building distributed file systems. xFS [13] proposes a serverless principle and distributes management and data access services over multiple machines. Frangipani [75] takes a similar design but relies on the underlying Petal [41] to improve system scalability. GFS [26] is a fault-tolerant distributed file system targeting large-scale data processing workloads. pNFS [32] extends NFSv4 with a layout driver, an I/O driver, and a file layout retrieval interface such that clients can perform direct access to remote storage. HDFS [73] serves as the storage backend for the Hadoop data processing framework. NOVA [78] optimizes the file system performance on hybrid memory systems (DRAM+NVM) using a log-structured design. Assise [14] materializes the client-local persistent memory module as a linearizable and crash-recoverable cache and improves the performance of distributed file systems.

Programmable Networks. An EBOF is partially motivated by reconfigurable switches [18, 31, 44, 48, 68, 69] and SmartNICs [19, 25, 28, 46, 49, 60–62, 67], which realize some functionalities of its data path (§3.2). Akin to an in-network telemetry system, our shadow view captures EBOF runtime statistics and serves as an assistant building block for others.

Storage Disaggregation. People have explored disaggregated storage extensively given the rising networking bandwidth and fast remote storage protocol [29, 33, 34, 36, 37, 43, 45, 47, 54–56, 64, 79]. Ana Klimovic *et al.* characterize the performance of iSCSI-based disaggregated storage [36]. Reflex [37] develops a customized kernel-bypass data-plane for remote NVMe accesses. i10 [34] develops an efficient in-kernel TCP/IP remote storage based on dedicated end-to-end IO paths and delayed doorbell notifications. LeapIO [43] unifies the address space across X86 CPUs and ARM coprocessors, exposing a virtual NVMe to an unmodified guest VM. Researchers [30] also report the performance characteristics of server-based NVMe-oF boxes. Gimbal [54] designs an efficient multi-tenancy mechanism to share a SmartNIC JBOF via traditional networking techniques. LEED [29] builds a fast and replicated key-value store over an array of SmartNIC-based storage appliances to improve energy efficiency. RackBlox [64] co-designs the software-defined networking and storage stacks, dividing storage functionalities between the programmable switch and the host I/O stack.

7 Conclusion

This paper explores how to use emerging EBOFs efficiently to serve storage applications. The linchpin is a distributed telemetry system (shadow view) that continuously monitors and reports the EBOF running condition. It enhances the static and opaque EBOF I/O processing pipelines with performance monitoring, resource accounting, and central and global coordination capabilities. Using it, we then design and implement an elastic block storage system over EBOFs and demonstrate considerable benefits compared with defacto schemes from performance, utilization, and multi-tenancy perspectives.

Pushing the Limits of In-Network Caching for Key-Value Stores

Gyuyeong Kim
Sungshin Women's University

Abstract

We present OrbitCache, a new in-network caching architecture that can cache variable-length items to balance a wide range of key-value workloads. Unlike existing works, OrbitCache does not cache hot items in the switch memory. Instead, we make hot items revisit the switch data plane continuously by exploiting packet recirculation. Our approach keeps cached key-value pairs in the switch data plane while freeing them from item size limitations caused by hardware constraints. We implement an OrbitCache prototype on an Intel Tofino switch. Our experimental results show that OrbitCache can balance highly skewed workloads and is robust to various system conditions.

1 Introduction

Key-value stores are the fundamental building blocks for online services owing to fast access to variable-length data [2, 5, 16, 30]. Workloads are generally read-intensive, and most items are hundreds of bytes [7, 8, 12]. A challenge in scaling key-value stores is mitigating load imbalance among storage servers caused by skewed key popularity (e.g., trending events). The load imbalance leads to overloading hot item servers, causing overall performance degradation [21,27,29].

In-network caching is a promising load-balancing approach that builds a cache in the switch by leveraging programmable switch ASICs like Intel Tofino [3]. The idea is to store hot items in the on-chip switch memory. Requests read the item value by referring to the cache lookup table where the item key is the table index. Compared to server-based caching, in-network caching provides much higher performance without extra cache nodes or accelerators thanks to a Tbps-scale processing throughput.

Unfortunately, existing solutions [21, 32, 34] can cache only tiny items due to hardware constraints. Specifically, the key size is limited to 16 bytes due to the maximum match-key width of the match-action table. A limited number of match-action stages and a small accessible byte size per stage make it difficult for the value size to exceed 128 bytes. These numbers are far from typical workloads where key and value sizes are still small enough to be stored in a single packet, but larger than the limit [7,8,12,33,37]. For example, in 54 Twitter workloads [37], most keys are tens of bytes, and many values are less than 1024 bytes. However, the existing solutions cannot cache even a single item in 42 out of 54 workloads because the keys and values are generally larger than the limits. Between the other 12 workloads, only 2 workloads have a portion of cacheable items larger than 50%. This trend is similar in Facebook workloads as well [12]. In this context, we ask the following question: *how can we cache variable-length items in the programmable switch for balancing typical key-value workloads?*

We present OrbitCache, a new in-network caching architecture that can cache variable-length key-value items in the switch data plane. Our idea is to make hot items visit the switch data plane continuously in the form of cache packets instead of caching the hot items in the switch memory. We efficiently use packet recirculation, a built-in feature of the programmable switch ASIC. This enables a packet to revisit the switch data plane through an internal loopback port without going outside. The switch can cache variable-length key-value pairs without being limited by the hardware constraints owing to circulating cache packets. For cache serving, the switch maintains small request metadata in the switch memory and forwards the cache packet to the client if there is a pending request for the key. To support variable-length keys, we use key hashes for cache lookups and resolve hash collisions at the client by comparing the requested key and the returned key, which is contained in the cache packet.

The key insight behind the idea is that it is hard to overcome the memory access constraint of switch hardware if we stick to the approach of caching items in the switch memory. For example, the idea of using key hashes for variable-length keys is difficult to realize in the existing solutions. This is because the switch does not have enough hardware resources to store keys and values together. In OrbitCache, cache packets contain both keys and values, allowing to handle hash colli-

sions at the client. Meanwhile, we may recirculate requests multiple times to read larger values. However, this limits scalability because the number of in-flight packets in the recirculation port increases proportionately to the number of requests, making a bottleneck. In addition, the switch has one internal recirculation port. OrbitCache avoids a bottleneck in the recirculation port. This is because 1) requests are never recirculated; 2) the number of in-flight cache packets is small and constant; 3) the switch can process multiple cache packets simultaneously with hardware-level parallelism, thus minimizing queueing between cache packets.

Realizing the idea imposes various technical challenges. First, the switch should buffer multiple request metadata for cached items. We design a request table as a circular queue structure using multiple register arrays. Our request table provides isolated data access among different keys. Second, a cache packet should serve multiple requests once fetched, rather than a single request. To achieve this, the switch clones the cache packet with low overhead before forwarding it to the client using the packet replication engine (PRE), a special module of the switch ASIC. Next, we should ensure cache coherence. We design an invalidation-based coherence protocol that can fetch new values and send back a reply to the client simultaneously. Lastly, the switch should deal with dynamic workloads where key popularity changes over time. We design an efficient cache update mechanism in the switch control plane.

We have implemented a OrbitCache prototype on an Intel Tofino switch. To evaluate OrbitCache, we build a testbed consisting of commodity servers. Our experimental results show that OrbitCache provides load balancing for many skewed workloads having diverse item sizes. In addition, OrbitCache is robust to various workload conditions like key access distributions, write ratios, and the number of servers. We also show that OrbitCache can adapt to dynamic workloads where key popularity changes over time.

In summary, this work makes the following contributions.

- We design OrbitCache, an in-network caching architecture where the switch can cache variable-length hot items to balance a wide range of workloads for distributed key-value stores.
- We propose several techniques to address technical challenges when realizing the idea of variable-length in-network caching.
- We implement a OrbitCache prototype on Intel Tofino switches and show the efficiency and robustness of OrbitCache through extensive testbed experiments.

2 Background and Motivation

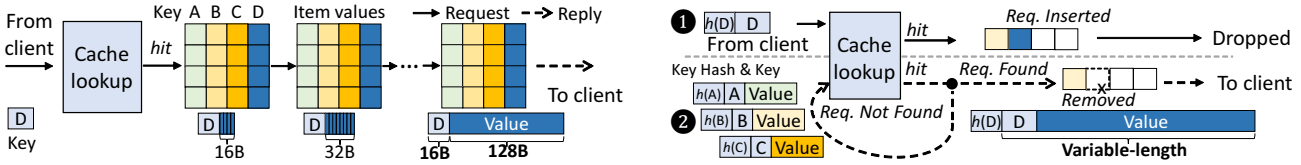
2.1 In-Network Load-Balancing Caches

Balancing key-value stores with a small cache. In distributed key-value stores, balancing imbalanced loads across storage servers caused by different key popularity is a primary challenge. Caching is a powerful technique to address the challenge, which is based on a theoretical result called the *small cache effect*: we can balance loads for N servers (or partitions) by caching the $O(N \log N)$ hottest items, regardless of the number of items [15]. Caching on commodity servers is a natural option to build the cache [15, 16, 29]. However, the performance of a cache node is not sufficient to handle many requests due to the limited throughput of CPUs. Building a high-performance caching layer using multiple replicated cache nodes is expensive and causes poor write performance for cache coherence.

Why in-network caching? Building a load-balancing cache in the switch by leveraging programmable switch ASICs like Intel Tofino [3] is an attractive approach. Unlike server-based caching, this approach can provide high-performance load balancing in a single box without additional nodes. This is because the switch is highly optimized for packet I/O and can process a few billion packets per second, which is an order of magnitude higher than that of the CPU in servers. The switch also provides a low packet processing delay within hundreds of nanoseconds.

Limited cacheable item size. Existing works [21, 32, 34] demonstrate the efficiency of in-network caching, but they limit the cacheable item size. Specifically, they support items of up to 16-byte keys and 128-byte values. In the reconfigurable match table (RMT) switch architecture [10] like Intel Tofino, the switch data plane consists of n match-action stages [3]. Each stage has a static memory and a few ALUs that can perform simple arithmetic operations on k bytes. The existing works store the value of cached items across multiple stages after fragmentation, limiting the maximum value size to $n \times k$ bytes. Unfortunately, $n \times k$ of the current switch is quite small, and the available number of stages for accessing the value is less than n since other non-caching functions also consume match-action stages. The key size is also limited by the maximum match-key width of the match-action table in a single match-action stage. This is because the existing works use a match-action table to implement the cache lookup table where the item key is the match key.

Why is it not enough? Many key-value items are indeed small, but typically exceed the existing size limits. We have analyzed 54 Twitter workloads [37], and observe that existing solutions are insufficient to handle typical workloads. For example, only 3.7% of the workloads have over 80% of keys $\leq$ 16 B. 38.9% of the workloads have over 80% of values $\leq$ 128 B. The existing works can cache less than 10% of items for 85% of the workloads because, to be cacheable, both key and value sizes must be within the limits. Furthermore, they cannot cache even a single item for 77.8% of the workloads. Facebook workloads [12] show similar size distributions. The average key size is 27.1 bytes, and the median value size is 235 bytes. These numbers exceed the size limits of the existing solutions.



(a) The NetCache architecutre [21]

(b) The proposed OrbitCache architecture

Figure 1: Comparison of the high-level idea with the NetCache architecture. *In NetCache, requests read fragmented values stored in the memory across stages. In OrbitCache, clients submit requests, and then circulating cache packets read request metadata. Since both keys and values are in cache packets, hardware constraints do not limit the item size.*

2.2 Variable-Length In-Network Caching

Design rationale. We argue that it is hard to overcome the memory access constraint if we stick to the approach of caching data in the switch memory because the constraint is determined at the time of manufacture. Therefore, we propose OrbitCache, a different approach to in-network caching.

Our high-level idea is to keep cached key-value pairs circulating within the switch data plane through packet recirculation, a built-in feature of the switch that makes the packet revisit the switch data plane. In our approach, cached items read requests rather than the requests read the cached items. Specifically, clients submit requests, and the switch maintains small metadata like the client IP address. *Cache packets*, which are reply packets containing the key and the value of cached items, continue to revisit the data plane via a recirculation port while actively checking pending requests. Note that cache packets do not go outside the switch. If a request for the key is found, the matched cache packet is forwarded to the client. Otherwise, the cache packet is recirculated. In Figure 1, we illustrate the difference between OrbitCache and the NetCache architecture [21], which is the reference architecture of existing in-network caching solutions [21, 32, 34].

Variable-length keys. Our approach enables us to support variable-length key-value pairs. For variable-length keys, one possible solution within the limited match-key width of the match-action table is to use a fixed-size key hash as the match key. To handle potential hash collisions, we should compare the requested key and the key of the value that has been read. To do this, the switch data plane should also store the item keys alongside values. Unfortunately, it is hard to realize in the existing architecture because there are not enough match-action stages to store both keys and values. OrbitCache can realize the idea of using key hashes since the switch maintains cached key-value pairs in the form of circulating reply packets. Therefore, the client can get the correct value from the storage server if the requested and returned keys differ.

Variable-length values. For variable-length values, a possible approach in the existing architecture is recirculating requests. Specifically, requests can access the switch memory multiple times using packet recirculation. However, this approach is not scalable because the number of in-flight packets per second in the recirculation port increases in proportion to the number of requests. For example, if every request is recirculated 7 times to read a 1024-byte value, the effective throughput of the recirculation port is reduced to 1/8 of the bandwidth. Unfortunately, a pipeline in the programmable switch has only one internal recirculation port, while there are tens of regular front ports. This means that the recirculation port limits the performance excessively.

Our recirculation-based caching design avoids the bottleneck in the recirculation port as follows. First, the switch never recirculates requests. Second, only a small, constant number of cache packets are recirculated. The time to recirculate and process a cache packet is a few hundred nanoseconds like normal packets. Therefore, the queueing delay in the recirculation port rarely increases as the request rate grows.

Trade-off. There is a trade-off of using recirculation to achieve variable-length caching. Although we are free from size limitations, we should limit the cache size. This is because, in OrbitCache, requests should wait until cache packets handle them. For a cache packet, the time to read a request is impacted by the other in-flight cache packets. This means that the number of in-flight cache packets in the recirculation port determines the latency for cache serving. Although the switch can process many cache packets simultaneously, the request may wait excessively until being served if there are too many cache packets. The sacrifice of cache size for variable-length caching is backed by the small cache effect. As described in Section 2.1, caching a small number of hot items is enough to balance skewed workloads [15, 27].

Technical challenges. We should address several technical challenges to translate the idea into a working system.

- The switch should maintain multiple requests, especially for the same cached item. If not, many requests for cached items would be forwarded to the server as they cannot be stored in the data plane.
- A cache packet should serve multiple requests once fetched. Otherwise, the switch must fetch the cache packet from the server again, degrading performance.
- We should design a cache coherence mechanism between the switch and storage servers. If not, a request may read a stale value for the requested key.

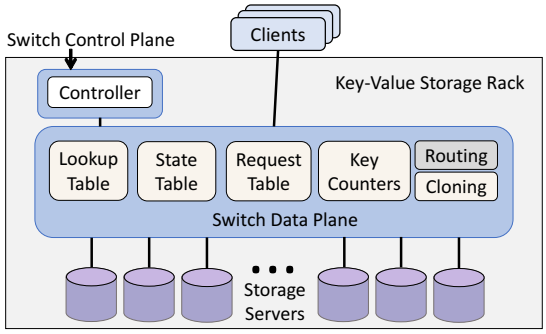


Figure 2: OrbitCache architecture.

- The switch should adapt to key popularity changes.

3 OrbitCache Design

3.1 OrbitCache Architecture

Figure 2 shows the overview of the OrbitCache architecture.

Switch data plane. The switch data plane in OrbitCache consists of several custom tables and modules as follows.

- *Lookup table* is for cache lookups, which is a match-action table that uses a hash of item keys as the match key. The table returns a table index needed to access other tables and modules. Cache entries are managed by the controller in the switch control plane.
- *State table*, implemented as a register array, maintains the validity of the value of cached items. This is needed to prevent read requests from obtaining the stale value when there are pending writes for the requested key.
- *Request table*, implemented with multiple register arrays and registers[1], stores request metadata like client IP address, L4 port number, and request sequence number.
- *Key counters* consist of two registers and one register array. The key popularity counter is a register array that tracks the key popularity for each key. The cache hit counter and the overflow request counter are registers that track the total number of cache hits and the total number of overflow requests for all cached keys. The controller uses these for cache sizing.
- *Cloning module* comprises a few match-action tables for cloning reply packets. Packet cloning is done by the PRE, a hardware module in the switch ASIC [3].

Meanwhile, the switch invokes the custom processing logic only for OrbitCache packets by referring to reserved L4 ports. We use UDP to handle messages for better latency like existing works [21,27,29] while using TCP for top-k item reports in cache updates. For normal packets, the switch only applies the traditional packet forwarding logic.

[1] In P4 language, a register means an indexed register array. However, in this paper, we define a register as a single-slot register and a register array as an indexed register array for better clarification.

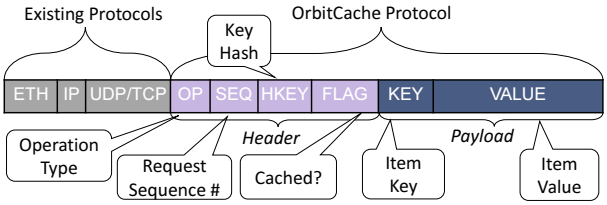

Figure 3: OrbitCache packet format.

Switch control plane. The controller in the switch control plane performs cache updates and switch configurations. It evicts the least popular keys and inserts new hot keys based on server-side periodic top-k reports for uncached keys and the switch-side report for cached keys. Note that while the controller handles key insertion, value fetching is done via the switch data plane. It also handles switch configurations like the rule update for packet forwarding tables.

Clients and servers. Clients should specify the operation type, the item key to request, and the key hash. Storage servers run a server application that acts as a shim layer that translates OrbitCache messages to API calls for key-value stores and vice versa. The server returns replies for read and write requests like regular storage servers. However, in cases of write requests for cached items, the server returns a write reply with the item value as well to fetch the latest value.

3.2 Packet Format

Figure 3 depicts the OrbitCache packet format. The message consists of the header and the payload. The switch only parses the header. The payload of OrbitCache message consists of the key and the value. Our header is 22 bytes. Therefore, OrbitCache supports a key-value pair of up to 1438 bytes for a single packet when we consider a 1500-byte MTU packet where 40 bytes are for L3/L4 headers. For example, the switch can cache an item with a 16-byte key and a 1422-byte value. Our header fields are as follows.

- `OP` (1 byte): the operation type, which can be `R-REQ` (Read request), `W-REQ` (Write request), `R-REP` (Read reply), `W-REP` (Write reply), `F-REQ` (Fetch request), `F-REP` (Fetch reply), and `CRN-REQ` (Correction request).
- `SEQ` (4 bytes): a request ID assigned by the client, which is used for resolving hash collisions.
- `HKEY` (16 bytes): the key hash as cache lookup index.
- `FLAG` (1 byte): a flag field to distinguish write requests for cached items from those for uncached items.

3.3 Basic Request and Reply Processing

In Figure 4, we illustrate the packet processing logic.

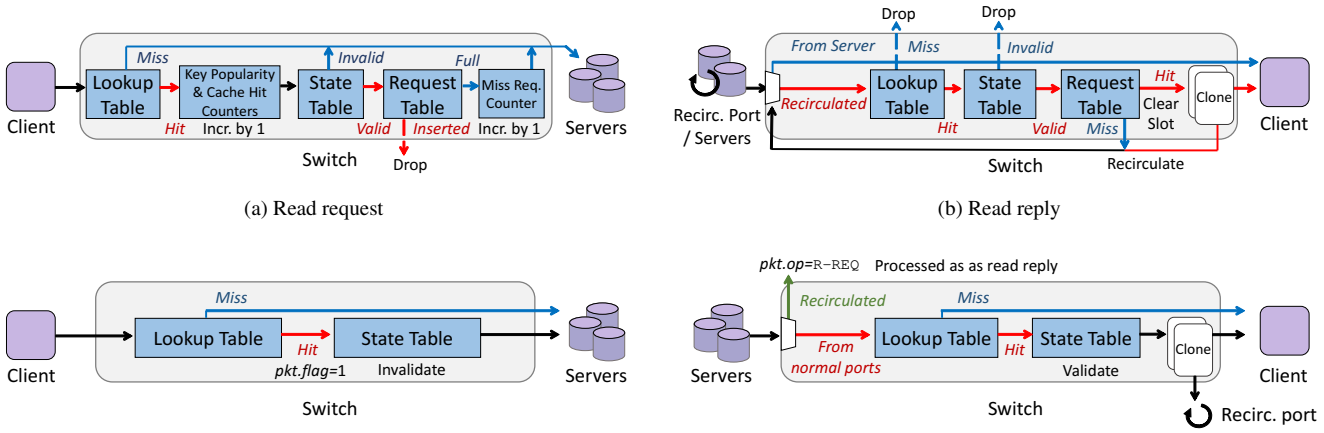

Figure 4: Request processing. *(a) the switch drops the request after inserting request metadata into the request table; (b) If a circulating cache packet reads request metadata, the switch clones the packet so that the original packet is forwarded to the client and the cloned one is recirculated again for further serving; (c) the switch invalidates the item to avoid inconsistent reads if a write request is for a cached item; (d) upon receiving a write reply for a cached item, the switch validates the item. After that, the switch clones the packet. The cloned packet is processed as a read reply after updating the operation type.*

Request generation at clients. Clients should specify the `OP` and `HKEY` fields. The `SEQ` field is increased by one for every request, which is used to resolve hash collisions. The destination storage server is determined by hashing the key.

Read requests. The switch first refers to the lookup table using a key hash to get a table index, which is used to access the slots in other tables. If missed, the switch forwards the packet to the server as the request is for an uncached item. In case of a cache hit, the key popularity counter and the cache hit counter are incremented by one. This key popularity is collected by the controller in the switch control plane periodically for cache updates. Next, the switch checks the validity of the requested key by looking into the state table. The state is binary: valid or invalid. Being invalid means that there are pending write requests for the key. In this case, the switch forwards the read request to the server to avoid reading stale item values. If the key is valid, the switch checks the request table to see whether there is a free slot. The switch puts the request metadata into the table when a free slot is found. Otherwise, the request is destined to the server after the overflow request counter is increased. Request metadata includes the client IP address, L4 port number, and `SEQ` as request IDs. After insertion, the switch drops the packet. This is acceptable since a cache packet will soon service the stored request.

Read replies. When receiving a read reply, the switch first checks to see if the ingress port is the recirculation port. If it is, the reply is a cache packet. Otherwise, it is a reply for an uncached item sent by the server. For cache packets, if the cache misses or the state of the value is invalid, the switch drops the packet. A cache miss for a cache packet means that the controller evicted the key from the lookup table due to a change in key popularity or the cache size. The invalid state indicates a write request with a new value is in progress.

The switch goes through the lookup and state tables, and then looks for pending requests in the request table. If a request is found, the switch forwards the cache packet to the client after updating the header with metadata and removing the metadata from the table slot. To make the cache packet serve more requests, the switch clones the packet before forwarding. The switch forwards the original packet to the client and the cloned one to the recirculation port. The switch recirculates the packet if there are no pending requests.

Write requests. The switch checks whether the requested key is in the cache lookup table. If it is, the value for the key is invalidated to prevent reading the outdated value. In addition, the switch sets the `FLAG` field to 1 to indicate that this request is for a cached item. This makes the storage server append the value in the write reply. Regardless of a cache hit, the switch forwards the request to the storage server to update the value of the key in the server.

Write replies. If the key is cached, the switch validates the value to allow read requests to get the latest value. The switch clones the packet so that the client receives the write reply while the switch has a new cache packet simultaneously. The switch updates the `OP` field to `R-REP` of the cloned packet after the first recirculation since cache packets should be read replies. For a cache miss, the switch forwards the packet to the client since the reply is for an uncached item.

Other types of messages. Fetch messages are for cache updates. Correction messages are for resolving hash collisions. Fetch/correction requests are delivered to the storage servers. The fetch reply is processed as a write reply.

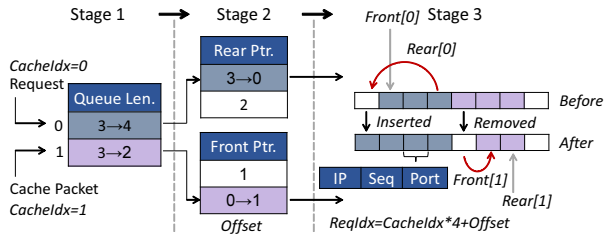

Figure 5: An example of operations in the request table.

3.4 Buffering Request Metadata

Circular queue-based request table. We should store multiple request metadata for cached items because the requests should wait until cache packets serve them. The switch should be able to buffer concurrent read requests for the same cached item. If not, many requests for the cached item would be forwarded to the storage server due to the lack of vacancies. Furthermore, a request for a key should be isolated from requests for other keys since the request may undergo excessive queueing delay due to the different requests.

We design a request table based on a circular queue structure. Our request table provides a logical queue for each cached key, and the queue can be accessed in $O(1)$ by efficient indexing. This provides fast and isolated queue access for a key regardless of other keys. The request table consists of 6 register arrays: the first three arrays are for storing request metadata for each key (i.e., client IP address, request sequence number array, and L4 port number). The other three arrays are for managing queue operations. The queue length array maintains the number of stored request metadata for each key. The front pointer array handles dequeue operations by tracking the first request metadata for each key. The rear pointer arrays perform enqueue operations by keeping track of the last request metadata for each key.

The queue management arrays are indexed using a table index ($CacheIdx$) returned by the cache lookup table. The request metadata arrays are accessed via a request index, which is defined as $ReqIdx = CacheIdx \times S + i$ where S is the maximum queue size per key and i is the offset for ith slot in the logical queue for a key and is given by the pointer arrays. The switch uses three match-action stages for a request table. Specifically, the switch first checks the queue status (Stage 1), and performs en/dequeue operations if the queue is not full/empty (Stage 2). Next, the switch gets/puts metadata from/into the request table (Stage 3).

An example for table operations. Figure 5 shows a simple example of table operations. We assume that the request table can maintain up to 4 requests for each key. We consider enqueueing and dequeueing operations using read requests and cache packets. In stage 2, the rear pointer changes to 0 from 3 since we implement a circular queue. It is also easy to see that the request metadata for different keys does not collide since we partition the metadata arrays using the indexing formula of $ReqIdx = CacheIdx \times S + i$.

3.5 Cache Serving

Handling multiple requests via packet cloning. In OrbitCache, cache packets pass through the switch data plane repeatably to serve pending requests for cached items. One challenge is serving multiple requests with a cache packet fetched only once because the cache packet is forwarded to the client after updating the header using the retrieved metadata. A strawman is to fetch the cache packet from the server again, but this approach is inefficient as the switch cannot serve pending requests for the key until the fetching is completed. Fetching multiple copies of the cache packet may be a solution, but this incurs excessive queueing delay between cache packets. In addition, it is hard to know how many cache packets should be fetched because we cannot predict the number of requests for each cached item in advance.

To address this, we utilize packet cloning, another built-in feature of the programmable switch ASIC besides packet recirculation. Packet cloning is done by the PRE, a hardware module specialized for packet cloning in the switch ASIC. Cloning has low overhead for the following reasons. First, the PRE is located after the ingress pipeline. This means the switch does not repeat the ingress pipeline processing for the cloned packet, not causing extra ingress processing delay. Second, the switch does not copy the entire packet. It only copies the small descriptor pointing to the memory location of the packet and reuses the packet data.

We use multicast to forward the original and clone packets. Through a match-action table using the destination IP address acquired from the request table, the switch gets a multicast group ID that specifies the regular port number directed to the client and the recirculation port number. The switch forwards the original packet to the client and the cloned one to the switch data plane again, making it serve more requests.

3.6 Handling Hash Collisions

The existing works use the item key as the match key of the cache lookup table, which is implemented as a match-action table. Since the match-key width is limited by hardware, we cannot use the key exceeding the size limit. We may use a register array, but the size limitation in the register index is stricter than in the match-action table. Therefore, we use the fixed-sized key hash as the match key. A challenge is how to resolve potential hash collisions. We should handle this because a request may read the wrong value of other keys.

Client-side collision resolution. We handle hash collisions at the client level by maintaining a list of the keys for each request that has not yet received a reply. The list is indexed by $pkt.seq$. Request packets contain both the original key and the key hash since we should use the original key

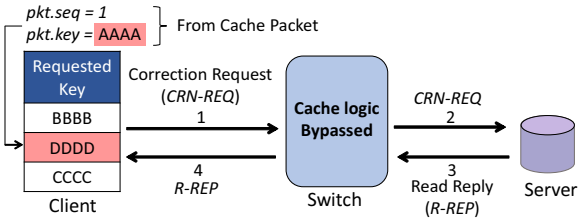

Figure 6: An example of handling hash collisions. *The client gets the correct value by sending a correction request.*

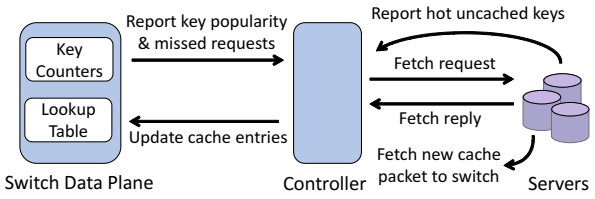

Figure 7: Cache update. *The controller updates the entries of the cache lookup table by tracking workload changes.*

to get the value in servers. Upon receiving read replies, the client checks whether the requested key in the list and the returned key in the reply header are identical. If different, the client sends a correction request to the server. The switch then forwards the request without applying the cache logic so that the client gets the correct item value from the storage server. We use a simple, low-overhead hash function to calculate key hashes. In addition, the complexity of accessing a matched slot of the key list is $O(1)$ as it is an indexed array. Note that a key in the list exists only until the reply arrives.

One issue is that requests for uncached but colliding keys always undergo this process. However, this is rare since our 128-bit key hash provides a low collision probability of $1/2^{128}$. In our experience, we never see a hash collision. There is a corner case when a new hot item uses the table index of the evicted item after cache updates. In this case, the pending requests for the evicted item are served by the new but wrong cache packet. However, they eventually get the correct value through the correction process with 1-RTT latency overhead. Meanwhile, the switch drops the colliding cache packet when hash collisions occur due to write requests. To handle this, the server can send the cache packet as a fetch reply to the switch again if the received write request is with $pkt.flag = 1$ but not in the hot key list.

An example of resolving hash collisions. We plot an example of handling hash collisions in Figure 6 where the requested key is `DDDD` but the returned key is `AAAA`. Upon receiving the reply, the client detects that the retrieved value is wrong by referring to the key list using $pkt.seq = 1$. The client then sends a correction request to the storage server. The switch bypasses the cache logic, and forwards the packet to the server. The storage server returns the value as a read reply, and the client finally gets the correct value for the key `DDDD`. The client removes the key from the list. $pkt.seq$ wraps around if it reaches the maximum value.

