Message from the NSDI '25 Program Co-Chairs

Welcome to the 22nd USENIX Symposium on Networked Systems Design and Implementation (NSDI '25).

We are pleased to bring to you an exciting array of papers representing the best work in the networked systems research community. We hope that you will come away from NSDI invigorated, inspired and reconnected with the cross-cutting work across the broad community.

In keeping with past years, NSDI '25 received a record number of submissions, a total of 666, 11% more than last year on a growing spectrum of research topics. There were 265 papers in Spring and 401 papers in the Fall cycle. Of these, only papers that addressed both network and systems challenges, with network contributions spanning multiple layers of the OSI stack were considered to be in scope (https://www.usenix.org/conference/nsdi25/call-for-papers). Out of the 565 papers deemed in scope, 83 were accepted into the program. The final program has a 12.5% acceptance rate, where 14.7% of the papers in scope were accepted. It is our hope to see the acceptance rate grow as the community adjusts to the scope changes in the future years.

To ensure that the submissions receive 3-6 reviews with adequate expertise, we assembled a Program Committee of record size, consisting of 198 members from 118 institutions across 20 countries. Of these, 87 committee members were chosen from 177 self-nominations; these included many first-time committee members. Our goal with PC composition was to balance many key factors, especially, expertise and seniority across NSDI topics. With this carefully chosen large PC, we were able to keep the reviewing load to at most 18 for the entire year; each member reviewed at most 6 papers in Spring and 12 papers in the Fall cycle.

Papers with at least one weak accept advanced from R1 to R2. In Spring, 87 of the 200 papers in R1 made it to R2 and in Fall, 201 of the 365 R1 papers made it to R2. More papers advanced in the Fall cycle because many papers lacked the necessary reviews to decide them. Overall, reviewers submitted a total of 2805 reviews, 868 in Spring and 1937 in Fall. Many reviewers helped out with last minute review requests, especially in the Fall cycle, to fill review gaps and keep us on time.

This year we introduced two additional committees to handle NSDI's growing scale.

To maintain NSDI's high standard of reviewing and to guide first time PC members, we recruited a Review Task Force of 24 experienced committee members who were tasked with reviewing paper reviews in lieu of a smaller reviewing load.

To ensure that submissions met the criteria in the CFP, such as anonymization, we formed the Pre-Review Task Force composed of 21 senior PhD students. These students were recruited from 81 nominations we received to an open call, based on their authorship experience in top-tier systems conferences. Both chairs reviewed every paper that the Pre-Review Task Force flagged to eliminate false violations. The Pre-Review Task force gets the credit for admitting very few CFP violations into the review pool. We hope that future program chairs continue to benefit from students' experience while providing them with valuable insight into PC operation. We also hope future chairs enhance the experience of students beyond what we did in NSDI '25 and provide them with exposure to members of the PC.

The SC has had the idea of limiting NSDI's scope for a few years now. We undertook the responsibility of defining what this scope should be and enforcing it in NSDI '25. Together with the SC, we determined that the desired scope of NSDI is defined by contributions that address both network and system challenges. Since the SC required this definition to be tested out before impacting the CFP, it was decided that the chairs would be responsible for flagging submissions that were out of scope to the SC by anonymizing them, and these would be cross-checked by the SC. This tight coupling between the SC and the chairs worked well in Spring, but fell apart in Fall when the submissions grew by 1.5x. The direct consequence of the chairs and SC assuming the burden of this tight coupling was the untimely delivery of scope rejections. We are happy to see our feedback to the SC reflected in a clear scope definition in NSDI '26 CFP and a more streamlined mechanism to deliver scope rejections.

Reflecting on our experiences, we have two key pieces of advice for future chairs as they consider scope implementations in the face of NSDI's growing submissions. First, to carefully consider how they split responsibilities with the Program Committee as they consider new ideas to implement. Second, to scale this partnership by communicating decisions and guidance to the community in a timely manner, ideally well before submission deadlines.

Our gratitude goes out to Usenix, the Steering Committee, past chairs, the Program Committee, the Review and Pre-Review Task Force, and the Award committee members for making NSDI '25 possible. Special thanks to Renata Teixeira for her multiple roles as a counsel, the co-chair for chair-conflict papers, Review Task Force and Awards Committee member; and to Jon Howell, Jay Lorch, Gianni Antichi and Sujata Banerjee for their counsel. Together, they contributed immensely towards making chairing a pleasure.

Theophilus A. Benson, *Carnegie Mellon University*

Abstract

For decades, Random Early Detection (RED) has been integrated into datacenter switches as a fundamental Active Queue Management (AQM). Accurate configuration of RED parameters is crucial to achieving high throughput and low latency. However, due to the highly dynamic nature of workloads in datacenter networks, maintaining consistently high performance with statically configured RED thresholds poses a challenge. Prior art applies reinforcement learning to predict proper thresholds, but their real-world deployment has been hindered by poor tail performance caused by instability. In this paper, we propose PRED, a novel system that enables automatic and stable RED parameter adjustment in response to traffic dynamics. PRED uses two loosely coupled systems, Flow Concurrent Stabilizer (FCS) and Queue Length Adjuster (QLA), to overcome the challenges of dynamically setting RED parameters to adapt to the ever-changing traffic pattern. We perform extensive evaluations on our physical testbed and large-scale simulations. The results demonstrate that PRED can keep up with the real-time network dynamics generated by realistic workloads. For instance, compared with the static-threshold-based methods, PRED keeps 66% lower switch queue length and obtains up to 80% lower Flow Completion Time (FCT). Compared with the state-of-the-art learning-based method, PRED reduces the tail FCT by 34%.

1 Introduction

Datacenters host a variety of services with distinct networking preferences. For example, storage [1] and data mining [2] require high throughput, while web search [3] and machine learning [4] services require low latency. To meet these application requirements, a lot of innovative congestion control algorithms (e.g., DCTCP [3], DCQCN [5], TIMELY [6], HPCC [7], Swift [8], BFC [9]) have been proposed to reduce the delay caused by in-network queuing.

These new congestion controls demonstrate tremendous improvements; however, deployment is a challenging issue. For instance, it takes Google a year to release a new kernel to support new network functions [8, 10]. Many congestion controls need to be deployed on hardware Network Interface Cards (NICs) (e.g., HPCC [7]) or require new switches to support them (e.g., BFC [9]), which cannot be deployed in heterogeneous datacenters made up of legacy devices [11]. In some particular scenarios, such as multi-tenant datacenter networks, it is also difficult to modify the network protocol stack at the end host [12, 13].

To compensate for the host-based new congestion control protocols, the community also explores more accurate in-network congestion signals [14–17]. For instance, Explicit Congestion Notification (ECN) [18] is widely deployed in datacenter networks as the new congestion signal besides packet losses. Random Early Detection (RED) [19], the algorithm that controls how to discard packets or how to mark packets for ECN, has also been integrated into switches as a basic Active Queue Management (AQM) function. Many production datacenter transport protocols rely on ECN and RED [20–22], such as DCTCP and DCQCN.

Broadly speaking, the prior work on addressing RED/ECN's shortcomings can be classified as either new AQMs (e.g., TCD [14]), case-based RED/ECN (e.g., ECNsharp [15], BCC [16]), or learning-based RED/ECN (e.g., ACC [17]). The new AQM relies on a new switch design, thus requiring a long product release cycle [17]. The case-based arts (e.g., ECNsharp, BCC) realize that RED/ECN with a fixed threshold is ineffective in datacenters and therefore propose to consider multiple cases during threshold adjustment. However, they only recognize a limited number of cases and still use fixed thresholds for each case (see details in § 6.3.2). Prediction model-based ACC [17] leverages the deep reinforcement learning (DRL) [23] to adjust the RED settings dynamically in reaction to network congestion. However, it might make the adjustment of the RED unstable, resulting in sharp changes in queue length and poor tail performance (see details in § 6.3.3).

Thus from a philosophical standpoint, it is worth asking: Why can't static RED adapt to dynamic traffic? Can the prob-

*Tong Li and Ke Xu are the corresponding authors.

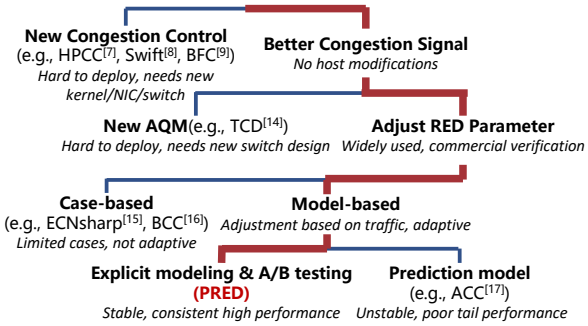

Figure 1: Design space in Datacenters.

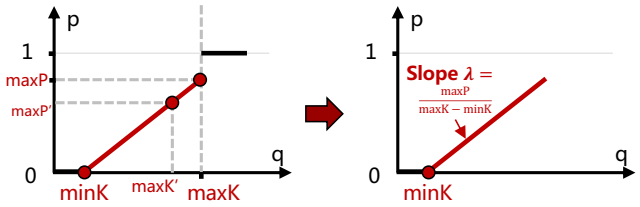
lem be solved simply by dynamically adjusting the threshold of the already widely used RED without modifying the algorithm itself? Is there a stable way to adjust the RED threshold? In this paper, we seek to answer these questions with a new scheme PRED (Performance-oriented RED).

Figure 1 surveys the design space for congestion control and places PRED in context by following the thick red lines through the design tree. At the highest level, PRED is an AQM implemented on the switches to provide a better congestion signal. Next, instead of designing a new AQM that needs an entirely new switch design, PRED dynamically adjusts the parameters of the widely commercially proven RED in datacenters. As shown in the lowest branch of the design tree, PRED falls into the category of explicit modeling and A/B testing approach that is more adaptive and stable.

Through experiments, we have discovered that the performance of RED is mainly influenced by the concurrency and distribution of traffic. Prediction model-based ACC [17] initially employed a traffic-aware approach to proactively adjust the RED threshold; However, it failed to provide stable adjustment due to two reasons: **the impact of rapid changes in concurrent flow numbers** and **inaccurate predictions**. Different concurrency levels require different settings, but because there is a mismatch between the delay of DRL and the delay of estimating concurrency, ACC cannot make adjustments based on concurrency levels. Moreover, due to inherent error rates in machine learning predictions, the design principle of ACC fails to achieve consistently stable performance.

PRED employs two loosely coupled systems, namely the Flow Concurrent Stabilizer (FCS) and Queue Length Adjuster (QLA), to address the difficulties associated with unstable adjustments in dynamically adjusting RED parameters. In order to keep the queue length stable under different concurrency levels, FCS uses modeling to adjust RED parameters by counting the number of concurrent flows on a switch port. In order to achieve stable real-time adjustment of the queue length to accommodate varying traffic, QLA employs a step-by-step approach, utilizing testing and verification methods, to gradually modify the RED parameters. With FCS and QLA, PRED can achieve consistently high performance under dynamic traffic in a more stable way without modifying the RED logic.



(a) Two-point form (b) Point-slope form

Figure 2: Two Forms of RED parameter configuration.

We implement a prototype of PRED using the barefoot Tofino switch [24] as the programmable data plane and evaluate PRED extensively using various use cases. Our testbed experiments show that PRED can keep queues stable under various flow-concurrent conditions. Based on real network workloads, we demonstrate that PRED can properly adjust the RED parameters to a more workload-friendly state to keep up with the traffic dynamics.

We further perform larger-scale simulations to evaluate PRED. Our quantitative results confirm that PRED advances state-of-the-art in various aspects. For example, compared with the algorithms with static thresholds, PRED can achieve up to 80% lower Flow Completion Time (FCT) for short flows. From the microscopic view of switch queues, PRED effectively mitigates queue buildups by keeping the switch queue length 66% lower than that of the static threshold algorithms (from 25 to 15 packets). We further demonstrate that PRED reduces the 99th FCT by 34% compared to ACC, the state-of-the-art DRL-based RED configuration approach, whose uncertainty results in suboptimal parameter selections in extreme cases.

The rest of the paper is organized as follows. We introduce the background in § 2 and the motivation of the PRED in § 3. § 4 illustrates the design of our solution. In § 5, we address the implementation of PRED on P4 [25]. In § 6, we evaluate PRED in NS-3 [26] and a small-scale testbed. § 7 surveys the related work. Finally, § 8 concludes this paper.

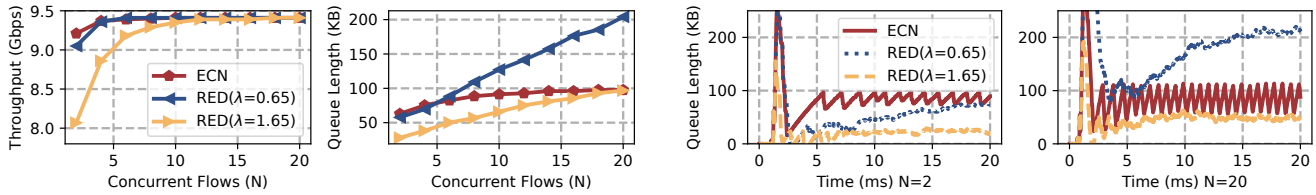
2 Background

2.1 The Form of RED Setting: Two-point Turns to Point-slope

RED [19] is the most widely applied AQM scheme and is commonly supported by commodity switches. [1] The state-of-the-art congestion control mechanisms have widely adopted RED in datacenter networks. For example, DCTCP [3] and DCQCN [5] adopt RED with the standard ECN on switches and use the marked-packet-aware rate control on end hosts. First of all, to facilitate the design of PRED in this paper, we revisit the RED parameter configuration by explaining why we replace the two-point form with the point-slope form.

Two-Point Form. RED works on switches and makes decisions about marking packets based on the output queue length

[1] We note that if not otherwise specified, RED adopts packet marking ECN instead of packet discarding in this paper.



(a) Testbed Result (b) Simulation Breakdown

Figure 3: RED performance with different flow concurrency levels (N).

(denoted by q). The decision-making is driven by three parameters, including the maximum marking probability (maxP), and two queue thresholds (minK and maxK). When the queue length is lower than minK, no action is taken. When the queue length exceeds maxK, every arrived packet is marked. When the queue length is between minK and maxK, RED calculates a probability p that the packet should be marked. In production networks, linear interpolation is the common practice to calculate p as $p = \text{maxP} \cdot \frac{q-\text{minK}}{\text{maxK}-\text{minK}}$. As plotted in Figure 2(a), the resulting curve of p is in the *two-point* form: point (minK, 0) and point (maxK, maxP).

Point-Slope Form. In this paper, we argue that applying the equivalent *point-slope* form makes the design of the RED parameter configuration more interpretable (see §2.2). As shown in Figure 2(b), we define λ ($\lambda \in (0, +\infty)$) as the slope of the line. λ is computed as $\lambda = \frac{\text{maxP}}{\text{maxK}-\text{minK}}$, and thus we have $p = \lambda \cdot (q - \text{minK})$. For example, given $\text{minK} = 0.005$ MB, $\text{maxK} = 0.2$ MB, $\text{maxP} = 0.1$, we have $\lambda \approx 0.5$.

2.2 The Essence of RED Setting: Controlling the Steady-state Queue Length

RED is a tool for congestion control convergence, so adjusting the RED threshold is essentially adjusting the steady-state queue length as it converges. To explain why we replace the two-point form with the point-slope form and the essence of the RED setup, we first take DCTCP as an example of the RED parameter breakdown based on a fluid model [3,5]. Considering N long-lived flows traversing a single bottleneck link with capacity C and propagation delay d (RTT without queueing), the relationship between the steady-state queue length (denoted by $\dot{q}$) and the RED setting is derived as follows[2] (see Appendix A for detailed derivations):

$$(\dot{q} - \text{minK})^2(\dot{q} + Cd) = \frac{2N}{(\frac{\text{maxP}}{\text{maxK}-\text{minK}})^2} = \frac{2N}{\lambda^2} \qquad (1)$$

λ can monotonically influence $\dot{q}$: The first thing we infer from Equation (1) is that λ can monotonically influence $\dot{q}$. This reveals that the point-slope form expresses a more clear physical meaning than the two-point one. If we adjust minK, maxK and maxP, different settings may lead to the same result, for example, (minK,maxK,maxP) and (minK,maxK',maxP') in Figure 2(a). It is easier for the operator to adjust the parameters if there is only one variable and the linear adjustment will result in a linear result. Therefore, the point-slope is better than the two-point because the monotone change in the λ in the two-point form results in a linear change in the steady-state $\dot{q}$. In the latter, we use (minK,λ) to replace (minK,maxK,maxP).

Key factors affecting the $\dot{q}$: From Equation (1), we can see that the steady-state $\dot{q}$ is only related to three key factors. **(a) The network-specific factor**, including the bottleneck link C and propagation delay d. Once the network topology is built, this factor will be fixed. **(b) The flow concurrency level** N. The larger N is, the larger $\dot{q}$ is. If the network experiences drastically changing N, the steady-state $\dot{q}$ will change accordingly. [3] **(c) The setting of RED parameters** (the only one that the network operator typically controls), i.e., λ and minK. By setting the RED parameters, we can properly adjust the steady-state queue length.

3 Motivation

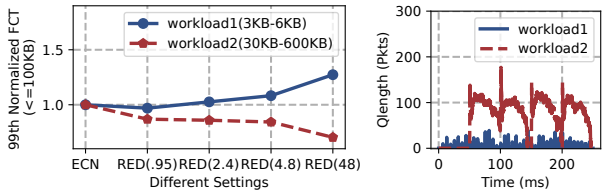
3.1 RED Requires Traffic Awareness

We define the *flow concurrency level* on a switch as the number of flows whose packets are buffered in the switch's output queue at a certain time, define the *flow distribution* as the distribution of flow sizes and define *steady-state queue length* (denoted by $\dot{q}$) as the average queue length of the switch output queue at the stable state. Based on the measurement studies on datacenter network workloads with varying flow concurrency levels and flow distributions, we observe two interesting observations in RED parameter configurations.

Observation 1 (Flow Concurrency): Steady-state queue length grows with the number of flows. From Equation (1) in § 2, we conclude that the larger N is, the larger $\dot{q}$ is. In this section, we also verify this observation through experiments. In these experiments, we run many-to-one (incast) tests with different flow concurrency levels through both testbed evaluation and NS-3 simulation (see setup details in § 6). *ECN* acts as the baseline, which represents the legacy way of marking packets using a single threshold [3], i.e., minK = maxK. *RED* ($\lambda = 1.65$) represents a more aggressive RED parameter setting with higher ECN marking probabilities, and *RED*

[2] Similar conclusions are reached by other ECN-based congestion controls, as demonstrated in studies [27]. Additional sources, including DCQCN and TCP [27, 28], also uphold consistent conclusions. For brevity, we skip the detailed discussion. The assumption of N long-lived flows is for simplicity in understanding the congestion model, but it is not a strict requirement.

[3] The RED capacity of queue adjustment is limited. When N becomes too large, Equation (1) becomes ineffective. The detailed discussion is in § 4.3.



(a) FCT (b) Queue length

Figure 4: RED performance with different workloads.

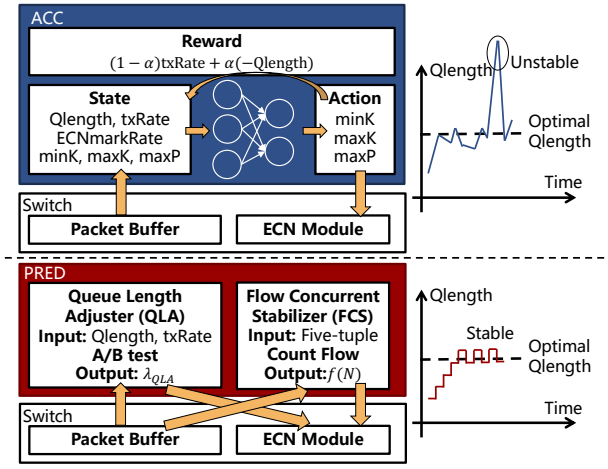


Figure 5: The design comparison of ACC and PRED.

($\lambda = 0.65$) represents a more conservative RED.

Figure 3(a) shows the testbed results of total throughput and queue length on the switch. Through experiments, we again verify that the queue length of both RED ($\lambda = 0.65, 1.65$) increases with the increase of N. This conclusion holds even in the case of multiple bottlenecks, where several hops before the last hop are also congested (see § 6). Datacenter network traffic can be very bursty, but the static RED algorithm increases $\dot{q}$ as the flow concurrency level increases. The tail FCT of short flows will increase with the increase of concurrency, which seriously affects the application performance. A large number of concurrent flows can also suffer from the TCP incast throughput collapse because the queue length is not bounded at the bottleneck switch. A high queue length may trigger back pressure mechanisms (e.g., ECN in DCTCP and priority-based flow control (PFC) in DCQCN) that restrain pushing more packets into the network.

We can also find that different concurrency levels require different λ. *RED* ($\lambda = 1.65$) suffers from under-bandwidth utilization when the flow concurrency level is low, and *RED* ($\lambda = 0.65$) suffers from high queuing delay (queue length) when the flow concurrency level is high. We further zoom into the run-time queue length via simulations for the case of $N = 2$ and $N = 20$. As shown in Figure 3(b), a larger λ (e.g., $\lambda = 1.65$) achieves better performance (i.e., high bandwidth and low latency) when the concurrency level is large (e.g., $N = 20$), and vice versa. Although *ECN* achieves acceptable bandwidth utilization and overall low latency, its amplitude of the steady-state queue length increases with the flow concurrency level. This indicates that applying the single threshold is insufficient to achieve consistent low latency. **To sum up, static RED is not suitable for dynamic flow concurrency.**

Observation 2 (Flow Distribution): Small flows require a large steady-state queue length, while large flows require a small steady-state queue length. In this experiment, we examine RED performance given different flow distributions. We created two different workloads to represent pure small flows and large flows: workload 1 has a flow distribution of size from 3 KB to 6 KB, and workload 2 has a flow distribution of size from 30 KB to 600 KB. In the many-to-one scenario, the number of concurrent senders is fixed at 18 (see setup details in § 6). Figure 4(a) plots the normalized 99th-percentile FCT of flows. The x-axis denotes different settings of λ. It is clear that under workload 1, FCT increases with λ, while under workload 2, FCT decreases with λ. This shows that the proper RED parameter configuration highly depends on the flow distributions in the workload.

For flow distribution such as workload 1, where small flows are dominant, the bottleneck queue is only occupied for a short time. The changes in queue length are spikes one by one in Figure 4(b). Link utilization is not full all the time. Therefore, in this case, increasing the ECN marking probability (increasing λ) will further reduce the link utilization, resulting in a larger FCT of the small flows. To achieve low FCT, the steady-state queue length is expected to be large enough (decrease λ) to avoid triggering packet marking at the bottleneck switch. On the other hand, for flow distribution such as workload 2, where larger flows are dominant, the high link utilization and high bottleneck queue occupancy will last for a long period. This queue occupancy is unnecessary and significantly impacts the latency of small flows. Thus, the steady-state queue length is expected to be small enough to achieve low FCT performance. **In conclusion, static RED is also unsuitable for dynamic flow distribution.**

3.2 Our Goals: Traffic Awareness and Stability

Since the influence of flow concurrency and flow distribution makes the static RED unsuitable for dynamic flows, a natural question is: Can we make the RED parameters configuration traffic-aware? ACC [17] and PRED share a common high-level approach of dynamically adjusting RED parameters. In the following sections, we will highlight the limitations of ACC and explain how PRED overcomes these limitations by achieving stable queue length adjustments.

Limitations of ACC. ACC was the first to use deep reinforcement learning (DRL) to adjust RED parameters to make RED traffic-aware. As shown in Figure 5, ACC takes the following four features as the input state: The current queuing length, the output data rate for each link, the output rate of ECN marked packets for each link, and the current ECN setting. The output action is the next ECN setting. Then, high throughput and short queues are used as reward functions to continuously train the neural network to learn historical data, so as to make

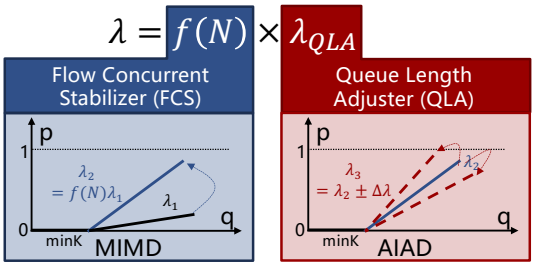

Figure 6: The design rationale of PRED.

predictions for future scenarios. DRL is a valuable approach for adapting to dynamic environments. However, as discussed in § 6.3.3, ACC tends to induce high instability in the queue, resulting in prolonged tail FCT and substantial degradation of the overall user experience.