3.7 Cache Coherence

To ensure cache coherence between the switch and servers, we design an invalidation-based coherence protocol illustrated in Figure 4 (c) and (d). The switch invalidates the value when handling a write request for a cached item and revalidates the value upon receiving a write reply. Ideally, the outdated cache packets should be replaced with the latest cache packet. However, requests may be returned with the stale value since the outdated packets are still circulating in the switch data plane even if the item value becomes invalid. To address this, the switch drops the cache packet if the item is cached but its value is invalid. Owing to the fact that the cache packet is dropped before accessing the request table, we can prevent read requests from retrieving the stale value until a new cache packet is fetched. The storage server sends a single reply packet, and the switch updates the value and replies to the client simultaneously by cloning the packet.

3.8 Cache Updates

To handle key popularity changes over time, we update cache entries based on periodic popularity reports from the switch and storage servers. We count the popularity of cached keys in the switch data plane using the key popularity counter. The controller keeps track of key popularity by reading the counter periodically. Meanwhile, storage servers periodically report the top-k keys to the controller, which are popular uncached keys. The servers use a count-min sketch with five hash functions to track key popularity in a memory-efficient manner while ensuring accuracy. To reflect the recent status only, we reset all the counters to zero after reporting.

If the cache needs to be updated due to a change in key popularity, the controller deletes the victim key from the cache lookup table and inserts a new popular key instead. The controller then sends a fetch request to the storage server containing the latest value for the key. Upon receiving the request, the server fetches a new cache packet to the switch data plane and replies to the controller. The new popular key inherits the table index (*CacheIdx*) of the evicted key. With this, the pending requests for the evicted key can be handled by the new cache packet and the hash collision resolution mechanism. Note that the hash collision here is due to the same table index, not that the hashes actually collide.

3.9 Handling Practical Requirements

Failure handling. For packet loss, we can use an application-level mechanism. Our controller uses UDP with a timeout-based mechanism to exchange fetch requests/replies. Storage

servers use TCP to report top-k items to the controller. Meanwhile, server failures do not cause a OrbitCache-specific problem. Switch failures result in the loss of cached items, but the cache can be reconstructed quickly by the controller after the switch is recovered because the switch failure is similar to the rapid key popularity changes.

Multi-rack deployment. OrbitCache can be deployed with multiple racks because the ToR switch caches hot items of storage servers belonging to its rack only. For example, assume that we have two racks where ToR switches, $ToR1$ and $ToR2$, are interconnected via a spine switch SPN. When CLI, a client in rack 1, sends a request to SRV, a server in rack 2, the path for an uncached item is $CLI-ToR1-SPN-ToR2-SRV-ToR2-SPN-ToR1-CLI$. If the item is cached, $ToR2$ is the only switch that applies the cache logic. There is no issue even if rack 1 is the replicated rack of rack 2 where the two ToR switches have the same cache entries because the request is handled by $ToR1$. If the client is located in another rack and the other two racks are replicated ones, we can balance requests by implementing load-balancing mechanisms in the ToR switch of the client-side rack.

3.10 Discussion

Multi-packet items. Many key-value items are less than the MTU size. Therefore, existing works in key-value stores generally consider item values up to 1024 bytes [6,17,26,29–31]. However, some items may exceed the MTU size, such as articles and photo objects for some workloads (e.g., Wikipedia and Flickr [8]). To cache multi-packet items, we should fetch multiple cache packets with fragmented values for the same key. To do this, we maintain the number of forwarded cache packets for each item by placing another register array alongside the request table, the *ACKed packet counter*. The initial value of each slot is 1 since most items are single-packet. When fetching item values, the storage server puts the number of packets comprising the item in the `FLAG` field. When handling cache packets, the switch retrieves metadata as usual, but it does not manipulate the slots of all register arrays in the request table if the slot value in the ACKed packet counter is not equal to `FLAG`. Instead, the switch increases the value by one. When the value in the counter equals to `FLAG`, the switch removes metadata as it is ready to be finished.

Write-back caching. FarReach [34] is a recent work that enables write-back caching. Although it still cannot serve many workloads due to the size limitation, it provides high performance regardless of the write ratio. OrbitCache uses write-through caching, and our performance gain decreases as the write ratio grows. The difference between write-through caching and write-back caching is whether a write request for cached items updates the storage server or not. Therefore, OrbitCache can also use write-back caching by letting the switch return write replies upon receiving write requests after updating the cache only, though we need extra modules like snapshot generation.

Multi-pipeline deployment. The multi-terabits performance of the programmable switch ASIC comes from the multi-pipelined architecture. Each pipeline consists of tens of regular ports and one internal recirculation port. Metadata and memory data are not shared between the pipelines. Therefore, the pipelines of client-directed ports and server-directed ports should be the same. Otherwise, cache packets in a pipeline may not read requests since they are in another pipeline. This can be addressed by mapping each pipeline of the ToR switch to a client-directed port on the spine switches. This is especially feasible when the clients and servers are in different racks. We expect this to be addressed more easily with a new programmable switch architecture like MP5 [35] that achieves high performance with a logical single pipeline.

4 Implementation

Client-server application. We develop an open-loop application in C using NVIDIA Messaging Accelerator library (VMA) [4]. VMA bypasses kernel network stacks by intercepting the socket function calls and translating them to native RDMA verbs. The client application measures throughput and latency by generating requests. The time gap between consecutive requests follows an exponential distribution. The server application has multiple threads where each thread is pinned to a disjoint CPU core. To emulate multiple storage servers, we assign a partition per thread so that each thread acts as an independent storage server. We also limit the Rx throughput of each emulated server to 100K RPS to ensure the bottleneck is at servers in our testbed. This technique is used in existing works [21,29,34] as well. In a similar vein, like NetCache [21], we implement a key-value store with TommyDS [1], a high-performance hash table library.

Switch. We implement the switch data plane in $P4_{16}$ [9] for Intel Tofino [3]. We use Intel P4 Studio SDE 9.7.0 to compile the switch data plane. Our prototype uses 9 stages and 6.67% SRAM, 7.38% Match Input Crossbar, 9.29% Hash Bit, and 30.56% ALUs. The request table has a maximum queue size of 8 for each key. The controller is written in Python 3. In our prototype, we use an additional register array for the request table to store the timestamp of the request for latency measurement. The OrbitCache header has 3 extra fields of 1-B `Cached`, 4-B `Latency`, and 1-B `SrvID`. The first two fields are required to separately measure the latency of requests. The last field is to store the server ID as we emulate multiple storage servers as dedicated threads in a physical node.

5 Evaluation

5.1 Methodology

Testbed setup. We build a cluster consisting of 8 nodes, which are connected by an APS BF6064X-T switch with the

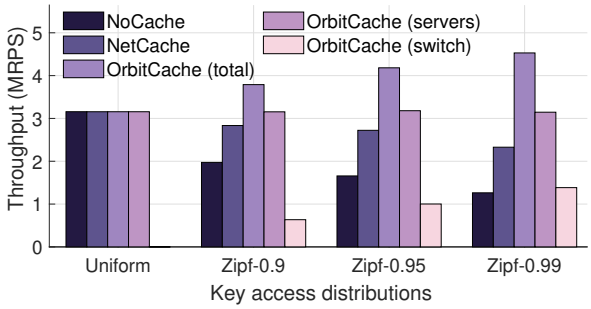

Figure 8: Throughput with different skewness.

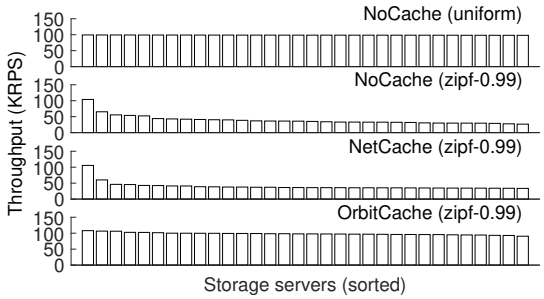

Figure 9: Load on individual storage servers.

Intel Tofino 1 [3]. The servers are equipped with a 10-core CPU (Intel i5-12600K @ 3.7 Ghz, 12 hyperthreads and 4 non-hyperthreads), 32 GB of DDR5 memory, and a 100GbE NVIDIA CX-5 NIC. The servers run Ubuntu 22.04 LTS with Linux kernel 6.5.0. The 4 nodes act as clients and the remaining 4 nodes are used to emulate multiple storage servers.

Compared schemes. We mainly compare our work with NoCache and NetCache [21]. NoCache is a mechanism without cache logic. NetCache is the representative in-network caching architecture. FarReach [34] and DistCache [32] also adopt the NetCache architecture. We implement the core caching logic of NetCache, but our implementation provides items up to 64-byte values across 8 stages with an 8-byte accessible size per stage. We find that the P4 compiler allocates only two cache read tables per stage, even with pragma statements. We suspect that this is due to compiler restrictions on our code. We clarify that this does not mislead the conclusions of our experiments, as there is a negligible difference in the latency required to read 64 bytes and 128 bytes at line rate using the same number of match-action stages.

Workloads. We emulate a single storage rack with 32 storage servers using 8 partitioned threads per node. We basically consider a workload with 10M key-value pairs whose key popularity skewness follows a Zipfian distribution with $\alpha = 0.99$, since it is regarded as typical skewness [7, 13]. Although both key and value sizes impact whether an item is cacheable by NetCache, we use 16-byte keys by default for simplicity, the maximum supported key size by NetCache. Instead, we represent the portion of cacheable items using different ratios between 64 bytes and 1024 bytes values. The 64-byte value represents a cacheable item value of NetCache. The 1024-byte value is a typical-sized item value in many workloads and is considered in many research papers [6, 17, 26, 29–31]. We use a bimodal distribution with 82% 64-byte and 18% 1024-byte values by considering the cacheable item ratio of NetCache for the `Cluster018` workload of Twitter [12]. Most experiments are for read-only workloads as we target read-intensive workloads.

Except for dynamic workloads, we preload the 10K and 128 hottest items for NetCache and OrbitCache, respectively. 128 is a nearly optimal cache size for OrbitCache that provides the best performance gains. Since NetCache can cache only 82% of items in the workload, the actual number of cached items is 8200, which is still larger than the cache size of OrbitCache by 64×. To be fair, we choose 82% of keys among the 10K hottest keys with a uniform distribution. We store the chosen keys as a text file to make experimental results consistent. The controller loads the file and puts the keys to the switch cache. We note that trends are usually consistent, even when using different key samples.

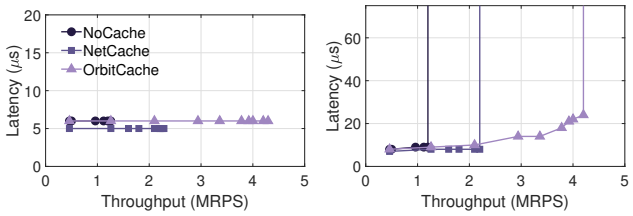
5.2 Main Results

Throughput with different key access distributions. We measure the throughput with different skewness and plot the results in Figure 8. We can see that OrbitCache provides high throughput regardless of skewness, unlike the others whose throughput decreases as the workload becomes more skewed. NetCache does not provide high throughput as expected since many hot items are not cacheable. In the Zipf-0.99 workload, OrbitCache has higher throughput than NoCache and NetCache by 3.59× and 1.95×, respectively. The server throughput in OrbitCache is consistent across the given skewness, and this means that the loads are balanced.

Individual server loads. We plot the load on individual servers in Figure 9. We can see that NoCache and NetCache do not balance loads well. This is due to the lack of caching logic for NoCache and many uncacheable hot items for NetCache. However, OrbitCache can balance the loads since OrbitCache can cache variable-length items.

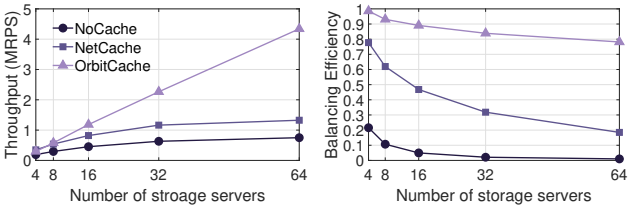
Latency vs. throughput. We measure the latency by varying Tx throughput. Figure 10 shows the median and the 99th percentile latencies as a function of Rx throughput. OrbitCache provides the best throughput but slightly higher latency than NetCache of 1 microsecond. This is because NetCache has a larger cache size, and requests handled by the switch dominate in latency data. In addition, in OrbitCache, requests for cached items should wait until cache packets read them. Although NetCache has slightly better latency, throughput is very limited since it fails to balance loads.

Impact of write ratio. Figure 11 reports the throughput as a function of write ratios. The throughput of OrbitCache



(a) Median (b) 99th percentile

Figure 10: Latency vs. throughput.



(a) Throughput (b) Balancing efficiency

Figure 12: Scalability.

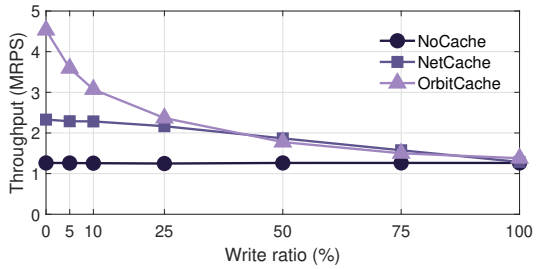


Figure 11: Impact of write ratio.

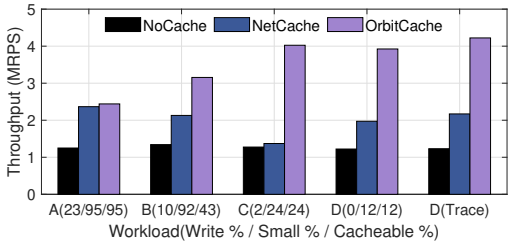

Figure 13: Performance with production workloads.

decreases as the write ratio grows. This is because the switch invalidates the cached key when handling a write request for a cached item to ensure cache coherence. The switch cache provides performance gains for read requests, the throughput is decreased with higher write ratios since read requests for invalid cached items are forwarded to storage servers. With the 100% write ratio, the throughput of OrbitCache converges to NoCache since the cache does not provide any benefit. Meanwhile, similar to OrbitCache, NetCache offers reduced throughput as the write ratio grows since it also invalidates the cached key if there is a write for the key.

Scalability. We now inspect whether OrbitCache can balance loads of different numbers of servers. In this experiment, we limit the Rx throughput to 50K RPS to ensure that the bottleneck occurs at the storage servers rather than the clients, even when using 64 servers. In Figure 12 (a), we can see that the throughput of OrbitCache is improved almost linearly while the others do not. Figure 12 (b) clarifies that this is because NoCache and NetCache fail to balance imbalanced loads. *Balancing efficiency* is defined as the minimum throughput between the servers divided by the maximum throughput between the servers.

Performance with production workloads. We conduct experiments with several workloads of Twitter [37] to see how OrbitCache works with various production workloads. We pick 5 workloads based on the cacheable item ratio. We assign the workload ID A to D for `Cluster045/016/044/017`. We still use the 16-B keys for simplicity but vary the write ratio, the portion of 64-B values. Unlike the other experiments, the cacheable item ratio is controlled by choosing keys with a uniform distribution independent of the portion of 64-B values. We also use a non-bimodal version of workload D, by referring to the real trace of values in `Cluster/017` to show the fidelity of bimodal distributions in our experiments.

Figure 13 shows the results. Although the difference in throughput varies depending on the used workloads, we can see that OrbitCache shows the best performance for all the workloads. There is a little difference for Workload A. This is because NetCache can cache 95% of items, and the write ratio is relatively high. Workload E is a workload that shows a significant performance gap. This is because only 1% of items are cacheable for NetCache. We can also see that the trend in workloads D and D(Trace) is very similar. The slight throughput difference in workload D(Trace) is because the real trace contains more item values of less than 1024 bytes than the bimodal version. This demonstrates that our bimodal-distributed workloads successfully reflect the characteristics of real-world workloads.

5.3 Deep Dive

Latency breakdown. Figure 14 (a) and (b) plot the median and the 99th percentile latency breakdowns, respectively. In the median latency, OrbitCache shows slightly higher switch latency than NetCache. This is because requests in OrbitCache should wait until circulating cache packets read them, resulting in latency overhead. In Figure 14 (b), we can see that the tail latency of OrbitCache (switch) increases as throughput grows. This is not surprising because we use a circular queue-based request table to maintain request metadata and packet cloning for a cache hit, resulting in additional latency overhead. We believe that this is acceptable since Or-

Figure 17: Impact of value size.

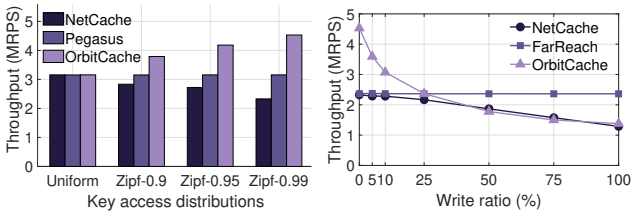
bitCache can provide much higher throughput than the others. In addition, the tail latency of the switch is still tens of microseconds even when the tail latency of servers soars by reaching the saturated throughput. We can decrease the tail latency of the switch by reducing the cache size as well. If the cache is based on a commodity server, the tail latency would be 10-100× longer than the switch cache.

Impact of cache size. Figure 15 plots the throughput breakdown, request latency handled by the switch, and the overflow request ratio of OrbitCache with different cache sizes. We can see that the total throughput increases as the number of cached entries grows. However, the throughput is saturated with around 128 cached items. Similarly, in Figure 15 (b), the tail latency increases quickly after 64-128 cached items. Figure 15 (c) clarifies the reason. From 256 cached items, the overflow request ratio rapidly increases, where the overflow requests indicate the requests for cached items forwarded to the storage servers due to the lack of free slots in the request table. The lack of free slots is caused by the excessive queueing delay between too many cache packets beyond the capability of the switch hardware. This clarifies that the cache size is the key to determining the performance. This also means we should choose an effective cache size between 32 and 128 to balance the trade-off.

Impact of key size. To see the impact of key size, we measure throughput and balancing efficiency using different key sizes. To show the impact of key size more clearly, we use a value of 100% 64-B. Figure 16 (a) shows that throughput decreases as key size increases. This is because the server consumes more computing power when key size is large. Figure 16 (b) shows that balancing efficiency remains high regardless of throughput changes.

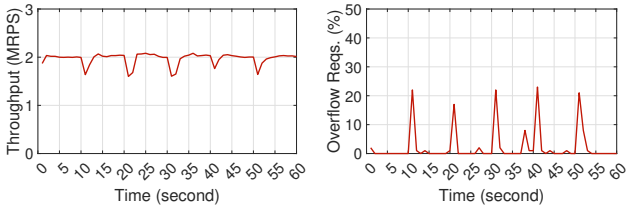
Impact of value size. We measure throughput, balancing efficiency, and the maximum cache size by varying the value size. In this experiment, we use the 100% same value size for all items to inspect how OrbitCache works in the worst case. Note that 16-B key and 1416-B value are the maximum size for a single packet payload with 28-B custom header fields.

Figure 17 (a) shows that OrbitCache can balance various workloads, including a workload where 100% values are MTU-sized. The slight drops in throughput are due to the increased value size. Figure 17 (b) shows the balancing efficiency. We see that OrbitCache generally maintains high balancing efficiency. Figure 17 (c) plots the effective cache size that provides the highest performance gain. We can see that



(a) Impact of skewness (Pegasus) (b) Impact of write ratio (FarReach)

Figure 18: Comparison to Pegasus [27] and FarReach [34].



(a) Throughput (b) Overflow request ratio

Figure 19: Performance with dynamic workloads.

the effective cache size decreases as the value size increases. This is because larger cache packets consume more switch resources, making the effective cache size small. Nevertheless, we can see that OrbitCache can balance the workloads well since we need only a small number of cached items to balance skewed workloads.

Comparison to Pegasus and FarReach. We now compare OrbitCache against Pegasus [27] and FarReach [34]. FarReach enables write-back caching in NetCache. Pegasus [27] is a selective replication solution where the switch replicates hot items across storage servers instead of caching items. We measure throughput using different key access distributions for Pegasus and different write ratios for FarReach. Figure 18 (a) shows the result for Pegasus. We can see that OrbitCache outperforms Pegasus for all the key access distributions. This is because the switch of OrbitCache provides extra throughput, whereas the throughput of Pegasus is limited to the throughput of storage servers. Pegasus is better than NetCache as it provides variable-length items. Figure 18 (b) shows the result for FarReach. OrbitCache outperforms FarReach until 25% of write ratio since FarReach has a limited cacheable item size like NetCache. However, when the write ratio grows, the performance gap with OrbitCache decreases. Over 25% of write ratio, FarReach shows better throughput than OrbitCache. This is because the write latency of FarReach is shorter than OrbitCache as it only updates the value of the item in the switch using write-back caching. OrbitCache updates the value of the switch and the server at the same time.

Handling dynamic workloads. We investigate how OrbitCache reacts to dynamic workloads. Like existing works [21, 29, 34], we use a *hot-in* pattern, which is the most radical workload change. We use 4 storage servers without server emulation and Rx rate limits similar to a previous work [34] to avoid inaccuracy due to the system state change. Every 10 seconds, the popularity of the 128 coldest items and the 128 hottest items is swapped.

Figure 19 (a) shows the throughput for 60 seconds. We can see that the throughput decreases when key popularity changes but recovers within a few seconds. This is because the controller in the switch control plane quickly updates the cache entries and fetches cache packets based on the top-k report of servers and the cache popularity counter of the switch data plane. Figure 19 (b) plots the change in the overflow request ratio over time. We can see that the ratio soars when the key popularity changes. This is because it takes time to fetch items from storage servers.

6 Related work

Storage systems are major target domains of recent in-network computing works (e.g., [11, 14, 18–25, 27, 28, 36, 38–40]). NetCache [21] shows the potential and limitations of switch-based caching. The limitation in the item size is passed down to recent works like FarReach [34] and DistCache [32]. OrbitCache enables variable-length in-network caching by leveraging built-in features of the switch. SwitchKV [29] employs the Openflow switch for cache lookups while items are cached in a cache node. Although this reduces the lookup overhead, it still provides limited performance due to server-based caching.

7 Conclusion

We proposed OrbitCache, an in-network caching architecture that is capable of variable-length caching in programmable switches. The key idea of OrbitCache is to make cached key-value pairs revisit the switch data plane continuously by leveraging packet replication efficiently. Experimental results demonstrated that OrbitCache can balance skewed workloads with diverse conditions. We hope that this work can contribute to the research community by providing insights that utilizing built-in hardware features has great potential to make in-network computing solutions effective.

Abstract

The inherent variability of real-world cellular networks makes it hard to evaluate, reproduce, and debug the performance of networked applications running on these networks. A common approach is to record and replay a trace of observed cellular network performance. However, we show that the state-of-the-art record-and-replay technique produces empirically inaccurate results that can cause evaluation bias. This paper presents the design and implementation of CellReplay, a tool that records the time-varying performance of a live cellular network into traces using preset workloads and faithfully replays the observed performance for other workloads through an emulated network interface. The key challenge in achieving high accuracy is to replay varying network behavior in a way that captures its sensitivity to the workload. CellReplay records network behavior under two predefined workloads simultaneously and interpolates upon replay for other workloads. Across various challenging network conditions, our evaluation shows that real-world networked applications (e.g., web browsing or video streaming) running on CellReplay achieve similar performance (e.g., page load time or bitrate selection) to their live network counterparts, with significantly reduced error compared to the prior method.

1 Introduction

Cellular network performance, including bandwidth and latency, can vary significantly due to factors such as wireless interference, environmental obstructions, and handovers, especially in mobile environments [12, 13, 22, 23, 34]. The gold standard for evaluating application and protocol performance on cellular networks is, hence, to test them directly on *live* cellular networks. However, live testing is time-consuming, as experiments must be conducted across many different network conditions and can produce different results—due to different signal strengths, types of wireless service (e.g., 5G millimeter wave, 5G low-band, and 4G), kinds of interference, rates of mobility, physical locations, etc. Repeating each experiment multiple times is crucial to ensure statistically reliable results given the performance variability in cellular networks. In addition to being time-consuming, experiments are often difficult to reproduce. A lack of control over the environment makes it infeasible, for instance, to compare the effects of a protocol change under identical network conditions.

Thus, researchers and app developers often turn to simulation or emulation for much of their evaluation, hoping to replicate a representative environment that yields performance similar to a live network. Simulators and emulators, such as `ns3` [28] or Linux's `netem-tc`, offer various options for configuring delay, jitter, bandwidth, packet loss, and more. While they can adjust these parameters to emulate specific and realistic conditions, properly tuning them to accurately represent the dynamic behavior of real-world cellular networks remains a challenging and open problem.

A more realistic approach is to *record* network performance traces (e.g., latency, bandwidth, or packet loss) over time using predefined workloads (e.g., RTT probing) on a real-world network and *replay* those traces in an emulated network for the tested apps. This method allows for recording different traces under various conditions (e.g., locations) and testing multiple apps using such recorded traces. Record-and-replay emulation was pioneered by Noble et al. [27]. More recently, the Mahimahi network emulator [25] can also replay recorded cellular network traces and has been instrumental in the design and evaluation of several notable networked systems and protocols (e.g., [5,14,18,20,24,26,30,31,36,37,39,41,43,45,46]).

However, we found that Mahimahi can produce inaccurate results compared to real-world tests in important cases, particularly for latency-sensitive and bursty workloads. For instance, in our evaluation, we observed an average bias of approximately 17.1% in web page load times (PLTs) when comparing Mahimahi emulation to running the application in the same commercial cellular environment where the traces were recorded. This error is a persistent underestimation of the PLT rather than just random variation. This issue affects other applications as well and the error may even be greater. For example, we observed a 49% error for 250 KB file downloads when Mahimahi emulated a commercial Verizon 5G as shown in §5.6.

Thus, despite record-and-replay emulation being practical and widely used, it does not support high-fidelity testing of networked systems and protocols. Minimizing emulation error is crucial, particularly for wireless protocol and application research, where record-and-replay emulations are often the most feasible evaluation platform. These errors could affect any evaluation and may even alter its conclusions, as we demonstrated in the ABR algorithms use case (§5.9). Therefore, we asked: What is causing this emulation error? And, is there a way to fix it to faithfully record and replay real-world cellular network performance?

Our first contribution is to study how the record-and-replay method used by Mahimahi can result in persistent bias (§3). Mahimahi records *packet delivery opportunities* by continuously saturating the link with packets (a "saturator" workload)

and noting when packets arrive at the endpoint. It then replays this trace as a schedule for when the link can deliver packets after delaying those packets using a *fixed* propagation delay, for any workload.

However, we found that this method causes two fundamental issues. First, it fails to fully capture network base latency changes, which are prevalent in cellular networks. In fact, our measurements show that Mahimahi underestimates RTT by 13.25% and 16.88% across two operators. Second, the available bandwidth that a cellular network provides to an end-to-end connection depends significantly on that connection's workload[1]. For example, in our measurement using Verizon 5G, a long train with 100 back-to-back packets experiences 2.6 times higher delivery rate than a short train with 10 packets. In such cases, Mahimahi's saturator (i.e., heavy traffic) would see a higher rate than what shorter traffic should experience. This dependency between cellular network available bandwidth and workload poses a fundamental challenge for record-and-replay because the whole point is to record *one* trace (which is necessarily running one workload) and replay that trace under a *variety* of applications for testing. If available bandwidth depends on the workload, is faithful record-and-replay feasible?

Our second contribution is to address these fundamental problems in a record-and-replay system called *CellReplay*. To solve the workload-dependence problem, one obvious approach would be to record performance under every possible workload. However, this is impractical and degenerates into simply testing every application directly on the live network, which is what record-and-replay emulation is trying to avoid. In other words, we can only record a *limited* number of different workloads. Another option would be to build a white-box emulation of providers' underlying resource allocation policies; but these are proprietary and vary across providers, so we seek a black-box method based on end-to-end observations.

The approach we take is to record just two representative workloads (*light* and *heavy*) simultaneously, chosen at extremes on the range of traffic patterns, and then interpolate between them during replay to achieve high accuracy across a wide range of workloads. During the recording phase, we use two phones: one running a heavy saturator workload and the other running a light workload. The light workload is calibrated to capture RTTs and light-workload bandwidth, but is not too light as to capture the network's transition from light to heavy bandwidth allocations. During replay, the emulator applies delay using the RTT trace and initially releases packets according to the light trace. It then splices in the heavy trace during longer packet sequences before eventually returning to the light trace after an idle period. This technique addresses the two key problems with Mahimahi's approach mentioned above, namely capturing (1) dynamic RTTs and (2) bandwidth that depends on workload.

We implemented CellReplay using an architecture similar to Mahimahi—an emulated network interface that can be used by unmodified applications. Using randomized trials, we evaluated CellReplay's accuracy by comparing the application performance when running under CellReplay emulation to the live networks. We tested two commercial providers' 5G mid-band and low-band deployments, and covered multiple network conditions, including non-ideal conditions (e.g., in a crowded library) and mobility (e.g., driving). We evaluated two real-world application traffic patterns: randomized file downloads and web page loads with HTTP/1.1 and HTTP/2. These applications cover a variety of workloads, ranging from periodic small to heavy flows in file downloads to complex interleaved traffic from web page loads. Additionally, we used CellReplay to evaluate the startup phase of multiple adaptive bitrate (ABR) implementations for 4K video streaming.

We find that CellReplay substantially reduces emulation error. In web page load tests, CellReplay reduces emulation error from 17.1% with Mahimahi to 6.7%, representing a 60.8% improvement. For randomized file download tests, CellReplay lowers mean file download time errors from 7.9%-49% with Mahimahi to just 0.2%-22.4%. Moreover, CellReplay achieves lower error when replicating application performance under non-ideal network conditions, such as inside a basement (15.22% error in Mahimahi vs. 5.87% in CellReplay) and a crowded library (22.51% vs. 8.47%), and during user mobility, such as walking (14.48% vs. 4.13%) and driving (13.15% vs. 6.97%). Finally, we demonstrate CellReplay's usefulness in evaluating ABR algorithms, as it preserves the relative ordering of ABR performance and avoids the biases observed in Mahimahi. We discuss challenges and future directions for improvement in §6. We release CellReplay alongside with its recorded traces as an open source at https://github.com/williamsentosa95/cellreplay

2 Background and related work

2.1 Cellular network record-and-replay

The goal of record-and-replay network emulation (within the scope of this paper) is to emulate the end-to-end network performance of an application communicating between two endpoints, ensuring performance similar to that of a live network counterpart. During the recording phase, user equipment (UE) and the server send traffic according to a predefined workload (e.g., sending packets beyond the link bottleneck rate), while observed performance metrics (e.g., throughput) are logged. This workload should be *independent* of the tested applications, allowing us to record traces *once* and reuse them for multiple applications, regardless of whether they are UDP- or TCP-based. During replay, this trace is consumed by an emu-

[1]To be clear, this effect is not due to queuing behavior of a traditional link with constant throughput and latency; nor is it caused by variations in wireless physical channel quality over time. Although commercial providers' internal policies are proprietary and opaque to us, the effect could be explained by a resource allocation policy (e.g. [9]) or a carrier aggregation policy (as observed in [40]) at the Radio Access Network (RAN) allocating some bandwidth for the client, but observing the client's injected packets and dynamically modifying that provided bandwidth.

lated network interface. Real applications (e.g., a web browser and web server) can connect through this interface, and traffic between the endpoints will experience artificial network conditions (e.g., time-varying latency and bandwidth) as if they were communicating over a cellular network, even though they reside on the same physical host. Our goal is for any metrics of interest—including transport-level and application-level metrics such as flow completion time or web PLT—to closely match those of the live network.

Record-and-replay can be applied to any type of network, but our interest here is on cellular networks. Their performance can be time-varying, vendor-dependent, and environment-dependent, making it difficult to generate conditions—whether in simulators, emulators with hand-picked or even calibrated [42] parameters, or testbeds—that match real-world complexity. Thus, record-and-replay is especially useful in such environments, but it is also challenging to execute well.

Note that record-and-replay deals with end-to-end conditions and does not require any link- or physical-layer information or support from network operators. Like past work, we do not need to determine which hops along the path cause certain performance effects. This means that the observed performance, and its replay, may result from a combination of sources (e.g., the 5G RAN, service provider core, or the Internet to a remote endpoint). However, major performance variations are expected to originate from the cellular network [22]. We sometimes refer to the observed performance as coming from a cellular link, the path, or simply the network; all terms are equivalent for our purposes.

2.2 Related work

Network emulators. Popular network emulators, such as NetEm [16] and dummynet [32], can emulate cellular networks. Google Chrome also provides configuration profiles with fixed latency and bandwidth for cellular networks, such as "Fast" and "Slow" 3G [3]. Pantheon [42] provides calibrated emulators based on parameters like fixed propagation delay, bottleneck link rate, isochronicity, etc. These configurations are tuned to match packet traces collected from a path (including cellular network) using various congestion control protocols. iBox [7] extends this by incorporating cross-traffic. However, fixed parameters, by definition, do not capture time-varying effects, which are common in cellular networks.

Record-and-replay network emulation. Noble et al. pioneered the concept of recording the end-to-end network characteristics of a wireless network and replaying them in an emulated network in 1997 [27]. However, it is designed to emulate WaveLAN, which differs fundamentally from modern cellular networks. More recently, NemFi [21] was introduced as a record-and-replay emulator for WiFi. NemFi's design is specific to WiFi (e.g., emulating frame aggregation) and it is not readily applicable to emulating cellular network paths.

Mahimahi. In 2015, Netravali et al. demonstrated a framework for recording and replaying HTTP traffic [25] called Mahimahi, which also included a network emulator derived from CellSim [38] to replay time-varying uplink and downlink rates in cellular networks. Mahimahi has since become the state-of-the-art record-and-replay emulator for cellular networks and is widely used to evaluate various networked applications.

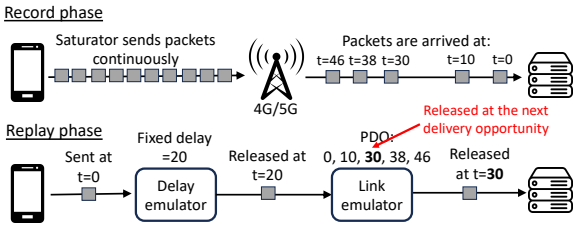

Figure 1: *An overview of Mahimahi's record-and-replay to emulate cellular uplink.*

We detail Mahimahi's record-and-replay approach[2], as it serves as an important reference for this paper. Fig. 1 illustrates the process for the uplink only, as the same approach applies to the downlink. Mahimahi records time-varying link rates using a *Saturator*, which saturates both the uplink and downlink with MTU-sized packets (e.g., 1500 bytes) to ensure that the base station always has packets to deliver. The endpoint then records the arrival time of each packet. During emulation, Mahimahi treats each arrival timestamp as an opportunity to deliver a packet. A sequence of such timestamps constitutes a *packet delivery opportunity (PDO) trace.* Each PDO entry represents an opportunity to deliver an MTU-sized amount of data, which can be either a single MTU-sized packet or multiple smaller packets whose combined sizes add up to the MTU. If no packets are queued for delivery when the PDO occurs, the opportunity is lost. Mahimahi also emulates the RTT delays on a cellular link, albeit using a *fixed* propagation delay. That delay is determined by measuring the minimum packet RTT (e.g., via ICMP ping) and halving that value.

3 Live record-and-replay is hard

Why is record-and-replay challenging? Also, why does the current state-of-the-art method (i.e., Mahimahi) fail to accurately replicate the performance of networked applications on a cellular network? Below, we answer both questions using measurements and insights from real cellular networks.

The measurements in this section were collected from two commercial cellular networks: T-Mobile 5G mid-band and Verizon 5G low-band, using a Samsung Galaxy S22 (SGS) phone tethered to a laptop. The laptop, equipped with an Intel i7 CPU and 16 GB RAM, ran Ubuntu 20.04 and served as our

[2]This method was introduced by CellSim. Mahimahi also provides traces recorded in CellSim's approach, which have been beneficial and used in past work (e.g., [20]). Due to its usefulness, other work has collected newer cellular network traces following CellSim's approach (e.g., [19, 26]) and replayed them in Mahimahi. For simplicity, throughout the rest of this paper, we refer to this record-and-replay method as Mahimahi.

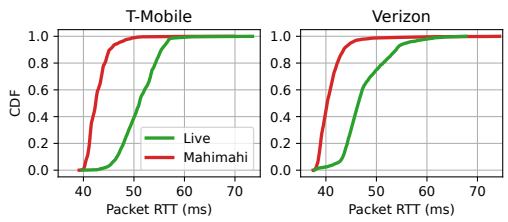

Figure 2: *Packet RTT CDF of Mahimahi emulation and live 5G networks. Mahimahi underestimates the RTT and fails to capture the RTT distribution.*

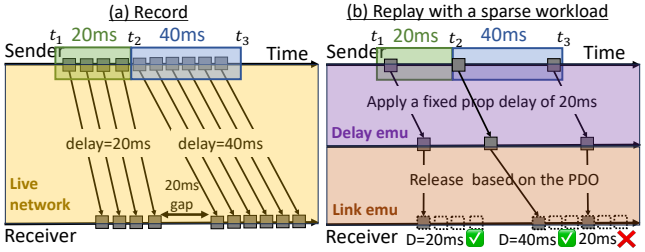

Figure 3: *Mahimahi PDO approach fails to capture the base delay changes for sparse workload.*

client. The server was located within close proximity (<10 miles) of the client. We confirmed that all results remained consistent when using a different phone model (Google Pixel 5).

3.1 Variability in base RTT

The base RTT is defined as the round-trip time (RTT) of a packet from the client to the server when there is no self-inflicted congestion. In cellular networks, this RTT is expected to be variable, as packets frequently experience delays (jitter) due to link-layer retransmissions, channel contention, base station scheduling, and device mobility. Emulating this variability is critical for testing latency-sensitive applications such as VR/AR and remote driving.

Mahimahi also emulates delay variability based on packet delivery traces. Despite using a fixed propagation delay, it must hold the packet until it sees a PDO before releasing it (Fig. 1). However, our measurements suggest that it fails to fully capture the base RTT variability. To quantify this error, we compared the packet RTT reported in live experiment with that of Mahimahi.

Specifically, we conducted repeated packet RTT tests and Mahimahi recordings individually over live networks, following the randomized trial approach (§5.3). The packet RTT test involves a client sending a 1400-byte UDP packet (roughly an MTU-size) every 50 ms to our echo server and noting each packet's RTT. We repeated this test 10 times, and both the RTT test and Mahimahi recording session lasting 60 seconds. Next, we ran the exact same packet RTT test under Mahimahi's emulated interface, using the recorded trace and setting the propagation delay to half of the minimum RTT from the live packet RTT tests.

Figure 2 shows the cumulative distribution function (CDF) of packet RTTs on the live network and Mahimahi replay. It indicates that Mahimahi underestimates packet RTT (by 16.88% and 13.25% at the median for T-Mobile and Verizon, respectively), and its distribution differs from that of the live network (as seen in the shape of the CDF curve). This suggests that simply increasing Mahimahi's fixed propagation delay (i.e., shifting the CDF curve to the right) does not capture the variability. Note that this experiment was performed under stationary conditions with a strong signal, where network performance is more stable. In a mobile scenario, where packet RTT can vary more or even change, Mahimahi's fixed propagation delay approach may perform even worse.

This is because PDOs, in principle, only *partially* capture base delay changes. Figure 3 illustrates a case where the packet base delay changes at t_2 from 20 ms to 40 ms, and Mahimahi fails to apply the correct delay for a certain packet. Note that base delay changes may occasionally occur in live cellular networks due to factors such as increased retransmission delays caused by a weakened radio signal. In this illustration, during the recording phase, the four packets delivered from t_1 to t_2 experience a 20 ms base delay, while packets from t_2 to t_3 experience a 40 ms base delay. The receiver indeed perceives a delay change since, after receiving four packets, it does not receive any packets for 20 ms before receiving the next set. This 20 ms "blackout" period is also reflected in the PDO trace during the replay.

A PDO blackout means no packet delivery. Any packets scheduled for delivery during this period will be delayed until the next available opportunity. As a result, only packets arriving during the blackout period (relative to the link emulator) will experience a delay, while others will *not*. However, sparse workloads, such as those in Fig. 3b, may have packets arriving outside the blackout period and thus not experiencing any delay.

Conclusion: Fixed propagation delay and PDOs are insufficient to model cellular network delay variability. Therefore, we need to record packet RTTs over time through probing during the recording phase and apply time-varying delays during the replay.

3.2 Performance depends on workload

Recall that Mahimahi uses a Saturator to ensure that the network always has packets ready to send, and so any available PDOs will be consumed and recorded. Then, a subset of those PDOs is used when replaying any given workload. An underlying assumption is that the same PDOs would have been available for the replayed workload. However, our experiments on live cellular networks show that *the network substantially changes the PDOs it provides depending on the workload*. We reached this conclusion upon observing that short flows consistently experience lower bandwidth than longer flows.

To demonstrate this, we conducted live experiments in which our server periodically sent *packet trains* to a client. Each train consists of N back-to-back UDP packets, each

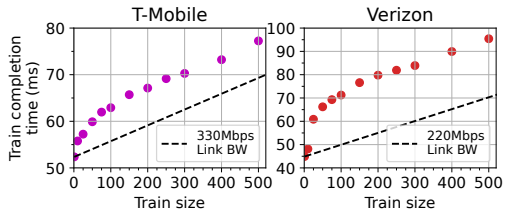

Figure 4: *Mean train completion time (TCT) of different sized trains (N), and TCT if trains were delivered according to the Saturator's observed bandwidth.*

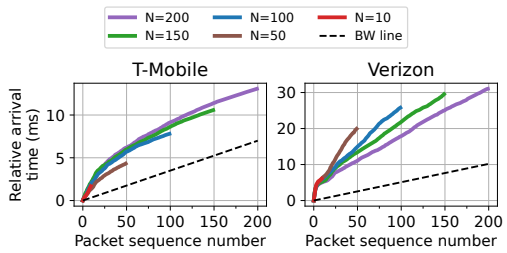

Figure 5: *Mean relative arrival time for each packet of different sized (N) trains.*

1400 bytes, followed by a 100 ms gap—long enough to clear out any packets from previous trains). We refer to N as the train size. Each packet in a train is tagged with a train number and a sequence number reflecting its order within a train $(P_0, \ldots, P_{N-1})$. The client then records each packet's arrival time. Additionally, the client sends a 100-byte ACK back to the server upon receiving the last packet of a train (P_{N-1}). The *train completion time* (TCT) is defined as the time at which the server receives the ACK minus the time it sent P_0. We performed this test with different train sizes following our randomized trial approach (§5.3). Each test lasted 5 seconds, and there are 12 tests with different train sizes (1, 10, 25, 50, ..., 500) in one trial. We repeated this trial 50 times. Finally, we also recorded network performance with the Saturator, as Mahimahi would.

Figure 4 shows the mean TCT for each train size on T-Mobile and Verizon 5G. The dashed black line represents the TCT if the link had a fixed bandwidth equal to that observed by the Saturator (equivalent to the mean TCT with Mahimahi replaying the Saturator). If network performance were independent of workload, then the mean bandwidth would remain the same for all train sizes, and the mean TCT would follow a linear function of the amount of data being delivered, i.e., a linear function of N. In particular, it should coincide with the bandwidth observed by Saturator. However, the observed TCTs do not conform to a straight line and generally do not match the Saturator line, with TCTs being up to 11.5% higher than the Saturator in T-Mobile and 35.8% higher in Verizon. This indicates that *the service experienced by the train workloads is consistently and significantly different than the service experienced by the Saturator's heavy workload.*

To better understand these observations, we examined the arrival times of packets within each train, revealing the PDO patterns recorded by different trains. For each packet $P_i \in \{P_0, \ldots, P_{N-1}\}$ in each train, we calculated its *relative arrival time* as $t(P_i) - t(P_0)$, where $t(\cdot)$ denotes the receiver's observed arrival time of a packet. We present the mean relative arrival time as a function of packet sequence number i for different train sizes N in Figure 5.

These results confirm that the link's rate (or PDO) depends on the workload. The network provides a lower delivery rate for the first few packets in any train (note that in these plots, a higher slope indicates a lower delivery rate). As the train progresses, the delivery rate increases, and the slope begins to approach that of the Saturator. We also repeated the same packet train tests in the opposite (uplink) direction but found that the link's rate remains uniform regardless of N (i.e., it follows a straight line). We suspect that the rate-workload dependence in the downlink results from the operator's proprietary packet scheduling implementation. For example, cellular network packet scheduling may depend on historical application traffic and the current queue depth when scheduling packets [9]. This rate-workload dependence was observed across all conditions tested in §5, including both peak and off-peak hours.

Interestingly, T-Mobile and Verizon have dramatically different implementations. T-Mobile's delivery rate approaches the Saturator's rate (slope) as i increases, mostly regardless of N. Verizon's delivery rate, on the other hand, asymptotes to significantly different values depending on N, with larger N approaching the Saturator's heavy-workload delivery rate more closely. Additionally, in T-Mobile, the first 50 packets of trains with $N > 50$ are delivered more slowly than the 50 packets of the train with $N = 50$, whereas Verizon shows an inverted behavior. This further complicates record-and-replay, as we aim for a general and relatively accurate approach across different operators and locations.

We also found a more minor way in which performance depends on workload: the RTT of a packet varies with packet length by an amount not explained by throughput. For instance, based on our measurements on Verizon, the RTT of a 100-byte packet is 6.8 ms faster than that of a 1400-byte packet, even though the difference in serialization time at the bottleneck link rate (60 Mbps) should have been only ≈ 0.17 ms. This outcome aligns with findings from the prior latency study on 5G [12] and may be attributed to the additional time required for reassembling larger data chunks. Due to space constraints, we omit detailed results.

Conclusion: Cellular network performance can depend significantly on the workload. Our observations indicate that cellular providers allocate delivery rates (i.e., bandwidth or PDOs) differently for *light* and *heavy* workloads. The Saturator forces the link into its heaviest workload mode, which generally increases the available bandwidth. Consequently, using Saturator's PDOs for a lighter workload can result in consistent bias (flows complete faster than they should). This suggests that diverse workloads are needed to capture differ-

ent PDOs, but choosing the right representative workloads remains challenging.

4 CellReplay

4.1 Design overview

At a high level, we want to solve the problems of capturing time-varying base RTT (§3.1) and workload-dependent performance (§3.2) in both record and replay.

We begin with the latter problem (§3.2). To achieve highly accurate emulation, an obvious solution is to record performance under different workloads. However, recording every possible workload is impractical and degenerates into simply testing the apps directly on the live network. We also aim for the recorded workload to be independent of the tested apps (§2.1). Therefore, we can only record a *limited* number of different workloads.

From §3, we observe that short and continuous traffic are handled differently, while medium-length flows exhibit performance somewhere between the extremes. Inspired by this observation, our key approach is to record two workloads chosen at the extreme points on the spectrum of traffic patterns: (1) *Packet train probing* to capture link PDOs under short and bursty load (light PDOs), and (2) *Saturator* to capture PDOs under heavy continuous load (heavy PDOs). These workloads capture the essential behavior of link rate differentiation under light and heavy flows. We used two phones to record both traces simultaneously and show in our evaluation that interference between them is limited in practice.

During replay, we leverage both PDOs to match the provided workload. When the application under test begins sending packets, we initially release the first sequence of packets according to the light PDOs and then transition to heavy PDOs as the packet sequence lengthens. After a certain gap in the workload, we return to the light PDO trace.

Returning to the problem of time-varying RTT (§3.1), we design the packet trains to avoid inflating queues, so that it gives us a good measurement of base RTT. The packet train probing serves a dual purpose: to record changing base RTTs (for any workload) and PDOs for shorter packet sequences.

Finally, the effectiveness of the above design depends on parameter choices. For example, a too-small train will not capture the network's light workload behavior completely, forcing us to go to the heavy PDO trace too soon; if the trains are too large, we cannot sample frequently as network performance may then resemble that of a heavy workload, and there is a risk of inflating base RTT measurements due to congestion. Thus, before recording, we conduct a calibration phase to determine train size, train gaps, and other parameters that will yield the least error.

In summary, CellReplay has *three* components. When recording network traces in a specific environment, we first perform an automated **calibration** of parameters in that environment, and then start **recording** live traces by running packet train probing and Saturator in parallel. These traces

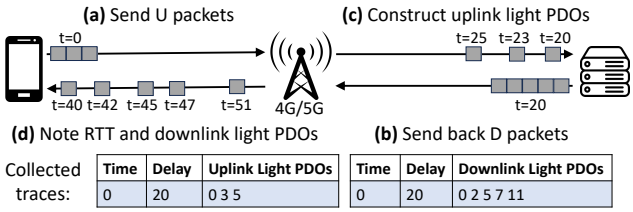

Figure 6: *Packet train workload alongside with its recorded base delay and light PDO traces for uplink and downlink.*

are then used to emulate the network during **replay**. The following subsections detail each of these components: record (§4.2) and replay (§4.3), before returning to calibration (§4.4), which is best understood after seeing the rest of the design.

4.2 Recording network traces

There are three time-series metrics we want to record: (1) base delay, (2) light PDOs, and (3) heavy PDOs.

Base delay and light PDOs. The base delay trace should reflect the network's round-trip time (RTT) without any queueing delays introduced by the workload itself. Ideally, this trace would be captured by periodically measuring the RTTs of small packets. The one-way base delay can be estimated by halving the RTT.

Light PDOs can be captured by periodically sending a limited number of back-to-back packets, i.e., a *packet train*, in both the uplink and the downlink. The number of packets should be small enough to capture the network's light workload behavior and ideally some of the transition to moderate workload, without pushing the network into heavy workload mode. In particular, the train should be short enough to avoid "warming up" the network for the following train. As a result, both the base delay trace and light PDOs share similar requirements. We can collect both simultaneously using a packet train probing workload on a single device. This workload uses MTU-sized packets, as a significant amount of traffic is still required to capture the transition point between light and heavy modes.

Figure 6 provides an example of how this process works. In every G ms, (a) the client sends U back-to-back MTU-sized packets to the server. Upon receiving the first packet of the train, (b) the server sends back D back-to-back MTU-sized packets. The server also (c) records each packet's arrival within that train and uses it to calculate the uplink light PDOs as the arrival time of each packet minus the arrival time of the first packet (since, during replay, the base delay will be added). When the client receives the corresponding downlink train, (d) it infers the current base RTT as the receipt time of the first downlink packet minus the send time of the first uplink packet (within that train). It then calculates the downlink light PDOs based on packet arrival times, just as the server did.

Heavy PDOs. The heavy PDOs are collected using a Saturator (similar to Mahimahi) that saturates the link with packets beyond its bottleneck rate, effectively "requesting" the link to remain in max bandwidth mode. In practice, we developed our

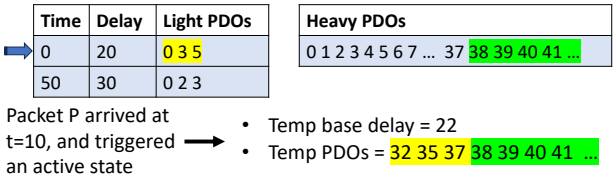

Figure 7: *Temporary base delay and PDOs constructed when a CellReplay first enters an active state.*

own Saturator tool, which sends MTU-sized packets in both the uplink and downlink at fixed upload and download rates, eliminating the need for two phones as in Mahimahi's Saturator [38]. We overestimated (by 25%) the max link bandwidth measured using an existing bandwidth test application like iperf or speedtest. We confirmed that the reported throughput from our Saturator is similar to UDP iperf.

However, running both Saturator and packet train probing on a single device is not feasible, as the Saturator will overload the queue, leading to two issues: inflating the base delay measurement and keeping the link in maximum bandwidth state. One solution is to run these workloads in separate trials, which may be permissible under stationary conditions but is less ideal under mobility. Alternatively, we chose to perform these workloads on separate identical phones placed in close proximity. This is possible since most (if not all) cellular network providers employ user-separated queues [38] such that the Saturator traffic will not inflate the packet train probing measurement results. Beyond the known separation of queues, we confirmed that light vs. heavy bandwidth allocation is also separated on both Verizon and T-Mobile: when one phone runs the Saturator, the other phone running packet train probing still experiences light-workload service.

Note that the two-phone method is not without limitations. The phones may not always connect to the same base station all the time, especially in a mobile environment where handoffs could occur slightly differently. We leave this discrepancy for future work.

4.3 Replaying network traces

CellReplay takes input traces of base delay, light PDOs, and heavy PDOs over time to emulate network performance in a virtual interface. At a high level, CellReplay first applies a base delay to each packet based on the delay trace, adjusts the delay for any latency offset from packet-size calibration (§4.4), and then releases packets according to either the light or heavy PDOs.

In more detail, CellReplay operates in two states: active and inactive. Initially, CellReplay is in the inactive state until it receives a packet at some time t, relative to the start of the emulation. This event triggers CellReplay to enter the active state, which involves preparation as shown in Figure 7. CellReplay searches for the most recent base delay ($DELAY$) and light PDOs ($LightPDO$) where the timestamp is $\leq t$. Since the trace is sampled per G, linear interpolation is used to assign $DELAY$ to packets arriving between two samples. CellReplay then saves $DELAY$ and constructs temporary PDOs ($TempPDO$) by adding every PDO entry in $LightPDO$ with $t + DELAY$. It then concatenates these with the suffix of the heavy PDOs, starting from $t + DELAY + max(LightPDO) + 1$. The system is now done entering the active state.

As long as the system remains in the active state, packets are initially delayed by $DELAY$ plus a size-based delay compensation $comp(size(P))$. As discussed in §3.2, base delay may depend on packet size; the specific adjustment $comp(\cdot)$ is determined during calibration. $DELAY$ and $TempPDO$ remain unchanged unless the system enters an inactive state[3]. After a packet is delayed, it is either placed in a PDO queue or dropped if the queue exceeds B bytes. Packets are dequeued according to the time schedule in $TempPDO$ using byte-wise dequeueing. This process mirrors Mahimahi's PDO replay, with CellReplay using the temporary (concatenated) PDO trace. As a result, early packets in the active state will experience light PDOs, while later packets will experience heavy PDOs. Once F milliseconds pass without any packets in the PDO queue, CellReplay returns to the inactive state. Any future arriving packet will then trigger the procedure to reenter the active state, as described above.

Table 1: *Parameters set in calibration phase (§4.4).*

Parameter	*Definition*
U	Number of packets per uplink train
D	Number of packets per downlink train
G_{min}	Lower bound of gap between trains (milliseconds)
F	Fallback timer to return to inactive state
$comp(s)$	Delay compensation for s-byte packets
B	Bottleneck buffer size in bytes

4.4 Parameter Calibration

We describe how to select values for the parameters in Table 1. The parameters U, D, G_{min}, F, and $comp(s)$ are exclusive to CellReplay and are calibrated in every new environment before recording traces. This process is automated. B is a standard network emulation parameter, derived using a classical max-min approach [11]. For details, see §A.3.

Setting U and D. We profile the network to determine a *packet train size* that provides the best overall approximation of the network across other sizes. We first conduct randomized experiments with different packet train sizes (the same as §3.2) using a fixed train gap that is conservatively large enough to ensure the link returns to its light-workload state.

[3]Replaying base RTT changes during the active period could lead to double-counting, as PDO traces already capture some RTT changes in the form of gaps between PDOs. While this might seem counterintuitive to our goal of emulating time-varying base delay, the issue discussed in §3.1 only arises when there is a gap in the workload packets that empties the queue. However, in such cases, CellReplay has an opportunity to re-enter the inactive state and select another base RTT. Although there is a slight chance that the workload gap is shorter than the inactive-state timer F, F is typically small (e.g., 5 milliseconds), so we did not find this to be a major problem in practice.

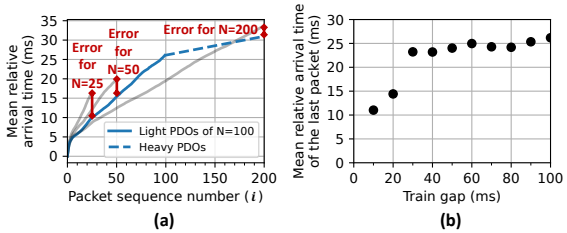

Figure 8: *(a) Estimating error if a 100-sized train is used to estimate {25, 50, 200}-sized trains. (b) G_{min} is chosen as the smallest train gap that results in performance similar to a large train gap (i.e.,* 30 ms*).*

In our implementation, we use a 100 ms gap, and the set of train sizes we consider is $\{5, 25, 50, 75, \ldots, X\}$ where X is chosen such that the resulting mean sending rate (including gaps between trains) is half of the bottleneck throughput.

After running for 10 trials, we compute $R_N(i)$ for each train size, which represents the mean relative arrival time of the i-th packet in an N-packet train. The relative arrival time is the packet's arrival time minus that of the first packet in its train. R_N essentially represents the mean light PDOs of an N-sized train. We further define $R^*_N(i)$ as the estimated mean arrival time of the i-th packet *in replay mode*, assuming we choose to record trains of size N. More specifically, recall that during replay, we follow light PDOs before splicing in the heavy PDOs; therefore, $R^*_N(i) = R_N(i)$ for $i \leq N$, and otherwise, $R^*_N(i) = R_N(N) + heavy(i-N)$, where $heavy(x)$ is the delivery delay of x packets based on the mean throughput of the heavy workload.

The purpose of $R^*_N(i)$ is to help us calculate the estimation error of $R_N(N)$ (i.e., the mean relative arrival time of the *last* packet of an N-packet train) for every other train size N that we have tested. Let L be the train size used to estimate the error for other trains. Fig. 8(a) shows the estimation error when using $L = 100$. The blue line is $R^*_{100}(i)$, which represents the PDOs based on the concatenation of mean light and heavy PDOs. If we use that to estimate $R_N(N)$ of *other* trains $N \in \{25, 50, 200\}$, the prediction will result in some error (shown in red). For each train size L, we compute the mean error over *all* tested train sizes, and our chosen train size is the L that yields the smallest mean error. We conduct the entire procedure in two directions (uplink and downlink) separately to choose the train lengths U and D.

Finding G_{min}. If the train gap G is too small, the link will not have enough time to reset to its light-workload mode before the next train arrives. We typically set $G = 50$ ms for stationary conditions and $G = 100$ ms for mobile conditions. However, in certain environments, this may not be large enough. We thus aim to find G_{min}, the smallest value at which the link has enough time to return to its light-workload mode, ensuring that our chosen G is at least that value.

We conduct another randomized experiment, this time testing different train gaps. Again, we send sequences of trains; however, in this case, we fix the train length at our chosen value (U or D, for uplink or downlink, respectively, in separate experiments) and vary the gap g. We begin with a conservatively large gap (as in the previous experiment) and test gaps of decreasing size; in our implementation, $g \in 100, 90, 80, ..., 10$ ms. Let $r_{last}(g)$ denote the mean relative arrival time of the last packet in trains with gap g. Intuitively, as g decreases to a too-small size, the link will begin staying in its heavy-workload mode, causing $r_{last}(g)$ to decrease. We set G_{min} as the smallest g for which $r_{last}(g)$ is within 20% of its value with the conservatively large gap, i.e., $r_{last}(100ms)$. In the example of Fig. 8(b), CellReplay selects $G_{min} = 30$ ms.

Inferring *F*. Recall that F determines how long CellReplay's emulated link remains idle in the active state before transitioning back to the inactive state. We derive F using the same data collected to select G_{min}, which involves calculating the difference between G_{min} and the time required for the queue to clear, which is observable as $r_{last}(G_{min})$. For details, see §A.2.

Inferring *comp*(). We profile how RTT is affected by packet size by sending randomly sized packets between {100, 200, ..., 1400} bytes every 50 ms to a receiver that responds with a 100-byte ACK. We then measure the RTT difference for a packet size of s compared to the RTT of 1400-byte packets and model this difference as $comp(s)$. We describe this in more detail in §A.1.

5 Evaluation

Our goal is to evaluate the accuracy of CellReplay's emulation in replicating application performance compared to its live network counterpart. We also compare CellReplay with Mahimahi [25]. We implemented CellReplay record tool in Java and Python 3 to send and receive UDP packets. We extended the Mahimahi shell to support CellReplay replay, allowing unmodified applications to run inside the shell and experience the emulated network conditions induced by CellReplay. For more details, refer to §B.

The evaluation includes experiments that test CellReplay's accuracy across (1) different networked applications, including web browsing and random file transfers using TCP, (2) different cellular providers and technologies, including T-Mobile, Verizon, 5G mid-band, and 5G low-band, and (3) different environmental conditions, such as good signal strength, weak signal strength, crowded areas, and various mobility levels (stationary, walking, and driving). For full details on the environments and their calibration parameters, refer to §C. Finally, we present a use case of using CellReplay and Mahimahi to evaluate ABR algorithms.

5.1 Experimental setup

We designed two test setups: a *live network* and an *emulation* test setup, as shown in Figure 9. The *live network* test setup was used for running application tests on the live network. During the tests, we tethered a laptop to phones connected

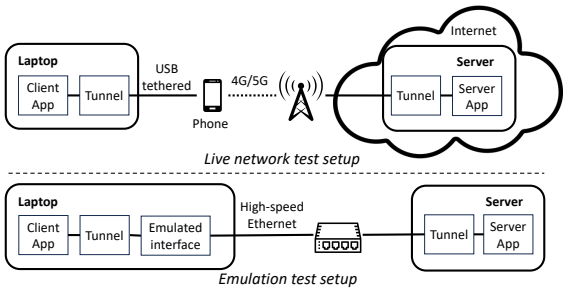

Figure 9: *Live network and emulation application test setup.*

to 5G or 4G networks. The client application (e.g., a web browser) and the application server (e.g., a web server) communicate via a UDP tunnel (based on [42]). We deployed our server (i.e., the remote endpoint) in the same geographical area–within 10 miles of the phones–to minimize the network path length and, consequently, reduce the likelihood of experiencing congestion over long paths. We also used a similar setup, albeit without a tunnel, to record the cellular network traces using UDP traffic. However, instead of a single phone, we used two identical phones to separately perform packet train probing and the Saturator workload.