There are two reasons for the instability of ACC adjustment: (a) **The impact of rapid changes in concurrent flow numbers:** ACC struggles to promptly adjust to varying concurrency levels because of the swift fluctuations in N, resulting in instability. Given that the delay in DRL falls within the millisecond range, while the calculation of concurrency level N operates at the microsecond scale, achieving real-time matching of N is infeasible. Even if ACC can match N in real-time, it also has the following problem. (b) **Inaccurate predictions:** ACC operates on a prediction model derived from observed and learned historical data to make decisions. However, incorporating additional network conditions does not ensure accurate predictions matching 100% real-world scenarios. Predictions inherently carry an error rate, and when an inaccurate prediction is made, the network's performance becomes unstable, ultimately leading to a degradation in tail FCT. Next, we will explain how PRED can be stabilized through the following two problems.

How to bound queue according to flow concurrency? Our answer is to count N directly in the switch and adjust the RED λ according to the flow concurrency. In Equation (1), we analyzed the relationship between $\dot{q}$ and N and λ. The left-hand term $(\dot{q} - \text{minK})^2(\dot{q} + Cd)$ of Equation (1) contains the steady-state queue $\dot{q}$, and if we want $\dot{q}$ to remain constant, then the right-hand term $\frac{2N}{\lambda^2}$ of Equation (1) needs to remain constant. N changes dynamically, but if the switch can calculate the current value of N and then increase/decrease the corresponding λ, then the steady-state queue length $\dot{q}$ will not change with N. We design the Flow Concurrent Stabilizer (FCS) to count the N and change the λ to the concurrency level. As shown in Figure 5, the input to the FCS is a five-tuple of each packet. It outputs the multiplier factor of the change in the RED parameter by calculating the number of flows over a period of time. In Figure 6, FCS works in the form of Multiplicative-Increase Multiplicative-Decrease (MIMD) because it can calculate the corresponding λ directly from N.

How can queue length adjustment be traffic-aware in a stable manner? Our answer to this question is that we test and then verify in small steps. The traffic is uneven and time-varying in datacenters. In order to achieve stable high performance, some workloads demand a smaller steady-state queue length to operate at the optimized point [29], while others demand a larger steady-state queue length to avoid inefficient link utilization. It is difficult for the switch to know the needed steady-state queue length. But the switch knows the queue length and throughput. If the switch can always maintain a high throughput and a low queue length, this queue length must be close to the needed steady-state queue length. We design the Queue Length Adjuster (QLA) to achieve traffic awareness at run time. In Figure 5, QLA takes throughput and queue length as input and outputs a corresponding linear factor λ_{QLA} through the A/B test. First, it sets a utility function in terms of goodput and queue length to judge the performance of the current RED setting. And then, as shown in Figure 6, it applies a direct small modification to λ_{QLA} to adapt λ to the traffic. To reduce the impact of noise, it is tested twice and adjusted only when the results are consistent. Note that any measurement behavior will affect the network performance itself, so the detection step of FCS should be small. Using any of the more aggressive detection algorithms here leads to instability in the network, such as Additive-Increase Multiplicative-Decrease (AIMD), binary search, and prediction-based machine learning algorithms. The QLA works in the form of Additive-Increase Additive-Decrease (AIAD) because it needs stable but fast convergence. AIAD is a heuristic process that relies on A/B testing. Unlike other methods, it demonstrates a clear convergence direction with incremental testing steps. However, it tends to operate at a slower pace compared to other algorithms, which may prioritize speed over stability.

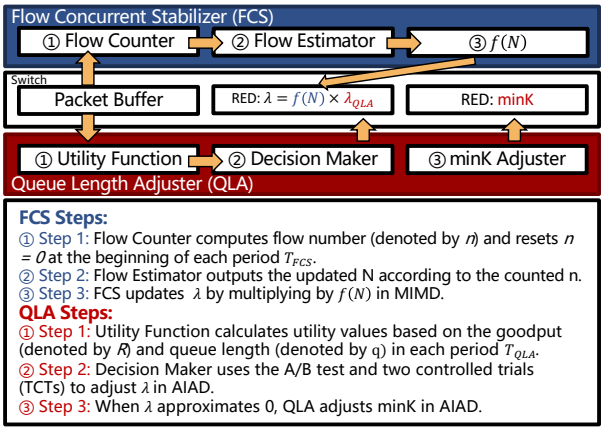

Figure 7: The design of PRED.

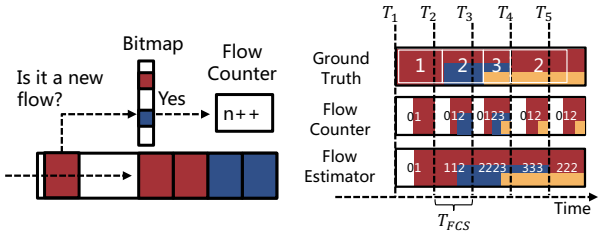
4 Design

In this paper, we propose PRED to answer the question of how to set RED settings dynamically. Figure 7 illustrates the design of PRED, primarily focused on adjusting λ to maintain an optimized $\dot{q}$. The FCS determines N using the flow counter and flow estimator. Subsequently, it applies $f(N)$, a monotonically increasing function of N, to dynamically



(a) Flow Counter (b) Flow Estimator

Figure 8: Examples of how the modules work in FCS.

adjust λ according to the concurrency level. The QLA directly modifies λ_{QLA} to achieve traffic-awareness at runtime. In the following sections, we will delve into each module, covering topics such as N estimation, utility function design, noise reduction through two controlled trials, and dynamic adjustments of minK.

4.1 Flow Concurrent Stabilizer

As shown in Figure 7, the FCS comprises three modules: Flow Counter, Flow Estimator and $f(N)$. (1) Within each T_{FCS} period, the Flow Counter computes the number of flows (denoted by n) traversing a port and resets $n = 0$ at the period's onset. (2) Simultaneously, the Flow Estimator calculates the updated value of N based on the accumulated n. (3) Subsequently, the FCS module adjusts λ by multiplying it with $f(N)$. In the following, we explain how the Flow Counter and Flow Estimator work and discuss the selections of $f(N)$.

Flow Counter (to count new flows). A flow can be identified by the hash of the five-tuple: <source_ip, destination_ip, source_port, destination_port, protocol>. We define the start of the flow as the first time a packet with a particular five-tuple appears at a switch and count the number of flows that send a packet within each timeout-sized interval T_{FCS}. This new-arrival count way helps to avoid biases in cases when the start of flows or the end of flows are missed [30]. The logic is straightforward, as in Figure 8(a), the Flow Counter checks if it is a new flow arrival by looking up the bitmap maintained for each port. If yes, the flow counter increases n by 1. For every period of T_{FCS}, bitmap and n are reset and recalculated.

Flow Estimator (to estimates N). Flow Estimator estimates N by taking into account both the current-period estimate n and the last-period estimate n_{last} output by the Flow Counter, which is $N = \max\{n_{last}, n\}$. Since Flow Counter always starts at 0, we can't treat n as the current N. Figure 8(b) shows an example. 'Ground Truth' represents the actual value of flow concurrency at the present moment. At T_2, the Flow Counter outputs $n = 0$, while the last-period estimate $n_{last} = 1$. If FCS uses n instead of N, FCS will get a bad flow estimate of 0. In this paper, we estimate N at T_2 as $N = \max\{n, n_{last}\} = 1$.

Selection of $f(N)$. In order to bound the steady-state queue length regardless of flow concurrency, according to Equation (1), $f(N)$ should meet $f(N) \geq \sqrt{N}$. Through experiments, we find that using $f(N) = \sqrt{N}$ cannot completely bound the length of the steady-state queue because Equation (1) assumes N synchronous traffic, which is difficult to meet when N becomes large. We test with the choice of $f(N)$ through experiments and choose $f(N) = N$. We have further given the reason why N is feasible in § 6.

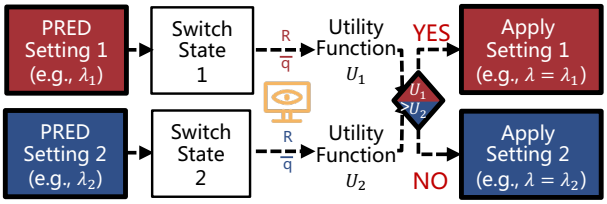


Figure 9: The closed-loop decision-making of QLA.

4.2 Queue Length Adjuster

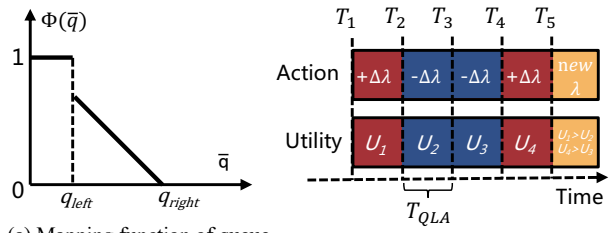
As shown in Figure 7, the QLA comprises three modules: Utility Function, Decision Maker and minK Adjuster. (1) The Utility Function calculates utility values based on the goodput (denoted by R) and the average queue length (denoted by $\bar{q}$) within each period T_{QLA}. (2) The Decision Maker employs the A/B testing and two controlled trials (TCTs) to adjust PRED in AIAD. (3) If deemed necessary (e.g., when λ approaches 0), it further adjusts minK using a similar approach.

The QLA module applies a closed-loop decision-making structure to set λ according to the demand of the traffic pattern. The efficiency of this performance-oriented learning approach is also validated in prior works (e.g., PCC [31–33]). As illustrated in Figure 9, the control action of QLA is its choice of PRED setting. The decision-making is based on the A/B testing of two actions, e.g., $\lambda = \lambda_1$ and $\lambda = \lambda_2$.These performance metrics are combined with the numerical utility values, say U_1 and U_2, respectively, via the utility function. The decision-making of λ is then based on comparing U_1 and U_2. However, the dynamic nature of the network can produce a lot of noise, which leads to inaccurate results in the A/B testing. To reduce the impact of noise, TCTs adjusts only when the results are consistent.

Utility Function (to decide trade-offs). From the network operator's point of view, we usually select the critical network performance metrics of latency and throughput as the reward function [17]. We define the utility function as a trade-off between latency and throughput (i.e., the trade-off between high utilization and low queue):

$$U(\lambda_t) = \beta \times \frac{R_t}{C} + (1-\beta) \times \Phi(\bar{q}_t)$$

R represents the average throughput of one egress queue, i.e., the amount of data delivered to the link during the time interval T_{QLA}. We normalize the R by the link bandwidth C to represent the link utilization. The latency is represented by the average queue length $\bar{q}$ to indicate the impact of queuing delay. β is a weight factor. We select the average value instead of the instantaneous queue length because the instant queue length varies in a large range, which can make utility unstable. $\Phi()$ is a mapping function as shown in Figure 10(a). Generally, the lower the queue length, the better. Note that when the



(a) Mapping function of queue length

(b) Two controlled trials

Figure 10: Design details of QLA.

queue goes short (e.g., $\bar{q} \leq q_{left}$), the marginal benefit of further reducing the queue length goes to zero. This avoids the situation where the utility function becomes unstable when the queue is too short.

Decision Maker (to reduce noise impact). A simple A/B test will be disturbed by network noise. To decide which direction and amount to change its value, QLA uses TCTs to reduce the noise impact. Assume QLA is currently at setting λ_{QLA}. As shown in Figure 10(b), QLA takes four consecutive T_{QLA} and divides them into two pairs. For each pair, QLA attempts a slightly higher $\lambda_{QLA}+\Delta\lambda$ and slightly lower $\lambda_{QLA}-\Delta\lambda$, each for one T_{QLA}. After the four consecutive trials, QLA needs to judge the next adjustment based on the four utility values ($U_i, i = 1,2,3,4$) obtained four times. If the higher λ_{QLA} consistently has higher utility ($U_1 > U_2$ *and* $U_4 > U_3$), then FCS adjusts its λ_{QLA} to $new\lambda_{QLA} = \lambda_{QLA}+\Delta\lambda$; and if the lower λ_{QLA} consistently has higher utility then QLA picks $new\lambda_{QLA} = \lambda_{QLA}-\Delta\lambda$; But, if the results are inconclusive, e.g., $U_1 > U_2$ *but* $U_4 < U_3$, QLA stays at its current λ_{QLA}.

Adjustment of minK. Besides λ, the other important value in the RED parameter is minK. The initial value of minK can be set very small so that λ can make the steady-state queue adjusted over a wide range ($[\text{minK}, +\infty)$) theoretically. However, in the design, we cannot use $\lambda = 0$ to get a large steady-state queue $\dot{q}$ because the FCS module fails. So when $\lambda < \lambda_{\min}$, QLA no longer adjusts λ and adjusts minK instead. Let minK change ΔminK each time and λ always stays λ_{min} for FCS. For example, in § 3.1, workload 1's burst flow does not occupy the buffer. In this case, minK should be bigger, and the steady-state queue $\dot{q}$ is further increased to avoid the burst being marked with ECN.

4.3 Discussion

Some notable design details of PRED are essential for reasoning about the differences from legacy RED. We briefly discuss these considerations below.

Range of PRED adjustment capabilities. The RED parameter adjustment has limitations, particularly when N surpasses a certain value. Through experiments, we test the adjustment range of PRED and observe that when the number of concurrent long flow N exceeds 32, PRED is unable to maintain queue stability (see Appendix D.6). Fortunately, the occurrence of concurrent long flows is rare [3], indicating that the range of PRED is generally adequate in practice. Moreover, to address high-concurrency short-flow bursts, FCS can rapidly notify the end nodes by adjusting λ to ensure fast convergence of the queue.

About the maxK. In PRED, we utilize the point-slope form (minK,λ) instead of the the two-point form (minK,maxK,maxP). This means that in the point-slope form, the maxK is implicitly incorporated within the parameter λ. However, we acknowledge that maxK is still necessary for final protection in practical implementation because the point-slope is still implemented on the two-point basis. To accommodate extreme scenarios, we set a larger fixed value for maxK. In our measurements, maxK is set to 500 KB.

Selection of T_{FCS}. The T_{FCS} should be carefully set as its accuracy significantly affects the performance. First of all, T_{FCS} must be greater than RTT because the estimate will be small because at least one RTT is required for all flows to pass through the switch. T_{FCS} should not be too big because when the flow number decreases, the update of N will be delayed. As shown in Figure 4.1(b), N remains 3 from time T4 to time T5, while the ground truth is only 2. Considering the queuing delay during congestion, we find that setting $T_{FCS} = 1.25RTT$ is applicable. We have also verified the parameter sensitivity analysis in Appendix D.5.

Selection of T_{QLA}. Note that T_{FCS} is independent of T_{QLA} because the two modules are separate modules. The setting of T_{QLA} is a tradeoff. The smaller T_{QLA}, the faster the convergence, but the more unstable. Vice versa. In addition, it is also limited by the location where the QLA module is deployed. If the QLA module is deployed on the control plane, the interaction delay between the control plane and the data plane should be considered. In our implementation, reading the register in the control plane takes 5 to 12 ms, and updating the RED table takes 80 to 110 ms. Therefore T_{QLA} is at least 200 ms due to hardware limitations. We discuss the details in Appendix C.2. In this paper, it is recommended $T_{QLA} = 5RTT$ in simulation (on the data plane) and $T_{QLA} = 400$ ms in the testbed (on the control plane due to hardware limitation). We have also verified the parameter sensitivity analysis in Appendix D.5.

Selection of other parameters. PRED also has some parameter settings that are trade-offs. In QLA, β is the weight that represents the bandwidth-delay tradeoff. The network operator can easily set the parameters based on the requirement of running applications. For example, our measurements are based on $\beta = 0.4$. The initial minK needs a relatively small value in order to ensure that the adjustment range of the λ can be larger. The initial minK is 10 packets. q_{left} is the parameter that QLA uses to ensure that the value of the utility function remains stable when the queue is small. The larger the q_{left}, the more stable the utility value, but the longer the queue length. q_{left} is set to 15 packets in this paper. λ_{min} is the dividing point between the adjusting λ and the adjusting minK in QLA, we use $\lambda_{min} = 0.05$, For the trial step parameter setting, the bigger the trial step, the faster the adjustment speed, but

the worse the stability, we use $\Delta\lambda = 0.025$, and $\Delta\text{minK} = 5$ packets in this paper. PRED tunes the RED parameters because they are sensitive to traffic dynamics. The parameters introduced by PRED are traffic-insensitive. However, fine-tuning these parameters remains essential, and enhancing the parameter selection process is a key focus of our future work.

5 Implementation

Ideally, PRED's FCS and QLA would be implemented in switch ASICs. We implement a prototype of PRED on Barefoot Tofino 1 programmable switch, including 12 MAU stages, 120 Mbit SRAM and 6.2 Mbit TCAM per pipeline. The development effort on the switch includes about 350 lines of *P*4 code [34] for the data plane and 300 lines of Python for the control plane. The FCS module needs to quickly recognize N, so it is deployed on the data plane. Theoretically, the QLA can be deployed on either the data plane or the control plane. Deployment on the control plane has low resource overhead but high latency, and vice versa. We chose to deploy the QLA to the control plane due to limited MAU stages. We have implemented PRED where both QLA and FCS are deployed on the data plane, but 17 stages are needed (see details in Appendix C). Tofino 1 [24] has only 12 stages, so we deploy the QLA module on the control plane. However, the new Tofino 2 and Tofino 3 switches support 20 stages [24], so the QLA and FCS modules can be deployed in the data plane at the same time. All implementation details are deferred to Appendix C.

6 Evaluation

In this section, we conduct both testbed experiments and NS-3 simulations[4] to answer the following questions:

- How does PRED perform in practice and scale to large datacenters?
- Why does PRED achieve high performance?
- What are the advantages of PRED compared to Deep Reinforce Learning methods?
- How do we decide the key parameters in PRED itself?

6.1 Methodology

Transport Protocol. We are using DCTCP [3] as the default congestion control at the end host. We also have experiments to verify the capabilities of PRED with DCQCN (details in Appendix D.1). Since the results are similar, we only use DCTCP later. In our testbed experiments, we used DCTCP from Linux kernel 4.15.0 [35]. The NS-3 simulation [26] implementation of DCTCP refers to the official implementation [36]. The parameters are set as suggested in [3].

Schemes Compared. We compare PRED against the following 9 schemes:

(a) RED [testbed, simulation]: RED's implementation is based on instantaneous ECN marking rather than weighted average queues, as in the DCTCP [3] and DCQCN [5] papers. For the testbed, we implement it on the Barefoot Tofino switch. For simulation, we start from the NS-3's RED implementation and add instantaneous ECN marking.

(b) ECN [testbed, simulation]: Here we refer to the single-valued RED algorithm as ECN, i.e., instantaneous ECN marking based on a single threshold $minK = maxK = K$.

(c) ECNsharp [simulation]: ECNsharp [15] marks packets based on both instantaneous and persistent congestion.

(d) CoDel [simulation]: CoDel [37] tracks minimal queueing over an interval to mark packets based on persistent queueing.

(e) ACC [simulation]: ACC [17] is a practical approach that allows automatic adjustment of ECN parameters at switches by utilizing deep reinforcement learning (DRL). We refer to the original design in paper [17] and re-implement ACC in the NS-3 simulation.

(f) Only FCS [testbed, simulation]: The particular PRED which contains only the Flow Concurrent Stabilizer.

(g) Only QLA [testbed, simulation]: The particular PRED which contains only the Queue Length Adjuster.

(h) TCN [simulation]: TCN uses instantaneous sojourn time to adapt to packet schedulers. We implement TCN based on the software prototype provided by TCN paper [38].

(i) HPCC [simulation]: HPCC [7] is a new congestion control scheme, which needs to modify the NIC and the switch that supports INT. HPCC can adjust the rate MIMD through the INT information.

Metrics. We use the Flow Completion Time (FCT) as the primary metric. Besides the overall average FCT, we also break down FCT results across small flows (< 100 KB) and large flows (> 1 MB). All are normalized to the results achieved by PRED. We also show a queue length timing diagram for a fine-grained comparison of the various algorithms.

6.2 Testbed Experiments

In this section, we analyze the performance of PRED. Our assessment aims to confirm the stability of traffic concurrency (FCS), assess the effectiveness of dynamically adjusting queues in response to traffic dynamics (QLA), and determine the importance of integrating both modules.

Flow Concurrent Stabilizer. We first tested PRED's stability of traffic concurrency, as well as different design options. We use the testbed in § 3.1 with 3 servers connected to a Barefoot Tofino switch with PRED 's implementation. There are 2 senders and 1 receiver. We used iperf3 [39] for sending traffic and measured the throughput and queue length by varying the concurrent flows sent by each sender. Using only two senders is to verify that concurrency problems still exist in the case of multiple bottlenecks (one at the sender and one at the switch). We use RED as a comparison. We pick initial λ whose effect is approximately equal when N=2. λ in FCS(N) and PRED is 0.1 ($2 \times 0.1 = 0.2$), λ in FCS(N^2) is 0.05 ($2^2 \times 0.05 = 0.2$), and λ in FCS($\sqrt{N}$) is 0.2 ($\sqrt{2} \times 0.2 = 0.28$).

Figure 11 shows the performance of PRED and only FCS with different design choices. We can see from Figure 11(a)

[4] The implementation in NS3 is identical to that of the programmable switch, yet the languages differ; NS3 is C++, and the testbed is P4.

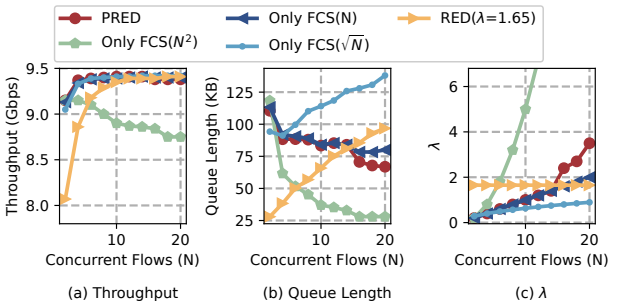


Figure 11: [Testbed] PRED performance with different flow concurrency levels (N).

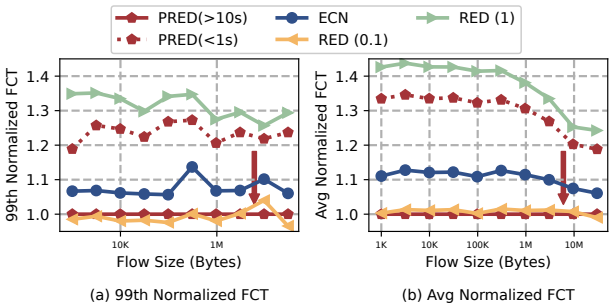

Figure 12: [Testbed] FCT statistics ($T_{QLA} = 0.4$ s).

that all algorithms except FCS(N^2) and RED can maintain a relatively high throughput of about 9.4 Gbps. FCS(N^2) sacrificed about 0.4 Gbps throughput due to low queue length. From Figure 11(b), the queue length of PRED and FCS(N) remained stable with the increase of N. The queue length of FCS($\sqrt{N}$) was still growing, but the queue length of FCS(N^2) was decreasing with the increase of N. The reason for the noise when $N = 2$ is that there is not enough concurrency. Figure 11(c) shows the λ as N changes.

The above analysis shows that it is most appropriate for PRED to select the N for the FCS module. In § 4.1, we analyze that $f(N) = \sqrt{N}$ can eliminate the influence of N on queue length. However, the modeling assumes concurrent traffic, so when N<5, the FCS module can still maintain a stable queue, but when N>5, the concurrent traffic assumption fails so that the queue will grow. We also tested $f(N) = N$ and $f(N) = N^2$, N^2 turns out to be too aggressive, while N is more feasible.

Finally, we compared PRED and only FCS (N) separately. As can be seen from Figure 11(b), when N>15, PRED will make the queue length lower without losing throughput. Compared with only FCS, PRED can further adjust the queue length by adjusting λ according to the network condition.

Queue Length Adjuster. We next tested PRED's ability to tune parameters dynamically. We use 7 servers connected to a Barefoot Tofino switch. There are 6 senders and 1 receiver. Each sender uses an open-source traffic generator [40, 41] to generate the benchmark traffic to the receiver. The network load is 60%. K in ECN is 70 packets. We generate traffic based on WebSearch [3] realistic workloads.

Figure 12 shows FCT on different flow sizes. From the results, we can see that the 99th FCT and average FCT of RED (λ =0.1) is the smallest, and the FCT of RED (λ =1) is the largest. With the same workload, PRED does not initially have a suitable λ, so the FCT of PRED (<1s) is close to RED (1). When run for about 10 s, PRED converge to the appropriate λ, so the FCT of PRED (>10s) converges to RED (0.1). Note that the implementation of PRED on Tofino 1 places QLA on the control plane, so $T_{QLA} = 0.4$ s. As discussed in § 5, the bigger T_{QLA} is, the slower convergence rate is, but the deterministic direction of adjustment is stable. If PRED can be implemented on Tofino 2 or a better switch, T_{QLA} can become smaller and PRED can converge faster.