We used the *emulation* test setup to test applications under an emulated network interface that employed either CellReplay's or Mahimahi's replay approach. Although this setup is similar to the live network test, we made two modifications: (1) we replaced the USB-tethered interface with a direct high-speed Ethernet connection to our server via a single switch, and (2) we ran the tunnel inside either CellReplay's or Mahimahi's replay network-emulation shell, which emulates the network using recorded traces. The same client and server devices were used for record and replay.

End-point specifications. We used two Samsung Galaxy S22 (SGS) and two Google Pixel 5 (Pixel) phones for testing. We had an unlimited data plan from both T-Mobile and Verizon. Since we observed no performance difference between the SGS and Pixel across different operators, we connected our SGS devices to T-Mobile and our Pixel devices to Verizon for convenience. The laptop in our setups featured an Intel Core i7 CPU, 16 GB RAM, and a 512 GB SSD, running Ubuntu 20.04.

5.2 Applications under Test

We tested CellReplay's fidelity using two real-world applications: (a) web-page loads, which exhibit complex traffic patterns and represent the most popular application type on mobile devices, and (b) random file downloads, which have simpler traffic patterns but involve large-sized flows.

Web page load test. Our client ran a Chromium browser to load a web page from our server. To generate the list of web pages for our testing, we began by randomly selecting 200 internal and landing pages from the Hispar list [6]. Using Chromium, we loaded all pages and recorded each page's total size of the compressed web objects. We then sorted the pages based on this total size and selected five pages each for landing and internal pages corresponding to the 10^{th}, 30^{th}, 50^{th}, 70^{th}, and 90^{th} percentiles of the distribution. We use 'L-ID' and 'I-ID' to refer to an individual landing and internal page, respectively. 'ID' is a number indicating the order based on page size, where lower values represent smaller page sizes. Refer to §D for the exact list of pages and their page composition).

We utilized Mahimahi's HTTP record-and-replay framework [25] to replay these pages, ensuring that the fetched content for a given page remained consistent across all trials. First, we recorded all HTTP requests and responses using `mitmproxy` [2], following Mahimahi's record format, while loading a web page using a headless Chromium browser. Next, we used Mahimahi's ReplayShell to serve the responses over the HTTP/1.1 (using Apache2) or HTTP/2 (using h2o from the [47] extension).

In our test setup (Fig. 9), ReplayShell was deployed on our server, while the laptop ran a headless Chromium browser to repeatedly fetch a web page. We cleared the browser and DNS caches before every web-page fetch, and we used TCP Cubic, the default TCP implementation on Linux, for this test. Lastly, we measured *page-load time (PLT)*, based on the `onLoad` event [29], as the application performance metric.

Random file download test. For this test, we implemented a client that sends download requests (each fewer than 10 bytes) to a server. Each request selects a file uniformly at random from a list of files of varying sizes, and the server delivers the corresponding file data. After completing the transfer, the client then sleeps for 50 ms before requesting another file. We implemented the client and server in Python and used TCP Sockets. We measured the *file download time* as the turnaround time between when the client sends its request and when it receives the requested file.

Adaptive video streaming over HTTP. We ran a client-server setup from [4, 20], which includes multiple adaptive bitrate (ABR) streaming implementations. However, instead of using the 2K video from that setup, our server hosts a 250-second-long AVC 4K video (`indoor soccer` from [35]) with a 4-second chunk duration encoded with 12 bitrates of [100, 200, 375, 550, 750, 1000, 1500, 3000, 5800, 7500, 12000, 17000]. We used a Chromium browser to run the video player.

5.3 Methodology

Randomized trials. When evaluating a networked system's performance on the CellReplay emulated interface versus the live network, we must account for cellular network variability. Thus, all our experiments used *randomized trials*. Each experiment comprised multiple trials, with each trial consisting of multiple tests and recording sessions. A test involved running an application (e.g., loading a web page) on a live network, while a recording session (e.g., CellReplay record) gathered a trace of the live network. The tests and recording sessions ran for the same duration, and we randomized the sequence

of tests and sessions within each trial. We then compared the application's performance (across multiple tests) on the live network to that on the emulated network to calculate the emulation accuracy.

Calculating the emulation accuracy. We quantified emulation error using the normalized difference between two distributions of application performance: one from the live network and the other from the emulation. To measure the difference between these distributions, we used Earth Mover's Distance (EMD) [33], defined as: $EMD(L,T) = \int_{-\infty}^{+\infty} |L(x) - T(x)|\,dx$, where L and T are the cumulative distribution functions (CDFs) of the observed application performance on the live and emulated networks, respectively. A lower EMD value indicates a high-fidelity emulation, meaning the performance distributions are more similar. Finally, we calculated the *emulation distribution error* by dividing the EMD with the mean (performance) value from the live network tests.

Other details. In each new network environment (or network operator), we first performed a calibration. To record CellReplay traces, we used one phone (*primary*) for packet train probing and the other (*secondary*) for running the Saturator. The *primary* phone was also used for calibration, testing applications on the live network, and recording Mahimahi traces using our own Saturator. For propagation delay, we provided Mahimahi with the minimum base delay observed from the packet train workload. During data collection, both phones (UEs) were held together at a close distance ($\approx$ 12 inches). We also confirmed that both probing devices were attached to the same cell in all tests, except in the driving case.

5.4 Microbenchmarks

We first evaluated how accurately CellReplay emulates the time-varying base RTT and the non-uniform delivery rate in a cellular network. We conducted packet RTT and packet train tests (refer to §3.1 and §3.2) as separate experiments. Each experiment consisted of 30 randomized trials, with each trial including two record sessions (CellReplay and Mahimahi) alongside packet RTT and packet train tests. The sessions (as well as tests) lasted for 10 s. All tests were performed under "good" network conditions, i.e., UEs were held stationary near a window.

First, CellReplay accurately records RTT changes over time, with the CDF of packet RTTs closely overlapping with the live network (Figure 10). As expected, Mahimahi persistently underestimates RTT (e.g., median RTT is underestimated by 16.88% on T-Mobile and 13.25% on Verizon) and produces an RTT distribution that deviates from the live network. Second, CellReplay captures the non-linearity in train completion times as train size increases more accurately than Mahimahi, thanks to its light and heavy PDOs approach. The packet train experiment demonstrates CellReplay 's interpolation error when using a pre-defined train size (e.g., 75 packets for T-Mobile) for workloads ranging from 1 to 200 packets. For trains longer than 75 packets on T-Mobile and 100 packets on Verizon, CellReplay achieves lower interpolation errors than Mahimahi's single (heavy) PDO approach, reducing errors from 26.68% to 6.44% on T-Mobile and from 43.24% to 7.74% on Verizon for a train size of 200. CellReplay 's interpolation errors for longer trains highlight an opportunity for future improvement.

When running these experiments, the primary phone recorded the base delay while the secondary continuously sent packets; the results, hence, suggest that the two-phone setup had minimal interference.

5.5 Web browsing test

We evaluated CellReplay's accuracy for the web browsing by fetching both landing and internal pages (listed in Table 3) using HTTP/1.1 and HTTP/2. As before, we conducted these tests under "good" network conditions, with the UEs placed near a window. For each operator, we conducted four experiments, with each randomized experiment consisting of 10 trials. Each trial included fetching five pages using the live network and two recording sessions–one for CellReplay and the other for Mahimahi. Each test and recording session lasted for 60 s. In total, we spent approximately 9.33 h conducting these experiments.

CellReplay outperforms Mahimahi across all page load tests (Figure 11). It achieves an emulation distribution error between 1.2%-17.7%, with a mean error of 6.7%. In contrast, Mahimahi has errors ranging from 4.5% to 42.6%, with a mean error of 17.1%. On average, CellReplay reduces emulation error by 60.8% for web-browsing apps compared to Mahimahi. Page load traffic is typically dominated by small object transfers, which are sensitive to RTT and categorized as *light* traffic. Mahimahi's underestimation of RTT and overestimation of PDOs from the Saturator lead to significant errors for small flows (see §5.6). All Mahimahi's errors stem from underestimating *all* PLTs, with a mean PLT of 2637 ms compared to 2918 ms in real networks. Meanwhile, CellReplay accurately captures the network RTT and provides a better representation of real available bandwidth for these transfers, although some error still persists.

Below, we examine two dimensions to highlight CellReplay's edge over Mahimahi.

Across different operators. CellReplay maintains low mean errors for both operators: 6.4% on T-Mobile and 7.1% on Verizon. Mahimahi has a mean error of 13.2% on T-Mobile and an even higher 21% on Verizon. Mahimahi's poor performance on Verizon is expected: Verizon tends to assign small bandwidth for small file transfers (see §5.6), and page loads primarily involve fetching small objects.

Across different protocols. CellReplay performs well on both HTTP/1.1 and HTTP/2, with mean errors of 5.8% and 7.7%, respectively In contrast, Mahimahi shows poorer accuracy, with a mean error of 12.6% on HTTP/1.1 and an even higher 21.6% on HTTP/2. The multiplexing behav-

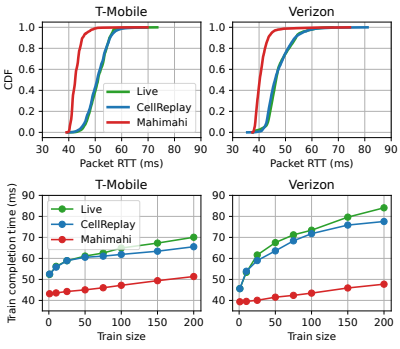

Figure 10: *The CDF of RTTs (above) and mean TCTs (below) from the packet RTT and packet train tests, respectively, run on both live network and emulations.*

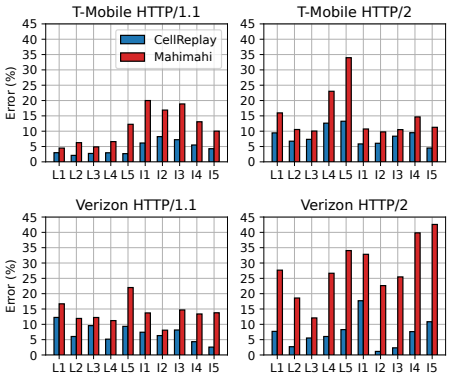

Figure 11: *Emulation distribution error across different web-page load tests with HTTP/1.1 and HTTP/2.*

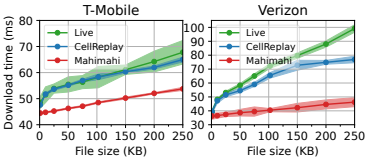

Figure 12: *Mean small file download times along with its 95% CI.*

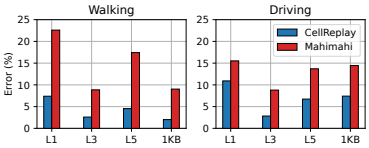

Figure 13: *Emulation distribution error of three web PLTs and 1KB file download time under mobility.*

ior of HTTP/2 may lead to a more complex traffic pattern compared to HTTP/1.1, leading to more frequent medium-sized flows. As a result, CellReplay often uses an interpolated PDO, increasing the error. For Mahimahi, the issue is even more pronounced, as it always applies the heavy rate, significantly underestimating flow completion times. Consequently, both methods experience higher errors for HTTP/2 than for HTTP/1.1.

5.6 Random file downloads test

To further evaluate CellReplay's accuracy, we conducted randomized file download tests with small-sized files (1 KB to 250 KB) and medium-sized files (1 MB and 10 MB) on both T-Mobile and Verizon. Unlike the web-page loads, download tests are not affected by non-network-related computations (e.g., JavaScript parsing). Additionally, unlike the packet train test, which sends fixed train sizes over time, the download test is fully random: the client selects each file randomly from a predefined list. This live experiment consisted of 20 randomized trials, each including: two test workloads (small and medium file downloads) and two recording sessions (Mahimahi and CellReplay). Each test and recording session ran for 60 s, resulting in a total experiment duration of 80 min per network operator. All tests were conducted under "good" network conditions.

Small-sized files. Figure 12 shows the file download times for sizes between 1 KB and 250 KB. Consistent with the observation in §5.4, download times do not conform to a straight line. Mahimahi significantly underestimates (mean) download times, with errors ranging from 8.4% to 20.7% on T-Mobile and 7.9% to 49% on Verizon. CellReplay manages to capture and emulate the non-uniform bandwidth availability with its light and heavy PDOs, resulting in significantly lower mean download time errors: 0.5%-3.5% on T-Mobile and 0.2%-22.4% on Verizon. CellReplay 's error increases with larger file sizes (e.g., 250 KB on Verizon) as it must interpolate once packet sequence lengths exceed a certain threshold.

Medium-sized files. CellReplay achieves a mean distribution error of 9.14% for 1 MB downloads and 6.54% for 10 MB downloads across both providers. In comparison, Mahimahi produces significantly higher errors of 23.35% and 17.06%, respectively, for the same file sizes. Surprisingly, Mahimahi's error increases further for 10 MB files, despite expectations that large file transfers would be dominated by heavy PDOs (i.e., the Saturator rate). We suspect that Mahimahi's inaccuracy stems from a combination of base RTT underestimation and available bandwidth overestimation. Refer to §E.3 for the full results, including mean file download times for 1 MB and 10 MB files and their respective distribution emulation errors.

5.7 Interpolation effectiveness

We evaluated the impact of CellReplay's PDO interpolation on emulation accuracy by comparing it to two variants: CellReplay with only light PDOs (CellReplay-light) and CellReplay with only heavy PDOs (CellReplay-heavy) for web page loading and file downloads. CellReplay-heavy resembles Mahimahi but incorporates variable base delay and delay compensation based on packet size. CellReplay-light does not transition to heavy PDOs when the light PDOs end; instead, it restarts from the beginning. We used T-Mobile and Verizon traces, as in §5.5 and §5.6, and reported the average error across both operators.

Figure 14 presents the results. For web browsing, CellReplay-light performs similarly to CellReplay with interpolation (i.e, our CellReplay) and beats CellReplay-heavy, as web browsing is a mostly light workload. For the 1 KB download, all three versions perform similarly since RTT dominates performance and bandwidth is less critical. As the workload increases to 10 KB, 100 KB, and 1 MB, bandwidth becomes a more significant component of download time, but CellReplay-heavy's emulation of bandwidth is inaccurate in this regime, leading it to have higher errors. However, at 10 MB, CellReplay-heavy's error decreases as the workload starts to resemble the Saturator. Meanwhile, CellReplay-light excels for smaller downloads (10 KB and 100 KB) but struggles with larger files (1 MB and 10 MB). This suggests that

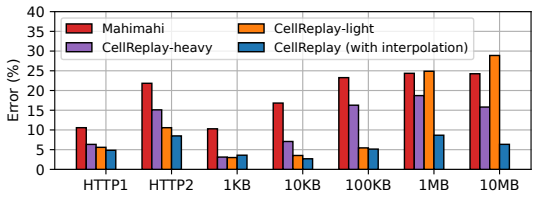

Figure 14: *Emulation distribution error of CellReplay with and without light and heavy PDOs interpolation.*

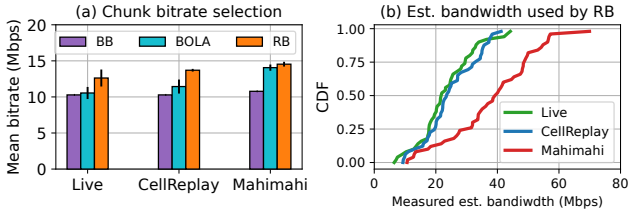

Figure 15: *(a) Mean ABR bitrate selection result. Mahimahi shows positive bias to BOLA. (b) Reported estimated bandwidth from RB.*

neither light nor heavy PDOs alone can accurately emulate the characteristics of the wireless channel.

Notably, the variable base delay and delay compensation in CellReplay-heavy reduce error to 11.67%, compared to Mahimahi's 18.77%. The error is further reduced by incorporating PDO interpolation, as in our full CellReplay system, bringing the error down to 5.68%. These results confirm that interpolating between light and heavy PDOs significantly improves emulation accuracy.

5.8 Mobility and other network conditions

We also evaluated CellReplay's accuracy under low and moderate mobility. For low mobility, a user walked through an office corridor in a loop while carrying the UE (connected to Verizon). For moderate mobility, the user drove around a university campus in a loop with the UE (connected to T-Mobile). We followed a fixed path while walking or driving in a loop to ensure consistent comparisons across trials. On average, a loop took 75 s while walking and 220 s while driving.

To reduce the number of tests, we performed web page load tests using only three HTTP/1.1 landing pages – L1, L3, and L5, which represent small, medium, and large web pages (§5.2), respectively. We also tested repeated 1 KB file downloads. To minimize variance, we limited each trial to two live tests and two recordings. We conducted two separate experiments: the first, with 1 KB file download and L3, and the second, with L1 and L5. We conducted 10 trials for `walking` experiments and 5 trials for `driving` experiments. Calibration was performed only once at the starting point. In total, we spent 1.67 h walking and 2.45 h driving around the loop.

Figure 13 shows the emulation distribution error for CellReplay and Mahimahi. Network conditions are more variable under `driving`, which may also introduce packet drop, a factor that CellReplay does not capture[4]. We indeed confirmed that `driving` triggered at least two handovers[5], and a few packets were dropped during certain periods of recording. Consequently, CellReplay's accuracy suffers more under `driving` than `walking`. However, despite this limitations, CellReplay still provides a noticeable improvement (1.8 times) over Mahimahi in both mobility scenarios. This improvement stems from CellReplay's ability to capture more performance variability than Mahimahi, as indicated by the shape of the CDF curve, which is closer to the live network's curve compared to Mahimahi. Refer to §E.2 for the CDF curve for 1KB download and L3 page load times.

Additionally, we tested CellReplay in a basement and a crowded library. In both conditions, CellReplay produced significantly lower error compared to Mahimahi, with an emulation distribution error of 5.74% (vs. 15.22%) in the basement and 8.47% (vs. 22.51%) in the crowded library. Refer to E.1 for more details.

5.9 Use case: evaluating ABR algorithms

Finally, we demonstrate a common application for record-and-replay emulation: evaluating ABR algorithms for 4K video streaming. ABR algorithms are reactive, meaning their bitrate selection for video chunk downloads can be influenced directly (rate-based) or indirectly (buffer-based) by observed network performance. Thus, accurately emulating network conditions is crucial to avoid bias in algorithm evaluation.

We compared three ABR algorithms[6] from [4] running on Verizon 5G under "good" network conditions using CellReplay and Mahimahi emulation: (1) Buffer-based (BB) and (2) BOLA, which make bitrate decisions based on buffer occupancy, and (3) Rate-based (RB), which estimates throughput from past chunk download times to select the next bitrate. Given the high download bandwidth reported by Saturator (270 Mbps), all three algorithms eventually select the highest bitrate (17 Mbps) and do not experience rebuffering. However, their startup phase [17] behavior differs, so we focused on bitrate selection for the first 10 chunks as our QoE metric. We conducted 10 randomized trials, each with three test workloads (streaming video using three ABRs) and two recording sessions (Mahimahi and CellReplay). Each test and recording session lasted for 30 s.

Figure 15a presents the mean bitrate results. As expected, Mahimahi reports a higher bitrate than Live-5G across all three ABRs, with an average overestimation of 17.73%, compared to 5.89% on CellReplay. This aligns with our findings that Mahimahi tends to overestimate network performance, leading to inflated application performance. But, more importantly, this also affects protocol evaluation. Mahimahi's

[4]This refers to the drop in IP packets. CellReplay can still capture the effects of the handover process through the increase in the base latency and PDO blackout and emulate it accordingly.

[5]There were a brief period (< 1 second) when the two devices were connected to different base stations due to the handovers were not done at the same time.

[6]This setup also includes MPC [44] and Pensieve [20], but these were not tested, as MPC requires modifying the hardcoded MPC table, and Pensieve requires retraining.

results suggest that RB and BOLA are the best protocols, with BOLA significantly outperforming BB by 30.43%. However, in reality in this environment, BOLA performs significantly worse than RB and is similar to BB. CellReplay 's results are much more aligned with the live network. This discrepancy is largely due to Mahimahi's overestimation of available bandwidth, particularly for smaller initial chunks, causing ABRs to quickly converge to the highest bitrate. In Figure 15b, we present the measured bandwidth estimation from RB, which shows that Mahimahi overestimates bandwidth by 44.38% in the median, compared to 7.96% on CellReplay. Unlike Mahimahi, CellReplay does not suffer from this bias and provides more accurate relative performance of ABRs due to its dual light and heavy rate approach.

6 Discussion and future work

We discuss CellReplay's use cases, limitations, and plans for future improvements.

Use cases. As shown in §5.9, CellReplay can be used to evaluate new applications and protocols on cellular networks and provide more accurate emulation of real network performance compared to the state-of-the-art approach. CellReplay is superior for latency-sensitive applications, as it can emulate base delay variability, and applications with variable flow sizes, as it can emulate the bandwidth-workload dependency. Adaptive applications (e.g., ABR) that react to network measurement will also receive more accurate performance results with CellReplay.

We also provide traces that researchers and developers can use for testing on CellReplay. While recording traces with CellReplay requires a bit more effort than Mahimahi due to the use of two phones, this is a minor issue, as once a diverse set of traces is recorded, users can easily replay them without the phones (just as in Mahimahi). Since CellReplay's implementation is based on Mahimahi's shell, unmodified applications can easily use CellReplay emulated interface.

Inaccuracies in CellReplay. While we have made significant progress in faithfully replaying cellular performance, CellReplay involves several simplifications and assumptions: (1) CellReplay does not record and replay random packet losses (although it drops packets when the queue overflows and can be manually configured for a set random drop rate). We notice, however, that cellular links under stationary conditions are robust to random packet drops (e.g., due to packet corruption) due to link-layer retransmission [22]. However, packet drops are more frequent during handovers in mobility [15]. (2) CellReplay uses fixed calibration parameters before each recording session. A more adaptive selection of parameters could help when network conditions change during recording. (3) CellReplay's two-phone setup has some weaknesses. Under mobility, both phones may connect to different base stations and report different performances. Moreover, although we did not observe major interference, greater interference may occur with other providers and conditions. In the future, we will be able to use a single phone with Dual-SIM Dual-Active (DSDA) modem [1] for recording, as DSDA allows simultaneous traffic transmission across two SIMs. Each of these areas represents an opportunity for future improvement. We note, however, that our evaluation results account for the errors caused by these inaccuracies.

Improving CellReplay interpolation accuracy. A straightforward approach is to gather additional data points for interpolation. However, since we need to record data simultaneously (e.g., while walking or driving), we are limited to running only a few workloads with a few phones. Another viable approach is to leverage ML to model complex, workload-dependent network performance and providers' resource allocation policies. We can train an ML model based on recorded workload and performance traces to predict network performance (e.g., PDOs) for a given test workload. However, this approach may require extensive data collection to capture RAN scheduling behavior, increasing the recording effort and making it time-consuming.

Adding more cellular network specific features. CellReplay could be improved by explicitly emulating cellular network-specific features, especially those that affect application performance. These include radio resource control (RRC) delays, handover, and other relevant factors.

Other limitations. CellReplay probes UDP traffic to record network traces, meaning it cannot capture the effects of network discrimination based on IP protocol types, such as from TCP middlebox intervention [8].

7 Conclusion

This paper exposes the difficulty of accurate record-and-replay emulation and presents CellReplay, which more faithfully captures real-world cellular network performance characteristics. CellReplay's approach of dual-workload recording and interpolated replay provides the community with a more accurate platform for evaluating research in cellular environments. We also hope this work inspires the community to explore future designs that can make record-and-replay emulation even more faithful to live deployments.

Acknowledgements: We sincerely thank our shepherd, Kyle Jamieson, and the anonymous reviewers for their valuable suggestions. We also thank Keith Winstein for helpful discussions on Mahimahi and CellSim. Additionally, we thank Qinjun Jiang, Sam Yuan, and Pradnyan Khodke, who helped drive the car while the author conducted experiments. This project was supported by gifts from T-Mobile and Cisco, and a grant from the IBM-Illinois Discovery Accelerator Institute.

A Calibration details

A.1 Inferring $comp()$: derivation

We examine the impact of packet size on RTT by sending packets with sizes sampled uniformly at random from {100, 200, ..., 1400} bytes every 50 ms to a receiver that replies to each with a 100-byte ACK. After running for a configurable time (5 minutes for our case), we calculated the mean RTT for each packet size x, denoted as μ_x. The compensation delay for a packet size s, or $comp(s)$, is computed as follows. If $s < 100$, $comp(s) = \mu_{100} - \mu_{1400}$. Otherwise, $comp(s) = (1-\alpha)\mu_i + \alpha\mu_j - \mu_{1400}$ where i and j are the tested packet sizes immediately less than and greater than s, respectively. The parameter α is set to linearly interpolate between the two observed means, i.e., $\alpha = (s-i)/(j-i)$. The compensation is always relative to 1400-byte packets because that is the size used to measure base RTT. This procedure is repeated separately for uplink and downlink measurements, with sender and receiver roles swapped.

A.2 Inferring F: derivation

Assume that internally, the bottleneck link remains in its heavy-workload state while it has queued packets to send, and then once it remains idle for some time F, it returns to the light-workload state. With the gap of G_{min}, this state change is just barely reached. Thus, we have $S + G_{min} \approx Q + F$, where S is the time the sender takes to send the train, G_{min} is the time it waits before beginning the next train, and Q is the time for the link to entirely clear the packet train out of its queue. Since S and G_{min} are both timed in user space, S is close to zero. Furthermore, because we have assumed the link of interest is the bottleneck, Q is observable at the receiver as the time between receiving the first and last packets of the train, i.e., $r_{last}(G_{min})$. Thus, we can estimate $F = G_{min} - r_{last}(G_{min})$. In Figure 8b, the G_{min} is 30 ms, and its $r_{last}(g_{min})$ is 23.23 ms. Thus, we compute $F = 6.77$ ms (and round it to 7 ms when setting the parameter).

A.3 Inferring B.

We use a classical max-min approach [11] to infer the bottleneck buffer size using the difference between the minimum and maximum RTT of packets under heavy load. Specifically, we run iperf and monitor it with tcpdump. The buffer size is calculated as $(RTT_{max} - RTT_{min}) \cdot C$, where C is the observed link capacity [10].

B CellReplay implementation

CellReplay's record client is implemented in Java to ease porting into Android. Meanwhile, the record server is implemented in Python 3. The client accepts workload configurations as user inputs, which are determined from the automated calibration performed separately. These configurations are then sent to the CellReplay server. For packet train workloads, the user must input: the number of packets per uplink and downlink train, and the gap between trains. Saturator workload requires the maximum upload and download bandwidth, which can be determined using other bandwidth probing tools (e.g., speedtest.com or iperf). Both client and server send 1400-byte UDP packets via a socket.

CellReplay's replay is built on top of the Mahimahi shell, extending all of Mahimahi's core functionality. This includes

the ability to run unmodified applications, or the option to nest the shell with another Mahimahi shell, such as the HTTP ReplayShell. The CellReplay shell accepts the base delay, light PDO trace, and heavy PDO trace as inputs. Similar to the Mahimahi network emulator shell, CellReplay controls a virtual network device (TUN) and captures all IP datagrams from an unmodified application running inside the shell. It then delays each packet before sending it to another interface, such as loopback or Ethernet.

C Experimental conditions

The environments used for evaluation are listed in Table 2.

E More evaluation results

E.1 Non-ideal network conditions

We evaluated CellReplay's accuracy under two challenging network conditions. In this first condition, labeled as '`stationary-weak`', UEs connected to T-Mobile were placed in a windowless basement inside a building. In the second condition, labeled as '`stationary-crowded`', we placed the UEs (connected to Verizon) in a library during crowded or rush hours. Both web-page loads and file downloads were tested under these conditions. To reduce the number of tests and minimize variance, we only selected pages corresponding

to the 10^{th}, 50^{th}, and 90^{th} percentiles of the HTTP/1.1 landing pages. We tested random file downloads with sizes ranging from 1 KB to 10 MB. The experiment was split into two parts: one for web-page loads and the other for file downloads. Each part consisted of 10 randomized trials. In the first part, each trial included loading three pages and two record sessions, while the second part had one random file download test and two record sessions per trial. Every test and record session lasted 60 s. The total experiment time under each network condition was 80 minutes.

Per Figure 17, across the two network conditions and

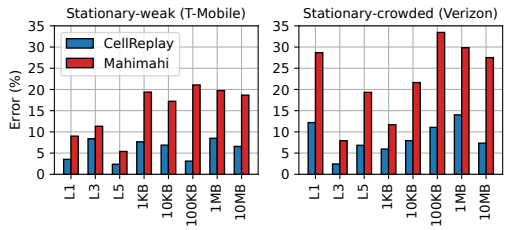

Figure 17: *The web PLT and file download emulation distribution error when testing under non-ideal stationary cases.*

Table 4: *Mean file download time (in ms) of medium-sized files with its emulation distribution error.*

		1MB	***10MB***
T-Mobile	Live	142.52	1056
	CellReplay	135.88 (7.82%)	978.18 (8.19%)
	Mahimahi	117.68 (20.17%)	847.45 (20.44%)
Verizon	Live	155.18	1069.25
	CellReplay	135.68 (10.46%)	974.98 (4.88%)
	Mahimahi	106.63 (26.5%)	762.3 (23.67%)

providers, CellReplay has an average distribution error of 5.96% for web-page loads and 7.9% for file downloads. Mahimahi, in contrast, has mean distribution errors of 13.63% and 22.02% for the same applications, respectively. Even under challenging conditions (`stationary-weak` and `stationary-crowded`), CellReplay still offers a respectable error rate and outperforms Mahimahi.

E.2 Experiments under mobility

Figure 16 demonstrates CellReplay's ability to capture application performance under mobility scenarios more accurately than Mahimahi.

E.3 Medium-sized file download test

Table 4 shows the mean file download time alongside its distribution emulation error for CellReplay and Mahimahi, compared to the live networks.

F Ethics

We note that CellReplay cannot be used to collect other users' packets; it only collects traces of its own user. Moreover, traces collected by CellReplay do not contain any private information. Hence, we believe our work does not raise any ethical concerns.

Large Network UWB Localization: Algorithms and Implementation

Abstract

Localization of networked nodes is an essential problem in emerging applications, including first-responder navigation, automated manufacturing lines, vehicular and drone navigation, asset tracking, Internet of Things, and 5G communication networks. In this paper, we present *Locate3D*, a novel system for peer-to-peer node localization and orientation estimation in large networks. Unlike traditional range-only methods, *Locate3D* introduces angle-of-arrival (AoA) data as an added network topology constraint. The system solves three key challenges: it uses angles to reduce the number of measurements required by 4× and jointly uses range and angle data for location estimation. We develop a spanning-tree approach for fast location updates, and to ensure the output graphs are rigid and uniquely realizable, even in occluded or weakly connected areas. *Locate3D* cuts down latency by up to 75% without compromising accuracy, surpassing standard range-only solutions. It has a 0.86 meter median localization error for building-scale multi-floor networks (32 nodes, 0 anchors) and 12.09 meters for large-scale networks (100,000 nodes, 15 anchors).

1 Introduction

A swarm of connected nodes is the underlying architecture for many emerging applications. Miniaturized sensing modules are scattered like seeds [37, 79] or carried by insects [7, 8, 38] to scale a vast region for fine-grained sensor networks toward border protection [10], animal migration tracking [44], or precision agriculture [23, 24, 81]. Flocks of drones can localize each other to fly in formation for charting inaccessible regions [22, 34, 71] or for airshows [2]. A smart network of tags can enable city-scale tracking of deliveries or missing objects in real-time [52]. Future of the cellular [21, 68] and vehicular networks [4] can pave the path toward autonomy [86, 95] and road safety [90]. Localization of the nodes in such large networks is an essential requirement and at the same time a challenging problem when the number of nodes is large. In this paper, we present *Locate3D*, a system that is grounded on both theoretical and practical foundations, providing a reliable framework for fast peer-to-peer localization as well as orientation of nodes on a large network.

Multidimensional scaling (MDS) has been the essence of nearly all large-scale localization algorithms for wireless networks. The primary reason MDS is adapted so widely is its ability to reconstruct the relative map of the network nodes with little infrastructural support, even in the form of the anchor nodes with known locations. MDS-based algorithms are fundamentally centralized ranging-based systems that consider inter-node distances in the Euclidean space to optimize for sensor locations. It, however, suited the capacity of the mobile nodes that can use the time of flight of the signal or RSSI-based model to estimate ranges without additional hardware requirements or computational complexity. However, recent mobile nodes have evolved not only to accurately sense the ranges but are also equipped with multi-dimensional antenna arrays to estimate reliable angles of the nodes. For instance, around 20 years after being released for commercial applications in 2002 [19], off-the-shelf UWB sensors can now sense the angle of the received signal [65, 66]. Unfortunately, the entire class of the MDS-based network localization algorithms can not take advantage of this new-found capability of the mobile nodes. Intuitively the angle information of the peer nodes can serve as additional constraints of the network topology leading to faster convergence to the location estimation. Moreover, the range and angles are estimated simultaneously per exchange of signals between nodes without incurring additional measurement latency. This convenient information is wasted as the MDS objective function can not jointly optimize on the Euclidean distance and angle plane. We develop a new network localization algorithm with a redefined objective function to include range and angle together for optimization to bridge this gap.

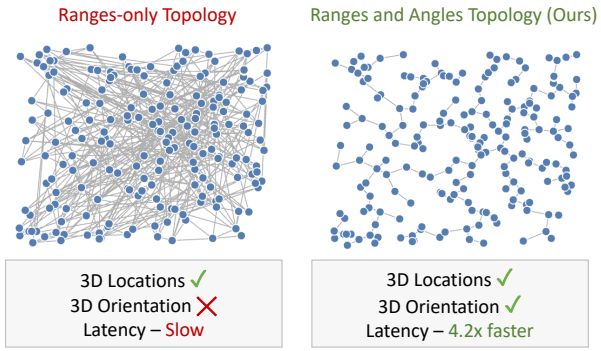

Figure 1: *Locate3D*'s approach to include both angle and edge constraints for faster and efficient localization.

The scalability of a network localization solution depends on several practical factors beyond the correctness of the theoretical formulations. The level of dependency on the infrastructure is the most crucial of them. In addition, a dynamic topology of mobile nodes requires short update latency of location estimations. Like any peer-to-peer localization system, *Locate3D* requires at least four anchor nodes for the unambiguous global 3D location of the nodes. However, the relative locations of the entire topology are correct with no assumption on the anchors. We enable our algorithms to incorporate any number of available anchor nodes and other infrastructural opportunities to create virtual anchors that enhance overall localization accuracy. In the proposed system, the joint range and angle-based optimization reduce the measurement and initial topology estimation latency, then a spanning-tree-based optimal edge selection expedites updates on locations after initial estimation, and finally, a graph rigidity-based solution makes the estimation robust to local occlusions or poor peer-to-peer connectivity.

A class of solutions for network localization resort to multimodal data to improve accuracy and reduce the update latency of the system. While effective in a small number of nodes and within restricted environmental conditions, the multimodality assumption limits the scalability of the system. It is infeasible to maintain homogeneous data quality with thousands of nodes spread across a large geographical region. For instance, some recent papers [51] use Visual Inertial Odometry (VIO) - a camera-based solution to track orientation - to improve localization accuracy. We argue that an unimodal solution is ideal for large networks in terms of consistency and ease of practical deployment and maintenance. It makes our solution equally applicable to the networks of resource-constrained low-power nodes. The core localization algorithm is, however, applicable to any modality that can measure the peer-to-peer range and relative angles, and naturally, the location accuracy is defined by the accuracy of the measurements. For instantiating the algorithm in a prototype and realistic large-scale simulations, we consider off-the-shelf Ultra-WideBand (UWB) wireless sensing nodes.

This paper strives to improve the accuracy of 3D localization of UWB-enabled nodes on a large single-modality network as shown in Figure 1. To this end, we have made the following three specific contributions at the current stage of this project:

- Developed a novel 3D network localization algorithm that jointly incorporates range and angle information for topology estimation. This algorithm achieves a 75% latency improvement and a median localization accuracy of 12.09 meters for a 100,000-node network spanning several kilometers, using only 15 static anchors. In a 32-node, three-floor building-scale experiment, the algorithm demonstrates a localization accuracy of 0.86 meters.
- Designed a system with a supporting algorithm that addresses challenges of occlusions and limited sensor field of view. The system includes an optimal spanning tree estimation algorithm and a decomposition technique that segments non-rigid graphs into smaller rigid subgraphs, considering both range and angle constraints.
- Implemented a working prototype with UWB-enabled nodes and evaluated its performance in real-world scenarios, including room-scale and multi-floor building experiments. Demonstrated the system's scalability through a city-scale simulation using real-world UWB measurement traces.

2 System Design

Our system, *Locate3D*, uses pair-wise Ultra-Wideband (UWB) RF measurements, specifically range and angle-of-arrival (AoA) information, to determine the precise 3D positions of interconnected nodes in relation to one another. The system is designed using four key components:

Joint range-angle localization: We develop an optimization method that uses range and angle measurements as constraints to build a network of localized nodes. Incorporating angles ensures an accurate location estimation with fewer number of edges compared to a range-only method, effectively reducing the latency up to 4.2×.
Reference frame transformation: Each node's angle measurement is a composite value of both the relative orientation (determined by the antenna angle with respect to the peer's antenna) and the AoA. *Locate3D* efficiently decomposes this combined measurement to transform all node axes to a common frame of reference.
Scaling to large networks: We develop an edge selection strategy that ensures the formulation of the optimal spanning tree, facilitating the interconnection of large topologies. Large networks often contain flexible or unconstrained edges, which can result in isolated but structurally rigid subgraphs. We aim to identify and resolve these subgraphs separately.
Opportunistic integration with infrastructure: *Locate3D* can leverage any pre-existing infrastructure, incorporating it as anchor points to refine localization accuracy. We further extend our system's capability by introducing the concept of virtual anchors. This mechanism temporarily designates specific mobile nodes as anchors and adjusts edge weights, disseminating the accuracy throughout the network. Below, we discuss the individual algorithmic contributions in detail.

2.1 Joint Range-Angle Localization

We formulate the localization problem as an optimization problem that aims to minimize the difference between measured pairwise distances and the distances corresponding to the estimated coordinates. There is a plethora of work done in network localization using range measurements only.

SMACOF [15, 33], non-metric MDS etc [9, 61, 78]. Some recent works also account for missing edges [72, 73] and NLOS cases [14, 17, 82]. However, none of the works have jointly incorporated AoA information in the network.

Problem formulation: Consider a topology of N nodes (mobile devices), with unknown locations $X = [(x_1, y_1, z_1), \cdots (x_N, y_N, z_N)]$. Suppose the nodes measure the range between each other, $\hat{r_{ij}}$ where (i, j) is the pair nodes i and j in the topology. We aim to solve for X while minimizing the cost function:

$$\min_X \sum_{i,j} w_{ij}(\hat{r_{ij}} - r_{ij}(X))^2 \tag{1}$$

where, w_{ij} is the weight assigned to edge between nodes i and j and $r_{ij}(X)$ is the euclidean distance between them given by Equation 2. We set $w_{ij} = 0$ for missing edges.

$$r_{ij}(X) = \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2 + (z_i - z_j)^2} \tag{2}$$

Adding angles in the topology: Incorporating angles into the network topology offers the benefit of reducing the necessary number of edges, which subsequently decreases latency. This approach, however, is not as straightforward due to the highly non-convex and discontinuous nature of angular loss functions when simply added with the range-based loss function.
Existing works [11,50,64] which use L1 and L2 losses directly on this loss function show that the objective function has many local minima.
We can compute the angular loss using the function $f(X)$, expressed as:

$$f(X) = \left[\hat{\theta_{ij}} - \arctan\left[\frac{y_i - y_j}{x_i - x_j}\right]\right]^2 \tag{3}$$

This function encapsulates the difference between the measured angles, denoted by $\hat{\theta_{ij}}$, and the angles calculated from the estimated coordinates. The non-convex nature of $f(X)$ occurs due to the arctangent and the least square operation on angles. This results in multiple local minimums, making it highly prone to generating inaccurate topologies. The primary contributor to this issue is the restrictive interval $[-\pi/2, \pi/2]$ that the arctangent function operates in, failing to account for points in the left quadrants of the plane, thereby resulting in the same angles for coordinates (x, y) and $(-x, -y)$. To address this, we first use the 2-argument arctangent, a variant of the arctangent function that considers both x and y inputs and adjusts for the signs, hence returning angles within the interval $[-\pi, \pi]$.
Unfortunately, the transformation is not enough, as the gradient consists of non-differential making it prone to getting ensnared in local minimums. To overcome this, we apply another transformation to the loss function. We take the negative cosine of the angles, creating a smoother, continuous, and differentiable function restricted within the $[0, 1]$ range. This transformation of the new loss function, is defined as:

$$f(X) = 1 - cos(\hat{\theta_{ij}} - arctan2(y_i - y_j, x_i - x_j)) \tag{4}$$

Finally, we combine the range and angular loss functions to efficiently integrate angles in the network topology optimization formulating a joint optimization problem.

$$\min_X \left[\frac{\sum_{i,j} w^r_{ij}(\hat{r_{ij}} - r_{ij}(X))^2}{\sum_{i,j} \hat{r_{ij}}} + \sum_{i,j} w^\theta_{ij}(1 - cos(\hat{\theta_{ij}} - \theta_{ij}(X)))\right] \tag{5}$$

where, $\theta_{ij}(X) = arctan2(y_i - y_j, x_i - x_j)$. Note that we scale the range loss function with $(\sum_i \sum_j \hat{r_{ij}})$. The range loss can be much higher compared to the angular loss, which is in the range $[0, 1]$, and can dominate the overall gradient/overshadow the angular loss. Hence, we normalize the range loss function before adding the angular loss part.

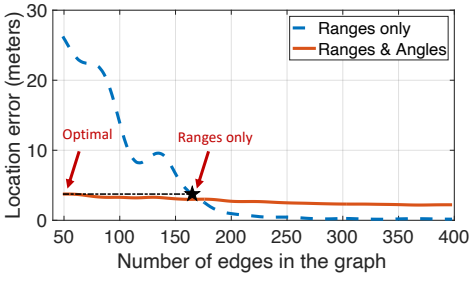

Figure 2: Comparative analysis of constraints: Incorporating angles reduces the number of edges required to attain the same level of accuracy as the "Ranges only" approach.

We conducted a simulation to evaluate the effectiveness of integrating angular measurements with distance constraints in topology optimization. The simulation involved a 50-node network within a $100m \times 100m$ area, incrementally adding edges under two constraint scenarios: ranges only, and both ranges and angles. Figure 2 shows that using only ranges required more than $3\times$ the number of edges to achieve accuracy comparable to our method combining ranges and angles. However, as more edges were added, the range-only approach eventually surpassed the range-angle method in accuracy. This can be attributed to the use of raw angles, which may include noisy measurements, and the random selection of edges rather than optimal spanning tree edges. Despite this, the method promises latency improvement over range-only methods without compromising accuracy even for a sub-optimal set of edges. We address the challenges related to noisy angle measurements and edge selection in Section 2.2, where we present techniques for filtering erroneous angles and constructing optimal spanning trees.

2.2 Scaling to Large networks

In this section, we detail how *Locate3D* can localize large node networks efficiently. To adapt to city-scale networks, we address three significant challenges linked with large networks.

• *Optimal edge selection*: Identifying the optimal edges to sample in the graph topology is vital to forming a unique, rigid structure while optimizing latency and accuracy.

• *Handling erroneous angles*: While in theory, all measured edges should have angle data, the limited FOV of commercial antenna arrays can sometimes result in inaccurate angle information. Correcting these errors is vital as they can adversely affect the graph's rigidity constraints.

• *Rigidity decomposition*: Large networks frequently consist of flexible or unconstrained edges which leads to smaller but rigid subgraphs. We need to identify and solve these subgraphs individually.

Next, we will elaborate on how *Locate3D* mitigates these challenges to scale to larger networks, introducing techniques that could reduce *Locate3D*'s latency by up to 4.2×.

2.2.1 Optimal Edge Selection

During any measurement time iteration, *Locate3D* compiles a list of optimal edges that are to be measured within the graph. These edges are chosen based on three criteria - (1) They form a rigid and unique topology, eliminating flexibility or ambiguity. (2) They are minimal in number to decrease overall latency. (3) They are feasible, meaning the edges fall within the necessary range and angle FoV.

In a topology comprising n nodes, a maximum of $n(n-1)$ edges are potentially available. However, acquiring data for each possible edge isn't viable as it is time-consuming and increases exponentially as n increases. Hence, rather than overconstraining the topology, we can create the topology with significantly fewer edges. According to Laman's condition [42], for a system that doesn't utilize angles, the minimum number of edges equals to $2n-3$ and $3n-4$ for 2D and 3D setups respectively. Interestingly, our approach necessitates only a *single* edge per node to constrain it, amounting to only $n-1$ edges in total. This efficiency stems from the fact that a single edge contains three constraints - range, azimuth angle, and elevation angle. Moreover, any random $n-1$ edges may not always be enough, as some edges could be redundant. Rather we need *well-distributed* $n-1$ edges to make the topology rigid and accurate. This renders our problem closely analogous to the *Minimum Spanning Tree problem* found in graph theory [28].

Minimum spanning tree: The minimum spanning tree (MST) is a subset of the graph's edges connecting all nodes with the least total edge weight. In our system, we utilize Kruskal's algorithm, a greedy algorithm that arranges the graph's edges in increasing order of their weights and adds edges to the MST as long as they do not form a cycle, thus guaranteeing the minimum combined edge weights.

Edge weight calculation: Our weight assignment algorithm minimizes localization error in the MST by utilizing prior knowledge of the network topology from the previous iteration, including estimated range (r) and angle (θ) values between nodes. The *area of uncertainty*, denoted as A, is calculated using sector area, $A = \pi(\alpha\sigma_r)^2\frac{\alpha\sigma_\theta}{2\pi}$, where σ_r and σ_θ are the standard deviations of the range and angle estimates, respectively, and α is a factor that scales the standard deviations based on LOS ($\alpha = 1$) or NLOS ($\alpha > 1$) conditions. The edge weight, w, is then computed as $w = A$, representing the potential location uncertainty based on the estimated range, angle, and their associated error distributions. Edges with shorter distances and smaller standard deviations inherently have a smaller area of uncertainty, and edges with available angle information are favored over those restricted to range data only. Figure 3a demonstrates that our algorithm's optimal spanning tree ranks within the top 1% of all possible spanning trees in terms of localization error. Algorithm 1 uses these estimated range and angle values to compute edge weights and form the MST, iteratively selecting the lowest-weight edges without introducing cycles. Actual range and angle measurements are taken for the selected edges once the MST is formed. During the cold start phase, when no prior knowledge is available, all nodes measure their neighbors, similar to traditional systems like [51, 94], resulting in increased latency for the first iteration. Subsequent iterations efficiently select edges for measurement by leveraging the prior knowledge of the network topology.

Algorithm 1 Optimal Edge Selection Algorithm

(a) (b)

Figure 3: (a) Histogram of localization errors for all spanning trees. (b) Reported angles by COTS UWB sensor.

2.2.2 Handling Erroneous Angles

In practical settings, nodes may not consistently measure each other's ranges or angles due to limited sensing range or angular FOV. This is due to the limited FOV of antenna arrays present in commonly used UWB modules like Decawave [65, 66] and NXP [54]. These modules typically restrict the AoA field of view (FOV) to between 90° and 120° to maintain a respectable accuracy in measured AoA, primarily because the AoA estimation algorithm, which depends on the phase difference of the incoming signal, can result in significant errors when the AoA approaches the broadside of the antenna. Figure 3b shows the reported angles by an off-the-shelf UWB sensor [54]. To address this, *Locate3D* employs two strategies for handling erroneous angles. First, we filter and flag angles as erroneous if they fall outside the range of $|FOV_{angle} - tolerance|$, effectively removing angles close to the broadside. Second, when available, *Locate3D* tracks the rotation of each node using its inertial sensors. Utilizing this rotation data, we can determine if any two nodes are within each other's FOV and flag the angles as valid or erroneous accordingly. In scenarios where some nodes lack inertial sensors or AoA estimation capability, *Locate3D* can still perform localization using the filtered angle data from the nodes equipped with these capabilities.

2.2.3 Rigidity Decomposition

While previous sections operate under the presumption of network topology rigidity, ensuring a unique realization of topology with given constraints, this isn't always the case. Notably, the optimal spanning tree derived earlier doesn't inherently ensure rigidity. Even fully connected graphs can remain non-rigid due to absent constraints, as illustrated in Figure 4 where spanning trees lack rigidity due to missing angle constraints. To address this, we develop a rigidity-based graph decomposition technique that segments the graph into smaller *rigid subgraphs*. These subgraphs can then be solved with refined edge weights ensuring that the topology is both rigid and uniquely realizable.

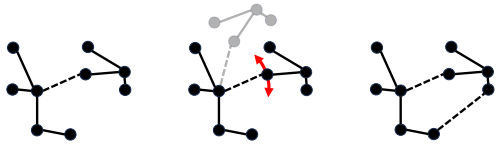

Figure 4: Different spanning trees representing rigid and non-rigid graphs. Solid lines indicate both range+angle edges, and dashed lines indicate range-only edges. (a) A connected but non-rigid graph due to missing angle information in an edge. (b) The subgraph is free to rotate. (c) Adding a range measurement makes the graph rigid.

Quantifying rigidity: The Rigidity of a topology determines whether it is possible to uniquely determine the location of all nodes in the topology with respect to other nodes. This leaves us with some trivial transformations of topology like translations and rotations in the space. The rigidity can be quantified using the degree of freedom (DoF) of the graph. Each node has three DoFs, representing movements in the x, y, and z directions. Thus, a graph with n nodes inherently has $3n$ DoFs. As constraints are imposed, the available DoFs decrease. A graph is deemed rigid if its DoFs are ≤ 3, with these residual DoFs accounting for the whole-graph translational motions.

Eigenanalysis of rigidity matrix: To identify independent and unconstrained motions that the topology can perform without violating the constraints, we perform the eigenvector analysis of the topology. To capture the constraints in a compact matrix form, we first introduce the rigidity matrix, R. Every row of R denotes a unique constraint equation, which could be a distance or angle constraint between nodes. Each column of R corresponds to the x, y and z coordinates for each node in the graph. Thus, for a graph having n nodes, the matrix expands to have $3n$ columns.
Each entry r_{ij} in this matrix is determined by the partial derivatives of the constraint equations 2 and 3, as given by:

$$r_{ij} = \begin{cases} \frac{\partial d_{ij}}{\partial x_m} \\ \frac{\partial \theta_{ij}}{\partial y_m} \\ 0 \end{cases} \begin{array}{l} \text{if edge } ij \text{ is a distance constraint} \\ \text{if edge } ij \text{ is an angle constraint} \\ \text{otherwise} \end{array}$$

$$R = \begin{bmatrix} \frac{\partial d_{1,2}}{\partial x_1} & \frac{\partial d_{1,2}}{\partial y_1} & \cdots & \frac{\partial d_{1,2}}{\partial x_n} & \frac{\partial d_{1,2}}{\partial y_n} \\ \frac{\partial d_{2,3}}{\partial x_1} & \frac{\partial d_{2,3}}{\partial y_1} & \cdots & \frac{\partial d_{2,3}}{\partial x_n} & \frac{\partial d_{2,3}}{\partial y_n} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \frac{\partial \theta_{1,2}}{\partial x_1} & \frac{\partial \theta_{1,2}}{\partial y_1} & \cdots & \frac{\partial \theta_{1,2}}{\partial x_n} & \frac{\partial \theta_{1,2}}{\partial y_n} \\ \frac{\partial \theta_{2,3}}{\partial x_1} & \frac{\partial \theta_{2,3}}{\partial y_1} & \cdots & \frac{\partial \theta_{2,3}}{\partial x_n} & \frac{\partial \theta_{2,3}}{\partial y_n} \\ \vdots & \vdots & \ddots & \vdots & \vdots \end{bmatrix}$$

Let $\lambda_1, \lambda_2, \ldots, \lambda_m$ be the eigenvalues of the matrix $M = RR^T$, where M is the symmetric and positive semi-definite matrix of R. Topology is uniquely rigid if the number of zero eigenvalues of M is equal to $3n-3$. A number of zero eigenvalues, or the degree of freedom, can be represented as:

$$DoF = \sum_{i=1}^{m} \delta(\lambda_i), \quad \text{where } \delta(\lambda) = \begin{cases} 1 & \text{if } |\lambda| < \varepsilon \\ 0 & \text{otherwise} \end{cases} \tag{6}$$

Here, ε is a small positive number close to zero, chosen to account for numerical inaccuracies (e.g., due to floating-point representation limits in computers). If $|\lambda_i| < \varepsilon$, it is considered a zero eigenvalue. Figure 5 illustrates the eigenvectors corresponding to the three zero eigenvalues λ_1, λ_2, and λ_3 showing the motion of each node.

Constructing subgraphs: By examining the zero eigenvalues, we gain insights into the *displacement vectors* of each node. For a fully rigid topology, these vectors maintain consistent magnitudes and directions across nodes. In contrast, non-rigid graphs display varied displacements.

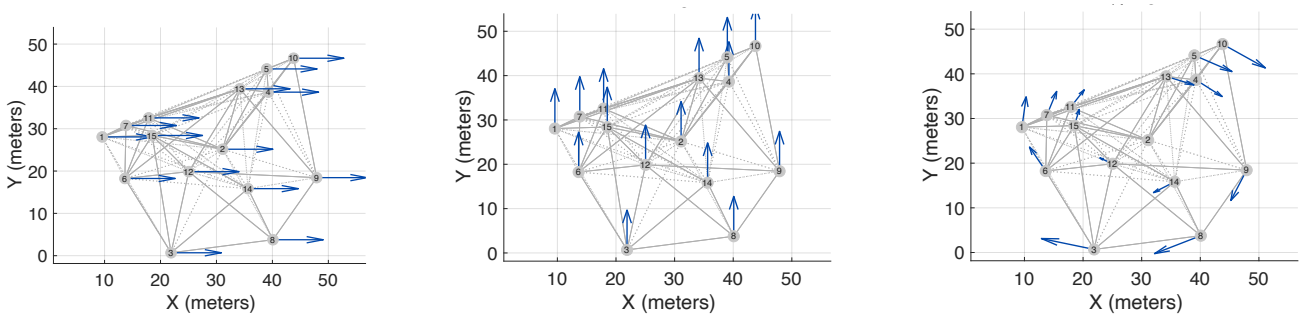

Figure 5: The displacements corresponding to zero eigenvalues represent the translational and rotational motions that the nodes can undergo without violating any constraint.

Our core intuition is that displacement vectors can be used for decomposition: nodes that have identical displacement vectors in terms of magnitude and direction inherently form a rigid subset. This means they can only undergo collective motion. To extract and group these subsets, we first reshape the eigenvector into a 3×n matrix to extract the displacement vectors of each node. Each row within this matrix signifies the displacement of a node across the three axes. Next, we identify the unique displacement vectors in this matrix where every unique vector signals the presence of a distinct "rigid subgraph" within the primary graph. By grouping the nodes corresponding to unique displacement vectors, we find the vertices belonging to the associated "rigid subgraph".

Critical edges list: Beyond recognizing rigid subgraphs, our approach also pinpoints the edges connecting the separate subgraphs. We term these edges as 'critical edges', as these edges are crucial for rigidity, serving as the connectors between independent rigid substructures. For enhanced analysis in subsequent iterations, we also prioritize these critical edges based on their latest computed locations. This prioritized list of edges underlines those edges that are more likely to come into proximity with one another, thus enhancing the overall scalability and rigidity of the graph.

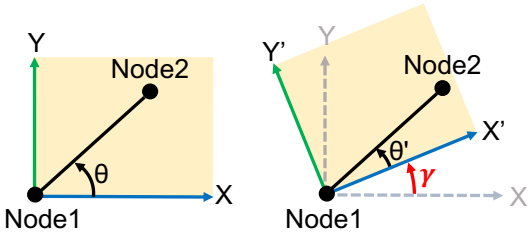

Figure 6: (a) When Node 1 is aligned with the global frame of reference, it reports that Node 2 is positioned at angle θ. (b) When Node 1 is rotated by γ relative to the global frame of reference in a 3D space, it reports a distinctly different angle θ′, for the same node.

2.3 Reference Frame Transformation

In the above section, we assume that all nodes share a common frame of reference. Here, we relax this assumption and address the challenges arising from differing local frames of reference for each node. Every node measures angles based on two factors: its relative orientation (defined by its antenna angle concerning another node's antenna) and the AoA. The challenge lies in the fact that these angle measurements are in the node's local frame of reference, which moves according to the node's orientation within a broader, global context. Consider the 2D example in Figure 6. In scenario (a), Node 1 identifies Node 2 at an angle θ. But in scenario (b), after Node 1 turns by an angle γ, it sees Node 2 at a different angle θ′. This change in reported angles is due to Node 1's rotation, even though the positions of the nodes didn't change. This issue gets complex in 3D, where nodes can rotate in any direction. Our goal is to deconstruct these angle measurements from orientation offsets and align all nodes to a singular, shared frame of reference.

2.3.1 Estimating Orientation Offsets

Every node's orientation in a 3D space is defined by a set of three rotation angles. Specifically, they depict the node's rotations about its X, Y, and Z axes and are recognized as the Roll(α), Pitch(β) and Yaw(γ) [89].

To estimate a node's orientation, we leverage a fundamental observation: When the orientations of nodes are in the same global frame, the measured azimuth AoA (θ) and elevation AoA (ϕ) are complementary, implying they obey the condition: $\theta_{ij} - \theta_{ji} = \pi$ and $\phi_{ij} = -\phi_{ji}$ (Figure 7). Using this insight, we formulate an optimization problem with the goal of estimating the rotation offsets (α, β, γ). The objective is to minimize the deviation from the above-mentioned constraints:

$$\min_{\alpha,\beta,\gamma} \sum_{i,j} (\hat{\theta}_{ij} - \hat{\theta}_{ji} - \pi) + (\hat{\phi}_{ij} + \hat{\phi}_{ji})$$

In this equation, $\hat{\theta}_{ij}$ and $\hat{\phi}_{ij}$ denote the rotated azimuth and elevation angles after the node has undergone rotation by α_i, β_i, and γ_i. Solving for this optimization provides us with the required orientation offsets to align all nodes in the system with the global frame of reference. The residual angles, $\hat{\theta}$ and $\hat{\phi}$, thus correspond to the AoAs in the global frame.

Next, we break down the steps in the optimization problem, detailing how we compute $\hat{\theta}$ and $\hat{\phi}$ through the rotation of local frames. The rotation in a 3D context can be decomposed into three unique rotations around the x, y, and z basis axes.

Step1 - Determine the unit vector based on the estimated

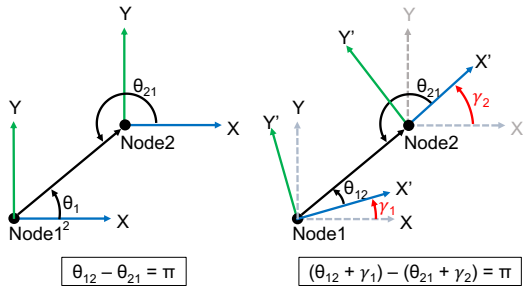

Figure 7: The relation between AoAs reported by two nodes (a) when nodes are perfectly aligned, and (b) when nodes are oriented with angle γ relative to the global frame of reference.

azimuth and elevation angles:

$$U = \begin{bmatrix} \hat{x} \\ \hat{y} \\ \hat{z} \end{bmatrix} = \begin{bmatrix} cos(\phi) * cos(\theta) \\ cos(\phi) * sin(\theta) \\ sin(\phi) \end{bmatrix}$$

Step2 - Apply the rotation matrix [76] to adjust the unit vector using the computed roll, pitch, and yaw angles (α, β, and γ). This results in a new unit vector, V, which reflects the node's orientation post-adjustment.

$$V = R_z(\gamma)R_y(\beta)R_x(\alpha)U$$

$$V = \begin{bmatrix} \cos\gamma & -\sin\gamma & 0 \\ \sin\gamma & -\cos\gamma & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \cos\beta & 0 & \sin\beta \\ 0 & 1 & 0 \\ -\sin\beta & 0 & \cos\beta \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\alpha & -\sin\alpha \\ 0 & \sin\alpha & -\cos\alpha \end{bmatrix} U$$

Step3 - Compute the azimuth and elevation angles from the rotated vector V to obtain the corrected AoA measurements.

$$\begin{bmatrix} \hat{\theta} \\ \hat{\phi} \end{bmatrix} = \begin{bmatrix} tan^{-1}(y/z) \\ tan^{-1}(z/\sqrt{x^2+y^2+z^2}) \end{bmatrix}$$

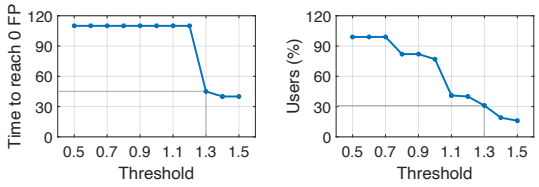
If we already have roll and pitch data from another sensor (e.g., IMU), the error function can become simpler. Instead of considering all three rotation angles, we can solve for yaw (γ). When the optimization is initiated with $\alpha_1 = \beta_1 = \gamma_1 = 0$, the first node sets the reference frame, and thus the orientations of all subsequent nodes are calculated relative to this frame.