Based on the above analysis, we know that PRED can bound steady-state queue length with dynamic flow concurrency and can make queue length adjustment traffic-aware in a stable manner to maximize the network effect.

6.3 Simulation Experiments

In this section, we will use simulation to analyze the performance of PRED. At the same time, we will fine-grain compare the differences between different algorithms and answer why PRED can have a good performance. First, the performance of PRED in real datacenters is tested by large-scale NS-3 simulation. Then we analyze why FCS and QLA should cooperate with each other through the sequence diagram of queue length and analyze why the performance of different algorithms is not optimal. Then we compared the differences between DRL-enable ACC and PRED. Finally, we analyze the PRED related parameter settings and packet scheduler in detail.

6.3.1 Large Scale Simulations

To complement our testbed experiments, we evaluate PRED on a larger-scale spine-leaf topology with realistic workloads.

Setup: We simulate a 128-host leaf-spine topology with 8 spine and 8 leaf switches. Each leaf is connected to 16 servers via 10 Gbps links. The spine and leaf switches are also connected via 10 Gbps links. The latency of the link is 10 μs. We use ECMP for load balancing. We generate traffic based on two realistic workloads in production: WebSearch [3] and DataMining [42]. Each sender sends messages in a Poisson flow, and the target loads for the fixed receiver range from 10% to 90%. K in ECN is 70 packets. The instantaneous marking threshold for ECNSharp is 80 μs, the persistent target threshold is 10 μs and the persistent interval is 150 μs. For CoDel, we set the interval to be 150 μs and the target to be 10 μs. The results are shown in Figures 13 and 14. Due to the space limitation, We listed the DataMining results in Appendix D.2. All results have been normalized to FCT achieved by PRED.

Results: As shown in Figure 13, PRED's small flow 99th FCT (1.4 ms) has a reduction ranging from 68% (ECNSharp, 4.34 ms) to 80% (CODEL, 6.68 ms) compared to ECN algorithms at 90% load. For Large flows, there was a negligible increase in the FCT of PRED (96.8 ms), ranging from 4.6% (CODEL, 92.5 ms) to 12.5% (ECNSharp, 86 ms) compared to ECN algorithms at 90% load. This proves that PRED can outperform other ECN algorithms in real-workload scenar-

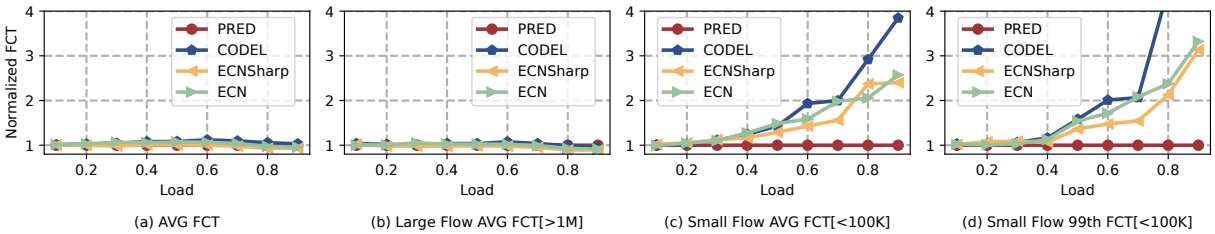

Figure 13: [Simulation] FCT statistics with different ECN algorithm.

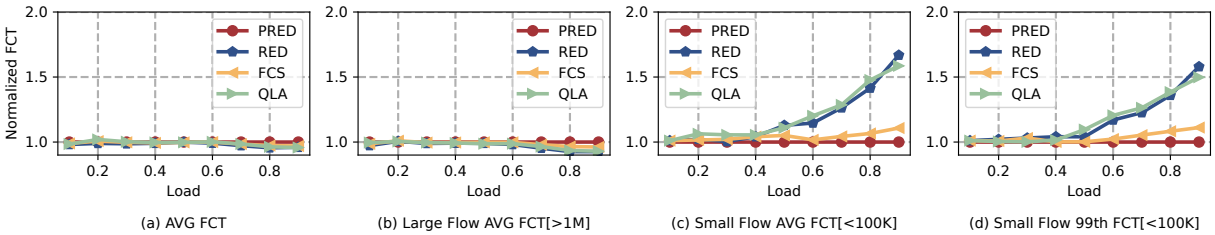

Figure 14: [Simulation] FCT statistics with different RED algorithm.

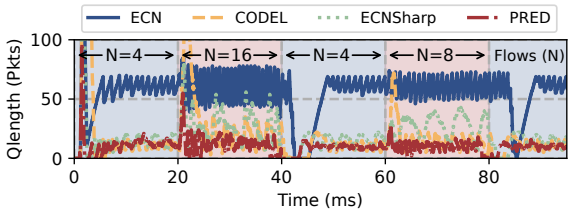
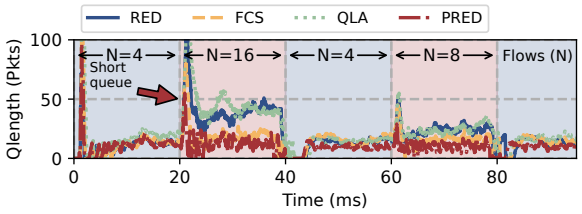


(a) Compare with ECN algorithm



(b) Compare with FCS and QLA

Figure 15: [Simulation] Queue Length.

ios. In Figure 14, PRED and FCS perform better than the static threshold RED. QLA alone does not improve performance. FCS alone is not optimal at high concurrency, and QLA should be combined to further reduce the FCT of small flows.

6.3.2 PRED Microscopic View

We want to know why PRED is better, so we conduct a comparative analysis through time sequence diagrams.

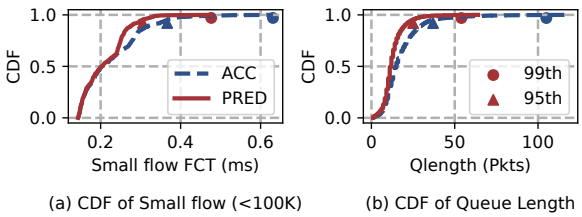
Setup: We use a simple 16-to-1 topology with 10 Gbps links, 16 servers are senders and 1 receiver. Other settings are similar to § 6.3.1. To provide a clearer illustration of how different schemes handle their queues, we sample the queue length of the bottleneck link every 10 μs. The number of concurrent flows is constantly changing.

Results: Figure 15 shows the queue changes of different algorithms at the bottleneck port. PRED effectively eliminates queue buildups by keeping the switch queue length 66% lower than that of the static threshold algorithms (from 25 packets to 15 packets). As can be seen in Figure 15(a), PRED gradually adjusts the queue length over time, making the queue lower than other algorithms. And since it is essentially a RED algorithm, probabilistic marking makes the queue more stable, and the vibration amplitude will be smaller. ECNsharp uses two ECN thresholds, but fixed adjustment makes the queue unstable as shown in Figure 15(a). In addition, PRED can converge faster when a burst is encountered, resulting in less queue fluctuation.

Figure 15(b) compares FCS and QLA. From Figure 15(b), FCS can converge rapidly but will keep the queue length stable at about 23 packets, while PRED will further reduce the queue length. Because QLA cannot adjust λ MIMD according to N, the convergence process is turbulent. Therefore, we can conclude that FCS and QLA need to cooperate so that PRED can achieve the best performance.

6.3.3 Compared with ACC

ACC uses DRL to automatically adjust the RED parameter. DRL requires a lot of data and training to use. We compare PRED and ACC with a simple many-to-one incast scenario. The RED part of ACC uses NS3 simulation and the Learning part of ACC uses NS3-GYM [43]. We use only one agent to learn the traffic conditions in the congested port, reducing the amount of data to learn. We use Double DQN [23] to implement ACC. The **State** is 6 normalized values $(\bar{q}, R, R^m, \text{minK}, \text{maxK}, \text{maxP})$. They are the queue length $(\bar{q})$, the port speed (R), the speed of marking ECN (R^m), and the current RED setting $(\text{minK}, \text{maxK}, \text{maxP})$. **Action** space dimension is $4 \times 3 \times 21$, i.e., $\text{minK}(2,4,8,16) \times \text{maxK}(20,50,100) \times \text{maxP}(\{1\%, j \times 5\%\}, \forall j \in [1,20])$. The **Reward** function is consistent with PRED's utility function. We train ACC for 200,000 epochs using the same trace for both training and testing. It's important to note that in our current testing, ACC encounters the same trace as during training. Even if we aim for deep reinforcement learning to over-fit the results, the stability of the outcomes cannot be guaranteed.



(a) CDF of Small flow (<100K) (b) CDF of Queue Length

Figure 16: [Simulation] CDF of FCT and Queue length.

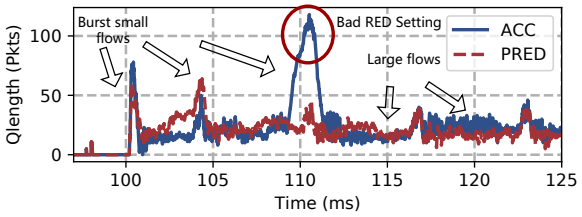


Figure 17: [Simulation] Qlength of ACC and PRED.

Setup: We use a simple 18-to-1 topology with 10 Gbps links, 18 servers are senders, and 1 receiver. Other settings are similar to § 6.3.1. We send flows from 18 senders to the receiver. The size of both large and small flows are generated based on two artificial workloads mentioned in § 3.1 (workload 1 (3-6 KB) for small flows and workload 2 (30-600 KB) for large flows). Both kinds of traffic are sent synchronously, and we measure the FCT of small flows (< 100 KB).

Results: Figure 16 shows the FCT and queue length of ACC and PRED in this particular scenario. As can be seen from Figure 16(a), FCT is similar at 50th, but PRED reduced 99th FCT by 34% compared to ACC (from 0.63 ms to 0.47 ms). From Figure 16(b), the tail of the queue length in ACC is also larger. The 95th percentile in the ACC is 37 packets, and the PRED is 25 packets; The 99th queue length ACC is 105 packets, while the PRED is 54 packets.

According to the above analysis, PRED was better than ACC in tail FCT and tail queue length. To further understand why PRED is better than ACC, we selected a time slice of the ACC runtime, shown in Figure 17. From the figure, the queue length convergence of PRED and ACC is similar because they share the same objective function. However, at around 110 ms, the ACC queue length significantly increases. The reason is that even after ACC is deployed, it still needs to have a random exploration probability from learning new network condition changes. Some bad RED Settings will be selected (around 110 ms in Figure 17), resulting in large queue lengths and high tail latency. In conclusion, the use of machine learning methods needs to be carefully set up in the exploration scheme, The unreadable and untunable model will affect the tail latency. A white-box PRED can ensure that the queue converges to the appropriate position.

6.3.4 100 Gbps with 1000s Concurrent Flows

We also evaluate PRED on 100 Gbps networks and with thousands of concurrent flows.

Setup: The topology is the same as the one used in § 6.3.1 with a 128-host leaf-spine topology and 100 Gbps links. The

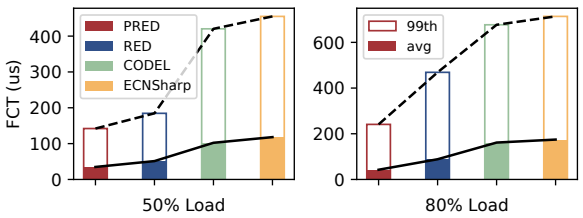

Figure 18: [Simulation] Small Flow FCT statistics with DataMining workload.

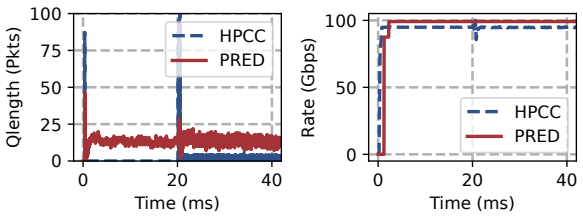

Figure 19: [Simulation] Comparison of PRED and HPCC.

latency of the link is 1 μs. On 128 hosts, randomly select 1000 senders, with an average of 7 senders started per host, and choose a fixed receiver. Each sender sends messages in a Poisson flow, and the target loads for the fixed receiver are 50% and 80% respectively. The DataMining [42] results are shown in Figure 18. Due to the space limitation, We listed the WebSearch results in Appendix D.3.

Results: As shown in Figure 18, PRED's small flow 99th FCT (240 μs) has a reduction ranging from 48% (RED, 468 μs) to 66% (CODEL, 713 μs) at 80% load. PRED's small flow average FCT (42 μs) has a reduction ranging from 52% (RED, 88 μs) to 75% (CODEL, 174 μs) at 80% load. This proves that PRED can outperform other ECN algorithms in 100 Gbps with 1000s concurrent flows.

6.3.5 Comparison of PRED and HPCC

We also compare PRED with HPCC [7] to show how PRED compares to the newer congestion control schemes. HPCC's convergence target is 95% bandwidth, so it can always keep the short queue length and is very friendly for short flows. HPCC needs to modify NICs and switches but PRED only needs to modify switches incrementally. Here we want to see how far PRED is from HPCC.

Setup: We use a simple 20-to-1 topology with 100 Gbps links, 20 servers are senders and 1 receiver. The latency of the link is 1 μs. The parameters are set as suggested in [7]. The NS-3 simulation implementation of HPCC refers to the implementation in [7]. Starting at 0 ms, start two long flows. At 20 ms, 6 long flows are started concurrently.

Results: Figure 19 shows the queue length and throughput of PRED and HPCC. As shown in Figure 19, HPCC has consistently maintained a low queue length of almost zero and 93% throughput. The PRED queue length gradually converges from 20 to 15, and it is always full throughput. At 20 ms burst, the PRED queue fluctuates less, mainly because HPCC does not have a slow start process, so the queue changes greatly.

6.3.6 Packet Scheduler and Parameter Design Choice

We also compare PRED with TCN [38] and ECNsharp [15] to show how PRED works with arbitrary packet scheduler and analyze parameter design choice. Due to space limitations, we present the results in Appendix D.4.

7 Related Work

The most relevant work for PRED is ACC [17], which has been discussed in detail in this paper. Next, we will introduce some other related work.

Dynamically Adjust the RED Threshold. Since the RED algorithm was initially proposed, many proposals studied how to adjust the RED parameters dynamically [44–48]. Feng's ARED [44, 45] adjusts the marking/dropping probability, maxP, in RED to keep the average queue size stable between minK and maxK, in the form of MIMD. Floyd's ARED [46] adjusts maxP in AIMD way to make the queue length fluctuate around a certain value. STAQM [48] adjusts AQM parameters by modeling and parameterizing the RED algorithm and PI algorithm [49] to estimate network state according to network measurement and estimation. These art demonstrate the benefits of dynamic RED parameters. However, they only assure convergence of queue length, while the exact converged queue length must be manually set. As a result, their applicability in datacenter networks is limited.

Recently, there also exist some new algorithms [14–16] for ECN proposed in datacenters. BCC [16] dynamically adjusts the RED algorithm based on the global shared buffer usage. Port-level RED is used when utilization is low, and the shared buffer RED is used when the utilization is high. TCD [14] finds that in lossless networks, the queue has an undetermined state between congestion and non-congestion. It is critical to identify the undetermined state and notify the end host. These art found that ECN with a fixed threshold would be ineffective in datacenters and therefore set more than one state during threshold adjustment. However, they still use fixed thresholds that cannot automatically adjust based on traffic dynamics.

Buffer Sizing and AQM in Internet. The most well-known rule of buffer sizing showed that the minimum buffer size should be $C \times RTT/\sqrt{N}$ when there are a large number of N long-lived TCP Reno flows [50]. Existing new congestion controls such as BBR [29] also require new theories to set buffer sizes [51,52]. Bruce et al. [30] also discussed how to estimate the number of N on a router. The above studies inspired PRED's motivation to dynamically adjust RED Settings by counting traffic numbers in datacenters.

Most ECN-based datacenter congestion control algorithms [3, 53, 54] set the two thresholds of RED to the same value, $\text{minK} = \text{maxK} = K$. The ideal ECN marking threshold K is given as $K = \lambda \times C \times RTT$ [3, 38, 41, 54, 55]. Different congestion controls have different λ, TCP is 1 [54], DCTCP is 0.17 [55]. Through experiments in §3.2, we found that the relationship between single-value RED and N is that the amplitude of the queue increases with the increase of N. Therefore, PRED does not regulate based on single values.

MQ-ECN [41] first pointed out the drawbacks of existing ECN/RED implementations in the packet scheduling context. To adapt to the varying queue capacity caused by packet schedulers, TCN [38] proposed to use instantaneous sojourn time to mark packets. ECNsharp [15] inherits the merit of TCN but further tracks the persistent congestion state to reduce long-term queue buildups. PRED can make the steady-state queue consistent for different priorities/queues so that it can be well adapted to different packet schedulers.

Congestion Control for Datacenters. Most of the network congestion problems are solved by proposing new congestion control solutions. HULL [56] sacrifice throughput in exchange for low latency. It marks the ECN by calculating link utilization rather than queue length. PRED can use a scheme similar to the HULL, but the difficulty is that it requires the endpoint to use the packet pacing function to ensure throughput utilization. pFabric [57], BFC [9], and HPCC [7] rely on precise in-network state information of switches and update transmission rate for each flow. pFabric achieves near-optimal FCT by using (infinite) priority queues on switches. The BFC enables the switch queue to reach one-hop BDP through the backpressure rate control of per-flow and per-hop. HPCC adjusts the speed MIMD through the INT information of the switch. PCN [58], Homa [59] rely on the receiver to send credit packets to determine the sending rate of each flow. TIMELY [6] and Swift [8] are RTT-based schemes to adjust the flow rate at end host. These approaches achieve remarkable performance. However, they require changes to the network stack that are not easy to implement on older hardware devices.

8 Conclusion

This paper revisits the RED parameter configuration and proposes the design of PRED by capturing the key features of datacenter traffic dynamics in terms of flow concurrency and flow distributions. Adaptively and effectively, PRED achieves automatic adjustment of RED parameters stably. Through evaluations, we demonstrate that PRED is more stable than ACC [17], the state-of-the-art learning-based approach. Without any modifications at the end host, and with a more stable RED parameter configuration that adapts well to traffic dynamics, as the future work, we believe PRED has good potential to be deployed in modern production datacenters.

Variable	Description
w	Window size
N	Flow concurrency level
α	Estimated congestion degree of DCTCP
g	DCTCP's parameter
t	Time
q	Bottleneck queue length
RTT	Round-trip time (RTT)
C	Bottleneck link capacity
d	Propagation delay

Table 1: Variables of fluid model.

A Problem Formulation

We take DCTCP as an example of the RED parameter breakdown based on a fluid model, as in paper [3, 5]. Table 1 summarizes the main notations in this paper. Note that we can also analyze other sources (e.g., DCQCN and TCP) in a similar way [27, 28], since the conclusions remain similar, we omit them here for conciseness.

In a fluid model, we consider N long-lived flows traversing a single bottleneck link with capacity C. The following nonlinear, delay-differential equations describe the dynamics of the window size $w(t)$, the DCTCP's estimated congestion degree $\alpha(t)$, and the queue size $q(t)$ at the switch:

$$\frac{dw}{dt} = \frac{1}{RTT(t)} - \frac{w(t)\alpha(t)}{2RTT(t)} p(t - RTT^*) \tag{2}$$

$$\frac{d\alpha}{dt} = \frac{g}{RTT(t)} (p(t - RTT^*) - \alpha(t)) \tag{3}$$

$$\frac{dq}{dt} = N\frac{w(t)}{RTT(t)} - C \tag{4}$$

Here $p(t)$ indicates the RED (ECN) marking process at the switch and is given by:

$$p(t) = \begin{cases} 1, & q(t) > \mathsf{maxK} \\ \frac{q(t)-\mathsf{minK}}{\mathsf{maxK}-\mathsf{minK}}\mathsf{maxP}, & \mathsf{minK} < q(t) <= \mathsf{maxK} \\ 0, & q(t) <= \mathsf{minK} \end{cases} \tag{5}$$

and $RTT(t) = d + q(t)/C$ is the RTT, where d is the propagation delay (assumed to be equal for all flows), and $q(t)/C$ is computed as the queueing delay.

Equations (2) and (3) describe the congestion window adjusting scheme of DCTCP at the source, and Equation (4) describes the queuing process at the switch. The source and the switch are coupled through the packet marking process $p(t)$. This feedback delay is approximately a fixed value $RTT^* = d + q_{avg}/C$.

Equation (2) models the window evolution and consists of the standard additive increase term, $1/RTT(t)$, and a multiplicative decrease term, $-w(t)\alpha(t)/2RTT(t)$. The latter term models the source's reduction of window size by a factor $\alpha(t)/2$ when packets are marked. Equation (3) is a continuous approximation of DCTCP's estimated congestion degree. Equation (4) models the queue evolution: $N\frac{w(t)}{RTT(t)}$ is the network input rate and C is the service rate.

By setting the LHS (left hand side) of Equations (2)-(4) to zero, we see that any fixed points of the DCTCP (if they exist) must satisfy:

$$1 - \frac{\dot{W}\dot{\alpha}}{2}\dot{p} = 0, \dot{p} - \dot{\alpha} = 0, N\frac{\dot{W}}{d + \frac{\dot{q}}{C}} - C = 0 \tag{6}$$

At any of the fixed points, we assume the value of p is $\dot{p}$, which is shared by all flows, and we can get:

$$\dot{p} = \frac{\dot{q} - \mathsf{minK}}{\mathsf{maxK} - \mathsf{minK}}\mathsf{maxP} = \lambda(\dot{q} - \mathsf{minK}) \tag{7}$$

Combining Equations (6) and (7), we eliminate the variable $\dot{p}$, $\dot{\alpha}$ and $\dot{W}$. After simplification, we see that the value of $\dot{q}$ is determined by:

$$(\dot{q} - \mathsf{minK})^2(\dot{q} + Cd) = \frac{2N}{(\frac{\mathsf{maxP}}{\mathsf{maxK}-\mathsf{minK}})^2} = \frac{2N}{\lambda^2} \tag{8}$$

From Equation (8), we can see that the steady-state $\dot{q}$ is only related to three factors. The first factor is related to bottleneck link C and feedback delay d. Once the network topology is built, this factor will be fixed. The second factor is the flow concurrency level N, and the larger N is, the larger $\dot{q}$ is. Due to the dramatic change of the flow concurrency N, the steady-state $\dot{q}$ will fluctuate sharply, which will affect the stability of the network. The last but most important factor is the settings of the RED parameter, i.e., λ and minK. We thus infer that the essence of configuring RED parameters is to adjust the steady-state queue length.

B Additional Discussion

Computing and storage overhead. The computing and storage requirements are minimal. FCS is designed to be pipelined on the data plane, allowing all steps to execute in parallel, regardless of the size of the topology or the number and types of present flows. QLA involves a simple comparison of several values, imposing small computational overhead. In terms of storage requirements, each port requires only a few registers to cache the traffic count N and a corresponding bitmap. For example, each port uses 128 bits, N uses 8 bits, and the remaining 120 bits are used as bitmap.

Highly dynamic traffic pattern. If the network is highly dynamic, PRED will tend to be stable, rather than a faster convergence or faster traffic prediction. In a highly dynamic network, the QLA will filter out the noise, and PRED will adjust the parameters only when there is a positive reward in the statistics within T_{QLA} time. § D.5 shows that PRED

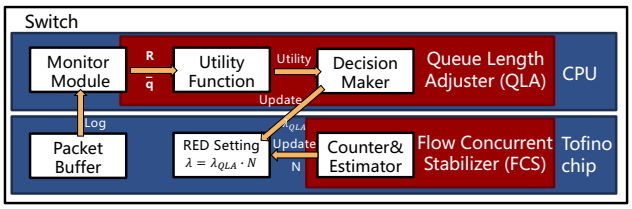

Figure 20: Hardware architecture of PRED on Tofino.

requires at least 200 ms to fully adapt to a purely short-flow load from a purely high-flow load.

Overestimating N or underestimating N. If the true N exceeds the capacity of the estimator, then N will be underestimated; If a lot of bursts come, then N will be overestimated. In this case, the FCS flow estimate will be biased, but the noisy N will still be better than the static threshold. As can be seen in § 6.3.2, PRED can quickly respond to changes in N, resulting in faster congestion adjustment and feedback even if inaccurate. In addition, QLA can also compensate for long-term estimation inaccuracies, so that PRED still keeps the switch statistically high performance.

C Additional Implementation

Figure 20 shows the hardware architecture of PRED on the Tofino switch.

C.1 Data Plane Modification

Counter & Estimator Module. PRED needs to know how many flows are passing through the port of the switch at a time interval. As described in § 4.1, switches only need a simple bitmap and counters to implement this module. However, each stage of the switch can operate on only one register, not an array of bitmap registers. Thus, the switch cannot bulk reset the bitmap registers periodically on the data plane. The control plane can reset the registers of the data plane, but it cannot be used because of the high API delay (>1 ms).