3 Opportunistic Anchor Integration

Locate3D is fundamentally designed to function without the necessity for anchors. However, when anchors are available in the infrastructure, *Locate3D* can seamlessly integrate them to refine location and orientation results and transition from relative to global coordinates. This capability offers an edge over range-only systems, which strictly require at least three anchors for global coordinates, which is a challenging requirement in highly mobile environments. We categorize anchors into the following two types:

(a) Static anchors: They are conventional infrastructure anchors with known locations. These anchors have higher edge weightage, which increases their likelihood of being selected in MST over mobile volatile edges. Their impact on the accuracy is evaluated in a later section with varying anchor densities.

(b) Virtual anchors: As existing infrastructure cameras are available in many applications, we explore the potential to perform accurate localization in the vicinity and assign users within the camera's field-of-view as *virtual anchors*. A virtual anchor is a user with a high-confidence location obtained by an external modality, such as an infrastructure camera. It is important to note that while cameras can provide valuable localization information, they have limitations, such as reduced accuracy in low-light conditions.



(a) Time taken (in seconds) (b) Percent of users

Figure 8: (a) Time to reach '0 False positives'. (b) Percentage of users registered for varying trajectory matching thresholds.

User registration: Our registration technique uses correlation in user trajectories to incorporate human motion dynamics, such as varying walking speeds and stationary periods. The system benefits from *heading direction*, *cosine similarity of motion*, and speed analysis. We observe a scenario where some users are equipped with our node, while others are not, all within the camera's FoV. Our primary objective is to accurately register the system users in the camera's FoV while avoiding misclassifications. To address this, we adopt a stringent approach to trajectory similarity, aiming for zero false positives (FP). As depicted in Figure 8, keeping a higher threshold for registration effectively achieves zero FPs. By windowing 45 seconds of motion data, we register approximately 30% of visible users. It is important to note that while the availability of anchors can improve the accuracy, *Locate3D* does not rely on them for operation. We evaluate the system's performance under various anchor densities, to show its adaptability to different infrastructure setups.

4 Implementation

To this end, we implement a prototype of *Locate3D* and perform experiments in room-level, building-level, and city-level scenarios.

Node prototype: We developed prototype mobile nodes of *Locate3D*, as shown in Figure 11a to evaluate the performance. Each node consists of a Raspberry Pi 3 [63] for computation, an Intel Realsense T261 [36] to collect visual inertial odometry data. We use the NXP SR150 UWB evaluation boards [54] to collect the range, azimuth, and elevation AoA data. We collect the UWB measurements at a rate of 20Hz. All the nodes are time-synced using NTP.

Software: All the prototype nodes are part of a network and communicate with each other using a UDP socket. We

collect and store the UWB range, AoA, and VIO data from all nodes using Python scripts running on Raspberry Pi. We then process all measurements offline using Matlab where our algorithms are implemented.

5 Evaluation

We evaluate *Locate3D*'s performance in three key scenarios: room-scale, building-scale, and city-scale. In each scenario, we compare *Locate3D* with state-of-the-art baselines and benchmark localization accuracy, system latency, and the impact of various conditions such as line-of-sight (LOS) and non-line-of-sight (NLOS), stationary and moving nodes, lighting conditions, and varying numbers of infrastructure anchors. To assess *Locate3D*'s performance, we have collected over 4 hours of real-world data using 32 nodes and employed a motion capture system [3] as a ground truth setup to evaluate the centimeter-level localization accuracy and sub-degree-level orientation accuracy. We compare *Locate3D* with two distinct baseline systems: an infrastructure-free system, Capella [51], that uses UWB+VIO for peer-to-peer 3D localization, and an infrastructure-dependent system, ULoc [94], that uses UWB anchors and angular information for parallel node triangulation. Additionally, we simulate a large city-scale network by stitching real-world measurements to evaluate *Locate3D*'s scalability for networks with up to 100,000 nodes.

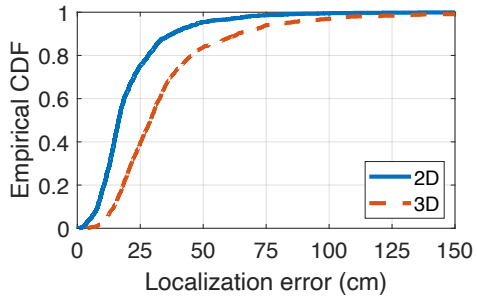


Figure 9: Room-scale evaluation: CDF of localization errors.

5.1 Localization Evaluation

5.1.1 Room-Scale Evaluation

We evaluate *Locate3D*'s performance in room-scale scenarios by conducting experiments in indoor rooms with dimensions of 6m $\times$ 8m and 4m $\times$ 20m, containing various furniture and equipment. We compare *Locate3D*'s performance with Cappella [51], a collaborative localization system that uses VIO for 3D tracking and inter-node UWB ranges to stitch individual trajectories using RBPF [80]. This evaluation involves 6 users walking naturally along random paths, emulating an AR/VR application, with additional users not participating in the system present to create a crowded and dynamic environment (Figure 11b). No anchors are used in these experiments as both *Locate3D* and Cappella are infrastructure-free. We use a Vicon motion capture system [83] as the ground truth, which provides sub-millimeter accuracy at a frame rate of 200Hz. The Vicon system consists of 12 Vantage V8 cameras mounted on the ceiling to track the ground truth locations and orientations of all nodes using active IR light and reflective markers attached to the nodes. We use 9 markers per node to ensure reliable tracking in all orientations. Figure 9 shows the CDF of the absolute localization error in 2D and 3D estimated by *Locate3D*, with median errors 18*cm* and 30*cm*, respectively, and 90th percentile errors of 38*cm* and 68*cm*.

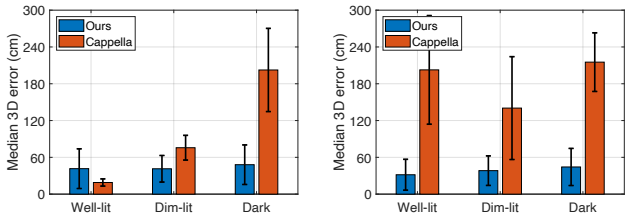

Figure 10: 3D Localization performance of *Locate3D* compared to baseline system - Cappella [51] - which uses visual odometry along with UWB. Results show performance in different lighting conditions for (a) Moving nodes and (b) Static nodes.

Effect of lighting: We evaluate *Locate3D*'s performance under varying lighting conditions to demonstrate its robustness to changes in illumination. As shown in Figure 10a, *Locate3D*'s performance remains consistent across different lighting conditions, while Cappella's performance degrades as indoor illumination decreases. The light intensity values for Well-lit, Dim-lit, and Dark conditions were 400, 150, 50 lux respectively which were controlled by analog light dimmers. This highlights *Locate3D*'s advantage of relying on RF-based peer-to-peer measurements, which are unaffected by visual conditions, in contrast to Cappella's reliance on VIO and visual features of the environment.

Effect of motion: Figure 10b shows that when nodes are static and the baseline system lacks a VIO trajectory tail, it fails to estimate 3D locations accurately. In contrast, *Locate3D* does not rely on odometry and can estimate the complete 6DOF location and orientation for all nodes, regardless of whether they are static or mobile.

5.1.2 Building-Scale Evaluation

We evaluate *Locate3D*'s performance in a multi-level building scenario using 32 nodes across multiple floors, as shown in Figure 11c, 11d. The experiments include a combination of LOS and NLOS conditions, with users walking in the building while holding nodes that capture images of calibrated AprilTags [87] placed on the walls for ground truth reference (Figure 11f). *Locate3D* achieves a median 3D localization error of 0.86 meters and an average orientation error of 4.5 degrees without using any infrastructure anchors. Figure 11e shows a snapshot of the estimated topology. To validate

(a) (b) (c) (d) (e) (f)

Figure 11: (a) Prototype built using Raspberry Pi, UWB sensor, Intel Realsense, IR markers for ground truth and a battery pack. (b) Room-scale evaluation. (c) Building-scale evaluation (d) 3D Lidar scan of the building for reference (not used in computation) (e) Snapshot of estimated locations and MST. (f) AprilTags [87] captured by nodes for ground truth (not used in computation).

the accuracy of the AprilTag-based ground truth system, we compared it against the Motion capture setup and found a 3D localization error of 0.11 meters. These results show *Locate3D*'s ability to provide accurate localization and orientation estimation in larger-scale, multi-level building environments without relying on infrastructure anchors. In section 5.2, we also do an ablation study to understand the contribution of each submodule to the system's latency and accuracy improvements.

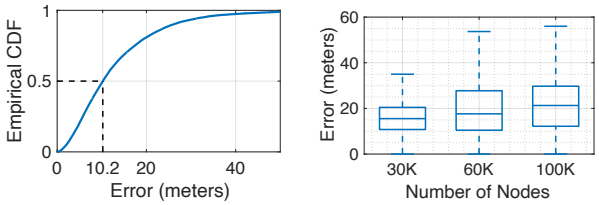

Figure 12: City-scale analysis: (a) CDF of localization errors of 30k nodes, 3800$m \times 3800m$ area, and 15 anchors. (b) Errors for 30k, 60k, and 100k nodes in 1500$m \times 1500m$ area and 1 anchor.

5.1.3 City-Scale Evaluation (Simulation)

We evaluate the performance of *Locate3D* in city-scale scenarios by simulating an environment with real-world collected data stitched in the simulation. The simulation incorporates real-world peer-to-peer measurements collected using 32 nodes in various environments, including indoor, outdoor, LOS, and NLOS scenarios. The dataset consists of 20,000 measurements covering ranges from 0.1 to 50 meters and AoA spanning the full 360 degrees from both static and mobile users. To emulate large-scale city networks with up to 100,000 nodes, we employ a data-driven approach by stitching together real-world measurements to preserve the noise properties. The simulation environment includes obstacles that mimic real-world urban settings, and the corresponding measurements are selected from the appropriate subset of the dataset (e.g., nodes 20m apart, 30° and 200° azimuth and elevation AoAs and NLOS edge) to maintain the integrity of the simulation. During the simulation process, we strictly adhere to the real-world measurements, ensuring that the nodes experience realistic noise and variations in range and AoA based on the specific distance and angle of the interaction. This enables us to evaluate *Locate3D*'s performance in large-scale networks while maintaining a strong connection to real-world conditions. Figure 12 shows the CDF of localization errors for 30k nodes using 15 anchors in a 3800$m \times 3800m$ area and the localization errors for 30k, 60k, and 100k nodes in a 1500$m \times 1500m$ area using 1 anchor (for global translation only). *Locate3D* achieves a median localization error of 12.09 meters for large-scale networks (100,000 nodes with 15 anchors) and 21 meters with 1 anchor.

We further evaluate *Locate3D* in a wide-area simulation of New York City, spanning approximately 22000$m \times 3200m$. We use 100k nodes with ground truth locations from the NYC transportation dataset [59], representing a Tuesday evening scenario. Figure 13 shows the results for configurations with 1 and 5 anchors. *Locate3D* achieved median localization errors of 82.31m and 34.19m for 1 and 5 anchors, respectively. The improved accuracy with more anchors demonstrates the system's ability to propagate location information effectively across wide-area environments.

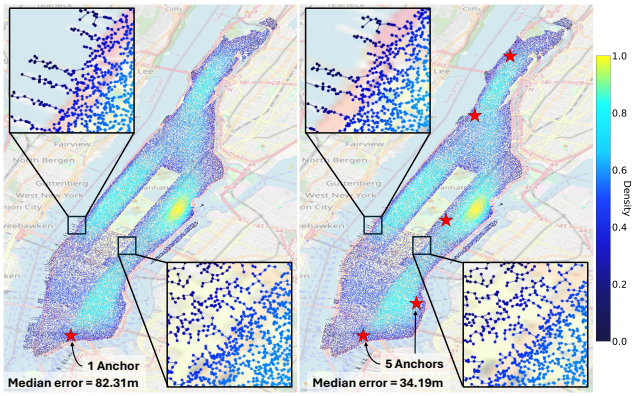

Figure 13: New York City wide-area simulation results: CDF of localization errors for 100,000 nodes using 1 (left figure) and 5 (right figure) anchors in a 22000$m \times 3200m$ area.

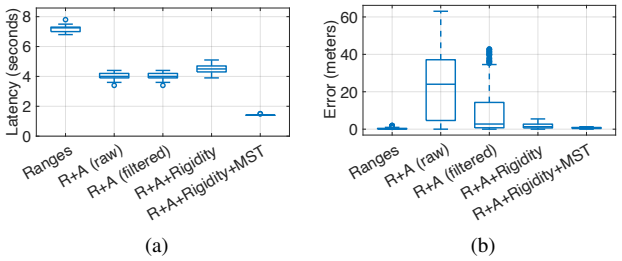
5.2 Latency Evaluation

To evaluate the effectiveness of each submodule in latency improvement, we conduct an experimental ablation study in the building-scale scenario. The results are shown in Figure 14. Starting with a baseline system that uses only range information, we observe that the introduction of

angle information (Range+Angle) significantly reduces the latency. However, the raw angle data leads to an increase in localization error due to the erroneous angles, as discussed in the section 2.2.2. To address this issue, we apply our filtering technique to fix erroneous angles which improves the accuracy while maintaining the latency reduction achieved by the introduction of angle information. The incorporation of rigidity constraints (R+A+Rigidity) further enhances the localization accuracy at a slight increase in latency compared to the filtered range and angle system. This is due to the addition of the critical edges that ensure a unique and unambiguous realization of the graph, as discussed in section 2.2.3. Finally, the optimal edge selection algorithm (R+A+MST) yields the most significant latency reduction while achieving localization accuracy comparable to the baseline system. This algorithm selects the optimal set of edges to minimize the overall latency while maintaining the graph's rigidity and uniqueness.



(a) (b)

Figure 14: Impact of submodules on (a) latency and (b) accuracy.

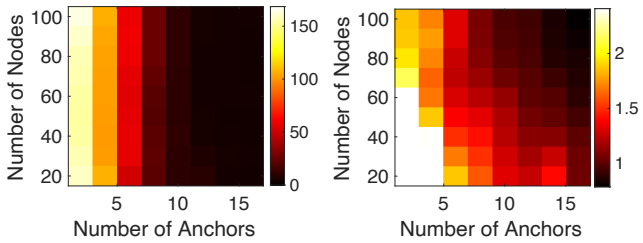
5.3 Micro-Benchmarks

5.3.1 Comparison with Infrastructure-Based Systems

To compare *Locate3D* with infrastructure-based systems, we evaluate the accuracy and scalability of *Locate3D* with a baseline infrastructure-based system ULoc [94], while varying the area, number of nodes, and number of anchors Our results show that *Locate3D* outperforms infrastructure-based systems in two key scenarios:

Sparse anchor deployments: *Locate3D*'s peer-to-peer network enables localization even when nodes are beyond the range of anchors, while ULoc fails in such cases. Figure 15 shows that both ULoc and *Locate3D* achieve meter-level errors when the number of anchors is high. However, as the number of anchors decreases, ULoc's average localization error increases due to nodes being out of range. Figure 16a demonstrates that with a fixed number of anchors and increasing area space, *Locate3D* can localize almost all nodes using its spanning tree, while the infrastructure-dependent technique loses connections to nodes making them unreachable.

NLOS edges: *Locate3D*'s edge selection algorithm prioritizes LOS measurements over NLOS, optimizing for overall noise reduction in the graph. In contrast, ULoc, being an infrastructure-based system, is constrained to using



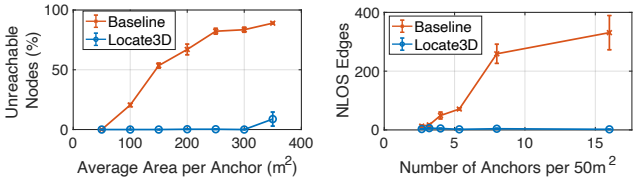
(a) Baseline (Infrastructure based) (b) *Locate3D*

Figure 15: Localization errors (in meters) for infrastructure baseline [94] and *Locate3D* for varying nodes and anchors.

anchor-to-node measurements regardless of whether they are LOS or NLOS. This limitation leads to the inclusion of noisy edges in the graph, affecting the overall localization performance. As shown in Figure 16b, *Locate3D* selectively includes LOS edges and minimizes the number of NLOS edges resulting in improved accuracy in realistic environments. By reducing the overall noise in the topology, *Locate3D* is able to provide more reliable and precise location estimates compared to ULoc, which is susceptible to errors introduced by NLOS measurements between nodes and anchors. This highlights the benefits of a peer-to-peer approach, which allows for greater flexibility in edge selection and noise reduction compared to infrastructure-based systems. However, infrastructure-based systems outperforms *Locate3D* in the following scenarios:

High anchor density and small-area experiments: As shown in Figure 15, infrastructure-based systems outperform in high anchor density cases where the error decreases due to close proximity with multiple anchors. Such small-scale scenarios with clear LOS and at least three anchors are where ULoc achieves better accuracy.

Locate3D's scope is to scale to a large number of nodes, while infrastructure-based systems are well-suited for small-scale deployments with sufficient anchor density.



(a) (b)

Figure 16: (a) Number of unreachable nodes and (b) Total number of NLOS measurements made with varying anchor area density.

5.3.2 LOS vs NLOS nodes

Figure 17(a) presents the CDF of the 2D and 3D localization errors in both line-of-sight and non-line-of-sight scenarios. In the NLOS scenario, there is a slight increase in localization error compared to the LOS scenario. This increase is primarily attributed to the higher noise levels in the received signals at the nodes due to obstructed signal paths and reflections. Specifically, in the 2D scenario, the median localization error

rises from 13*cm* in LOS to 28*cm* in NLOS. Similarly, in the 3D scenario, the median localization error increases from 31*cm* in LOS to 39*cm* in NLOS.

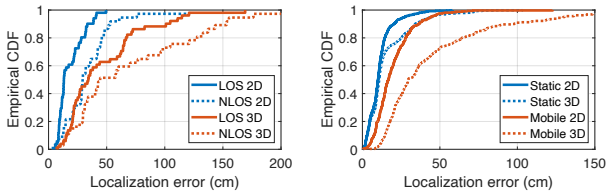


Figure 17: (a) LOS and NLOS localization errors. (b) Static vs Mobile nodes localization errors

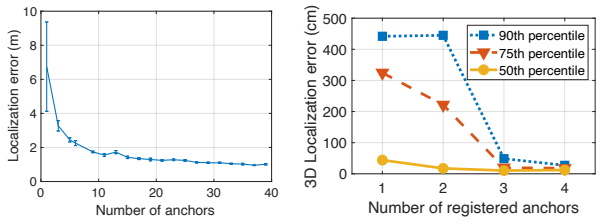
5.3.3 Static vs Mobile nodes

To assess the impact of node mobility on the performance of *Locate3D*, we conduct experiments to compare static and mobile node scenarios. Figure 17(b) presents the CDF of 2D and 3D localization errors in both static and mobile node configurations. In the mobile scenario, the system experiences a slight degradation in performance due to varying environments and node vibrations. In the 2D scenario, the median localization error increases from a low of 6*cm* in the static setup to 13*cm* in the mobile scenario. Similarly, in the 3D scenario, the median localization error rises from 6.5*cm* in the static scenario to 26*cm* in the mobile scenario.



(a) (b)

Figure 18: (a) City-scale results for a 1000 node topology simulation in a $200 \times 200 \times 50$ meter 3D space for a varying number of static anchors. (b) Room-scale localization error for real-world 20-node experiments with varying numbers of anchors registered.

5.3.4 Impact of Anchor Density

We evaluate the impact of anchor density on localization performance in both large-scale simulations and real-world room-scale experiments. While *Locate3D* does not require anchors for operation, the presence of anchors can improve absolute localization accuracy in relative global coordinates. In a large-scale simulation with 1,000 nodes distributed within a 200m $\times$ 200m $\times$ 50m 3D space, *Locate3D* achieves a localization error below 2 meters with just 5 anchors (Figure 18a). In a real-world room-scale experiment, we evaluate the localization error while varying the number of registered anchors. *Locate3D* can peg the entire topology using only two anchors by leveraging angle information alongside location estimates. Figure 18b shows that the localization error decreases as more anchors are registered, with the main source of error being the rotation of the topology when only one anchor is present.

5.3.5 Ranging and AoA Performance

The localization errors inherently depend on the raging and AoA accuracies. We report the ranging and AoA estimation performance of the UWB sensor used in our implementation. While our system can be applied to any technology, here in the implementation we have used the UWB radio to get the distance and AoA error. So in this section, we report the accuracy of the ranging and angle estimation accuracy.
Figure 19 shows the ranging and AoA performance of our node for varying distances and incoming angles. We see that there are biases in certain angles as it is likely due to multipath. But still the 90^{th} percentile error remain within $\pm 5^{\circ}$.

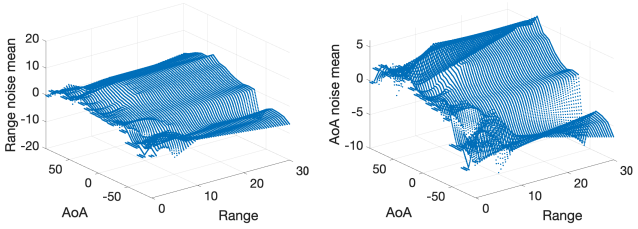


Figure 19: Ranging and AoA errors for various range-angles.

5.3.6 Orientation Estimation Accuracy

Figure 20(a) presents the CDF of the error in orientation estimation results. It is highly important for our system as these orientations play a critical role in transforming AoAs from the local frame of reference of the nodes to the global frame of reference, which is then used localization of nodes within a 3D space. Figure 20(a) shows that *Locate3D* consistently estimates accurate node's orientation with a median error of 4 degrees which is competitive with an inertial sensor.

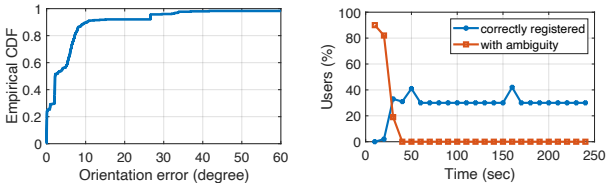

Figure 20: (a) CDF orientation errors. (b) Percent of users registered as Virtual anchors over time.

5.3.7 Virtual Anchor Registration

We evaluate the virtual anchor registration technique through a building-scale experiment with a network-connected camera. This setup included four node users and three non-participants walking within the camera's FoV, simulating typical crowd dynamics. Figure 20(b) shows the results that within the initial 40 seconds, the system registered 40% of the users as virtual anchors, while distinguishing between system users and non-participants.

6 Discussion

Scalability in real-time implementation: An extension of the proposed system with a semi-distributed approach can further improve its worst-case latency and robustness. In this case, the network is divided into sub-graphs managed by a local leader node. The leader nodes compute MSTs per sub-graphs in parallel and later aggregate to form the complete graph. This distributed architecture can offer better handling of high mobility scenarios subjected to future research.

Bootstrapping: *Locate3D*'s initial bootstrapping phase establishes the first set of measurements and constructs the initial graph without assumptions about node locations or network topology. Each node measures all neighboring nodes, building the graph incrementally based on responses. While this cold start phase naturally adds to the latency, it does not compromise localization accuracy. The duration of this phase depends on factors such as the number of nodes and application requirements. In subsequent iterations, *Locate3D* uses previous iteration information to efficiently select edges, reducing latency. While cold start is a common issue in state-of-the-art peer-to-peer localization systems, optimizing the bootstrapping process can be a direction for future work.

Applications: *Locate3D* caters to a wide range of applications requiring accurate and fast localization in infrastructure-free networks. Inspired by first responders scenarios, real-world experiments in multi-level buildings demonstrate the system's potential in emergency response scenarios. *Locate3D*'s ability to operate in GPS-denied environments and adapt to changes in network topology makes it suitable for disaster management and rescue operations. Its scalability, demonstrated through our city-scale simulations, shows its potential for smart city applications such as asset tracking, crowd monitoring, and urban planning. *Locate3D*'s framework can be easily adapted to incorporate application-specific parameters and constraints.

Advancements in angle field-of-view: Future sensor advancements, such as increased antenna counts, may enable 360° field-of-view coverage. In such cases, the spanning tree algorithm can be adapted to consider either range+angle edges or no edges, and account for varying noise distributions across different incoming angles. *Locate3D*'s framework is flexible to accommodate these advancements and generate optimal spanning trees without significant modifications.

Subgraphs without proximity for extended periods: Our critical edges technique addresses cases where subgraphs are out of vicinity for long durations. However, prolonged reliance can lead to drifting. Reinitializing the tree or cold-start can mitigate this issue. Presence of anchors in subgraphs can also provide reference points to align relative topology.

Other RF modalities: Our framework is adaptable to other modalities beyond UWB, including RF and acoustic sensors that can measure pairwise ranges and AoA [47, 48, 62, 88].

7 Related Work

Infrastructure-based systems: Motion tracking cameras (OptiTrack [1], Vicon [3]), passive markers (ARTags [41, 55], AprilTags [39, 87, 93]), and beacon-based solutions (UWB [57, 60, 75], Bluetooth [13, 43, 74], ultrasound [27, 43, 45]) are used for localization. These methods often combine ranging with odometry from IMU or VIO [16, 26, 49, 60, 69, 77, 85]. However, infrastructure-based systems are limited to prepared environments. *Locate3D* leverages peer-to-peer UWB ranges and angles, eliminating the need for infrastructure.

Infrastructure-free systems: Infrastructure-free localization determines relative positions between users without global references. This has been explored in sensor networks for stationary [56, 70] and mobile [18, 20, 53, 67] nodes, and in robotics using visual object detection [58, 84, 96] or odometry and distance measurements [6, 12, 31, 32, 46, 91, 92]. Recent research [51, 91, 92] employs visual-inertial features and UWB ranges for localization, but have limited scalability.

UWB localization: UWB-based systems have shown decimeter-level accuracy [25, 29, 30, 35, 40]. However, these systems often require a high number of infrastructure anchors, limiting their scalability. ULoc [94] uses AoA for triangulation but requires dense anchor deployments. XRLoc [5] employs a single large specialized anchor with multiple UWB nodes, focusing on small-scale, meter-level applications. SALMA [29] uses only one anchor but is limited to 2D and supports a small number of concurrent tags. In contrast, *Locate3D* is an infrastructure-free system that leverages both range and angle information for 6DoF localization. Unlike Cappella [51], which relies on VIO and UWB measurements, *Locate3D*'s performance is independent of lighting conditions. Moreover, *Locate3D* achieves localization without depending on odometry, preventing error accumulation.

8 Conclusion

This paper presents *Locate3D*, a peer-to-peer 3D localization and orientation estimation system for large networks. Our novel optimization and edge selection algorithm integrates both range and angle-of-arrival measurements for enhanced network topology estimation, demanding fewer edge measurements. As a result, *Locate3D* improves the latency by 75% without sacrificing accuracy, outperforming conventional range-only solutions.

Towards Energy Efficient 5G vRAN Servers

Anuj Kalia *Nikita Lazarev*[†] *Leyang Xue*[‡] *Xenofon Foukas* *Bozidar Radunovic* *Francis Y. Yan*[⋆]

Abstract

We study the problem of improving energy efficiency in virtualized radio access network (vRAN) servers, focusing on CPUs. Two distinct characteristics of vRAN software—strict real-time sub-millisecond deadlines and its proprietary black-box nature—preclude the use of existing general-purpose CPU energy management techniques. This paper presents RENC, a system that saves energy by adjusting CPU frequency in response to sub-second variations in cellular workloads, using the following techniques. First, despite large fluctuations in vRAN CPU load at sub-ms timescales, RENC establishes safe low-load intervals, e.g., by coupling Media Access Control (MAC) layer rate limiting with CPU frequency changes. This prevents high traffic during low-power operation, which would otherwise cause deadline misses. Second, we design techniques to compute CPU frequencies that are safe for these low-load intervals, achieved by measuring the slack in vRAN threads' deadlines using Linux eBPF hooks, or minor binary rewriting of the vRAN software. Third, we demonstrate the need to handle CPU load spikes triggered by control operations, such as new users attaching to the network. Our evaluation in a state-of-the-art vRAN testbed shows that our techniques reduces a vRAN server's CPU power consumption by up to 45% (29% server-wide).

1 Introduction

Virtualized RANs, which run the cellular radio stack on commodity servers instead of specialized hardware, are gaining adoption in modern cellular networks (e.g., 5G), owing to advantages such as a multi-vendor ecosystem, easier maintenance, and faster feature upgrades. This paper targets the energy efficiency of vRANs, focusing on the "Distributed Unit" (vDU) servers that perform real-time base station functions. Base stations are a major energy consumer: For instance, a recent report from China Mobile [49] estimates the deployment of 2.1 million 5G base stations (roughly three sectors/cells per base station) in China alone. Given today's 240-watt vRAN servers (§3.2), even a modest 1% reduction in server energy usage can translate to ∼44 million kWh/year.

Two unique attributes of vRAN software—stringent real-time deadlines and black-box nature—preclude the use of standard CPU energy saving techniques. The lower vRAN layers running in the DU have hard deadlines on the order of the sub-ms Transmission Time Interval (TTI) of the wireless protocol, which must be met for functional correctness. Conventional energy-saving techniques, e.g., OS-controlled CPU frequency scaling or deep CPU sleep states, operate at tens of milliseconds and fail to meet these deadlines, with consequences as extreme as crashes or malfunctioning of the vRAN software. As a result, today's vRAN deployments disable these optimizations and instead maintain the CPU at a consistently high frequency regardless of the traffic [45].

This paper presents RENC, an energy-saving system that dynamically adjusts the DU's CPU frequency in response to sub-second changes in cellular workloads. Our design is based on the observation that cellular networks experience low utilization during most of their operational time. This leads to significant intervals of low CPU load where there is slack in the deadlines, i.e., a large deadline fraction remains unused, and there is room to reduce CPU frequency.

The central challenge for CPU energy saving in vRANs is the high variability in CPU load at sub-ms timescales. A sequence of TTIs that need few CPU cycles may be followed by a TTI with the maximum load, e.g., due to a traffic burst or a control plane operation. If the system is in low-power mode at this time, the DU can miss its deadlines with severe consequences (Section 2.1). The central idea in RENC is to establish "low-load" intervals for energy saving. We define "low-load" in terms of cellular traffic, as periods with data traffic below a small threshold (e.g., 10% or 1%), and with no expensive control plane operations. RENC needs to (1) separate these intervals from the opposite "high-load" intervals, and (2) determine safe low CPU frequencies for the low-load intervals. In high-load intervals, RENC keeps the CPU at a high frequency to ensure that deadlines are met.