To solve this problem, PRED uses a time interval sequence counter and a write-after hashing operation to calculate the number of concurrent flows. Algorithm 1 shows the FCS data plane processing logic. When a packet $\mathcal{P}$ arrives, the switch first checks whether the current time *now* has been more than an interval T_{FCS} since the last update T_{start}(line 1). If the time is over this interval, some registers need to be updated and reset (lines 2-5). If not, the packet $\mathcal{P}$ needs to be checked to see whether it belongs to a new flow (lines 7-11).

We first analyze the reset process after the timeout (lines 2-5). T_{start}, n_{last}, n_{now}, $Interval_{seq}$ and $Bitmap$ are all Registers. T_{start} is the beginning of the interval (line 2) and needs to be set to the current time *now* after the timeout occurs. n_{last} is the flow number collected in the last interval (line 3), which should be set to n_{now} after the timeout. n_{now} is the flow number

Algorithm 1 Data Plane Processing Logic.

1: **if** $now - T_{start} > T_{FCS}$ **then**
2: $\quad$ UpdateReg$_{T_{start}}(now)$ ▷ Next time interval
3: $\quad$ UpdateReg$_{n_{last}}(n_{now})$ ▷ Record the last interval flow number
4: $\quad$ UpdateReg$_{n_{now}}(0)$ ▷ Reset the current interval flow number
5: $\quad$ UpdateReg$_{Interval_{seq}}(+1)$ ▷ Update the interval sequence
6: **else**
7: $\quad H_{new} \leftarrow$ Hash$(Packet5Tuple, Interval_{seq})$ ▷ Derive flow hash from packet 5-tuple and interval sequence
8: $\quad$ $S_{id} \leftarrow H_{new}[IndexSize : 0]$ ▷ Derive storage index
9: $\quad H_{old} \leftarrow$ Read&UpdateReg$_{Bitmap}(S_{id}, H_{new})$ ▷ Get the old hash value from the bitmap and set the new value
10: $\quad$ **if** $H_{new} != H_{old}$ **then** ▷ New flow is detected
11: $\quad\quad$ UpdateReg$_{n_{now}}(+1)$
12: $F_{Num} \leftarrow MAX(n_{last}, n_{now})$
13: $Prob \leftarrow ReadTable_{PRED}(q, F_{Num})$
14: **if** $Prob > Random()$ **then**
15: $\quad MarkECN(\mathcal{P})$

collected in the current interval (line 4), which needs to be set to 0 after the timeout. $Interval_{seq}$ is the serial number of the time interval (line 5), which is used to distinguish different time intervals. $Bitmap$ is a hash table of length $2^{IndexSize}$.

Next, when there's no timeout (lines 7-11), we analyze the most critical process of counting flow numbers. The packet $\mathcal{P}$'s flow hash H_{new} is computed by hashing over the packet's 5-tuple and interval sequence number $Interval_{seq}$ (line 7). Then the last $IndexSize$ bits of the hash value is used as the storage index S_{id} (line 8). The most crucial step is to read the stored flow hash H_{old} in the S_{id} position in the hash table $bitmap$ and overwrite the H_{new} in the corresponding position (line 9). Then PRED checks whether the values of H_{new} and H_{old} are equal and if they are not, then the new flow is detected (lines 10-11). The reason for using interval sequence number $Interval_{seq}$ for packet hashing is that we want flows across different time intervals to be recounted at different time intervals. To this end, the same flow must have different hash values at different time intervals. With the above steps, PRED does not need to bulk reset the value in the bitmap register periodically on the data plane because the new hash value is overwritten each time. Two conflicts may affect the flow count, i.e., hash conflict (different hash parameters but same hash value) and position conflict (different hash value but same S_{id}). The hash conflict causes conflicting flows to be viewed as one flow, and the position conflict causes conflicting flows to alternately overwrite the same register, bringing unusually high flow counts. However, the chances of the two conflicts are low, and thus they have little effect on the performance.

RED Setting Module. Because the P4 switch has no direct division to use for the RED Setting Module, here PRED programs the RED algorithm into the PRED table (line 13). The

table's key is the queue length and the flow number, and the table's value is the marking probability. After obtaining the marking probability, PRED compares it with the random value. If the marking probability is greater than the random value, ECN labeling will be tagged (lines 14-15).

Packet Buffer Module. The packet buffer module provides some queue information to the control plane, including $\bar{q}$ and R. R can be obtained directly from switch statistics. The instantaneous queue length cannot match the performance of the switch. Therefore, PRED samples the queue length multiple times, sum it and saves it in the register. The control plane can read the register to get the sum value and the sampling times to infer the average queue length.

C.2 Control Plane Modification

The QLA module needs at least 6 additional stages in the Tofino switch if it is to be deployed in the data plane. We have implemented PRED where both QLA and FCS are deployed on the data plane, but a total of 17 stages are needed. In § 4.2, we introduced that the QLA module needs to save four utility function values to judge the adjustment of λ_{QLA}. These operations require at least 3 stages, two for reading/writing the register and one for comparison operation. Since the RED table requires additional Key entries to identify the λ_{QLA}, the additional stages need at least 3 stages. For pure FCS modules, 11 stages have been used, so the existing Tofino switches do not support deploying both modules to the data plane at the same time. However, the new Tofino 2 and Tofino 3 switches support 20 stages [24], so the QLA and FCS modules can be deployed in the data plane at the same time.

In this paper, we deploy the QLA module on the control plane. The Monitor Module subscribes raw data from the Register for features analysis, including the total bytes sent and egress queue depth. In detail, at each time interval T_{QLA}, the Monitor Module achieves the subscribed data from forwarding chips's registers. Then, the utility function calculates the current utility value and passes it to the Decision Maker. The control module makes a judgment every 4 intervals T_{QLA} and sets the new RED setting to the data plane.

Discussion. There is a problem with implementing the QLA module in the control plane. Reading the register in the control plane takes 5 to 12 ms, and updating the Red table takes 80 to 110 ms. Therefore T_{QLA} is at least 200 ms due to hardware limitations. We discuss the setting of T_{QLA} in § D.5. The larger T_{QLA} is, the slower convergence will be. Therefore, if the implementation is upon Tofino 1, PRED has a slower convergence rate. However, we believe that if implemented upon Tofino 2 or Tofino 3, this problem would not occur.

D Additional Simulation Results

D.1 PRED with DCQCN

Setup: We use a simple 20-to-1 topology with 40 Gbps links, 20 servers are senders, and 1 receiver. The latency of the link is 2 μs. The parameters are set as suggested in [5, 27]. The NS-3 simulation implementation of DCQCN refers to the implementation in [27].
Results: Figure 21 shows the PRED performance with DCQCN. Figure 21(a) shows the average queue length and 99th queue length as N increases. The queue length for both RED (0.2) and RED (2) increases with N, and PRED avoids this problem. Figure 21(b) shows the time sequence diagram when N=2 and N=20. PRED at low concurrency (N=2), queue length changes close to RED (0.2) to ensure throughput. At high concurrency (N=20), PRED is close to RED (2) to ensure low latency. To sum up, PRED can also cooperate well with DCQCN.

D.2 Large Scale Simulation in DataMing workload

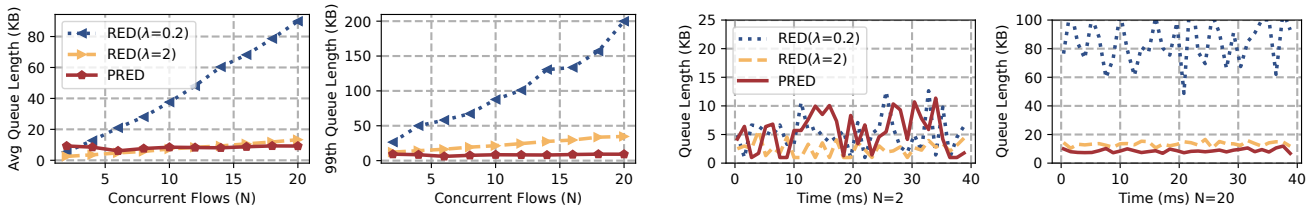
Figure 22 is the result under the DataMining workload. For details, refer to § 6.3.1. As shown in Figure 22, PRED's small flow 99th FCT (0.76 ms) has a reduction ranging from 58% (ECNSharp, 1.83 ms) to 86% (CODEL, 5.28 ms) compared to ECN algorithms at 90% load. For Large flows, there was a negligible increase in the FCT of PRED (44 ms) ranging from 6.3% (ECN, 41.36 ms) to 8% (ECNsharp, 40 ms) compared to ECN algorithms at 90% load. This proves that PRED can outperform other ECN algorithms under the DataMining workload.

D.3 100 Gbps Large Scale Simulation in WebSearch workload

Figure 23 is the result under the WebSearch workload. For details, refer to § 6.3.4. As shown in Figure 23, PRED's small flow 99th FCT (142 μs) has a reduction ranging from 27% (RED, 171 μs) to 59% (CODEL, 350 μs) at 80% load. PRED's small flow average FCT (29 μs) has a reduction ranging from 52% (RED, 61 μs) to 75% (CODEL, 117 μs) at 80% load. This proves that PRED can outperform other ECN algorithms in 100 Gbps with 1000s concurrent flows.

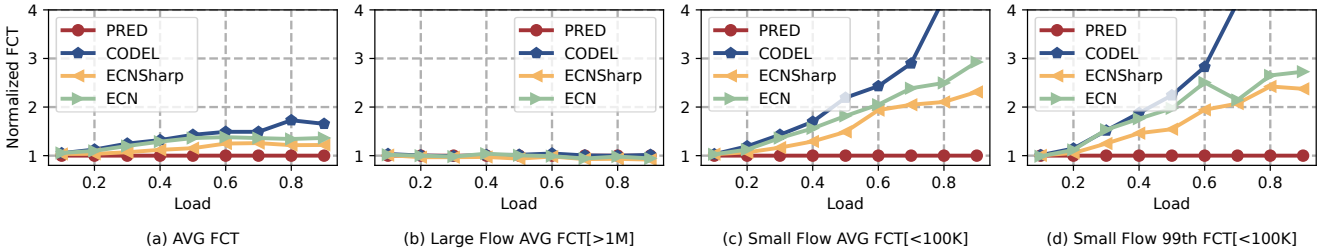
D.4 Packet Scheduler

Setup: We configure the switch with Deficit Weighted Round Robin (DWRR) with 3 queues/services. The weights among the 3 queues/services are 2: 1: 1. We first start a long-lived TCP flow from sender 1 and classify this flow into queue/service 1, then from sender 2 and classify it into queue/service 2,



(a) Different flow concurrency levels (b) Breakdown

Figure 21: [Simulation] PRED performance with DCQCN.



(a) AVG FCT (b) Large Flow AVG FCT[>1M] (c) Small Flow AVG FCT[<100K] (d) Small Flow 99th FCT[<100K]

Figure 22: [Simulation] FCT statistics with different ECN algorithm. All are normalized to the results achieved by PRED (DataMining Workload).

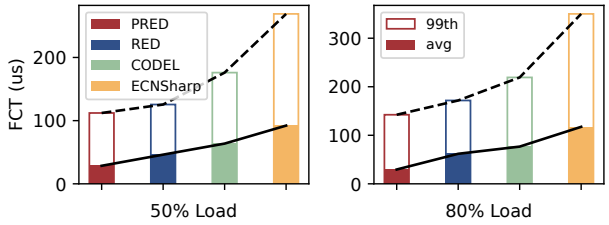


Figure 23: [Simulation] Small Flow FCT statistics with WebSearch workload.

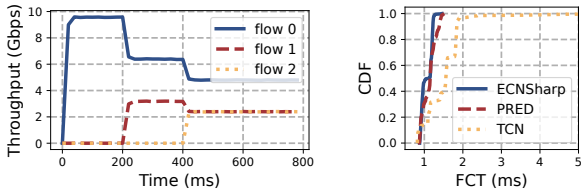

(a) Flow throughput (b) FCT of small flows

Figure 24: [Simulations] PRED with packet schedulers.

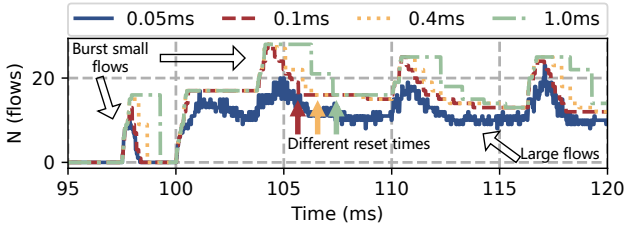

Figure 25: [Simulation] N Estimator of Different T_{FCS}. (RTT is 0.08 ms)

and finally from sender 3 into queue/service 3. We also randomly start small flows (the size is from 3 KB to 60 KB) from the rest of the senders to probe the queue occupancies. We set the TCN marking threshold to 150 μs to avoid throughput loss. The other settings are identical to §6.3.1.

Results: Figure 24(a) shows the throughput of flows achieved by PRED. We observe at the beginning that only queue 1 is active, flow 1 achieves around 9.6 Gbps. After flow 2 starts, queue 2 becomes active, and flow 1 achieves 6.42 Gbps while flow 2 achieves 3.18 Gbps. Finally, when three queues all become active, flow 1, flow 2 and flow 3 achieve around 4.82 Gbps, 2.40 Gbps and 2.40 Gbps goodput, respectively, which strictly preserves the packet scheduling policy.

We also measure the FCT of small flows among all queues, and the results are shown in Figure 24(b). PRED is similar to ECNsharp and superior to TCN in small flow. In summary, PRED can strictly preserve the packet scheduling policy with multiple queues/classes.

D.5 Parameter Design Choice

We focus here on the two most important time parameters T_{FCS} and T_{QLA} in PRED, and we will discuss the other parameters in future work. We analyzed how to set these in § 4, and we verified these by experiment in this section.

Setup: The topology, parameter settings, and traffic patterns are all similar to the previous subsection.

Results: Figure 25 shows the estimation of flow number under different T_{FCS}. The burst state and the stationary state of the

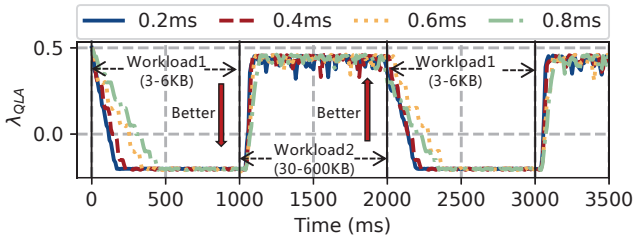

Figure 26: [Simulation] λ_{OLA} of Different T_{OLA}.

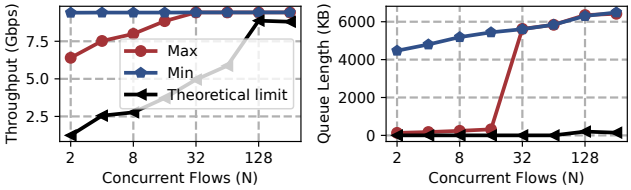

Figure 27: [Testbed] Range of PRED adjustment capabilities.

large flows both have 18 flows. When burst flows and large flows are concurrent, there should be 36 flows. From figure 25, when $T_{FCS} < RTT$, PRED cannot accurately estimate the correct N. Because all the traffic does not pass through the port completely. When $T_{FCS} > RTT$, PRED can estimate the correct N, but with the increase of T_{FCS}, the reset time of N is also increasing. So T_{FCS} should be slightly larger than RTT, and our rule of thumb is 1.25RTT.

Figure 26 shows the convergence of λ_{QLA} for different T_{QLA}. The workload 1 (3-6 KB) ranges from 0 to 1,000 ms and from 2,000 to 3,000 ms. Workload 2 (30-600 KB) is 1,000-2,000 ms. In workload 1, all flows are small, so the smaller the λ, the smaller the FCT. Therefore, it can be seen that PRED can rapidly reduce λ when 0-500 ms, while it can rapidly increase λ when 1,000 ms. And the smaller T_{QLA} is, the faster it converges, but the more unstable. Therefore, T_{QLA} is recommended to be 5RTT.

D.6 Range of PRED Adjustment Capabilities

We tested the range of PRED adjustment capabilities using Testbed. As shown in Figure 27, the throughput and queue length change with the number of concurrent N. The blue line indicates the parameter setting with the minimum λ and the lowest ECN probability, and we can see that its queue length is large and its throughput is high.

The red line indicates the parameter setting with the maximum λ and the maximum ECN marking probability. It can be seen that when $N < 32$, there is a loss in throughput and the queue length is small. When $N > 32$, the parameter Settings in the adjustment range cannot limit the stability of the queue. This means that PRED limits the number of concurrent requests to no more than 32 within the range of optional parameters. However, in practice, there are not that many concurrent long flows in the datacenter [3], and the range of PRED is sufficient.

The black line represents per-packet ECN, that is, every packet that enters the switch is marked with an ECN. It can be seen that the adjustment range of the black line is very large. However, the adjustment granularity is too large, and the change of very small parameters will lead to drastic changes in the queue and throughput, so the adjustment range of PRED is only between the red line and the blue line.

Rajomon: Decentralized and Coordinated Overload Control for Latency-Sensitive Microservices

Jiali Xing[1], Akis Giannoukos[1], Paul Loh[1], Shuyue Wang[1], Justin Qiu[1], Henri Maxime Demoulin[2], Konstantinos Kallas[3], and Benjamin C. Lee[1]

Abstract

Microservices are increasingly central for cloud applications due to their flexibility and support for rapid integration and deployment. However, applications often experience overload or sudden traffic surges that exceed service capacity, resulting in increased latency or service failures. Moreover, microservices are decentralized, interdependent, and multiplexed, exacerbating risks from overload.

We present RAJOMON, a market-based overload control system for large microservice graphs. RAJOMON controls overload through distributed rate-limiting and load shedding. Clients attach tokens to requests and services charge a price for each API, dropping requests with insufficient tokens. Tokens and prices propagate through the entire call graph, piggybacking on requests and responses. Thus, RAJOMON is the first decentralized, end-to-end overload control system.

We implement and evaluate RAJOMON on a setup of up to 140 cores and on a variety of applications from academia and industry. Experiments indicate RAJOMON protects microservice goodput and tail latency from substantial demand spikes, even in the case of mixed request types and deeper service graphs. For high-load scenarios, RAJOMON reduces tail latency by 78% and increases goodput by 45% when compared against state-of-the-art overload control for microservices.

1 Introduction

Microservices enable extensible and flexible software architectures, advantages that have led to their adoption in many large, production systems [6, 7]. Effectively managing overload, where demand exceeds the system's capacity for computation, is essential for performance and reliability. Demand spikes might arise from expected events, such as sales or holidays, or unpredictable variations in client behavior. Supply inefficiencies might arise from hardware issues, such as power throttling, or software issues such as system misconfiguration or garbage collection. Overload can severely degrade user experience and system reliability [3, 52]. It is the principal culprit for cascading failures within service graphs [2].

Microservice applications, compared to monolithic systems, have several characteristics that make overload control more challenging. First, microservices are deployed automatically and managed in a decentralized manner [19]. Second, microservices are highly interdependent, creating the risk that congestion at one node can propagate along the execution path, turning localized overload into cascading failures [13]. Finally, microservice nodes are often multiplexed, serving multiple request interfaces. Each interface may involve different downstream call graphs but share the same nodes, making it difficult to detect which interfaces are overloaded [24, 25].

An effective, responsive overload control framework should incorporate three elements: (1) decentralized detection and decisions to improve responsiveness; (2) coordination across the call graph to control load early in the execution path, ideally at client side; and (3) the ability to distinguish and manage overload at interface granularity.

Current systems handle request surges with load shedding and rate limiting (Table 1), but they do not provide the key elements for effective overload control. Centralized approaches struggle to respond to overload in a timely manner because they rely on extensive telemetry and computation [34]. Without coordination across the call graph, many requests are processed by some nodes and dropped by others, wasting computational resources and lengthening queues. [52]. Without interface granularity, overloaded and idle interfaces are treated equally, causing head-of-line blocking and dropping requests [3]. These limitations hinder the practical deployment of previously proposed frameworks.

We respond to these challenges and propose RAJOMON to achieve key desiderata with tokens and price tables. Clients are granted *tokens* at predefined rates, and these tokens are attached to each request and its sub-requests. Each microservice maintains a table of *prices*, which specify the number of tokens required for an interface. First, RAJOMON decentralizes overload control as clients rate limit themselves when their token holdings are insufficient while services reject requests with insufficient tokens. Second, RAJOMON coordinates control across the microservice graph without extra

Frameworks	Decentral-ization	Coordi-nation	Client Rate Limiting	Interface Granularity	Time Scale
Dagor	✓	Pair-wise	✗	✓	1s
Breakwater	✗	✗	✓	✗	< 1ms
BreakwaterD	✓	✗	✓	✗	< 1ms
TopFull	✗	✓	✗	✓	10s
Rajomon	✓	✓	✓	✓	< 1s

Table 1: Related work of microservice overload control, with time scales represented in seconds (s) and milliseconds (ms).

network overheads. When a service experiences overload, it increases prices and attaches updated prices to responses, thereby informing upstream services and end-users about congestion, who then proactively limit new requests before they are issued to overloaded execution paths. Finally, prices are updated independently for each interface based on their downstream interfaces, ensuring that overloaded interfaces are properly throttled while idle ones remain unaffected.

RAJOMON is designed and implemented as a gRPC interceptor package that does not modify application code [5]; we will release the source code. We evaluate RAJOMON using service graphs, with varied depths and sizes, from academic benchmarks and industrial traces. Compared to state-of-the-art baselines [3, 34, 52], RAJOMON improves goodput (*i.e.*, throughput within latency requirements) by 117–266% and reduces latency by 33–46% under challenging system conditions. When traffic surges, RAJOMON goodput recovers within a second, four times faster than baselines. RAJOMON's differentiates between concurrent requests across different interfaces, increasing goodput by 45–245% and reducing latency by 78–94%.

2 Motivation

Overload occurs when computational demands exceed system capacity, causing requests to queue, violate service-level obligations, or crash the service. For instance, the release of Taylor Swift's 'Midnights' album drew overwhelming traffic and caused a global outage of Apple Music and Spotify [15]. Another example is Coinbase's Super Bowl ad, which crashed its own website [37]. Such outages cause financial losses and harm user experience; 61% of users immediately turn to competitors when they have difficulty accessing websites [17].

We motivate an overload control framework that targets microservice-based applications, detailing their characteristics that lead to unique challenges. We address these challenges by specifying desiderata for the control framework. We also describe limitations of existing solutions.

2.1 Microservices

An application structured using microservices breaks down functionality into separate components, each of which is implemented in its own service [13, 25]. Each service provides an interface (API) that supports specific requests and communicates with other services, through remote procedure calls (RPCs), to perform an end-to-end task. By tracking services invoked for the task, we can construct a call graph. Several properties of the microservice computation – decentralized operation, interdependent requests, multiplexed services – pose significant challenges for overload control.

Decentralized Operation. Microservices are loosely coupled, through RPCs, and each is usually implemented, maintained, and managed by a different organization or team [19]. This decentralized structure makes traditional, monolithic overload control methods impractical because there is no single entity that has ownership or visibility over all services. Furthermore, large microservice applications tend to include hundreds or even thousands of services [25]. At this scale, even distributed tracing incurs significant delays. For instance, Dapper takes up to 15 seconds to propagate trace data, while Jaeger also operates asynchronously, adding further delay [11, 36]. As a result, centralized control mechanisms are unable to respond quickly enough because they first need to observe the state of all services.

Interdependent Requests. Microservice-based applications have graph structures with complex dependencies. According to Alibaba, 30% of graphs are wide and exhibit a fan-out pattern in which a service calls many others [24]. Many other graphs are deep and exhibit long chains of services. An overloaded service can cause cascading quality-of-service violations throughout the graph [13]. When an upstream node exhibits increased queuing delay, request queues have already lengthened in downstream nodes [25].

Multiplexed Services. Services are often multiplexed and shared by multiple applications and types of requests, which invoke different application programming interfaces (APIs). Approximately 90% of call graphs contain multiplexed services that are included in other call graphs and interact with various upstream and downstream services [24, 26]. With such multiplexing, one type of request might overload a shared service, causing head-of-line blocking and affecting the processing of other non-overloaded interfaces [25]. On the other hand, overload control actions suitable for one interface could be too conservative and starve other interfaces [34]. Determining the optimal rate for concurrent APIs given the varying capacities of downstream servers is challenging.

2.2 Control Desiderata

We design and implement RAJOMON to address the unique challenges from microservices. Our framework supports three key properties for effective overload control.