For separation, RENC uses both proactive and reactive techniques, as well as careful timing. For example, we use the MAC scheduler for proactive rate limiting to prevent

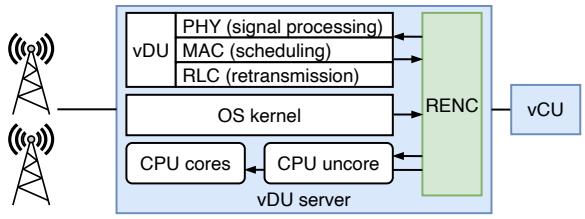

Figure 1: Overview of a vRAN deployment with RENC.

traffic bursts until RENC switches to high-load mode. RENC carefully orchestrates the timing of changes in MAC rate limits and CPU frequency, e.g., by ensuring that the increased CPU frequency is effective before lifting the rate limit. In addition to tackling user traffic-related CPU load, we also recognize control plane operations, such as user equipment (UE) attachments, as a cause of CPU load spikes. These can be handled in a reactive manner due to the longer control-plane latencies. RENC detects control plane messages using a small amount of telemetry from the vRAN and temporarily boosts CPU frequency to handle them.

The next challenge is to determine safe low CPU frequencies for the low-load intervals. This requires first measuring the "deadline slack" for each core, defined as the minimum unused fraction of the deadline. This is challenging because vRAN software is typically proprietary and closed-source, delivered to cellular operators by specialized vendors as a black-box binary. It is difficult for operators to directly add slack measurement code, especially since this must be done separately for each vendor. Instead, RENC aims to measure slack transparently to the extent possible: For interrupt-driven threads, we use eBPF [32] programmability in the Linux kernel scheduler, with no source code knowledge. For polling-based threads that do not yield to the OS, we use binary rewriting for a few DU functions. When the slack measured during low-load intervals remains high (e.g., above 10%) over a large number of samples, RENC chooses an iteratively lower CPU frequency for these intervals.

Inter-operability of RAN applications (such as energy-savings [6, Sec. 4.21]) across vRAN implementations is a key tenet of RAN virtualization and the "O-RAN" standards [4], which most vRAN vendors are adopting. The principle is to rely on interfaces exposed by vRAN components instead of internal details, to make wide deployment feasible. For this reason, we design RENC to run outside the vRAN software, and interact with it via well-defined interfaces.

Our evaluation in a commercial-grade 5G vRAN testbed, with two 5G 100 MHz 4x4 cells and nine commercial 5G UEs, shows that during periods of low traffic, RENC reduces the power consumption of vRAN CPUs and servers by up to 45% and 29%, respectively.

2 Background

Figure 1 shows a high-level overview of a vRAN deployment with RENC, focusing on the DU server that our work targets. It consists of one or more (typically three, corresponding to a three-sectored cell site) radio units (RUs) that connect to the DU via an Ethernet fronthaul link. For sub-ms latency, the DU server is close to the cell site, in a cabinet or a small nearby datacenter. Multiple (e.g., 100s) DU servers connect to a "centralized unit" (CU) server, which handles the non-realtime, less compute-intensive layers of the vRAN stack.

The DU runs the lower layers of the vRAN stack: the Physical (PHY) layer that does wireless signal processing converting signal samples to bits and vice-versa, the Media Access Control (MAC) layer that schedules wireless resources, and the Radio Link Control (RLC) layer that handles reliable in-order delivery etc. RENC runs externally to the DU as a userspace agent, with an in-kernel eBPF component.

Sources of energy consumption Cellular networks consume a huge amount of energy, of which the RAN consumes a majority (e.g., GSMA estimates 73% [40]). Within the RAN, the RU and the DU consume the most energy. The energy split between the two is variable, ranging from near-equal for small radios, to 9:1 for large massive MIMO radios [31,49]. For example, our DU server consumes around 236 W, whereas each of our 4x4 indoor radios (one server can theoretically handle six such radios) consumes around 45 W when active. This works focuses on the DU server, whose energy efficiency is a topic of wide industry interest [37, 39, 42, 43, 54, 59, 63]. RU energy is complementary to our work, which we plan to tackle in the future. RUs require different types of optimizations, e.g., achieving large savings requires turning off analog components (e.g., via MIMO- and cell-sleep [24]), which are controlled at longer timescales (hours) than the sub-second variations that our work targets.

2.1 Distinct characteristics of the vRAN DU

Real-time deadlines. Unlike typical applications—which are the focus of most prior work on energy efficiency (cf. survey [50])—where work can be queued-up if CPU power is insufficient, the vRAN DU has strict real-time deadlines. The deadline for most threads is the TTI, which is 500 µs in 5G deployments in sub-6 GHz bands, which are vRAN's focus today; it is even lower (125 µs) in mmWave deployments. The computation needed per TTI is highly variable, and can change from near-zero to maximum in consecutive TTIs. The consequences of violating deadlines range from alarming (e.g., dropped calls), to catastrophic (e.g., a cell going offline due to the vRAN software crashing). This requires that energy management be done without affecting the vRAN's real-time performance.

Black-box nature. Although energy efficiency for real-time systems is well-studied [21, 58], the vRAN software's proprietary and closed-source nature makes it difficult to simply apply existing techniques. The basic method from this literature is to measure, at a given CPU speed, the task's deadline *slack*, i.e., the minimum unused fraction of the realtime dead-

line. The CPU speed can be reduced while the slack stays above a threshold. For example, if tasks use only 100 µs of a 500 µs deadline in the worst case (i.e., 80% slack), CPU speed can be safely reduced by a small amount, and the slack re-evaluated. While the high-level method is simple, applying it to vRANs presents several challenges (§4.1).

2.2 Techniques in traditional base stations

In traditional base stations (e.g., using in-house DSPs [13]), energy efficiency has been extensively studied for over a decade (cf. surveys [64, 65]). The problem is less explored for vRANs, which are a recent advancement. Non-virtualized base stations save energy by opportunistically turning off different hardware components. Debavilli et al. [29] provide a power model for different base station sleep modes, characterized by the time to enter and exit the mode, ranging from sub-100 µs to one second, and the power consumption in the mode. Base stations based on specialized hardware may have proprietary and tightly hardware-integrated sleep mode implementations that are co-designed for RAN processing [22, 24]. In contrast CPUs have only general-purpose sleep modes, which are not easily applicable to vRANs (§3.2).

2.3 CPU and OS features

CPU energy management consists of mainly dynamic frequency scaling (P-states), and CPU sleep states (C-states). Today's vRANs typically disable these features (e.g., FlexRAN [45]), consuming high power at all times [27]. RENC uses P-states and shallow sleep states (§3.2).

eBPF in the kernel. RENC uses eBPF to transparently measure deadline slack for some vRAN threads. eBPF [32] is a modern framework for running user-provided programs called codelets at predefined code points (called *hooks*) in unmodified binaries. eBPF codelets are written in a restricted C-like language, and are compiled to a bytecode that is verified for safety and then JIT-compiled to native code for high performance. The typical use case for eBPF is to augment the Linux kernel with new functionality. The recent Janus system [36] uses vendor-provided eBPF hooks in vRAN binaries to add custom functionality to the vRAN.

3 Motivating observations

3.1 Low utilization in cellular networks

Cell sites have low utilization, as a natural consequence of the physical cell tower infrastructure being dimensioned for peak traffic separately in each area. Today's vRAN servers also run at a CPU capacity sufficient to handle the maximum traffic at all times, frequently wasting energy.

Although large-scale traces of cell site traffic at sub-second granularity are not publicly available today, several studies provide evidence for this. For example, an Ericsson report on RAN energy efficiency for LTE concludes that *"even a future network, where hotspot peak-hour traffic might be 1,000 times greater than today, will still feature low traffic loads most of the time and in most locations." [57].* Another report from Ericsson mentions that *"Half of the sites have long periods of just idling and waiting for users to make use of the capacity available."* [24]. In fact, a study of RU energy efficiency by SK Telecom and NTT Docomo evaluates the power draw of only idle RUs, since that is the common case [31].

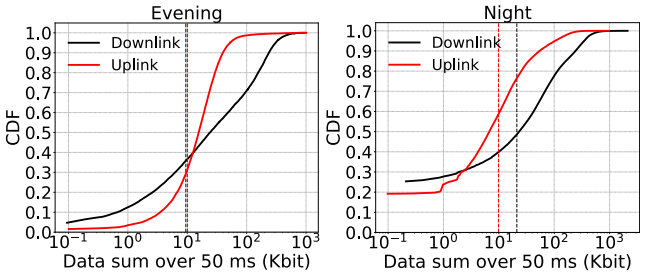

Figure 2: CDF of cumulative transport block size (TBS) measured every 50 ms, for two LTE cells. Vertical lines show 1% of peak traffic.

	C1	C1E	C6	P-states
Residency time	1 µs	4 µs	600 µs	N/A
Wakeup time	1 µs	4 µs	170 µs	N/A
Applicable to vRANs	✓	✓	?	✓

Table 1: Comparison of C-/P-states for our Ice Lake CPUs

To illustrate this, we collected TTI-level traces from two commercial LTE cells, using the Falcon LTE sniffer [34]. Since RENC waits for 50 ms to transition to low-load (§4), we plot the CDF of the total traffic measured every 50 ms in Figure 2. The left figure shows a 9:30–9:47pm trace for cell #1, located in a major university; the right for 10:11pm–0:11am in cell #2, located in a residential area close to a different university. These are busy locations, and we expect that these evening/night measurements approximate typical cells during day hours. In cell #1, over 50% of the 50 ms intervals have less than 1% of the peak traffic; such periods reach 60–80% in cell #2. These intervals represent opportunities for RENC to save energy. We currently target durations with <1% traffic, but relaxing this to 10% is possible in our system (§9.1).

3.2 CPU power management

Choosing between P- and C-states. RENC uses P-states and shallow C-states, but not the deep sleep states. Modern Intel server processors support C1, C1E, and C6 states. C1 and C1E are shallow and save far less energy than C6, but their sub-5 µs latencies make them easily applicable to vRANs.

Can RENC use the deep C6 state? Table 1 shows why this is difficult. A C-state's "residency time" is defined as the minimum time that the core must stay in that state to save energy, to break-even from the sleep and wakeup overheads. For our Ice Lake CPUs, C6's high 600 µs residency time—required to flush the large L2 cache—plus its 170 µs wakeup time, exceeds the sub-500 µs TTI used in 5G networks. Most vRAN threads must run in every TTI—this pattern is followed by all six

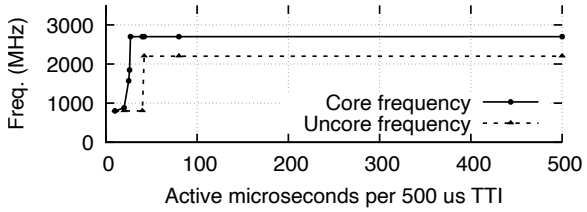

Figure 3: HWP-picked frequency for varying TTI activity levels

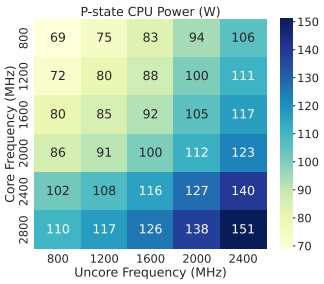
Component	Power
CPU (Xeon 6338N)	129 W
DIMMs (8x 32 GB)	14 W
Miscelaneous	93 W
Total	236 W

(a) Server power breakdown.



(b) Effect of core & uncore frequency

Figure 4: Components of vRAN server and CPU power

DUs that we have studied, including open-source [9, 15, 30], and proprietary [16, 33, 46]—so the CPU cores cannot remain inactive in C6 for long enough to save energy. We therefore focus on P-states instead, which allow the CPU to be active at all times and fine-grained frequency control. Recent advances reduce the impact of CPU frequency changes on core blocking time [28], and jitter on other cores [44]. C6 may be feasible for some DU threads with multi-TTI deadlines; we discuss this and its limitations in Appendix A.

CPU firmware controlled P-states. Can we simply let the CPU scale its own frequency? This does not work because the CPU's general-purpose P-state control loop is (1) too slow, and (2) not vRAN-aware. In modern CPUs, firmware-based frequency control (e.g., Intel's Hardware P-states [3], or HWP), is preferred over the older OS-based control. The firmware's simple 10 ms+ control loops are effective for general workloads, but vRANs require control at 1 ms timescales. For core P-states, we measured that HWP takes 60 ms to react after a sudden spike in CPU utilization; Schone et al. show that the uncore's reaction time is ~10 ms [60].

Figure 3 shows the CPU core and uncore frequency chosen by our server's HWP, (§ 8) in an experiment where one CPU core is active for varying fractions of a 500 µs TTI, and is asleep for the rest. We find that with only HWP picks the maximum core and uncore frequency with just 27 µs and 42 µs of activity, respectively. In contrast, RENC can recognize this thread as having high slack (over 90% of the TTI is unused), and choose a lower frequency.

CPU power breakdown. RENC focuses on CPU power since it is the largest component of DU server power. Figure 4a shows a wattage breakdown of our commercial-grade vRAN server (used in real vRAN deployments), when running two cells with no traffic and no energy management

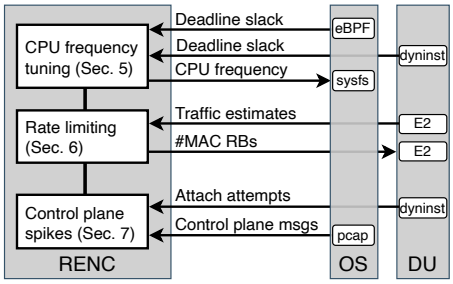


Figure 5: Overview of RENC's operation

features enabled (details in §8). The CPU consumes the largest share of the power, eclipsing the power consumption of typically power-hungry components like DRAM. Our server's Baseboard Management Controller (BMC) not provide a breakdown of the "Miscellaneous" component, which divides among the motherboard, devices (NIC, PHY accelerator, NVMe SSDs), cooling fans, and conduction loss [17]. This remains fairly constant in our experiments regardless of user traffic, so we ignore it.

Uncore frequency. In addition to CPU cores, the CPU's "uncore"—the L3 cache, memory controller, PCIe controller, etc—is a major power consumer, since it represents a large fraction of the CPU's die area (e.g., over 50% [26]). Figure 4b shows the CPU's power draw at different core and uncore frequencies. Both are significant, so RENC tunes both.

4 Design overview

We target three design goals for RENC.

G-1. Minimize energy during low-load periods. Since most cell sites have low utilization most of the time (Section 3.1) RENC targets saving energy during these periods. We leave energy saving during high load to future work.

G-2. Transparency to vRAN software and platform. Since vRAN software is often proprietary and multi-vendor, and provided by a different vendor than the hardware/OS vendor, we design RENC following O-RAN [4] principles of clear interfaces that require only minimal information from the vRAN and platform. Specifically, we need only (1) names and deadlines of realtime DU threads, (2) the signatures of key functions in poll-mode vRAN threads, and (2) low-latency access to standard MAC layer metrics and control knobs.

G-3. Low resource overhead. RENC must consume few CPU resources, else it will negate some energy savings. In particular, RENC must not require a dedicated CPU core, which would reduce cores available for the DU.

4.1 Overview and challenges

C-1. Finding slack. When measured simply across all time, there may be no slack in some DU threads. Here we explain this intuitively, and show it experimentally in §9. Figure 6 shows three TTIs (#1, #2, and #n) for a DU thread with a one-TTI deadline. TTIs #1 and #2 belong to RENC-controlled

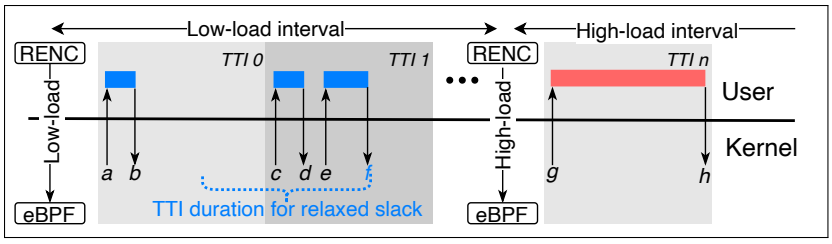

Figure 6: In this timeline for an interrupt-driven DU thread, RENC's eBPF program updates the relaxed slack for low-load intervals (blue) by summing over the dotted TTI-duration window at time f, i.e., $TTI - ((f-e)+(d-c))$. The userspace RENC agent tells the eBPF program the current low/high load type, so the latter ignores *TTI n* with zero slack.

low-load intervals, by their low traffic rate and no expensive control plane operations. For these TTIs, the DU finishes work well before the deadline. In contrast, processing in the high-load TTI #n takes almost the entire deadline duration.

The key observation is that if we compute slack across all TTIs #1–#n, we will find no slack, i.e., the minimum unused deadline fraction is near-zero because of TTI #n. Without slack, RENC cannot reduce CPU frequency without risking deadlines, especially uncore frequency which affects all cores. However, if we carefully separate the low- and high-load intervals, we may find significant slack in the former. RENC introduces new techniques to (1) establish low-load intervals, (2) measure slack for precisely these intervals, and (3) limit energy saving to them. For low-load intervals, RENC iteratively computes the lowest safe frequency for each CPU core and the uncore. For high-load intervals, RENC runs the CPU at the highest configured frequency.

C-2. Separating low and high CPU load intervals. How can RENC ensure that the DU does not admit more load than the CPU can handle at low frequency? Prior work partially tackles this problem, e.g., PR3 [25], vrAIn [20] and CRT [55] use MAC-layer rate limiting to adjust traffic to match CPU frequency. However, these are best-effort, with no deadline guarantees that are crucial in commercial vRANs. For example, unlike less-performant open-source vRANs used in prior work [9, 15], our PHY (Intel's FlexRAN) is optimized to keep intermediate computation buffers sufficient for only the deadline period, minimizing its cache footprint for efficiency. Upon missing a deadline, there is no option but to crash the program. There are recent proposals that aim to alleviate this problem [38], but these require re-designing the DU.

Our solution is to couple MAC rate limiting with CPU frequency changes, by strictly ordering them. Before reducing frequency, RENC first applies a MAC layer rate limit to disallow sudden traffic bursts (§6). Similarly, RENC lifts the rate limit only after fully applying a CPU frequency increase. RENC also transitions to the high CPU load state on detecting CPU-intensive control-plane messages (§7).

C-3. Mostly-transparent slack measurement. Cellular operators typically receive the DU as a binary from a vendor, making it challenging to measure slack. We aim to infer slack externally as much as possible, for the two reasons. First, external measurement works generally for all DU implementations, increasing RENC's applicability to the diverse vRAN ecosystem. Second, some cores may run multiple realtime DU threads and have interference from unavoidable OS threads, in which case slack is best measured externally.

We have created two new techniques to measure slack, which rely on minimal information from the vendor that is easily available. First, we observe that the OS provides a vantage point to observe the activity of DU threads that yield to OS in every deadline interval. In the DU that we use (Section 8), five out of the seven types of realtime DU threads follow this pattern. For these threads, RENC measures slack with no code information from the vendor except thread names and deadline durations. Our insight is to use eBPF hooks in the Linux scheduler for this, since standard OS mechanisms are too coarse (§5).

For DU threads that do not yield to the OS, we require the function names and signatures of the realtime DU functions. Usually there is one top-level function that encapsulates the DU's computation in a deadline interval. RENC then uses binary rewriting to capture the start and end of these functions to measure the per-thread slack.

5 Measuring deadline slack

This section describes how RENC measures the slack for low-load intervals at runtime, while excluding high CPU load intervals whose slack can be zero; the next two sections describe how RENC keeps low-load intervals free from high load. RENC then uses slack measurements to iteratively reduce uncore and CPU cores' frequency until slack drops below a threshold (default 10% in our implementation) (§5.4).

In contrast to static measurement in prior work, RENC measures slack and tunes CPU frequency at runtime. For example, CRT [55] requires manual experiments to compute safe frequencies for different traffic loads by noting the CPU frequency at visible errors occur, e.g., UE disconnections and errors in the vRAN code. RENC provides an automated and principled solution to this problem. The heterogeneity of vRANs further complicates static approaches: vRAN sites may run different RAN configurations (e.g., different number of cells or wireless configuration parameters) with different server hardware, which change the CPU requirements.

5.1 Types of vRAN threads

RENC requires some basic information about the DU software from the RAN vendor, including whether the thread is interrupt-driven or busy-polling, and the thread's deadline. Table 5 shows our DU' threads, their types, and their

deadlines. For busy-polling threads, RENC also requires the names and signatures of the task functions (typically one per thread) executed by the thread. In our DU, we use three functions corresponding to three PHY layer thread types: a function called at the start and end of each TTI; a function that handles fronthaul Ethernet packets; and a function for processing accelerator and shared-memory queues.

We develop two different approaches to measure slack.

Interrupt-driven threads are woken up by the OS at the start of each TTI, e.g., via a timer interrupt, or a semaphore from another thread. The thread performs its tasks for the TTI (e.g., MAC scheduling) and then yields. All MAC- and RLC-layer in our DU fall in this category. RENC uses eBPF hooks in the OS scheduler to measure their slack (§5.2).

Busy-polling threads run completely in userspace, i.e., they do not yield to the OS scheduler and instead constantly poll for work. In our DU, the PHY layer threads fall in this category, likely because of the PHY's high compute and efficiency requirements. We use binary rewriting for a few functions to measure the slack for these threads (§5.3).

5.2 Handling interrupt-driven threads

Can we simply use standard OS mechanisms to measure slack for these threads? This is not possible today, since the OS-exposed time measurements are too coarse, using "jiffies" (10 ms) as the unit of time. Our insight here is that eBPF provides the required fine-grained kernel programmability. To our knowledge, RENC is the first system to use eBPF to track thread execution time for energy saving, and we believe that it is a promising direction for non-vRAN systems as well.

In-kernel eBPF programs consist of simple, provably-safe code that is JIT-compiled to native machine code. The program has access to in-memory maps to store data, data structures, and high-resolution timers. RENC uses the eBPF hook at the Linux scheduler's `sched_switch` function, which is called whenever the thread running on a CPU core changes. Using the example in Figure 6 (see the caption for a detailed explanation), `sched_switch` can capture all user-kernel transitions, indicated by the arrows labeled with timestamps a–h. The correct low-load slack for the case shown is $TTI - ((f - e) + (d - c))$, since (1) the activity during *TTI 2* exceeds *TTI 1*'s activity ($= b - a$), and (2) the higher activity during *TTI n* ($= h - g$) must be ignored because it is in a high-load interval. Note that in practice we can have tens of active intervals per TTI, e.g., caused by the vRAN software's structure, as well as unavoidable kernel tasks such as IRQ and read-copy-update (RCU) pre-empting the DU threads.

5.2.1 Dividing between eBPF and userspace

What part of the slack measurement should run in eBPF within the OS, and what part in userspace? In RENC, we chose to implement slack measurement fully in eBPF, without any userspace involvement. The userspace RENC agent periodically (once every five seconds by default) retrieves the slack measurements from the eBPF program, and uses them to tune CPU frequency. This section describes the rationale behind this design, and how our implementation works.

An intuitive approach that we implemented first is to use a minimal eBPF program that simply passes all scheduling events to the RENC agent in userspace. This was convenient because all logic stays in userspace, easing development and debugging. However, we abandoned this approach because we found that sending messages to userspace for every scheduling event is fraught with issues. The compute overhead is a clear one: For example, with 10 thread switches per TTI (500 µs) across 10 DU cores, there are 200K kernel-user messages per second. This required dedicating a CPU core for the RENC agent to constantly poll an eBPF ring buffer for new messages, else messages are dropped.

We noticed more insidious issues, too. The high amount of kernel processing for message handling can get deferred behind the high-priority DU threads, causing subsequent bursts of kernel activity that cause the DU threads to miss their deadlines. Sending messages to userspace from a scheduler hook can also cause an infinite loop of messages leading to a kernel hang, since the act of sending a message can cause further scheduling events to handle the message.

5.2.2 In-kernel slack measurement

To avoid the issues with heavy scheduler-to-userspace messaging, we instead measure slack in the kernel. Surprisingly, we found that today there is no easy way for eBPF programs to know when a TTI starts and ends: At the time of writing, Linux's eBPF does not support the system wall-clock (`CLOCK_REALTIME`), supporting only monotonic clocks (e.g., `CLOCK_MONOTONIC`). The wall clock is the DU's heartbeat: it is synchronized with the RUs via the Precision Time Protocol (PTP), and is used to time TTIs. A patch to add wall clocks to Linux eBPF was submitted in 2020, but abandoned in part due to concerns about the likelihood of programmers' incorrect use of a non-monotonic clock [53].

Relaxed slack. Due to eBPF's lack of a TTI-synchronized clock, we use a conservative estimate of slack that does not rely on TTI boundaries, defined as follows (assuming a one-TTI deadline). We measure the maximum fraction in *any* TTI-length interval that the core is active in; the relaxed slack is one minus this fraction. The chosen interval may overlap TTIs (see Figure 6), making the relaxed slack a conservative estimate. This works well in practice because DU tasks run at the beginning of each TTI. For low-load intervals, the latter portion of TTIs is idle, so the selected interval will align with a TTI unless utilization is very high, in which case RENC does not attempt to save energy for this core.

To keep our implementation within the eBPF verifier's limits, we use a fixed-size array of intervals for each CPU core. Each interval is a pair of timestamps for when any thread was active, i.e., the kernel's idle task was not running. We deliberately chose to include *all* threads and not

just DU threads, to include OS thread overheads which can be significant in real systems, e.g., following a NIC driver update that causes interrupts to land on DU cores. When a thread switch occurs at time t, the eBPF program sums all intervals overlapping with $(t - TTI, t)$. If the sum exceeds the current maximum, the program updates the maximum deadline utilization and the minimum slack.

The userspace RENC agent reads the per-core slack values from the kernel only when tuning frequency, i.e., once every five seconds by default. The user-kernel message overhead is now negligible, a significant reduction from the per-scheduling-event rate. We manually ensure that the in-kernel eBPF codelet has few instructions, and measure its overhead as <5% of the context switch cost (§9).

Handling load type changes. Our eBPF program maintains two arrays of intervals per core, one for each load type. When the userspace RENC agent decides to change the load type (§6), it indicates this to the eBPF program using a syscall to update a BPF map entry. The vertical "low-load" and "high-load" arrows between RENC and eBPF in Figure 6 show these updates. On every `sched_switch` invocation, our eBPF program sums up the intervals in the array corresponding to the current load type, keeping the two separate. While measurements for high-load intervals are not necessary for RENC, we still keep them to aid debugging.

5.3 Handling busy-polling threads

We use the popular `dyninst` framework to instrument the call and return instructions of the main datapath functions of busy-polling DU threads. Additionally, we use an internal tool that allows inserting userspace eBPF programs at the instrumented code points. Since these programs can access the wall clock, slack measurement is straightforward.

In our DU, we use this approach for the busy-polling PHY layer threads, specifically (1) the PHY signal processing threads' top-level function called at the start and end of TTI processing (`ebbu_pool_event_set_state()` in FlexRAN), and (2) the fronthaul packet I/O threads' top-level per-symbol callback function (`sym_ota_cb()` in FlexRAN). For the PHY signal processing thread, we also need the description for the enum values of its argument, e.g., specifying whether TTI processing is starting or ending. We chose to not instrument one PHY thread type ("PHY SHM rings" in Table 5) because it splits its work across four functions, making it cumbersome to instrument all of them though this can be done if needed. This thread's processing is largely independent of the traffic load, so we manually confirm that it can safely run at the lowest frequency.

5.4 Iterative CPU frequency tuning

Collecting slack samples. At each CPU frequency configuration, RENC collects slack measurement samples for low-load intervals, filtering out high-load intervals. We continue collecting samples until the cumulative duration spent in low-load intervals exceeds a large value V, to try capturing the full range of CPU activity possible in low-load intervals. We expect V to be several hours in real deployments, but use a shorter 5-second interval for testing to speed convergence.

Prioritizing uncore frequency. After RENC has sufficient slack samples, it tries to reduce CPU frequency. We set our slack threshold to 10%, leaving some headroom for cases not covered by the observation period. We prioritize the uncore, since it has a large impact on power draw (§9.4) and affects all cores. If all cores have >10% slack, and uncore frequency is not at the minimum, RENC reduces it by the supported quantum (100 MHz). Otherwise, sys starts reducing CPU core frequencies for cores with >10% slack. Then RENC starts a new observation period.

6 Coupled CPU frequency and MAC control

This section describes how RENC coordinates changes in CPU frequency and MAC rate limits to separate low- and high-load intervals. Neither take effect immediately, so RENC must control their order and timing.

6.1 Forecasting DU traffic

RENC uses DU-exposed telemetry for uplink and downlink traffic to measure the current traffic demand, and determine when to transition to low or high load. Among the several metrics that can be used to measure traffic, we use the one that provides the earliest indication of traffic demand. This allows quickly removing the rate limit when there is a surge in traffic, minimizing the impact on RAN performance.

RENC requires low-latency access to DU telemetry and control interfaces that DU vendors typically already implement, e.g., for the O-RAN E2 interface [18]. Our DU vendor provides access to these via a local UDP port.

Uplink traffic estimation. We use the per-UE Buffer Status Reports (BSRs) to estimate the uplink load. UEs send BSRs to the DU to indicate buffered data size. These are sent *before* the UEs send the actual data, and hence provide an early indication of the uplink traffic demand.

Downlink traffic estimation. For downlink traffic, we use the throughput at the DU's interface with the CU. While this is not as early an indication as the BSRs, it is the earliest indication of downlink traffic that is available to the DU.

6.2 Low/high-load classification

Our current implementation simply uses recent traffic samples as indicators of future load, though more sophisticated techniques (e.g., time-series analysis) may be applied. We define $R_{dir,t}$ as the traffic sample received at time t, summed over all UEs and cells, for uplink or downlink direction *dir*. We also define M_{dir} as the statically-measured maximum traffic sample for each direction; in our DU, this is 150 kB for the cumulative BSR, and 450 Mbps for the downlink throughput.

RENC transitions to low-load if all samples in the last n milliseconds are below 1% of M_{dir}; $n = 50$ in our implemen-

tation, i.e., we transition to low-load if there is little traffic for roughly three RTTs on our network (Figure 2). RENC transitions to high-load when the latest traffic sample exceeds 1% of M_{dir}. By not waiting for multiple >1% samples, RENC minimizes its impact on user-visible performance, at the cost of possibly reduced energy savings, e.g., when the high traffic sample is a transient spike. Note that some impact is acceptable, e.g., Ericsson uses a "Low Energy Scheduler" (LESS) that packs data in the frequency domain to make it sparse in the time domain [23].