Decentralized Decisions. Every client rate limits and every service sheds load independently. Decentralized decisions require exchanging and propagating load signals. Yet no service

blocks on communication or commands from other services, ensuring timely reaction to overload.

Coordinated Control. Services propagate load metadata, recursively and eventually, to upstream services and clients. Metadata flows through the microservice graph based on paths taken by varied request types. Thus, services are aware of downstream overload and proactively reduce the rate of upstream requests. Such collaborative load shedding reduces wasted computation throughout the graph.[1]

Interface Granularity. Clients and services monitor and control overload for each interface separately. Control at interface granularity is more efficient than prior approaches, which operate at client granularity [3], because overload often occurs at specific interfaces rather than broad services or certain clients. RAJOMON applies rate limits and active queue management differently for each request type. Its approach can be viewed as *virtual multi-queues* for head-of-line blocking in the microservice context.

2.3 Existing Approaches

There exist several established approaches for overload control, but none adequately address the challenges inherent to microservice-based applications, as shown in Table 1.

Dagor implements decentralized overload control [52]. Each server monitors its queuing delay to determine the admission level. Dagor attaches a priority score to each request and expresses admission level as a priority cut-off. Each server drops requests that fail to meet this cut-off. Services communicate admission levels to their senders so that load is shed one tier before hotspots within the graph.

Breakwater implements single-layer overload control to manage interactions between one server and its clients [3]. The front-end service adjusts total credits based on queuing delays and then issues credits to each client to explicitly control the number of requests they can send. The front-end increases server utilization by over-issuing credits and then dropping requests when the excess of credits overload the server.

TopFull is an adaptive overload control framework for microservice applications that operates in a top-down manner [34]. It dynamically controls API load by adjusting request rates at the front-end. It first clusters APIs according to their graph structure and shared nodes. For each cluster, reinforcement learning throttles requests at API granularity based on observed end-to-end goodput and latencies.

Empirical Comparison. For motivation, Figure 1 presents throughput, dropped requests, and total demand for the *Compose Post* request in a social network application. Initially, all

[1]Note that Dagor also implements collaborative load shedding, but does so between single sender-receiver pairs, which limits scalability to larger applications [52].

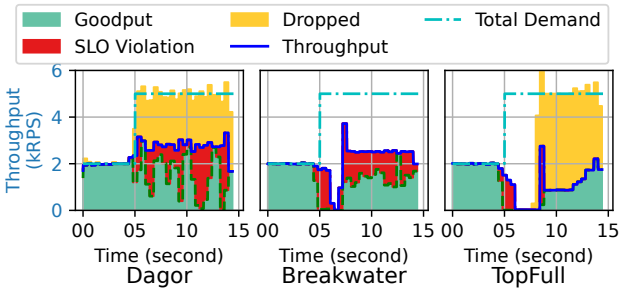

Figure 1: Existing OC approaches failed to handle the overload.

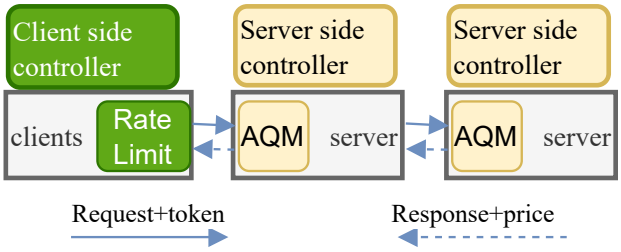

Figure 2: RAJOMON architecture.

frameworks are able to match goodput to total demand. But when demand spikes at 5 seconds, performance degrades.

Dagor lacks end-to-end coordination, shedding load only at nodes that precede hotpsots in the graph. This wastes resources and slows response time as many requests are processed by other services but are ultimately dropped. Breakwater, enabled only at the front-end, is unaware of real-time load conditions at downstream services such that overload causes service failure for 2 seconds. Moreover, Breakwater's decisions are misaligned with actual back-end capacities, leading to incorrect rate limits and causing half of requests to violate service-level obligations. TopFull's centralized reinforcement learning policy also experiences service failure for 4 seconds. Although it eventually recovers, communication and computation overheads delay system adaptation.

3 RAJOMON Design

Tokens function as a universal currency for computations requested by a sender (clients or upstream services) from a receiver (downstream services). Unlike conventional token bucket systems, RAJOMON's tokens accompany requests as they traverse the call graph. From the sender's perspective, tokens dictate each client's capacity to send requests. From the receiver's perspective, tokens signify each request's relative priority and enable collective agreement on which requests to shed first during overload (*i.e.*, those with fewer tokens).

RAJOMON employs tokens for two reasons. For clients, tokens permit differentiated rate limiting, which is important for microservices with multiple interfaces and diverse load dynamics at each interface. Clients should issue different

request types at different rates.

For services, tokens permit coordinated load shedding, which is important for efficiency. Applications often exhibit wide fan-outs in which one node in the call graph issues requests to and waits for multiple downstream nodes [24]. When load shedding is required, downstream nodes should coordinate and drop all sub-requests originating from the same request. Because all sub-requests must complete, the system need not compute for some when others are dropped. Tokens, attached to requests, provide the needed metadata about the original request and avoid additional communication for coordinated load shedding.

Prices represent the current demand and supply of computational resources at each service. Practically, prices set a threshold for the number of tokens required for a request's admission. Prices rise to curtail admissions during overload and fall when load eases. Prices propagate from downstream nodes toward clients, providing updated signals about system load to all services in the graph. A price is set for each interface. A table holds all prices for a service's interfaces.

Prices are necessary for sharing congestion information across nodes. Because each service interface calls different downstream services, its computational capacity depends on related downstream capacities. Determining whether a particular interface is overloaded requires callees that share their congestion levels with callers. Prices permit this coordination and decentralized overload control at interface granularity.

Controllers. Each node runs a local RAJOMON controller (Figure 2). The **Client-Side Controller** prevents clients from overwhelming the system by regulating the rate of outgoing requests. It generates tokens at a rate defined by its policy. Before a client issues a request, its controller ensures sufficient tokens are available for the corresponding interface. If not, it rate-limits and drops the request. Otherwise, it removes tokens from its pool and attaches them to the outgoing request. Periodically, the controller updates its price table based on the latest information received from the server.

The **Server-Side Controller** performs admission control, comparing tokens attached to incoming requests with the price of the requested interface. If tokens are insufficient, the request is dropped. Otherwise, the request is admitted and tokens are attached to any subsequent requests sent to downstream services. The controller periodically updates prices based on local queuing delays and feedback from downstream services to reflect the graph's current load conditions. Price updates are communicated back to upstream services and clients as part of the response metadata. Thus, controllers independently assess and manage load for each call path, enabling decentralized yet coordinated adaptive queue management.

3.1 Mechanisms for Overload Detection

The visibility of load conditions is limited because tasks require computation across many microservices loosely connected by RPCs. Measuring resource availability and service capacity is complicated by diverse graph topologies and request types. Simple indicators for overload in a single server, such as CPU utilization or queuing delay [3, 52], do not apply.

RAJOMON supports decentralized overload detection for loosely connected services. A service calculates its price for computation based on local queuing delays. Each of its interfaces sets its own price, allowing the system to track and manage congestion separately. Moreover, to capture end-to-end load conditions and quantify the total price a request must pay, prices accumulate from back-end services to clients.

When a service receives a price update from downstream callees, it updates the total price and shares with upstream callers. This backward propagation of prices informs clients and callers of the overload status for all downstream interfaces. Prices circulate asynchronously without requiring a centralized message broker.

3.2 Mechanisms for Overload Control

Each RAJOMON controller acts independently, making decisions about rate-limiting or adaptive queue management based on requests' attached tokens and interfaces' prices.

RAJOMON's control decisions account for call graph topology to minimize wasted computation. To reduce waste in parallel computation, which arises when one caller's requests fan out to multiple callees, RAJOMON uses token holdings to coordinate load shedding across downstream services. Overloaded services collaboratively shed sub-requests originating from the same caller's request, thereby avoiding unnecessary computation in parallel branches of the service graph.

To reduce waste in sequential computation, which arises when a client requests computation from a chain of microservices, RAJOMON controls load earlier in the call graph. Ideally, load is shed at clients or upstream services. By the time a request arrives at downstream services, its computation has already consumed significant service capacity and, for efficient goodput, should be completed if possible.

3.3 Policies for Client Control

Policies are devised to tune system responsiveness to overload while maintaining flexibility. These policies optimize the rate and granularity at which tokens and prices are updated.

Asynchronous Token Generation. The Client-Side Controller requires policies for token generation and spending, which should ensure stable throughput and smooth transitions between rate limiting and load shedding levels. RAJOMON uses a Poisson process to replenish tokens, which disperses token generation and client requests across time.

In contrast, generating tokens at some constant rate tends to produce bursty requests and oscillating goodput as clients simultaneously or synchronously replenish their token holdings. For example, when every client replenishes tokens every

10ms, they all send more requests at the beginning of the 10ms period. Randomizing the number of replenished tokens ameliorates this problem but does not fully resolve it.

Randomized Token Spending. RAJOMON selects a uniform random number of tokens for each outgoing request, yielding a range of tokens attached to requests such that the number of dropped requests increases gradually as the price increases. This policy provides a smoother reaction to overload and enhances system responsiveness.

Attaching a deterministic number of tokens to requests destabilizes throughput. A simple strategy spends all available tokens on the next request. But because clients may hold a similar number of tokens, the all-in strategy produces requests with similar numbers of tokens. Under this policy, token-based adaptive queue management is ineffective because the controller cannot distinguish priority across requests.

3.4 Policies for Server Control

Regularly updating and sharing prices are essential for timely overload control. Prices must reflect system dynamics and load conditions from nodes throughout the call graph.

Proportional Price Updates. The Server-Side Controller compares queuing delay against a threshold at regular intervals, determining whether price must be updated for a particular service interface. Threshold and interval are configurable parameters that typically range from 1ms to 20ms.

RAJOMON increases price by an increment that is proportional to queuing delay. The greater the queuing delay in excess of the threshold, the greater the price increase. Practically, when queuing delay exceeds the threshold by 1ms, the price increases by approximately 3 to 13 tokens. When queuing delay is less than half the threshold, the price decreases by 1 token. Otherwise, price is unchanged.

Traditionally, additive-increase / multiplicative-decrease (AIMD) algorithms adjust rates in token bucket mechanisms (*e.g.*, SEDA [41, 42]). AIMD divides admission rate by a constant factor (*e.g.*, two) during overload. But it throttles incoming requests by the same factor regardless of overload severity. AIMD cannot precisely control load.

Lazy Price Propagation. The Server-Side Controller sends prices to upstream nodes in the call graph with a lazy update policy. Lazy updates mitigate overheads associated with price updates. Because microservice functions and their corresponding RAJOMON controllers run on multiple threads, overheads could arise from ensuring thread safety for price updates. Because applications are implemented with tiers or layers of microservices, an overhead added to each layer can easily accumulate in deep call graphs and increase end-to-end latency. These overheads are modest when RAJOMON need not attach metadata to every response in the call graph. Upon sending a response, the controller attaches its price information with a configured probability, *e.g.*, 20%, updating the upstream services with the current local prices.

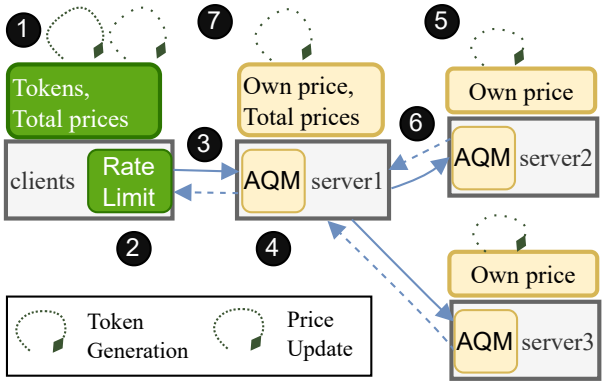

Figure 3: RAJOMON example.

Maximum Total Price. The Server-Side Controller determines the price of its computation by combining its local price with downstream price data. A service's price is the price of local computation plus the maximum of prices published by relevant downstream services. This policy emphasizes the most overloaded downstream service, allowing rapid responses to hotspots. Moreover, this policy is easy to implement. RAJOMON simply forwards a request's token holdings through the graph as it proceeds from client to back-end.

In contrast, an intuitive policy would resemble supply chains. A service's price is its local price plus the sum of prices for all relevant downstream services. If prices are additive, then token spending must also be additive. Whenever a request fans-out and triggers parallel sub-requests for downstream service, its token holdings must be split, allocated, and attached to those sub-requests. We must split tokens so adaptive queue management at back-end services are effective, but doing so adds complexity and latency.

3.5 Example

Figure 3 provides an example of RAJOMON's operation. A client requests computation from three services. Suppose server 1's `login` interface calls both server 2's `authentication` and server 3's `homepage` interfaces.

1 The **Client-Side Controller** generates tokens periodically as determined by its policy (*e.g.*, 10 tokens every 10ms). 2 The client issues a request to `login` if it holds enough tokens for the interface. Here, the client holds 10 tokens and `login`'s price is 5 tokens. 3 The client spends 5 tokens, attaching them to the outgoing `login` request.

4 The **Server-Side Controller** checks the request's tokens against the price, admits the request, and attaches 5 tokens to each sub-request to `authentication` and `homepage`. 5 The server periodically updates prices based on queuing delays, increasing prices for `homepage` and `authentication` to 7 and 8 tokens, respectively. 6 Servers 2 and 3 drop in-

coming requests, which hold 5 tokens, and responds to server 1 with updated prices. ❼ Server 1 adjusts its price table based on local queuing delay and the maximum price of downstream services (*i.e.*, 8 tokens). When server 1 receives and drops incoming requests with insufficient token holdings, it will respond to upstream clients with updated prices.

This example illustrates how RAJOMON coordinates load shedding and rate limiting for microservice graphs. For fanned-out microservices, suppose Servers 2 and 3 must drop half their requests. Since sub-requests inherit tokens from their originating request, the servers can identify and drop the half with fewer tokens attached. The servers would focus on completing the remaining sub-requests and better translate computation into goodput.

For a chain of microservices, when Server 1 receives increased prices from Servers 2 and 3, it immediately adjusts its price and drop more incoming requests. Doing so mitigates overload earlier in the graph and reduces load shedding at Servers 2 and 3. Moreover, Server 1 propagates its increased price to clients and prompt more aggressive rate limiting.

4 Implementation

The RAJOMON prototype is implemented as an open-source gRPC package [48] in 948 lines of Go code [5, 9]. The implementation includes three parts. First, for overload detection, RAJOMON implements a goroutine that periodically measures queuing delays for other running goroutines. Go uses goroutines instead of threads and our implementation is analogous to prior techniques that monitor thread queuing delays [3, 52]. Second, for price tables, RAJOMON uses synchronous maps with built-in support for concurrent use [16]. Third, RAJOMON implements gRPC interceptors for service receivers, service senders, and clients. Interceptors implement rate-limiting and adaptive queue management (§3).

Baselines and implementation. We compare RAJOMON to state-of-art microservice overload control frameworks—(i) Dagor, (ii) Breakwater, (iii) Breakwaterd, (iv) TopFull—which were introduced in Section 2.3. Breakwaterd is a distributed implementation of Breakwater that rate limits across all sender-receiver pairs in the service graph. This was suggested as a future work, but was neither implemented nor evaluated in the original study [3].

For fair comparison, we implement all baselines in Golang as gRPC libraries. The re-implementation follows the original design, but as a gRPC interceptor, we removed Breakwater's dependencies on certain hardware or operating system kernels [3, 12, 32]. We open source our implementation for Dagor, Breakwater(d), and TopFull [23, 46, 47].

Benchmarks. We evaluate RAJOMON using academic benchmarks and industry traces from Alibaba (Table 2). We re-implement academic benchmarks, Social Network and Hotel Reservation, in GoLang with gRPC and Redis based on code from [49]. SLOs for each interface are set to 5× its 95th-percentile latency under normal conditions.

We use microservice application traces from Alibaba [24] to generate synthetic benchmarks (traces are not deployable applications). We consume service call graphs and each service's computation times to produce corresponding service instances in Golang. Each service runs a busy-loop to emulate each request's computation. We focus on three highly demanded microservice endpoints—S_102000854, S_149998854, S_161142529—which we denote *S1*, *S2*, and *S3*. Endpoints are representative of call graphs of different sizes (10-20, 20-30, 30-40 nodes).

App	Interfaces	Depth	Width	#Nodes	SLO (ms)
Social Network	Compose Post	4	3	9	90
	User Timeline	4	2	7	20
	Home Timeline	4	1	5	20
Hotel Reservation	Search Hotel	4	3	9	60
	Reserve Hotel	3	2	5	25
Alibaba	S1	5	10	20	250
	S2	9	10	33	600
	S3	6	6	18	375

Table 2: Microservice benchmarks and SLOs.

Parameter Tuning. Overload control frameworks commonly involve four key parameters. First, queuing threshold specifies when overload control is triggered. Second, update frequency specifies how often control variables such as token holdings and prices adjust. Third, step width specifies the magnitude of the updates to control variables. Finally, client-side parameter include the token generation rate in RAJOMON and the expiration time in Breakwater. We allow Breakwaterd to have two sets of parameters—one for the front-end service and another for the other services—resulting in twice the number of parameters compared to Breakwater.

We use Bayesian optimization to tune overload control parameters for each application on its slowest request interface (*e.g.*, *Compose Post* for *Social Network* and *Search Hotel* for *Hotel Reservation*). The objective function for tuning is a weighted sum of goodput and tail latency, specifically defined as $goodput - 10 \times \max(0, latency - SLO)$, following similar methods from prior work [3, 4, 34]. In each iteration of the optimization procedure, we generate a traffic surge from 80% to 200% of the application's maximum sustainable load and then measure goodput and tail latency.

For TopFull, we adhere to their transfer learning process. We implemented a graph-based simulator to first train the RL model in the simulated environment before fine-tuning it on the real application. We use the same reinforcement learning model and parameters as described in the original paper.

5 Evaluation

We evaluate RAJOMON performance characteristics to answer the following questions.

1. How does RAJOMON affect the goodput and latency of microservice graphs under various loads? (§5.2)
2. How does RAJOMON impact the time required for goodput to recover from an overload condition? (§5.3-5.4)
3. What is the impact of RAJOMON on the goodput and latency of multiple, concurrent request interfaces? (§5.5-5.7)
4. How large is RAJOMON's parameter variation compared to other control schemes?(§5.8)
5. What is the latency overhead of RAJOMON compared to other control schemes? (§5.9)

5.1 Experimental Setup

Testbed. We perform most experiments on seven CloudLab m510 servers, equipped with 8-core Intel Xeon D-1548 CPUs, 64GB DDR4 RAM, 256GB NVMe SSDs, and 10GB NICs, unless otherwise stated. For *Social Network* and *Hotel Reservation* experiments involving multiple interfaces (§5.5, 5.6), we scaled up to seven c220g2 servers, each equipped with 20-core Intel Xeon E5-2660 v3 CPUs, 160GB RAM, and 10GB NICs. All servers run Ubuntu 18.04 LTS with kernel 4.15.0. Services are deployed with Kubernetes [21]. One dedicated node runs the control plane and clients while all other nodes run microservices. All nodes communicate through a single router. Each experiment for the *Social Network* or *Hotel Reservation* applications runs on eight nodes, while the Alibaba application runs on twenty nodes.

Load Generation and Measurement. We extend *ghz* for load generation [8]. On the client node, 1000 workers establish 1000 concurrent gRPC connections and issue requests asynchronously to the application. Requests follow a Poisson process with some rate specified by the experiment. We randomize input data for *Hotel Reservation* and *Social Network* requests because experiments focus on success rate rather than the content of responses.

Each experiment consists of a warmup (5s) and overload (10s) phase unless otherwise noted. For experiments with a single request type, we warm up with load at 80% of the application's maximimum sustainable throughput subject to its SLOs and then overload to some rate specified by the experiment. For experiments with multiple concurrent request types, we warm up with fast, computationally light requests and then overload with slow, computationally heavy requests.

We measure end-to-end request latency during overload and report 95th-percentiles for latency and goodput (*i.e.*, number of requests processed within the SLO). We do not report warm-up performance unless otherwise noted.

5.2 Performance for Single Interfaces

Figure 4 presents data for *Search Hotel* from the *Hotel Reservation* app and *Compose Post* from the *Social Network* app. Each experiment includes a warm-up phase—4k requests per second (RPS) for *Search Hotel* and 2k for *Compose Post*—followed by an overload phase with varied load spikes on x-axis. Data is the average of five experiments with error bars indicating variance in latency and goodput.

Results. For *Search Hotel*, RAJOMON ensures tail latency remains below 200ms and sustains goodput of approximately 3k RPS during overload. Goodput drops only marginally as traffic load increases. In contrast, baseline techniques cannot maintain performance as load increases. Once load exceeds 12k RPS, their tail latencies are five times that of RAJOMON's and their goodputs are less than half of RAJOMON's. TopFull maintains lower, steady goodput at 1k RPS but suffers from much higher tail latencies of 750ms.

For *Compose Post*, RAJOMON's tail latency increases modestly above the 80ms SLO, approaching 100ms, while goodput remains stable above 2k RPS. In contrast, baseline techniques exhibit a piecewise linear trend. Tail latencies spike to 800ms when load is 5k RPS and then stabilize. Goodput drops to 500 RPS and then stabilizes. Dagor is a bit more robust and sustains performance until load is 7k RPS.

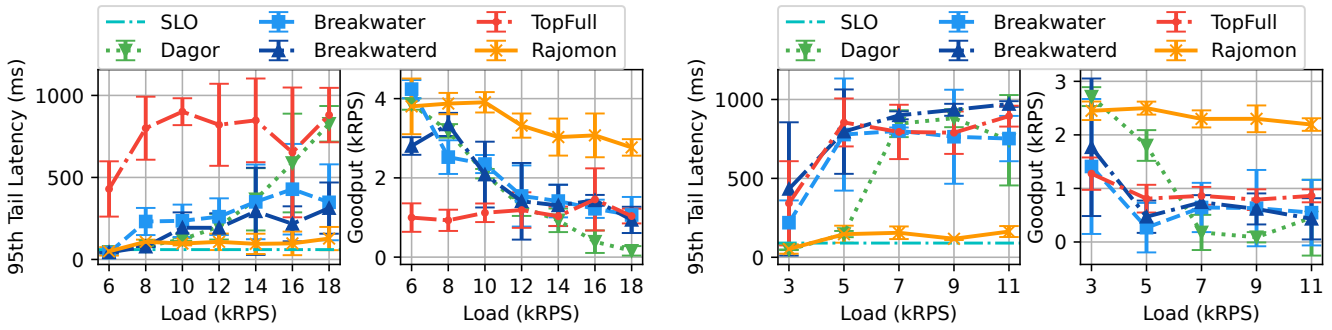
Discussion. RAJOMON's decentralized control delivers uniquely robust performance. It keeps tail latency low by quickly shedding load. Price updates regulate the rate of incoming requests from upstream clients and services. Moreover, RAJOMON's collaborative control keeps goodput high, even under heavy load conditions, as back-end services drop sub-requests that originate from the same upstream request.

In contrast, Breakwater is designed specifically for front-end services and lacks downstream visibility, which delays and diminishes any adaptation to overload in back-end services. Less effective adaptation means lower goodput and higher latency, especially under heavy load because requests can quickly accumulate in queues before overload is detected.

Dagor sheds load to counter request incast, but wastes server-side computation as client-side rate limiting would be more efficient. Shedding becomes more aggressive as load increases, which leads to lower goodput and higher latency.

Breakwaterd extends Breakwater to each sender-receiver pair in the graph but suffers for the same reasons as Dagor. Requests are rate-limited and dropped only in the node preceding an overloaded hotpsot because overload signals do not propagate through the graph. As load increases, more partially processed requests are ultimately dropped.

TopFull is limited by its coarse timescales. Within the 10-second overload phase, TopFull experiences an initial period of service unavailability followed by a slow recovery as it begins adaptation. Delayed detection and response means lower goodput and higher latency, which is consistent with its own experimental evaluation [34]. Although it is slow to



(a) Tail latency and Goodput during overload of *Search Hotel*

(b) Tail latency and Goodput during overload of *Compose Post*

Figure 4: Overall performance of RAJOMON and other baselines for *Search Hotel* and *Compose Post* requests.