6.3 Rate-limiting

RENC controls the number of wireless resource blocks (RBs, each RB corresponds to a small piece of spectrum) allocatable by the MAC for rate limiting, achieved via 3GPP's slice control interface [11]; this resembles the "ECO-Mode" optimization in some radios, which can power-down amplifiers for some RBs during times of low traffic [23]. This basic approach can be improved by using more information such as signal-to-noise (SNR) ratio, which affects the number of bits per RB. RENC allows a small percentage of RBs (10% by default in our implementation) to be used during low-load intervals. This is larger than the 1% threshold for traffic metrics, to account for the variable bits per RB.

6.4 Ordering and timing of changes

The process of changing CPU core/uncore frequency, or applying a MAC rate limit, is not instantaneous; RENC must ensure that these changes are applied in the correct order.

1. **CPU frequency and MAC rate limiting:** RENC must prevent high traffic while the CPU is at a low frequency.
2. **OS eBPF and MAC rate limiting.** RENC's kernel eBPF program must not pollute low-load slack measurements with those of high-load intervals (§5.2.2).

We next discuss how we apply these changes, and their maximum latencies measured when the system is running at RENC's low CPU frequency (§8.1). We use Linux's `sysfs` and MSR (Model-Specific Register) interfaces to control CPU core and uncore frequencies, respectively. We measure the maximum delays for these as 1100 µs and 2300 µs, respectively, which match prior work [60]. We define the time to change CPU frequency as the higher of the two, i.e., d_{cpu} = 2300 µs. Our DU applies RB changes in the TTI after it receives the request; The RB change latency equals RENC's maximum's latency to the DU's control UDP port (600 µs), plus one TTI (i.e., d_{rb} = 1100 µs). We use a syscall to update the load type in a BPF map in the eBPF program. This is a blocking call that takes at most 15 µs (= d_{ebpf}).

Figure 7 shows how RENC orders these changes. When transitioning from low to high load, it first increases CPU frequency and sets the eBPF load type to high-load. It waits for $max(d_{cpu}, d_{ebpf})$ for both changes to take effect, then lifts the MAC rate limit. Note that this sequence allows our kernel eBPF program to account slack for low-load TTIs to the high-load type, which is safe since it does not pollute the low-load slack measurements that RENC cares about. To transition to low load, RENC first applies the MAC rate limit, and waits for d_{rb} for this to take effect. It then reduces the CPU frequency and sets the eBPF load type to low-load.

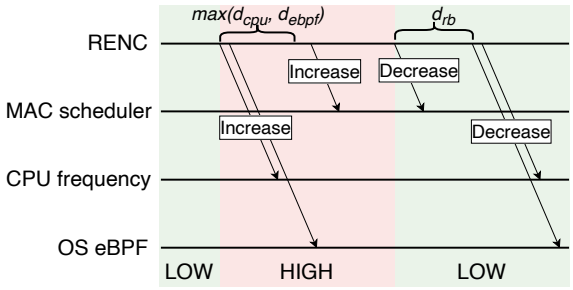

Figure 7: Ordering & timing of RENC's load-type transitions

Time	Event
34.448 s	Random access attempt from PHY (trigger)
34.469 s	CPU load spike; sudden slack decrease to 0%
48.515 s	UE Context Release Request from CU (trigger)
49.167 s	CPU load spike; sudden slack decrease to 68%

Table 2: Example of high load due to control messages

7 Control operation CPU spikes

The discussion until now has focused on handling variations in the DU threads' slack caused by changes in the traffic load. However, this alone may not ensure that the DU meets its deadlines: In addition to the user traffic, the DU's control plane processing (e.g., UE attachments) can also be a source of sudden bursts of compute load. The key challenge here is detecting these spikes and reacting to them in a timely manner, with few modifications to the vRAN software for transparency and ease of deployment.

7.1 Discovering spike-causing events

The following insight helps to systematically and transparently determine the causes of compute spikes related to control messages. DU control messages are carried on formally-specified interfaces, i.e., the Functional API (FAPI) between the MAC and PHY [1], and the F1AP interface between the CU and DU [12]. Control messages can therefore be observed by simply interposing on the interface, ignoring the internal complex details of the vRAN implementation. The messages can be captured along with sudden dips in the DU threads' slack (corresponding to a compute spike), and correlated to identify the causing message.

Table 2 shows example timeline for two sudden dips in a DU thread's slack when running a cell initially with no UEs attached, whose slack is initially 84%. These are caused by a (1) UE attaching and (2) detaching in our testbed (§8). The first dip is caused by a PHY-to-MAC Random Access

DU Server	HPE DL110 Gen10 "telco" server Xeon 6338N CPU (32c), 8 ×32 GB DDR4 DIMMs 1 TB NVMe SSD, Intel E810 NIC, ACC100 card [10]
Software	Realime Linux v6.1; Intel FlexRAN PHY [46] CapGemini DU and CU, commercial 5G core
5G cells	FoxConn 4×4 RUs at 3.5 GHz, 100 MHz bandwidth 30 KHz subcarrier spacing, TDD (DDDSU)
Lab #1	Two cells in building, nine (4 + 5) Raspberry Pi UEs 13 realtime DU CPU cores, FlexRAN version 22.11
Lab #2	One cell, one OnePlus 5G phone and Pi UE 11 realtime DU CPU cores, FlexRAN version 22.03

Table 3: Evaluation testbeds' hardware and software

Channel (RACH) Indication message, sent when a UE tries to attach. When this happens, the DU must initialize UE state, which causes the compute spike. The second spike is similarly caused by a F1AP UE Context Release Request message, which is sent by the CU to the DU when a UE detaches. Currently, we correlate events to spikes manually, but this can be automated using time series correlation methods. We expect that other events, such as UE handovers will also cause spikes, and leave this for future work.

7.2 Reacting to control messages at runtime

Control messages being delay-tolerant can be handled reactively, i.e., a proactive approach such as RENC's rate limiting of data traffic is not necessary. For example, in Table 2, the attachment-related spike happens 21 ms after the random access control message. The detachment related dip happens 435 ms after the corresponding control message.

On detecting a spike trigger, RENC transitions to the high-load state, and stays there for the maximum time between the trigger and the corresponding spike. To leave sufficient error margins, currently RENC stays in the high-load state for 200 ms after the attachment trigger, and for 1 second for the detachment trigger. This is a conservative choice that can be optimized. In our DU, UE detachments force high-load for a long time which is undesirable, but these are rare since UEs typically detach infrequently to minimize signaling, staying in an idle/inactive state [41] during periods of inactivity.

To detect FAPI RACH messages, we intercept the PHY's top-level call to its FAPI interface to the MAC, which uses a publicly-available shared library ("Wireless Service Library", or WLS [5]). This library has a public, well-defined interface for compatibility with different MAC layer vendors [2], allowing us to de-parse the messages list to detect RACH Indications. To detect spike-causing F1AP messages, we use Linux's packet capture (pcap) interface and decode them to find the target message types.

8 Evaluation

8.1 Experiment setup

We implemented RENC in 2500 source lines of code in C++ and C, and 100 lines of eBPF (`libbpf`) code. Table 3 summarizes our testbeds, which use state-of-the-art commercial-grade vRAN hardware and software that closely resembles real-world deployments [7]. To focus on the DU server, we run the CU and a commercial 5G core network on other servers. We use two labs, with different DU versions to test our design's generality. Lab #1 has two 5G cells on different building floors, with nine total Raspberry Pi UEs (four or five per floor) with Quectel RM500Q modems. We use the smaller lab #2 for experiments that need higher throughput, since it has better signal quality and modem. The small size of our testbeds is a limitation of our work, though lab #2's size is close to real deployments, which often have 10–20 active users per cell [56, Fig. 10]; Our cells can achieve 30 Mbps uplink and 500 Mbps downlink TCP throughput, matching commercial 5G sub-6 GHz networks [52, Fig. 6,7].

DU CPU core configuration. Our DU uses 13 realtime CPU cores for the two-cell configuration, and 11 for the one-cell configuration. Table 5 shows the latter; the two-cell configuration doubles the MAC layer cores. We did not design these configurations for RENC, but rather used the default stable configurations created over months with the vendors' help. The functional purpose of each thread is not important for RENC, but we include it for completeness. We minimize the energy effect of the unused DU server cores by setting them to the lowest 800 MHz frequency. Our default stable configuration disables Hyper Threading (HT), but RENC can be extended to support it by using the minimum of the two HT siblings' slack to tune the core's frequency.

Energy measurement. Our vRAN server's management interface (HPE iLO) provides full-server power measurements at coarse 10-second intervals. For fine-grained CPU power measurements, we use the CPU's RAPL (Running Average Power Limit) counters, which are accurate [48].

CPU frequencies. Our default server configuration before RENC used 3400 MHz for CPU cores, and 2400 MHz for the uncore, which we use as the baseline. RENC successfully separates-out low-load intervals that can run at the minimum CPU frequency that we allowed: 1000 MHz for all DU cores, and 800 MHz for the uncore. (Going further to 800 MHz for the CPU cores saves very little energy but costs 20% CPU performance.) We report per-core slack measurements, and the marginal impact of core and uncore frequencies in §9.

8.2 Idle-mode power consumption

We start by measuring RENC's idle-mode power (§3.1) savings, which is a key energy metric for RAN equipment [31]. We attach all nine UEs in lab #1, to the two cells, which then remain idle. We use three baselines: (1) the default configuration with no energy optimizations, (2) enabling C1 states, and (3) CPU's hardware-based automatic frequency scaling (HWP, §3.2). When using HWP, we set its "energy-performance bias" policy in the BIOS to favor energy. We ignore C1E states since they save negligible energy (< 1%) in

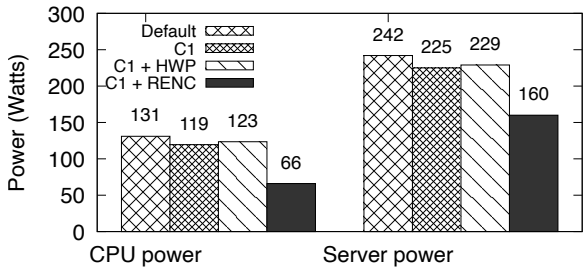

Figure 8: Idle-mode CPU and server-wide power consumption, with different energy saving configurations.

	DL Mbps	UL Mbps	Ping ms
Without RENC	486–520	29.6–29.7	27.1 (3.3)
With RENC	499–520	29.7–29.7	27.9 (3.4)

Table 4: Basic Internet performance without and with RENC

our experiments. Figure 8 shows that that enabling C1 states reduces CPU power from 131 W to 119 W, and server power from 242 W to 225 W. Enabling RENC on top of C1 further reduces CPU power by 45% to 66 W, and server power by 29% to 160 W, respectively.

Comparison with HWP. CPU power draw with HWP enabled (123 W) is 1.8x higher than with RENC. Counter-intuitively, HWP does not save power even when cells are idle, for two reasons: First, a vRAN being a realtime system creates a non-negligible amount of CPU activity even when idle. Our vRAN's realtime threads run every TTI, and do a small amount of computation which is nevertheless large enough to cause HWP to pick high core and uncore frequencies (Figure 3). Specifically, HWP runs all PHY cores and most MAC and RLC cores at too-high frequencies (2.5–2.7 GHz). Similarly, it picks a too-high uncore frequency (2200 MHz); artificially forcing the uncore (permitted via Model Status Registers even when HWP is active) to 800 MHz brings down CPU power to 83 W, which is still higher than RENC's 66 W by 26%. Second, enabling HWP *increases* power draw, because HWP (a) prevents us from fixing unused cores to 800 MHz, and (b) chooses slightly higher frequencies for these.

8.3 Energy savings with data traffic

Effect on network performance. RENC aims to save energy without significantly affecting network performance. Here we study high-level metrics, and run micro-benchmarks in §9. Since performance with multiple UEs is noisy due to spectrum sharing and interaction with TCP, we use lab #2 in this experiment. We use SpeedTest [8], and ensure that all tests use the same SpeedTest server. We run three tests both with and without RENC, and report the maximum and minimum values. Since SpeedTest's ping latency varies widely, we use a different ping application to measure the average and standard deviation of latency to cloudflare.com. Table 4 shows the results. The throughputs and latency of the two configurations are similar, which meets our goal.

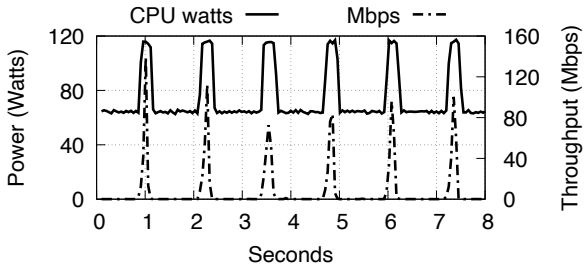

Figure 9: One UE repeatedly downloading a 1 MB file.

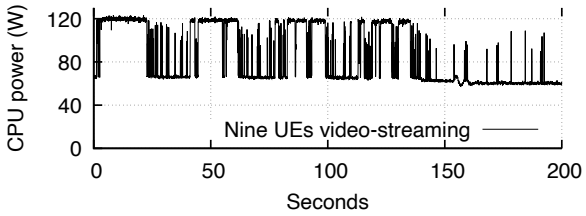

Figure 10: Energy saving with nine video-streaming UEs.

We next evaluate RENC in the larger lab #1 with real traffic.

File downloads. In this experiment, one Pi UE repeatedly downloads a 1 MB file from a lab server at 1 s intervals. Figure 9 shows the DU CPU's power draw measured at 10 ms intervals, along with downlink bandwidth. RENC successfully reacts to the load spikes by increasing CPU frequency, and reduces it when the load drops.

Video streaming. We use video streaming as an example application to show how RENC can save energy even during active user sessions. Here we use all nine Pi UEs, which stream a 720p video from a popular Internet site, using a headless mpv player [51]. The UEs start at roughly the same time. Figure 10 that, in the beginning, RENC keeps the DU server primarily in high-load mode as the UEs fetch the initial parts of the video. After the UEs buffer the video, there are gaps between video chunk downloads, during which RENC successfully saves energy. The average power draw with RENC is 83 W, compared to 121 W without (not shown).

Traffic mix. We use the nine UEs to create a traffic mix representative of a real-world workload: we run three video streams, two 1 MB file downloads and two 256 kB uploads at 1s intervals, two long-lived 1 Mbps iperf3 download streams, and one 1 Mbps iperf3 upload stream. Figure 11 shows how RENC saves energy during the traffic gaps, reducing average CPU power from 121 W to 109 W.

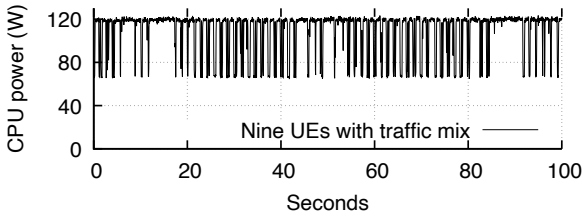

Figure 11: Energy saving with nine UEs running a traffic mix.

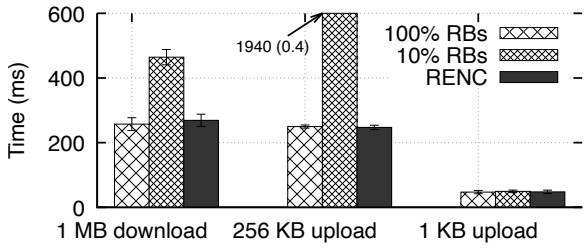

Figure 12: File transfer time with MAC rate limiting.

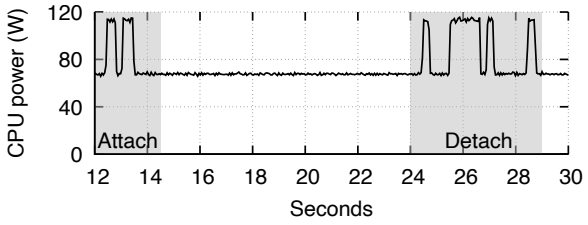

Figure 13: Handling of control message spikes.

9 Microbenchmarks

We next evaluate some aspects of RENC's design in isolation.

9.1 Effect of MAC rate limiting

To quantify how RENC's MAC rate limiting affects network performance, we measure the time for small file transfers that stress RENC's reactiveness; our SpeedTest experiment showed RENC's negligible impact on long transfers. Since RENC dynamically scales the allowed RBs between 10% and 100%, we show the download time with static 100% and 10% RB limits for reference. The experiment uses a simple Python HTTP client and server. Since downlink speed is higher than uplink, we use a larger 1 MB for downloads than uploads (256 kB). These are smaller than average mobile web page sizes today (e.g., 2 MB in one study [14]). Figure 12 shows that transfer time with RENC is close to the static 100% allocation (<2% higher), and better than the static 10% allocation. For small 1 kB uploads, common in IoT devices [62], all three perform similarly since the DU always stays under 10% RBs.

Sensitivity analysis. We have focused on a 1% threshold for traffic metrics, but this is tunable. Increasing it to 10% allows RENC to save more energy, but may affect user performance unless the algorithms in §6 are improved. For example, using a 10% BSR threshold in the 256 kB upload experiment increases the mean transfer time from 200 ms to 231 ms, due to the DU's slower reaction to the uplink traffic burst.

RU power. RENC's rate limiting may slightly increase the amount of time that the RU is active, increasing its power draw. We currently lack the precise RU power measurements needed to quantify this, but we expect it to be small since RENC lifts its rate limit in milliseconds in response to traffic.

9.2 Slack measurement

We conduct the following experiment to test RENC's establishment of low-load intervals that are safe for CPU frequency scaling. Since this experiment requires stressing the DU's compute resources, we use lab #2 to generate high traffic. We run two tests: without RENC, and with RENC, shown in the rightmost two columns of Table 5. In each test, we attach the phone, run two SpeedTest sessions, and then detach the phone. In the first case, the DU runs without RENC at a constant low frequency of 1000 MHz for all cores and 800 MHz for the uncore; this configuration frequently crashes the DU due to deadline violations, but we run it for this experiment. In the second case, RENC is enabled.

We make three observations (Table 5). First, without RENC, several DU threads have zero slack. The MAC scheduler thread has 8% slack, but that leaves insufficient safety margins. This confirms that this DU cannot run at this low frequency without RENC, since slack measured simply across all time is zero. Second, RENC successfully establishes low-load intervals with sufficient slack for frequency scaling. Third, some threads (e.g., the PHY threads and the RLC timer thread) have significant slack even without RENC, making it possible to statically configure them to run at a low frequency. ("PHY timer" has lower slack with RENC because its processing time depends more on CPU frequency than user traffic.)

Importantly, note that knowing whether a CPU frequency configuration is safe, or which threads have high slack, is difficult without our new slack measurement techniques. For example, simply running coarse-grained tool like `top` always shows <9% and <27% or the MAC-to-PHY and MAC scheduler threads, respectively, but their actual TTI deadline utilization without RENC reaches 100% and 92%, respectively.

9.3 Control message handling

Figure 13 shows the DU's CPU power draw when a Raspberry Pi UE attaches and detaches in lab #2. There are two high-load intervals during attachment because of a failed attempt followed by a successful one, which is common in cellular networks. The detachment event has one long high-load interval, and multiple three short ones caused by spurious attachment attempts that our UE makes when we turn on flight mode to detach it. This experiment shows how RENC successfully handles CPU load spikes from control processing, and handles unexpected behaviors of UEs. RENC also handles the more challenging case with nine UEs simultaneously attaching and then detaching.

9.4 Breakdown of energy savings

Table 6 shows that both uncore and CPU core frequency scaling contribute significantly to energy savings. Reducing the uncore frequency alone from 2400 MHz to 800 MHz reduces CPU power by 32% from 117 W to 80 W. Adding core frequency scaling reduces CPU power by a further 16% from 80 W to 67 W. A takeaway from our work is that uncore frequency scaling provides a convenient and effective knob for reducing CPU power. Since it is just one value, an operator

Thread name	Description	Running mode	Deadline	Slack w/o RENC	Low-load slack with RENC
F1 worker	Communication with CU	Interrupt-driven	1×TTI	0%	64%
RLC timer	RLC timekeeping	Interrupt-driven	1×TTI	62%	75%
RLC worker	RLC processing	Interrupt-driven	1×TTI	0%	76%
MAC scheduler	Wireless scheduler	Interrupt-driven	1×TTI	8%	79%
MAC-to-PHY	MAC-PHY messaging; UE context management	Interrupt-driven	1×TTI	0%	72%
PHY BBU pool (4x)	Wireless signal processing	Busy-polling	3×TTI	20%	28%
PHY timer	Symbol timing; callbacks	Busy-polling	Symbol ($\frac{TTI}{14}$)	72%	56%
PHY SHM rings	Network/accelerator I/O	Busy-polling	1×TTI	N/A (§5.3)	N/A (§5.3)

Table 5: Threads with realtime priority running at the DU: low CPU frequency vs RENC.

CPU cores freq	Uncore freq	CPU power
3400 MHz	2400 MHz	117 watts
3400 MHz	800 MHz	80 watts
1000 MHz	2400 MHz	105 watts
1000 MHz	800 MHz	67 watts

Table 6: Effect of CPU core (12x) and uncore frequency scaling

can adopt RENC by gradually reducing uncore frequency while monitoring low-load slack.

9.5 Overhead of RENC

Userspace agent. We measure the CPU cost of RENC's userspace agent as 20% of a CPU core, when running the CPU at low frequency. RENC does not require a dedicated CPU core nor does it busy-poll. It runs on shared cores used for other tasks such as the DU's management/logging threads.

Kernel eBPF. We measure the execution time of RENC's eBPF program as 70 ns per invocation at 1 GHz, using Linux's BPF stats functionality via the `bpftool` command. This is tiny when compared to the total cost of context-switching between threads, which is around 3 µs on our system even when running at 3.4 GHz. The eBPF program is called twice per context switch, costing <4.6% of a context-switch.

10 Related work

Section 2.2 covered energy saving techniques in traditional base stations. We present related work in other areas below.

Approaches that target vRANs. CRT [55] statically precomputes CPU core frequencies for different MAC modulation and coding schemes (MCS); this is done in an adhoc way, e.g., by checking if errors appear in code execution. Compared to CRT, RENC adds (1) principled deadline slack measurement which is done at runtime, (2) coupling of MAC scheduling and CPU frequency changes for safety, (3) handling of CPU spikes from control messages, and (4) evaluation in a real testbed. Ayala-Romero et al. [19] develop Bayesian algorithms to jointly optimize vRAN power consumption and performance. However, the system does not account for realtime deadlines. While these systems target open-source RAN implementations (OpenAirInterface and srsRAN), RENC tackles the additional challenges that arise in closed-source, binary-only setups, as well as in the comparatively higher complexity of commercial vRAN sofware.

Multi-server approaches. China Mobile has published details of a large RAN energy efficiency effort in China, which uses machine learning to pick cells to power-off [49]. A large body of theoretical work studies the bin-packing of RUs to the fewest DU servers, aiming to save energy during low load periods [61]. Cellular operators also optimize energy consumption at longer time horizons to match the diurnal traffic patterns [49], e.g., MIMO-level sleep, and cell-level sleep [22, 24]. RENC's single-server and sub-second optimization is complementary to these approaches.

Single-server approaches. Recent techniques for sharing the DU's realtime CPU cores with non-realtime workloads may be adapted for DU energy saving: Concordia [35]'s prediction of PHY task execution time can be used to place PHY cores in a deep C6 sleep state to save energy, although it will need to overcome C6's high residency time (Table 1, Appendix A). Nuberu [38] re-designs the PHY layer to better co-exist with interference from other workloads. If a DU implements a Nuberu-like technique, it can simplify RENC design by allowing rare deadline violations.

11 Conclusion

RENC takes the first step towards building a complete energy saving system for servers running commercial vRAN software. The difficulty lies in the closely-guarded nature of the software code that makes it a black box for operators, coupled with sub-ms real-time deadlines that must be met for functional correctness, as well as a highly bursty CPU load. We solve this challenge by carefully establishing intervals of low load that are safe for energy saving, and using new systems techniques such as our eBPF program to measure the available slack for CPU frequency reduction. An evaluation in a state-of-the-art vRAN testbed shows promising results, with up to 45% reduction in CPU energy compared to default settings.

A Appendix

Applicability of C6 sleep state to vDUs

C6 may work for some DU threads with multi-TTI deadlines. In our DU, these are only FlexRAN's PHY signal processing threads (which run on four of 11 cores in our DU, Section 8), whose deadline is three TTIs. Although FlexRAN provides a partial implementation for C6 [43], it is incomplete at the time of writing; FlexRAN's public C6 description suggests that it puts threads to sleep one TTI at a time with `usleep(500)` [43], which will not save energy on our CPUs, and may have been designed for older processors e.g., Cascade Lake, with 276 µs [47] C6 residency time.

On our Ice Lake CPUs, we found that a CPU core goes into C6 when an application requests a sleep of at least 650 µs (e.g., via `usleep(650)`). The call to `usleep(650)` returns after up to 820 µs, due to the 170 µs wakeup latency of the C6 state.

Building Massive MIMO Baseband Processing on a Single-Node Supercomputer

Xincheng Xie, Wentao Hou, Zerui Guo, Ming Liu

University of Wisconsin-Madison

Abstract

The rising deployment of massive MIMO coupled with the wide adoption of virtualized radio access networks (vRAN) poses an unprecedented computational demand on the baseband processing, hardly met by existing vRAN hardware substrates. The single-node supercomputer, an emerging computing platform, offers scalable computation and communication capabilities, making it a promising target to hold and run the baseband pipeline. However, realizing this is non-trivial due to the mismatch between (a) the diverse execution granularities and incongruent parallel degrees of different stages along the software processing pipeline and (b) the underlying evolving irregular hardware parallelism at runtime.

This paper closes the gap by designing and implementing **MegaStation**[1]–an application-platform co-designed system that effectively harnesses the computing power of a single-node supercomputer for processing massive MIMO baseband. Our key insight is that one can adjust the execution granularity and reconstruct the baseband processing pipeline on the fly based on the monitored hardware parallelism status. Inspired by dynamic instruction scheduling, MegaStation models the single-node supercomputer as a tightly coupled microprocessor and employs a scoreboarding-like algorithm to orchestrate "baseband processing" instructions over GPU-instantiated executors. Our evaluations using the GigaIO FabreX demonstrate that MegaStation achieves up to 66.2% lower tail frame processing latency and 4× higher throughput than state-of-the-art solutions. MegaStation is a scalable and adaptive solution that can meet today's vRAN requirements.

1 Introduction

Massive MIMO (multiple-in multiple-out)–equipping a base station with an array of radio antennas to serve many users simultaneously–has become the essential wireless technology in modern cellular networks such as 5G. It boosts spectral efficiency via multi-antenna techniques and increases network coverage, capacity, and throughput, which many 5G mid-band deployments have adopted [3–5, 12, 14, 38].

RAN virtualization has gained significant traction. It has been employed by many mobile network operators [11, 15, 35, 43, 50–53] and strongly advocated by industry players [36, 118]. It replaces specialized RAN hardware with general-purpose commodity servers or programmable accelerators for baseband signal processing, entailing a slew of benefits, such as mitigating vendor lock-in, offering better inter-operability and operational visibility, reducing the total cost of ownership, and improving network management agility.

However, realizing massive MIMO under vRAN is challenging due to the high computational demands and single-digit millisecond processing deadline of its baseband processing. It consists of a pipeline of non-trivial matrix manipulation tasks–like FFT/IFFT, equalization, and en(de)coding–and converts between radio bits and data packets for each antenna-user pair at every subcarrier frequency. The compounding effect of continuously massive MIMO dimensional scaling [63, 64, 117], the rising number of subcarrier frequencies, increasing radio units being deployed at a cell site, and stringent performance requirements [18] necessitate enormous execution parallelism and computing power, which are hardly met by today's vRAN computing substrates.

People have tackled this problem by either building rack-scale distributed baseband processing systems [71, 121] or developing specialized accelerator-based platforms [28, 58, 79, 100]. For example, Hydra [71] splits the frame processing pipelines [65] over multiple X86 servers and designs efficient synchronization to minimize the data shuffling overheads. When scaling, one has to use multiple servers, adding capital/operational costs and taking more physical space, which is a key concern for future Telco site infrastructures [6, 39]. LuMaMi [100] develops a bespoke testbed using 50 Xilinx Kintex-7 FPGAs and supports one modest-sized MIMO (100×10) configuration. The system is not flexible and requires relaying out the software-defined radio array and partitioning symbol processing paths when updating the MIMO settings or accommodating user traffic vagaries. Therefore,

[1] MegaStation is available at https://github.com/netlab-wisconsin/MegaStation.

prior solutions struggle to provide adequate computing parallelism with flexible programmability at an acceptable cost.

Empowered by recent cluster interconnects (like Routable PCIe [2] and UALink [54]), infrastructure composability becomes possible, and an emerging computing platform–called **single-node supercomputer (SNC)** [44]–receives great attention and interest. It is a physically compacted testbed, comprising one server host and a composable GPU pool (enclosing tens of GPUs in standalone chassis), connected through backplane or external fabric switches, such as the GigaIO SuperNODE [44]. An SNC (a) holds substantial execution parallelism where remote GPUs behave as local ones and run host-native system stacks, (b) provisions adequate and consistent bandwidth for host-GPU and GPU-GPU communication, and (c) allows incrementally on-demand GPU scaling, making it a promising target for running highly parallel and compute-intensive applications, like AI/HPC.

In this paper, we design and implement **MegaStation** that harnesses the computing power of an SNC to process the baseband for vRAN-based massive MIMO. This is challenging because of the mismatch between the application software parallelism and the underlying hardware computing parallelism. The MIMO baseband processing pipeline comprises a sequence of stages that run at different execution granularities (such as antenna, user, and subcarrier) with incongruent parallel degrees. State-of-the-art solutions [65, 71, 100, 121] parallelize the pipeline at the frame, symbol, or task level. They are all suboptimal and would gradually make the underlying hardware parallelism irregular, adversely affecting the baseband processing performance (§3). Thus, without careful coordination and scheduling, one would experience radio bandwidth drops, frame processing deadline violations, and computing resource waste.

MegaStation addresses the challenge by revamping the baseband processing pipeline and applying techniques from the computer architecture field. *Our key idea is to model the single-node supercomputer as a tightly coupled microprocessor and employ a scoreboarding-like scheme [115] to schedule "baseband processing" instructions based on GPU hardware status.* MegaStation comprises four software modules: (a) *an instruction unit* that translates frame sequences to task instructions and analyzes their data dependency and structural hazards; (b) *processing function units*, which holds baseband processing instructions and runs over GPUs; (c) *the scoreboarding*, a centralized bookkeeper that continuously tracks the execution status of inflight instructions and performs resource accounting of the GPU pool, serving as the basis for other components; (d) *a pipeline scheduler*, orchestrating instruction execution via a new algorithm (called LROC) that sparingly synthesizes the least slack time scheduling with instruction reordering, over-commitment, and coalescing techniques. Therefore, MegaStation adjusts the execution granularity and reconstructs the baseband processing pipeline on the fly based on the dissected hardware parallelism status.