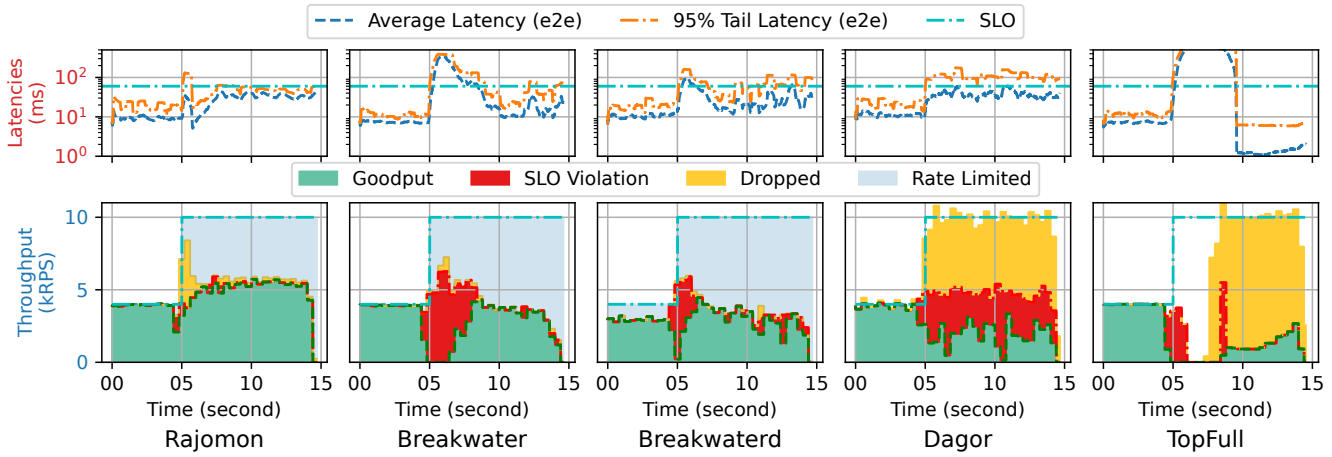


Figure 5: The throughput and tail latency under traffic surge of *Search Hotel* (single interface).

respond, TopFull's capable reinforcement learning model can eventually stabilize performance at medium and high load.

Across all baselines, performance losses are more pronounced for *Compose Post* because its back-end services require more intensive Redis writes. When not managed effectively, overload produces much greater increases in latency.

5.3 Control Dynamics for Single Interface

Figure 5 illustrates system dynamics. Client demand is 4k RPS during warm-up followed by 10k RPS during overload. The first row shows latency across time. The second row shows how requests are either rate-limited, dropped, or processed with a response time that may or may not satisfy SLOs.

Results. When overload begins at 5 seconds, RAJOMON drops many requests and then, over the next 2 seconds, steadily recovers goodput until it reaches 5k RPS. Most excess load is controlled through rate limiting thereafter. Latency initially spikes to 100ms but quickly returns to SLO target.

Breakwater(d)'s responses to overload do not occur until 2 to 4 seconds after its onset. During these periods, 50% to 100% of requests violate the SLO target latency. Eventually, latency returns to target but goodput stabilizes at lower levels, below the 4k RPS during warm-up.

Dagor maintains throughput of 5k RPS and aggressively drops the additional 5k RPS of overload. However, 95th percentile latency exceeds 100ms and most of its throughput violates the SLO. TopFull encounters 4 seconds of unavailability due to overload, followed by many dropped requests and slow goodput recovery.

Discussion. RAJOMON promptly detects server-side congestion and drops excess requests at 5 seconds. After this initial reaction, RAJOMON propagates updated prices upstream to clients, which rate limits subsequent requests. According to RAJOMON's lazy update policy, price updates are included in 20% of responses, which explains the 2-second transition from server-side load shedding to client-side rate limiting, which stabilizes latency and maintains goodput.

In contrast, Breakwater(d) experiences delays and inefficiencies due to a lack of coordination. The Breakwater front-end requires 2 seconds to detect queuing delays from back-end overload. Even after detection, back-end delays are higher

than those at the front-end. Since Breakwater issues credits based on front-end delays, this mismatch adds another 2 seconds to load adjustment even though Breakwater is tuned to update credits every 1ms.

Breakwaterd responds more quickly as it reduces load at intermediate tiers. When the back-end becomes overloaded, mid-tiers rate-limit and queue incoming requests, which eventually time out. However, timed-out requests do not signal upstream services or clients, leading to wasted computation on requests that are ultimately discarded. This inefficiency explains Breakwaterd's sub-optimal goodput.

Dagor's lack of rate limiting leads to many dropped requests, which slows down the system. Dagor drops requests only in the nodes preceding hotspots. For four-tier *Search Hotel*, most services continue processing 10k RPS even though half of these requests are dropped at the second-to-last tier. This wastes upstream computation and increases latency.

TopFull's centralized, front-end-only design inherits the limitations of both Breakwater and Dagor. It detects overload only after end-to-end goodput drops, preventing timely reactions to overload and causing extended service downtime. Moreover, load is shed only at the front-end, which wastes computation on requests that cannot satisfy SLOs and contribute to goodput. Reinforcement learning should eventually adapt to new load conditions but over a long timescale.

5.4 Recovery Time

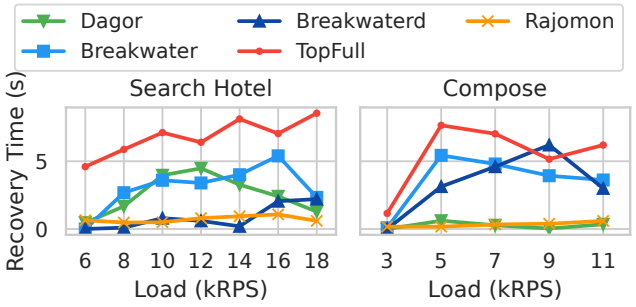

Figure 6: Recovery time of RAJOMON and baselines for *Search Hotel* and *Compose Post* request.

Figure 6 plots average recovery time under varying load conditions. We define *recovery time* as the period between the onset of overload and goodput stabilization at some level.

Results. RAJOMON consistently maintains sub-second recovery regardless of load conditions. Although baselines demonstrate sub-second recovery at low loads, they often struggle at higher loads. For Breakwater, recovery time rises to around 4 seconds as load increases. For Breakwaterd and Dagor, recovery times vary depending on the workload. Breakwaterd responds slowly for *Social Network* and Dagor for *Hotel Reservation*; recovery times range from 3 to 5 seconds depending on the severity of overload. Topfull is slow and often requires more than 5 seconds to recover.

Discussion. RAJOMON is the only framework that consistently recovers in less than a second. Its decentralized overload control is fast and responsive, regardless of load.

In contrast, baseline techniques present a trade-off between recovery time and stable goodput. Breakwaterd and Dagor's decentralized designs help them react to overload and reach equilibrium faster, but at the expense of goodput. They respond quickly, in part, because their stable goodput after the onset of overload is much lower than RAJOMON's. Similarly, as load increases, Breakwater reports lower goodput and shorter recovery times. TopFull suffers from longer recovery times due to its centralized architecture.

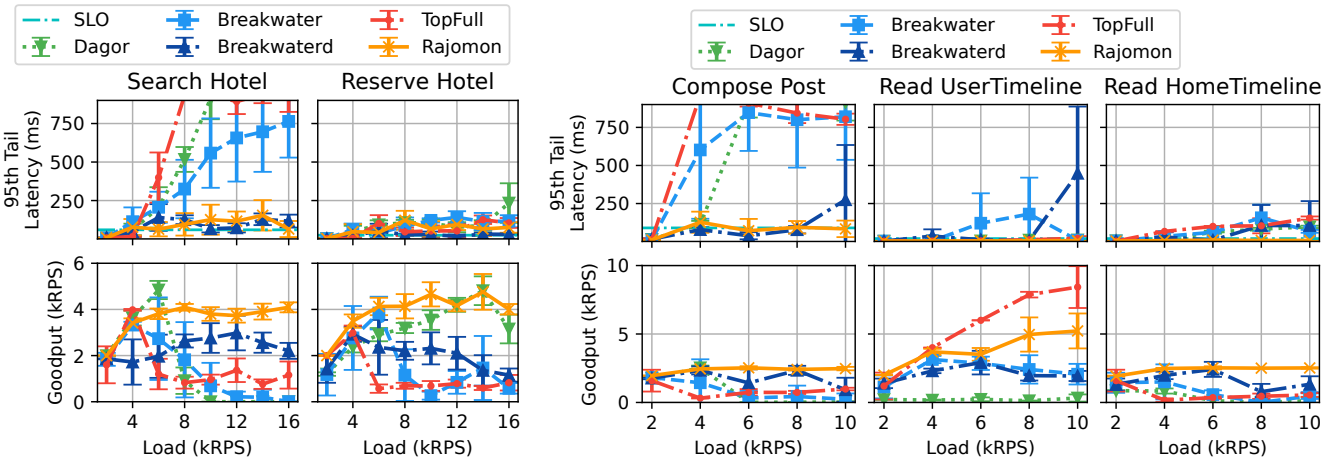
5.5 Performance for Multiple Interfaces

Figure 7 details RAJOMON's performance for concurrent requests to multiple interfaces. For the *Hotel Reservation* application, we generate *Reserve Hotel* requests at a certain rate during warm-up and add an equal amount of *Search Hotel* traffic during overload. For the *Social Network* application, we generate *Read User Timeline* requests during warm-up and add *Compose Post* and *Read Home Timeline* traffic during overload. Note x-axis reports load per interface and, for example, $x = 10$k RPS in the *Social Network* application means 30k RPS total load from three request types.

Results. In Figure 7a, RAJOMON maintains a latency of approximately 100ms and a goodput of 4k RPS for both *Search Hotel* and *Reserve Hotel* requests, even as the load increases. In contrast, Breakwater, Dagor, and TopFull maintain low tail latencies for *Reserve Hotel* but exhibit increased latencies for *Search Hotel* as the load increases. The goodput of most baselines for both interfaces drops from 4k to 1k as load approaches 14k RPS. Two exceptions are Breakwaterd for *Search Hotel* and Dagor for *Reserve Hotel*, both of which maintain goodput above 2k RPS while sustaining low tail latencies.

In Figure 7b, RAJOMON maintains latency within SLOs across all request types. It sustains *Compose Post* and *Read Home Timeline* goodput at 2.5k RPS, while *Read User Timeline* goodput increases to 5k RPS as load intensifies. Most baselines exhibit reduced goodput and increased latencies for *Compose Post* once the load surpasses 4k RPS. For *Read User Timeline* and *Read Home Timeline*, baseline goodput diminishes to less than half of RAJOMON's performance as the load nears 10k RPS. Notably, Topfull achieves higher *Read User Timeline* goodput beyond 6k RPS but at the expense of *Compose Post* and *Read Home Timeline* interfaces. Breakwaterd stands out by maintaining latency within SLOs for most interfaces; however, it experiences a decline in goodput.

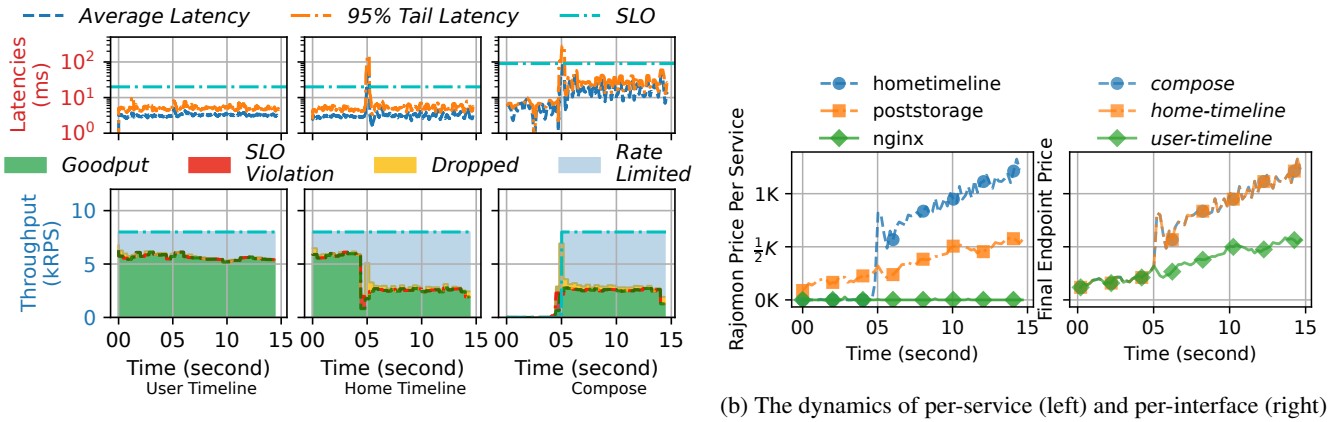
Discussion. RAJOMON demonstrates low latency and high goodput even under heavy concurrent loads from multiple request types. It achieves this by combining AQM with rate-



(a) The performance of OC on concurrent *Search Hotel* and *Reserve Hotel* requests.

(b) The performance of OC on concurrent *Compose Post*, *Read User Timeline*, and *Read Home Timeline* requests.

Figure 7: The performance of RAJOMON and baselines on concurrent requests (up to 30k RPS in total).



(a) The dynamics of the latency and throughput.

(b) The dynamics of per-service (left) and per-interface (right) prices.

Figure 8: The dynamics of the throughput, latency, and prices for concurrent *Social Network* requests.

limiting and assessing the maximum sustainable load for each interface separately. RAJOMON's advantage is particularly evident for *Read User Timeline*, which has the potential for higher goodput and lower latency because these requests do not share hotspots with *Compose Post* and *Read Home Timeline*. Only RAJOMON manages to realize this potential by avoiding head-of-line blocking. Per-interface pricing effectively virtualizes a multi-queue system and sets distinct admission rates for each interface.

Dagor distinguishes between interfaces, but its adaptive queue management lacks coordination across the service graph. The same inefficiencies observed in Figure 5 persist: The massive load shedding in mid-tier services increases the latencies of *Search Hotel* and *Compose Post* requests. This finding highlights that interface granularity must be combined with end-to-end coordination to be fully effective.

Breakwater are oblivious to interfaces and suffer from head-of-line blocking because, for instance, they cannot rate limit the slow requests (*Search Hotel* and *Compose Post*) independently. As a result, other interfaces also suffer from low goodput. If Breakwater could differentiate between interfaces, they could issue fewer credits for slow interfaces, ensuring performance for all interfaces. Breakwaterd achieves low tail latencies but at the expense of reduced goodput. This occurs because Breakwaterd reduces load in intermediate tiers without coordinating with frontend and end users, as previously discussed in Sections 5.2 and 5.3. Therefore, effective rate-limiting mechanisms should incorporate interface granularity and end-to-end coordination to optimize request rates.

TopFull cluster interfaces based on shared hotspots and implements admission control for each cluster. In our case, *Search Hotel* and *Reserve Hotel* form one cluster, *Compose*

Post and *Read Home Timeline* form another, and *Read User Timeline* forms a third. This approach can sometimes work. The control agent sets a 6k RPS rate for *Read User Timeline* while keeping latency within SLOs. But, for other clusters, the lack of decentralized control and client-side rate-limiting constrains performance. Although TopFull can set different rates for *Search Hotel* and *Reserve Hotel*, its slow reaction times prevent it from handling even 1k RPS effectively.

5.6 Control Dynamics for Multiple Interfaces

Figure 8 analyzes system dynamics for the *Social Network* application's multiple request types. Figure 8a follows the same interpretation as Figure 5, except for the presence of multiple concurrent requests. Figure 8b details service prices at interface granularity. Recall that the price of a service is the maximum of all the downstream prices paid by its sub-requests.

Results. Figure 8a indicates a negligible number of dropped requests and SLO violations. Once *Compose Post* requests arrive, RAJOMON immediately rate limits *Read Home Timeline*. Figure 8b illustrates how RAJOMON dynamically adjusts prices for different services to reflect their load. During warm-up, *post storage* service is the only hotspot and its price dictates prices for all request types. During overload, *post storage*'s prices keep increasing slowly so *Read User Timeline* interface remains inexpensive. In contrast, *home timeline*'s price increases substantially within half a second, indicating an emerging hotspot. The price increase propagates upstream such that *Compose Post* and *Read Home Timeline* both become much more expensive.

Discussion. RAJOMON's dynamic prices play a crucial role. First, prices reflect real-time load and delay across services. When *home timeline*'s delays are immediately reflected in *Compose Post* and *Read Home Timeline* prices, ensuring that overload control is precise and timely.

Furthermore, prices at interface granularity isolate *Read User Timeline* requests, which do not involve the overloaded *home timeline* service. These requests are neither rate limited nor dropped, ensuring consistent performance even when other parts of the system are under stress.

5.7 Performance for Alibaba Traces

We further evaluate three real-world traces from Alibaba (Section 4). We construct a service graph that is the union of *S1*, *S2*, and *S3*, which makes it much larger than *Hotel Reservation* and *Social Network*. We start *S1* and *S3* during warm-up and then add *S2* during overload.

Results. Figure 9 indicates RAJOMON maintains latencies below 200ms and goodput at 4k RPS for all interfaces and varied loads. Collectively, the baselines are less effective. As load approaches 8k-10k RPS, latency increases exponentially beyond 500ms and goodput falls by half.

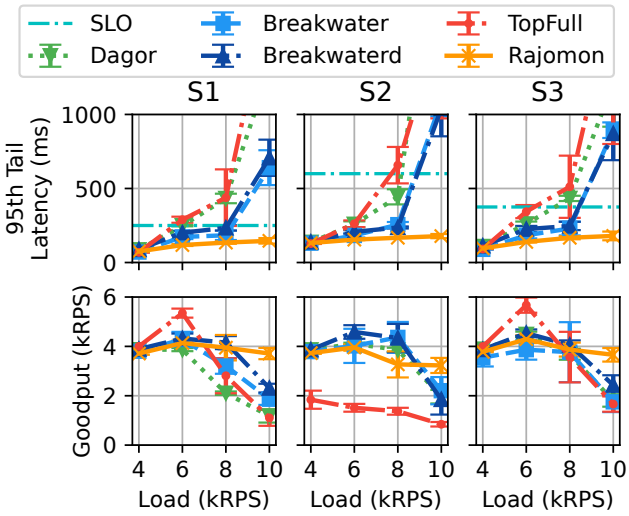


Figure 9: The performance impact of RAJOMON and baselines on large service graphs (up to 30k RPS in total).

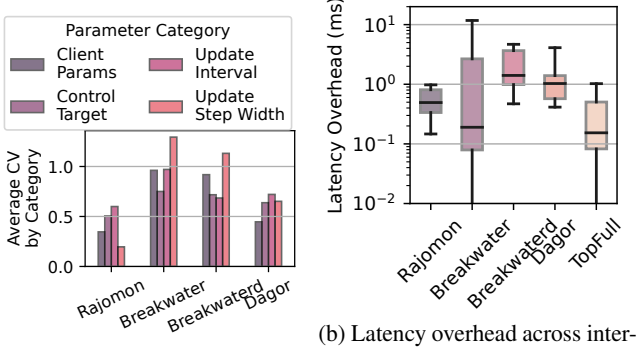
Discussion. RAJOMON manages overload efficiently at scale, maintaining low latencies and high goodput even under extreme load. In contrast, baselines struggle under high load. Breakwater's rate limiting scales better and achieves consistently lower latencies than Dagor's adaptive queue management (*i.e.*, dropping requests) as detailed in §5.2. TopFull's RL agents set effective admission rates for *S1* and *S3*. But the reason for *S2*'s rate is unknown because TopFull is a black-box that does not detail the interactions between its RL agents. Yet its centralized approach for dropping requests suffers from higher latencies and lower goodput for all interfaces.

5.8 Parameter Variability



(a) CV of tuned parameters.

(b) Latency overhead across interfaces.

Figure 10: Comparison of parameter variability and latency overhead.

Overload control frameworks must be tuned for each application to be effective [3, 34]. A robust framework should

be less sensitive to tuning parameters. Such a framework would reduce tuning time and effort, while providing more consistent performance across varied applications and system conditions, given specific parameter values.

We quantify robustness with the Coefficient of Variation (CV) for tuned parameters.[2] CV measures the relative variability of parameters, permitting comparisons across control frameworks. We calculate CV of each framework's optimal parameters in Table 3 across the three applications in Table 2.[3]

Figure 10a indicates RAJOMON performs well with similar parameters for varied applications. It exhibits the lowest variability in tuned parameter values, indicating we need not extensively tune and optimize for each application.

Breakwater(d) exhibits higher variability, indicating the difficulty of re-tuning its parameters for each application and highlighting the risks from inconsistent performance. Breakwater's credit-based rate limiting requires precise control over the total number of credits issued and held by each client, making performance more sensitive to parameters. Dagor exhibits lower variability than Breakwater(d) because priority-based adaptive queue management does not cause abrupt changes in traffic and tends to be more robust [3].

5.9 Overhead Comparison

We assess overheads by measuring differences in median latency with and without control for a system with modest 2k RPS load. Figure 10b presents the distribution[4] of latency overheads across eight service interfaces in Table 2.

RAJOMON's overhead is low for two reasons. First, it maintains and propagates only necessary state such as tokens per request and price per interface. In contrast, Dagor updates large matrices at all microservices that track request priorities and determine admission levels based on a priority cut-off: (B,U). These matrices, which grow linearly with the number of interfaces and user groups, suffer from lock contention. Note that Dagor and Breakwaterd's accumulate across tiers in deep microservice graphs, harming end-to-end latency.

Second, RAJOMON performs local price calculations asynchronously and off the critical path. TopFull also incurs low overheads because it uses only one token bucket at the frontend and its reinforcement learning decisions are asynchronous. In contrast, Breakwater calculates a client's new credit holdings c_x^{new} before every response. This overhead lengthens queues and harms latency, especially under higher loads.

6 Related Work and Discussion

Network Congestion Control Extensive work has addressed congestion control at the network layer [1, 18, 20, 22, 28, 44, 51]. RAJOMON, however, accounts for microservice-specific factors like call graphs and interdependencies. Future work could integrate RAJOMON with these mechanisms to improve end-to-end performance.

Load Balancing and Autoscaling. RAJOMON complements existing resource management strategies. While autoscaling increases service capacity, it is inherently slow and typically requires 40–200 seconds [30, 33–35, 38–40, 50]. In contrast, RAJOMON provides rapid overload control on a subsecond timescale, mitigating performance issues before autoscaling adjustments take effect. Once autoscaling provisions additional resources, the prices fall accordingly to accommodate higher throughput. Moreover, the tokens and prices primitives provide insight into request characteristics and downstream loads. This information can enhance load balancing and job scheduling decisions. Finally, even with optimal scheduling and load balancing, systems can experience overload due to unexpected traffic bursts that exceed capacity [14, 29, 31, 43, 45]. In such scenarios, RAJOMON serves as a safeguard, maintaining performance when other strategies are insufficient.

Malicious Clients. RAJOMON assumes trusted clients, such as proprietary mobile apps or Internet-of-Things devices that account for most traffic [27]. However, untrusted clients may attempt to exploit the framework for more resources or disrupt services. To prevent this, RAJOMON would require a server-side validation module to ensure token spending aligns with token generation policy and history. Trust models and validation techniques are an avenue for future research.

Dynamic Service Graphs. We focused on applications with deterministic execution paths. In practice, microservices may have dynamic call paths. If call paths depend on request metadata, such as branching based on payload, these requests can be treated as different interfaces upon receipt. If call paths are random and unknown upon receipt, for example, due to cache misses, one extension for RAJOMON could use probability theory to update its price table based on the expected value of downstream costs. For instance, if the price is 10 for a cache hit and 50 for a miss, with a 10% miss rate, the local price should be 15, based on expectation. Future work could explore other pricing policies for dynamic paths and flexible microservice settings.

7 Conclusion

RAJOMON presents a novel, market-based overload control system for microservices, using tokens and price tables for distributed rate limiting and load shedding while coordinating control throughout service graphs. RAJOMON significantly outperforms state-of-the-art baselines, improving goodput by more than 45% and reducing latency by more than 78% under high load. Its fast and precise control, with sub-second recovery times, ensures system reliability and efficiency in complex microservice systems.

Abstract

To ensure that application network traffic is prioritized correctly within data center networks, it is critical to align the configuration of network QoS in packets to the intended priority of the application. These QoS configurations, typically encoded in the DSCP bits in the IP header, are interpreted by network switches and routers to determine the resources such as buffer space and scheduling priorities, for network traffic. Conceptually, it appears fairly straightforward to map the application priorities within data center networks to network QoS configurations, as long as the mapping is well defined. In this work, we describe our experience of aligning network QoS settings for intra-cluster storage traffic to application priorities on a per-RPC basis for a large data center network, with well-defined static mappings from priorities to QoS traffic classes. We describe some unexpected insights learned from the deployment experiences, e.g., downgrading traffic to use a lower QoS does not always imply worse network latency due to over-used QoS bands in the network. We also share some challenges encountered along the way to reach the goal of a fleet-wide deployment, including the concerns of potential performance regressions due to QoS downgrades. These lessons provide guidance on the use of a QoS-based scheduling strategy to meet service guarantees and can be deployed to networks of any scale.

1 Introduction

Performance of network services heavily depend on the delay along the network path, as well as other factors such as server load [1–4]. Network delays can be much higher under congestion when the load imposed by arriving traffic exceeds network capacity [5–9]. This affects both wide-area network (WAN) links and paths within data centers, as traffic traversing both types of networks can experience queuing delays from congestion. While various host-based and network-based techniques such as admission control [10–14] can help reduce the traffic demands to minimize congestion, transient congestion can still occur due to bursty traffic patterns [3, 15–17]. This causes switches along the network path to drop packets when faced with full buffers.

The latency of higher-level application entities, such as Remote Procedure Calls and Remote Memory Accesses, plays a crucial role in the applications' performance. Different applications exhibit varying sensitivities to these delays; some, particularly those that prioritize tail latency, cannot tolerate any packet loss, while others focus on average latency or overall throughput. To manage network performance, switches utilize Quality of Service (QoS) bits in packet headers to deliver tailored service levels and latency expectations based on application demands. In general traffic is distributed across various QoS levels based on the specific requirements of workloads, allowing QoS queues to establish priorities according to their latency expectations. When congestion occurs, this prioritization enables the dropping of packets for lower-priority traffic, thus minimizing the impact on more latency-sensitive workloads. Thus, designing the right priority enforcement within data-center networks requires marking traffic according to the intended priority at the application layer.

In [14], Aequitas was introduced as Google's solution for aligning application priorities with network QoS. It was argued that this enforcement was most effective at the Remote Procedure Call (RPC) level and the work primarily focused on the design aspects with some production examples from early rollout. In this work, we expand on ideas introduced there and focus on our deployment experience from implementing the primary phase of Aequitas in Google's storage systems. We show production examples that justify the originally proposed design and offer new insights regarding the complex relationship between QoS queues and network latency.

In summary, our work focuses on these practical aspects of deploying Aequitas in Google networks for the storage services, which all fall under Phase 1 in [14]: (1) defining the static mapping from application priority to network QoS, (2) enforcing these QoS settings on traffic at the RPC level based on the priorities, and (3) supporting any exceptions to bypass this scheme due to special requirements.

[*]Work completed while the students were at Google

Thus, we clarify the goals of deploying Aequitas for storage to prevent priority inversion, which occurs when traffic of higher priority receives less network resources compared to traffic of lower priority. These are a refined set of goals as compared to [14] based on our deployment experience.

- *RPC level enforcement*: The granularity of RPC level enforcement of QoS configuration is necessary so that it is sufficiently fine-grained to enable different priorities of RPCs within a task or job for a given application.
- *Distinction between network regions with different bandwidth management policies*: The enforcement mechanism should distinguish network boundaries when adjusting network QoS. This is needed as traffic provisioning and engineering may vary significantly across different regions. For instance, bandwidth is often more constrained for WAN links—where users are typically charged for bandwidth—compared to intra-fabric bandwidth within the data center, which is generally abundant for applications, except in rare tail cases.
- *Efficient and practical deployability*: We require a method to classify RPCs according to application-level priority and then assign QoS to this traffic based on a pre-defined mapping. This must be performed without incurring excessive overhead or high resource usage.
- *Positive overall performance incentive for applications*: The new enforced QoS mapping needs to bring an overall positive performance for applications (in terms of latency). Thus, it is important that the highest priority traffic experiences minimal regression (if any) in performance after the QoS alignment.

The journey to deploying Aequitas as the default QoS authority across Google storage systems has been a long one, spanning multiple years, and there is still a lot of work to be done. We have gained valuable insights regarding the complicated interaction between network QoS and delay as well as the diverse needs of users and how that influences their view of the network. Even with a partial rollout, Aequitas is currently affecting millions of RPCs per second. Aequitas is a mature technology that has been integrated into RPCs to and from LL storage for an extended period. It has also been actively utilized for various client-facing services. Our findings can serve as a guide for other network operators aiming to differentiate traffic through QoS. The main takeaways are the following:

- **Priority is the correct network scheduling unit:** We show that prioritizing RPCs based on priority, not size, leads to significant latency reductions for critical traffic with minimal impact on lower-priority classes. This highlights that priority is the more effective unit for network scheduling.
- **Lower QoS does not imply higher latency:** Contrary to popular belief, we demonstrate that users can experience decreased latency when moving to a lower weight QoS queue if that queue is sufficiently underutilized relative to its weight (§2.3 and §4.2).
- **All can win:** We show that Aequitas is not a zero-sum game and we observe examples across production clusters where traffic at all priorities see decreased latency (§4.3). We show that these learning are consistent and hold true across different layers of the storage stack.
- **Benefits arise even under incremental deployment:** We provide production examples detailing how even under a gradual rollout process users can experience performance improvements (§5). This shows that network operators can still realize benefits from QoS assignment schemes when an all-or-nothing approach is infeasible.

The paper is organized as follows. In §2, we describe background for this project and the motivation for Aequitas, followed by a discussion of operational challenges in §3.2. Key learnings from our deployment experience are explained in §4. The detailed progress in QoS alignment is covered in §5, followed by a discussion of results and future work in §6. Related work is covered in §7, before we conclude in §8.

2 Background and Motivation

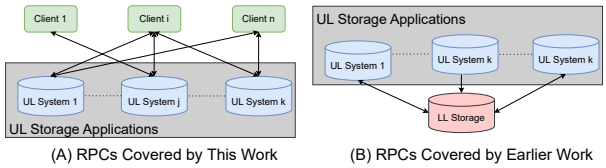
We give an overview of the Aequitas system first introduced in [14], discuss the relevant details of Google storage systems, and highlight the insights that motivated Aequitas' design.

2.1 Aequitas Overview

Aequitas operates at the RPC layer. An RPC is a programmatic request for information in which a client instructs a server to execute a procedure and receives a response. Application-level operations can be composed of hundreds of RPCs so that application performance is dependent on RPC performance. Currently, in Google production datacenters, more than 95% of application traffic is generated by RPCs [14]. Aequitas aims to inform the network of RPC level objectives and increase the number of RPCs that meet their service-level objectives (SLOs). In general, RPCs from micro-services often have SLOs that vary widely based on application needs. Here, we focus on Google storage as $\sim 75\%$ of all fleetwide non-ML related RPCs are to or from these systems [14].

Aequitas uses QoS to differentiate traffic and ensure that the most critical RPCs are given the needed network resources. The feasibility of this design was shown in [14] with results from both simulation and production rollouts. A theoretical framework was also given, based on network calculus [1], detailing the complicated relationship between QoS weights and worst-case network delay.

Figure 1 shows the high-level architecture of Google storage systems. We have n internal clients which connect to any number of k Upper Level (UL) databases (Bigtable [18], Spanner [19], etc.). These UL systems connect to Colossus [20], a



(A) RPCs Covered by This Work (B) RPCs Covered by Earlier Work

Figure 1: Storage RPCs Covered by Aequitas

common Lower Level (LL) system responsible for physically storing data. Thus, the UL systems provide different abstraction layers atop LL storage and clients can use any number of these abstractions depending on application needs.

The figure also highlights the differences between our previous results and the current work. In [14], the deployment and analysis focused on RPCs between UL systems and LL storage (Figure 1(B)). We have since expanded this to also handle traffic between clients and the various UL systems (Figure 1(A)) while also finalizing the deployments started in the previous work.

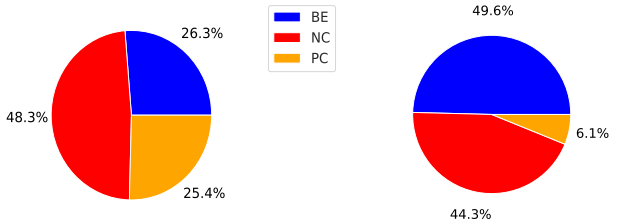
2.2 The Case for Aequitas

In [14], the notion of race-to-the-top was introduced for the first time. That is, in times of network overloads, some applications experience increased delay, causing them to miss their SLOs. In response, the corresponding developers request (and are often granted) higher QoS under the belief that a higher QoS will decrease delay and the probability of the corresponding RPCs missing their SLOs. However, these decisions are often independent of the overall QoS mix in the datacenter. In the extreme all users move their traffic to the highest QoS bands and there is no differentiation among traffic. For a given QoS band, QoS_h, there is a point at which it is no longer beneficial to upgrade traffic to QoS_h.

Over the last several years there has been an explosion of works that aim to integrate application knowledge into network scheduling decisions [21–26]. However these solutions treat all traffic belonging to an application or a coflow as identical from the network's perspective. Aequitas takes the view that there exist different classes of traffic even within one application. In our storage systems we observe that RPCs can be broadly categorized as Performance-Critical (PC), Non-Critical (NC), or Best-Effort (BE). PC RPCs have the most strict SLOs in term of latency and are generally interactive user-facing traffic. NC traffic often constitutes bulk storage operations[1], while BE RPCs are generally the background analytic traffic in our storage systems.

Figure 2 shows the priority distribution for request (response) traffic to (from) Colossus and demonstrates that there is a large amount of traffic for each of the three priorities. Moreover, the UL storage systems are composed of a multitude of jobs from clients around the globe and we see that even within an individual job multiple priorities can be used.

[1] these are large throughput-intensive procedures destined to storage



(a) Request (b) Response

Figure 2: Priority Distribution for Colossus Traffic

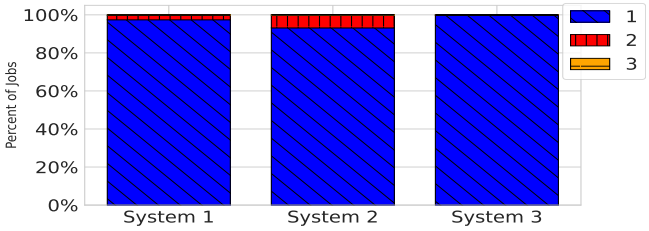


Figure 3: Percentage of Jobs Using 1, 2, or 3 Different Priorities Across Three UL Systems

Figure 3 shows the percentage of jobs that use one, two, or three priorities among BE, NC, and PC, across three different UL storage systems. We see that most jobs stick to only one priority. However, there are a small proportion of jobs that use two or more priorities and these jobs tend to be much larger, accounting for the majority of traffic. This can be seen in Figure 4 which shows the percent of request traffic in each of the three UL storage systems for jobs that use one, two, or three priorities among BE, NC, and PC. The story for response traffic from the UL systems to clients is similar.

These measurements demonstrate that simply setting a network priority at the application or job level fails to account for the different categories of traffic within a job. Instead, the evidence suggests that RPCs are the right unit for QoS enforcement as proposed in the initial Aequitas design [14]. More specifically, Aequitas takes the approach of broadly classifying RPCs as either BE, NC, or PC. It then maps these priorities to different QoS classes, implemented with Weighted Fair Queuing (WFQ)[2]. That is, BE, NC, and PC are mapped 1:1 to QoS classes QoS_l, QoS_m, and QoS_h where QoS_i corresponds to a queue with scheduling weight w_i and $w_l < w_m < w_h$. Thus the network is informed of the relative importance of different classes of RPCs, without the need to differentiate at the application level.

2.3 Determining the Correct QoS Mix

As discussed, clients are usually hesitant to change QoS, especially to one with worse latency guarantees. However, as

[2] In WFQ, switches are set up with various queues where queue i has weight w_i. Then the traffic in queue i receives w_i fraction of a link's capacity in the long run.

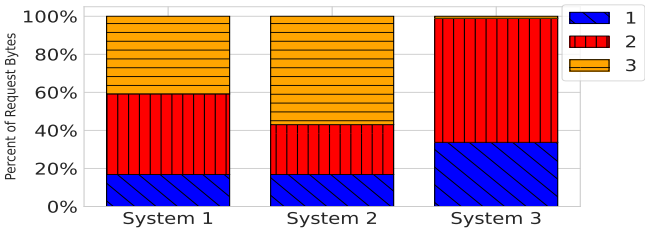

Figure 4: Percent of Request Traffic for Jobs Using 1, 2, or 3 Different Priorities Across Three UL Systems

evidenced by the race-to-the-top phenomenon, clients' QoS selection rules are usually arbitrary. So we aim to answer the following question: *what are the conditions under which a user should prefer one QoS class over another?*

Consider a WFQ with k QoS classes corresponding to k queues with weights $w_0, w_1, ..., w_{k-1}$. We let λ_i be the total load on QoS_i and let β_i^c be the load belonging to client c on QoS_i. Pick two of these QoS classes, QoS_0 and QoS_1 with $w_0 > w_1$. We can show that under a mild set of assumptions, client c can achieve a better service rate by shifting a small amount ε of traffic from QoS_0 to QoS_1 if

$$w_1\left[\frac{\lambda_1-\beta_1^c}{\lambda_1(\lambda_1+\varepsilon)}\right] > w_0\left[\frac{\lambda_0-\beta_0^c}{\lambda_0(\lambda_0+\varepsilon)}\right] \quad (1)$$

This improved service rate occurs despite the fact that a small amount of traffic is moved to a lower weight QoS band and stems from the fact that QoS_0 is overloaded relative to QoS_1. More details on this can be found in Appendix A.

This serves to illustrate that a QoS class with a higher scheduling weight does not always imply better service. The work in [14] showed the conditions for priority inversion (when a higher weight QoS class has worse performance as compared to a lower weight QoS class). But that analysis focused on all traffic sharing the same queue. Here we analyzed the conditions under which a particular user receives better service on one QoS class compared to another. We see that there are scenarios in which it is beneficial for a user to transfer a portion of their traffic from a QoS class with a higher weight to one with a lower weight. Thus, there are situations in which priority inversion exists. Indeed, in §4 we see scenarios in Google production datacenters in which users benefit from a lower weight QoS class.

As the storage systems represent a significant portion of Google traffic, we desire that the mix of (QoS_l, QoS_m, QoS_h) within the storage systems is close to an ideal QoS mix fleetwide. The Google-wide mix should not have any priority inversions, and so for a particular application a we say that a has an unhealthy mix for (QoS_i, QoS_j) with $w_i > w_j$ if β_i^a:β_j^a is greater than w_i:w_j. Note, if a is the only job in the cluster then this is equivalent to the notion of priority inversion we outlined above; a has overloaded QoS_i relative to its weight as compared to QoS_j so that we would expect moving a sufficiently small volume of a's traffic from QoS_i to QoS_j would yield a better service rate. Thus, this is a restriction of priority inversion to a specific application and serves to identify applications or users that are most responsible for an overall unhealthy QoS mix. Appendix B examines instances of unhealthy QoS in Google storage systems.

In the presence of priority inversion, performance on each of the QoS classes becomes unpredictable, making it difficult to decide to which QoS queue traffic should be assigned. RPCs in the wrong queue can miss their SLOs when the latency experienced is higher than the queue weights would suggest. Aequitas' goal is thus to manage the assignment of traffic to the different QoS queues in order to avoid priority inversion and thus provide more predictable performance for each queue. This in turn ensures that SLOs for the given queues can be set accordingly so that traffic priorities can be assigned appropriately, leading to fewer SLO violations.

3 Deployment: Strategy and Challenges

In this section we discuss our strategy to deploy Aequitas and challenges faced along the way.

3.1 Deployment Strategy

At the surface, it appears that the work required to extend Aequitas is fairly straightforward and is simply a matter of enforcing QoS mappings based on application priority. However, even the initial step of defining these mappings is non-trivial as RPCs are scattered across multiple storage systems, each with their own notion of priority. This disparate collection of priorities must each be mapped to the same finite number of QoS queues, while accounting for the different SLAs across these systems. Moreover, in contrast to our previous results, we are now handling RPCs that either directly originate from or are destined to end users. These clients have a diverse set of demands on the network and many directly measure RPC performance. Thus, a large number of users have configured their own QoS and do not necessarily want to conform to the QoS assignment dictated by the mappings, making it difficult to coordinate large-scale changes.

On a per RPC basis, Aequitas leverages information about the source and destination IP addresses as well as the application priority and requested QoS to make its decisions. However, which packets of an RPC are affected by Aequitas' selection depends on the destination. The LL storage is often obscured from users and as a result the Aequitas team elected for a server-side implementation for QoS enforcement on the traffic between UL and LL systems. Under this approach, the first few packets of an RPC are sent using the original, unaltered QoS. Upon arriving at an LL server, Aequitas chooses a QoS for the RPC based on priority and all subsequent packets sent on this connection, in either direction, use the updated QoS. Such an approach allows for quicker adoption as all

users interacting with the same server experience the change.

In contrast, each of the UL systems is visible to clients and clients monitor RPC-level metrics for the storage systems with which they interact. As such, a server-side implementation in these UL systems would obscure information from users and would not account for their varied SLOs. For example, in the case of Spanner, client-side implementations allow Spanner clients to see the QoS changes of their RPCs before they are sent over the network. In contrast, under a server-side implementation, the client's chosen QoS is reflected in the Spanner client library but the actual QoS chosen by Aequitas at the server can be different, causing a mismatch. This obscures information from users, making it unclear why this mismatch occurred. The Aequitas team therefore decided on client side implementations to expose these changes to users and to more easily reason about how the changes affect different clients. In this setting, Aequitas intercepts RPCs before they enter the network and chooses the correct channel based on the decided QoS. Note that clients do not directly interact with Aequitas. Each storage system has its own API for setting priority and Aequitas is integrated into these APIs to seamlessly pick QoS based on the pre-defined mappings. Appendix C discusses the impact these decisions had on deployment.

The Aequitas implementation is currently restricted to intra-cluster traffic. Aequitas over the WAN is a much more challenging issue due to the longer network latencies and the interaction with BwE [27]. While the proportion of intra-cluster RPCs varies across time and clusters, it accounts for a significant portion of all traffic. Customers typically try to keep traffic within the same cluster due to the inherently lower latency. Aequitas uses data in the backend UL systems to map source and destination IP addresses to clusters and determine which traffic is eligible for QoS enforcement.

3.2 Operational Challenges

Downgrading QoS: By far, the most challenging aspect of Aequitas was convincing individual clients and the teams managing the various storage systems to assign a lower QoS than originally requested for some RPCs. Aequitas distributes RPCs across QoS_l, QoS_m, and QoS_h by RPC priority.

Figure 5 shows the distribution of requested QoS within priority for all request traffic associated with Spanner. There is a high degree of misalignment between the scheme proposed by Aequitas and the current state of the cluster. In particular, there is heavy usage of QoS_h for NC RPCs and more than half of the BE RPCs use QoS_m. There is very little usage of QoS_l acoss all priorities. Imposing Aequitas across the cluster leads to both QoS downgrades (ie. BE RPCs on QoS_h downgraded to QoS_l) and QoS upgrades (ie. PC RPCs on QoS_m upgraded to QoS_h). We see similar misalignment across clusters and various storage systems, for both request and response traffic.

As discussed in §2.2, the notion of race-to-the-top suggests that users are often supportive of moving traffic to a higher

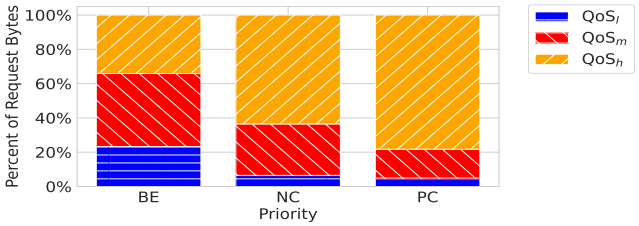

Figure 5: Intra-Cluster QoS Breakdown Within Priority (by Request Bytes)

QoS. This is due to a commonly held belief that higher QoS implies better network performance. This implies that the converse is also a widespread belief: lower QoS leads to worse network performance. §2.3 argued that this is not always the case and traffic can benefit from lower QoS when that QoS class is underloaded relative to its weight. Yet, there can also be cases where users have carefully tailored QoS in order to meet their SLOs and a change in QoS can be the difference between acceptable performance and SLO violations.

As such, enabling Aequitas fleet-wide within a short time could cause multiple production issues. Instead, the Aequitas team used a gradual approach; in some cases enabling the change for individual clients and monitoring performance before moving onto cluster level or multi-cluster rollouts. While this required considerable effort from the team and greatly extended the timeline for widespread adoption, it also allowed for detailed studies of the effects of Aequitas to understand the impact on individual users as well as entire clusters.

Avoiding other Performance Bottlenecks: While Aequitas aims to avoid priority inversion and help more applications meet their SLOs, we do not want to introduce bottlenecks in other areas. A reasonable measure to assess the impact of Aequitas is how it affects RPC network latency (RNL), which is the time that the RPC spends in the network. However, not all developers have intimate knowledge of how the network functions and thus often do not know how to correctly configure network QoS, one of the main motivations for Aequitas.

Developers put most of their attention on end-to-end RPC performance metrics like total RPC latency, memory usage and other general performance indicators. While Aequitas can improve overall network performance through better QoS configuration, for an individual RPC the choice of QoS must be made with minimal overhead to avoid adding unnecessary latency at other points throughout the life of an RPC.

In our evaluations we consider both RNL and overall RPC latency. Throughout the rollout process we also tracked memory usage, error rates, cache misses, and many other metrics, observing no noticeable changes attributed to Aequitas.

Inferring Effects under Incremental Changes: As detailed earlier, due to both Google's scale and availability concerns, we cannot simply roll out Aequitas for all users simultaneously. This challenge is well-known in practice and several methods for running experiments on production servers

while ensuring system availability have been proposed previously [28]. This is especially challenging for client side implementations and often led to several user-level pilot rollouts before moving to cluster level rollouts.

As discussed in [14] and further argued in §2.3, for a particular client the performance of their traffic on one QoS band compared to another depends not only on the QoS distribution of their traffic but also the QoS distribution of all traffic traversing the same switches. This is in addition to all the usual network factors that impact performance: overall load, burstiness of traffic, presence of congestion, etc. This implies that enabling Aequitas for a few clients or a few servers at a time does not paint an accurate picture of its effects. To fully understand the impact of Aequitas requires measurements when no traffic uses Aequitas versus measurements after the policy has been enabled for all RPCs.

However, due to the incremental rollout strategy, the traffic distributions can change significantly between a point in time before Aequitas is enabled and when Aequitas has fully rolled out. This is especially true in the case of client side changes; clients are often synced to different versions of the code. Thus, even in cases where we can enable Aequitas for all clients simultaneously there is often a significant time gap between when the first client picks up the change and when the change is adopted by the final user. Indeed, we saw production examples in which the distribution of a clients' RPCs across priorities greatly changed during the rollout. In the extreme, we observed scenarios where a user's volume of PC traffic grew by 5x during rollout. We thus adopted two major strategies as part of the deployment process.

The first was to target clusters in which a small number of users (ideally one) account for the majority of the cluster's traffic. In this way, once these small number of users have adopted Aequitas we can obtain accurate measures of overall cluster performance. Moreover, it normally requires significantly less time for a small group of users to adopt the change as compared to all clients using the cluster, allowing for a more accurate before and after comparison; in the case of a single dominant user we can measure performance just before the user adopts the change versus performance immediately after adoption. Note that there are in fact clusters at Google that exhibit this behaviour. We have users that account for more than 50% of request and response traffic within a cluster. As a result, applying Aequitas to such a client provides a good indication of overall cluster performance.

Second we implemented a feature that allows us to enable Aequitas for a fraction of traffic, either at the cluster level or at the granularity of individual clients. For example, enabling at 50% for one client means that 50% of the client's RPCs will be randomly chosen to be included in Aequitas whereas the remaining RPCs are unaffected. This is especially useful in cases not covered by the first strategy, where cluster traffic is composed of many small clients, with no client dominating. This random sampling adequately controls for other confounding factors and allows us to tease out Aequitas' effects by comparing traffic sampled versus the RPCs not sampled[3]. This approach is also more appealing to individual customers and owners of the storage systems as it offers a more conservative alternative to the all-or-nothing approach where clients or clusters are either in Aequitas or not.

4 Key Learnings from Production Examples

We next present case studies that highlight key insights we have gained from enabling Aequitas across a diverse user base. As alluded to earlier, the actual code changes for Aequitas are only a small part of the overall challenge. The biggest obstacle is integrating the changes for various clusters that span the globe. In §4.1 we discuss the methodology used to perform analysis and infer the affects of Aequitas. §4.2 and §4.3 provide examples demonstrating our main takeaways.

4.1 Analysis Methodology

Aequitas aims to maximize the volume of PC RPCs that meet their network SLOs. This means lowering the RNL for PC RPCs, but without introducing intolerable latency to NC and BE RPCs. We also want to ensure that Aequitas does not lead to performance regressions in other areas, such as increasing overall latency at the expense of decreased RNL latency, increased memory usage, or general connection errors.

Throughout this section we present experiments that compare traffic that obeys the Aequitas policy (aligned) against traffic that does not (misaligned). For each of these experiments, 50% of traffic was randomly sampled for Aequitas. While cluster utilization and latency numbers can fluctuate during the experiment, we chose highly loaded clusters for these studies and users reported no adverse effects in terms of increased packet loss nor unacceptable memory usage. In fact, in some cases where Aequitas reduced latency we also observed decreased packet loss rates and higher throughput. During Aequitas rollouts, users have a general idea that the change is coming but they are not aware of the exact time of change as it depends on internal deployment cycles. While not a true A/B experiment, we made efforts to simulate it as closely as possible with methods like random sampling to control for other confounding factors. A true A/B experiment is not feasible in our production environments.

Monarch [29] allows clients to monitor the performance of their jobs. It exposes dashboards showing job performance across several key metrics, aggregated over all the RPCs of the job. As detailed in [30], it is not possible to collect a vast array of metrics for every RPC due to Google's scale. Thus, these dashboards allow users to assess overall performance

[3] While there are other sampling techniques to more directly control for confounding factors, we find that either we do not have a priori information to perform such sampling (in the case of RPC size) or that it would add unnecessary overhead (in the case of priority based sampling). However, we see that due to the scale of the Aequitas experiments, random sampling often does a good job of controlling other confounding factors.

but do not contain all the metrics necessary to assess the impact of Aequitas. Crucially, Monarch does not contain the application-specific priorities as these differ by application and collecting these would limit Monarch's scalability.

Instead, Dapper [31] is our primary analysis tool. Dapper is Google's distributed tracing infrastructure that exposes intuitive APIs for developers to add custom annotations to their traces. Fathom [30] metrics have been integrated into Dapper, providing fine-grained decomposition of latency numbers attributed to the various systems traversed by the RPC. We also export custom annotations from the Aequitas logic indicating the priority of the RPC, the requested QoS, and the QoS chosen by Aequitas. This allows us to examine RNL latency, and its contributing factors, on a per priority basis.

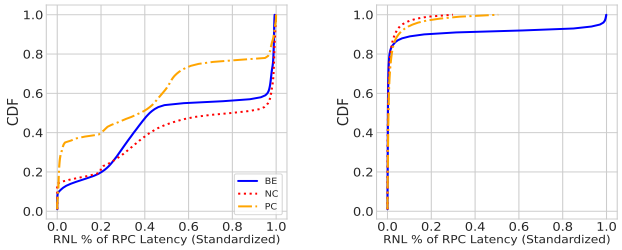
In order to operate Dapper at Google's scale, the RPCs are necessarily sampled. Sampling rates can differ depending on characteristics such as job size, RPC importance, and frequency of errors (with higher error rates necessitating higher sampling to debug performance issues). To account for this, the Aequitas analysis restricts to uniformly sampled Dapper traces and weights each trace by the inverse of its sampling rate. For example, consider three traces from Dapper, one of which represents an RPC of size 1MB sampled at rate 1, while the other two traces represent RPCs having size 2MB and are sampled at rate $\frac{1}{2}$. Then this represents a total of 5 RPCs ($\frac{1}{1} + \frac{1}{1/2} + \frac{1}{1/2}$) having an average size of 1.8MB ($1 * 1$MB $+2 * 2$MB $+2 * 2$MB = 9MB / 5 RPCs).

To assess the performance of Aequitas we are not only interested in average performance but also behaviour at the tail. There is a concern that due to sampling, some behaviour at the extreme is not accounted for. Thus we supplement our Dapper analysis by comparing the results to the high level metrics exposed in Monarch dashboards. We do this for clients with the most traffic impacted by Aequitas and continue to monitor performance after Aequitas adoption. We observe that the findings from the two tools are consistent.

4.2 Key Finding 1: Priority, not Size, is the Correct Network Scheduling Unit

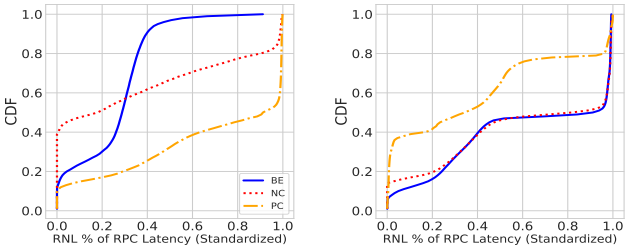
As the name suggests, PC RPCs are the most critical, and thus we want these RPCs to spend as little time as possible in the network. Instead these RPCs should spend most of their time in computation. In contrast, BE is treated as a scavenger class for RPCs, which can thus tolerate slightly increased time in the network in favor of prioritizing NC and PC RPCs [32]. We thus examine RNL as a percent of total RPC latency and would expect that this quantity is lower for PC RPCs as compared to BE or NC RPCs. We deem this quantity as RNL proportion. RNL is also the portion of total latency that the network has control over, as discussed in [14].

In Figure 6, we examine RNL proportion across priorities and RPC sizes. This snapshot was taken from Spanner when



(a) RPC size < 1KB (b) RPC size $\geq$ 2MB

Figure 6: RNL for different RPC sizes under High Misalignment



(a) RPCs on QoS$_l$ (b) RPCs on QoS$_h$

Figure 7: RNL for small RPCs ([0, 1KB)) across different QoS under High Misalignment

there was still a high degree of misalignment[4], allowing us to tease out the effects of QoS. These latency numbers are taken across clusters with differing load characteristics: from underutilized to clusters at or above capacity. Figure 6a shows results for small RPCs ([0, 1KB)) while Figure 6b shows the same plot but for RPCs that are at least 2MB. In both plots we normalize by the maximum RNL proportion so that both figures range from 0.0 to 1.0 with at least one value achieving 1.0. In the case of large RPCs, both NC and PC traffic have a much shorter tail compared to BE, as expected. Moreover, for small RPCs, RNL accounts for a smaller portion of total latency for PC traffic as compared to BE and NC. However, as there is still a high degree of misalignment in this snapshot, we observe that for small RPCs median RNL proportion is higher for NC as compared to BE.

To further understand the effect of QoS on RNL, Figure 7 looks at RPC performance across priorities for different QoS for small RPCs. These numbers were also taken across all clusters showing varying network load profiles. Figure 7a depicts RPCs that use QoS$_l$ whereas Figure 7b shows RPCs using QoS$_h$. In both figures the values are normalized by the maximum value of RNL proportion across all small RPCs, regardless of QoS, to facilitate a comparison across figures. We see a substantial reduction in RNL proportion for PC

[4] As this is production traffic, some traffic is naturally already aligned and so we cannot compare to a perfect control with 100% misalignment

	p50		p95		p99	
Priority	**Mean**	**Max**	**Mean**	**Max**	**Mean**	**Max**
BE	0.02	0.04	0.14	0.17	1.02	1.55
NC	0.02	0.04	0.17	0.56	0.42	1.75
PC	0.17	-0.73	-1.49	-34.01	-3.89	-263.95

Table 1: Aligned RNL Improvement over Misaligned by Priority (Negative Values Indicate Improvement)

	p50		p95		p99	
Priority	**Mean**	**Max**	**Mean**	**Max**	**Mean**	**Max**
BE	0.00	0.00	0.00	-0.02	0.00	-1.82
NC	0.00	0.00	0.00	0.05	-0.04	-3.65
PC	-3.06	-3.50	-81.57	-2419.22	-134.45	-2419.51
All	0.00	0.00	-0.11	-0.17	-0.66	-5.66

Table 2: Aligned RPC Latency Improvement over Misaligned by Priority (Negative Values Indicate Improvement)

RPCs for traffic using QoS_h as compared to QoS_l. Moreover, we see high median and tail numbers for BE and NC RPCs even when they use QoS_h, with slightly better performance for NC RPCs. RNL represents a larger proportion of total latency for NC RPCs on QoS_l as compared to BE traffic. This suggests that better prioritization in the network, in the form of higher-weight QoS, has a more significant impact on PC RPCs as compared to lower priority RPCs and BE traffic is the least sensitive to network prioritization.

Note that Figure 6 shows that both small and large RPCs are distributed across all three priorities, suggesting that prioritizing based on RPC size is too coarse grained and fails to capture the needs of RPCs operating on different priorities. This is consistent with the findings in [14] and combined with the above analysis demonstrates that Aequitas can correctly translate priorities to the network through its QoS mapping.

To further tease out the effects of Aequitas, we look at a particular client (denoted c) in a large, highly loaded cluster. c accounts for over 50% of all traffic in the cluster and was one of the initial pilot customers of Aequitas for Spanner. We look at a snapshot when Aequitas was rolled out at 50% for c. In the absence of Aequitas, all of c's traffic uses QoS_h with a small amount of traffic on QoS_m. Thus Aequitas upgrades a small fraction of c's PC traffic on QoS_m and either downgrades or leaves unchanged all of c's BE and NC traffic.

Table 1 shows the improvements (or regressions) in RNL for traffic aligned under Aequitas versus misaligned traffic for c. A CDF of RPC performance is computed every hour for a 4-day window and then we compute the mean and maximum values seen over the analysis period for the p50, p95, and p99 for each priority. These calculations are done for both aligned and misaligned traffic and then the differences are normalized by the standard deviation of p99 of misaligned traffic across all 3 priorities[5]. For example, if $s^c_{RNL,m}$ is the standard deviation of p99 RNL of misaligned traffic, then the mean p99 of -3.89 for PC traffic means that the 99^{th} percentile latency averaged over all the 1-hour windows for aligned traffic is lower than misaligned traffic by $3.89 \cdot s^c_{RNL,m}$. We see that while the alignment increases RNL latency for BE and NC traffic, this is a small fraction of the reduction in latency experienced by PC RPCs. The reduction in maximum p99 latency for PC traffic is over 150x (263.95 / 1.75) the increase in maximum p99 latency for NC RPCs.

Table 2 shows the same statistics for total RPC latency. Here we normalize by the standard deviation of p99 RPC latency for misaligned traffic, denoted $s^c_{RPC,m}$. We observe practically no change in the total latency numbers between aligned and misaligned traffic at p50 and p95 for BE and NC RPCs. Somewhat surprisingly however, the maximum p99 values see a reduction for both BE and NC traffic. While it is difficult to definitively determine the causes of these reductions, analysis suggests that a small fraction of BE and NC RPCs experience longer queuing delays in the QoS_h queues due to the high volume of traffic assigned to this queue (in the absence of Aequitas, more than 99% of client c's traffic uses this QoS class) and Aequitas is able to better isolate traffic in the different queues, causing less contention overall.

The table also highlights significant reductions in PC RPC latency numbers at all the measured percentiles. The standard deviation of p99 of RPC latency is an order of magnitude larger than the standard deviation of p99 RNL, so these reductions in total RPC latency are significantly larger than the corresponding reductions in RNL. This suggests that for many misaligned PC RPCs, network is the bottleneck, as is consistent with the results in Figure 10 of [32]. By assigning this traffic to the highest QoS we can effectively alleviate the bottleneck without introducing major latency degradation for traffic using the other priorities. The last row of Table 2 shows the same statistics, but aggregated across all 3 priorities. Here we see far less extreme values than those seen for PC RPCs as around 90% of client c's traffic uses BE or NC. However, we still observe a large reduction in maximum p99 RPC latency for aligned traffic compared to misaligned.

These results demonstrate that PC RPCs are far more sensitive to network latency as compared to BE and NC traffic. Thus, by assigning PC traffic to the highest QoS class, Aequitas can significantly reduce both RNL and overall RPC latency for this traffic with comparatively small increases for BE and/or NC RPCs. Moreover, other clients exhibited similar performance and we continued to observe behaviour consistent with these findings over longer time horizons and as the rollout reached 100% for various users across diverse clusters with different load characteristics.

4.3 Key Findings 2&3: Lower QoS does not imply Higher Latency, All can win

As discussed in §2.3, for QoS_i and QoS_j with $w_i > w_j$ it is possible for a client to experience lower latency on QoS_j, despite the lower weight, if QoS_i is significantly overloaded

[5] This is done to keep Google latency numbers confidential and to facilitate comparison across different clients and types of latency.

	QoS_m:QoS_l	QoS_h:QoS_l	QoS_h:QoS_m
Unhealthy Cutoffs	4:1	8:1	2:1
Mix in Cluster	10.69:1	0.52:1	5.54:1

Table 3: Unhealthy QoS mix thresholds and actual QoS mix in one cluster prior to Aequitas rollout

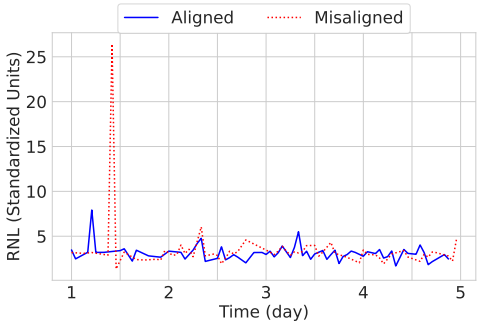


Figure 8: Aligned vs Misaligned p99 RNL for BE traffic of client $\bar{c}$

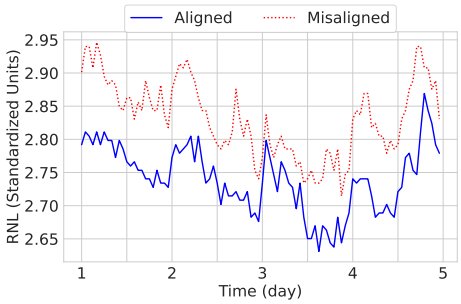
relative to QoS_j. Here we show a production example of this phenomenon. We piloted changes with a large Spanner client (denoted $\bar{c}$) that had previously exclusively used QoS_m across all three priorities. When approached for the pilot study, client $\bar{c}$ was very willing to participate and acknowledged that the current QoS settings had been decided through trial-and-error without any definitive guiding principle. The Aequitas team started a pilot in one cluster before expanding fleetwide for this user. This user was chosen as they have a high volume of traffic across several clusters that routinely experience high utilization. We study the result of a 50% rollout in one such cluster to highlight the behavior of interest.

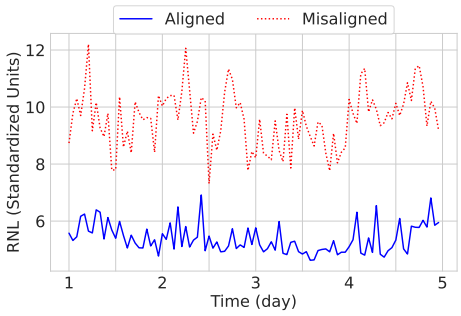
The ratio of weights for QoS_h:QoS_m:QoS_l is 8:4:1. Using the terminology of §2.3 the cluster has an unhealthy QoS mix between QoS_l and QoS_m if the volume of traffic on QoS_m is more than 4 times the amount of traffic on QoS_l. The first row of Table 3 shows the unhealthy QoS cutoffs for the 3 pairs of QoS bands. Ratios higher than these cutoffs correspond to an unhealthy mix. The second row shows the actual mix within the cluster, prior to enabling Aequitas at 50% for $\bar{c}$. QoS_m is severely overloaded relative to QoS_l. Aequitas downgrades BE traffic to QoS_l, so using the analysis of §2.3 we would expect this downgraded traffic to experience reduced latency compared to its misaligned counterpart.

Indeed, Figure 8 shows the p99 RNL for aligned and misaligned BE RPCs. For both types of BE traffic we compute a CDF every hour for a four day period and then normalize by $s^{\bar{c}}_{RNL,m}$, the p99 RNL of all misaligned traffic for client $\bar{c}$.

The average p99 BE for aligned traffic is lower than the corresponding misaligned traffic by $0.35 \cdot s^{\bar{c}}_{RNL,m}$. Moreover, the maximum across all p99 values is $18.51 \cdot s^{\bar{c}}_{RNL,m}$ lower for BE aligned traffic as compared to BE misaligned traffic. The standard deviation of 99^{th} percentile for BE traffic is $2.15 \cdot s^{\bar{c}}_{RNL,m}$ lower for aligned RPCs. Thus, we see that despite



(a) p50



(b) p99

Figure 9: Aligned vs Misaligned RNL aggregated across all priorities for client $\bar{c}$ at the (a) 50^{th} and (b) 99^{th} percentiles

the fact that aligned traffic uses QoS_l while misaligned traffic uses QoS_m, aligned traffic experiences lower latency as QoS_l is severely underloaded relative to QoS_m. In addition, the p99 BE RNL for aligned traffic is more stable over time as compared to misaligned RPCs, providing more predictability for $\bar{c}$ in terms of worst case behaviour of BE traffic.

Figure 9 shows the p50 and p99 for aligned and misaligned traffic sampled from the same user aggregated across all priorities. Again, these numbers are computed hourly over a four day period and normalized by $s^{\bar{c}}_{RNL,m}$. We see clear differences in performance between aligned and misaligned latency with the aligned percentiles showing lower latency values, even at p50. While the gap between aligned and misaligned RNL is not large at p50 (aligned RNL is $0.09 \cdot s^{\bar{c}}_{RNL,m}$ lower on average), the aligned RNL is always lower than its misaligned counterpart, while for p99 we see a larger separation. On average, the aligned values are $4.19 \cdot s^{\bar{c}}_{RNL,m}$ lower than the misaligned values. The maximum p99 BE RNL for aligned traffic is $5.29 \cdot s^{\bar{c}}_{RNL,m}$ lower than the maximum BE RNL for misaligned RPCs. Moreover, QoS queues can sometimes become overloaded due to a high volume of traffic at that QoS, leading to latency spikes. We consistently observed that these spikes were more common with misaligned (non-Aequitas) traffic vs the Aequitas counterpart which shows smoother, more predictable latency, as evidenced by the figure.
Comparing Figures 8 and 9b, we see that on average the reduction in aligned RNL across all priorities is larger than the reduction for BE traffic. However, the reduction in maximum

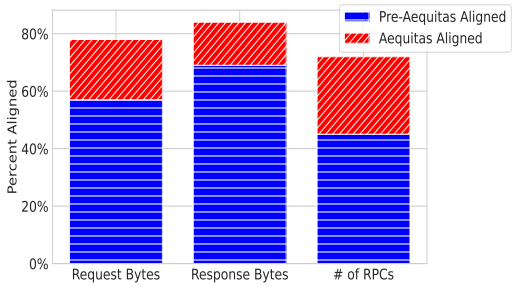


Figure 10: Aequitas Alignment Status of Spanner by Response bytes, Request bytes, and Number of RPCs

for BE traffic is larger as compared to the reduction across all priorities. This not only shows that we can decrease the latency of PC traffic through QoS upgrades but that Aequitas can also lead to improvements in worst-case behaviour for BE traffic by reassigning it to a lower, under-utilized QoS band. In the long run, this also benefits all traffic on the overloaded QoS_m band due to the reduced load at this QoS, lowering contention for RPCs in this queue. After the full rollout for client $\bar{c}$ we observe a 31.04% reduction in RNL for NC RPCs, despite the fact that these RPCs were already aligned before the Aequitas implementation. The results for BE and PC traffic after full rollout are consistent with those at 50% rollout.

This demonstrates that QoS alignment under Aequitas is not a pure zero-sum game and in fact all traffic under a particular user can benefit from better alignment. This is consistent with the theoretical justification given in Appendix A.

5 Fleetwide Performance

Previously, we provided examples of key findings from enabling Aequitas for a diverse set of clients. Here we discuss overall Aequitas performance across Google storage systems and argue that benefits of correct QoS alignment arise even under incremental deployment. Deployment results in [14] are related to traffic to/from the HDD LL storage systems. We have expanded Aequitas to also affect SSD LL storage traffic. The results for SSD LL storage traffic show that the improvements brought by correct QoS enforcement hold true across different layers of the storage stack. The detailed results are discuess in Appendix D.

As mentioned, Aequitas is implemented on the client-side for UL systems, making rollout much more gradual as compared to LL storage. Figure 10 shows the progress for a planet-scale UL system. The quantities for **Pre-Aequitas Aligned** represent the alignment status of the system in the absence of Aequitas, whereas the values for **Aequitas Aligned** represent the additional alignment gained through Aequitas deployment. While the marginal alignment through Aequitas can be small in some cases ($\sim$ 15% of Response bytes), without Aequitas the **Pre-Aequitas Aligned** RPC alignment is not enforced and it can change over time. As discussed in §2, we observe race-to-the-top QoS behavior with users selecting higher QoS for their jobs after SLO violations. Thus, we would expect to see the **Pre-Aequitas Aligned** numbers shrink over time without enforcement. With Aequitas, the alignment is the combination of **Pre-Aequitas Aligned** and **Aequitas Aligned** so that $\sim$ 72% of RPCs are aligned, representing $\sim$ 84% of all response bytes and $\sim$ 78% of all request bytes.

The Aequitas team conducted pilot studies for four of the five largest customers of Spanner and have made Aequitas the default in all clusters. However, some clients have developed a set of complex QoS assignment policies in collaboration with other internal teams and are not currently included in the Aequitas logic. We are currently tackling these exceptional cases, but even in the current state we have a large proportion of RPCs under Aequitas and clients can still see benefits. This shows the power of Aequitas even under partial rollouts.

The first pilot customer from Spanner was a large query service that operates across the fleet. This service can account for over 15% of all RPCs in the system and operates on PBs of data daily. Utilization across clusters varies with time. However, as this service is a crucial part of Google's infrastructure, it is exposed to varying load profiles across the fleet.

Figure 11 shows the priority distribution of the client's response traffic. The workloads are more response heavy (corresponding to reads) and the traffic is dominated by NC and PC RPCs with very little BE usage. The request traffic distribution is more PC-heavy due to the importance of reliable low-latency writes.

Figure 12 examines the QoS distribution of response traffic by priority for the service. The situation for request traffic is similar. The client almost exclusively uses QoS_m and QoS_h, even for its small number of BE RPCs. There is also a high degree of misalignment, especially in the case of BE and NC traffic. Figure 13 further shows that this misalignment varies across cells. There are many cells with a high degree of misalignment (up to 100%) regardless of whether we aggregate by request bytes, response bytes, or number of RPCs.

After Aequitas, almost no traffic is misaligned. The rollout process for this client was gradual, increasing the percentage of RPCs affected in several canary cells before expanding fleetwide. However, after complete rollout, the Aequitas team made a change to facilitate expanding the logic to other customers and inadvertently turned off Aequitas for this service. While this was unintentional, it allowed us to gather data just before enabling Aequitas again across all the clusters.

Figure 14a shows the p99 RNL hourly over a 4 day period for NC and PC RPCs prior to re-enabling Aequitas. Figure 14b shows the same data but for a 4 day period after the Aequitas rollout with the days ranging from 8 to 12 as this is a 4-day period exactly one week after the results in Figure 14a. Both plots are standardized by the value of PC latency. We omit BE numbers as there was almost no BE traffic in the pre-Aequitas period. By monitoring over a longer time horizon, we witnessed only a slight regression in BE RNL and there have been no episodes of intolerable latency in over 2

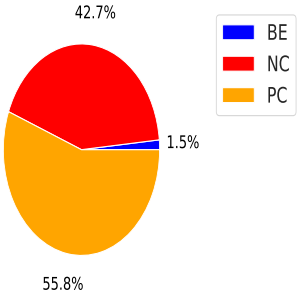

Figure 11: Priority Distribution of Query Service for Response Traffic

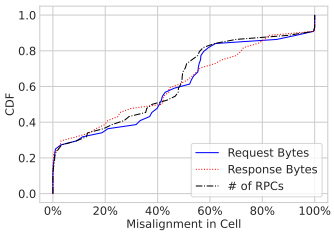

Figure 13: Query Service Misalignment Across Cells prior to Aequitas

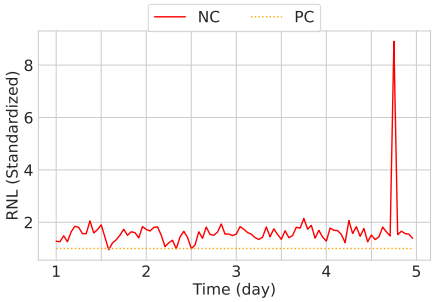
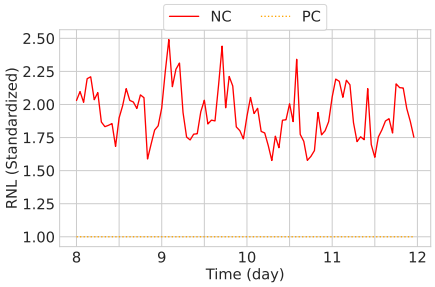


(a) pre-Aequitas



(b) post-Aequitas

Figure 14: Latency by Priority (Standardized to PC Latency)

	Avg	Max	Std Dev
NC	16.24%	−68.91%	−68.62%
PC	−3.77%	−36.45%	−70.03%

Table 4: Percentage Change in p99 RNL Statistics for a Query Service Post-Aequitas (Negative Values Imply Improvement)

years since rollout. The small regression for BE is also much smaller than the improvement for PC.

Before Aequitas, the gap in latency between NC and PC RPCs was often small and at times NC p99 RNL was smaller than PC p99 RNL, indicating priority inversion. Post-rollout there is a clear separation in RNL between NC and PC RPCs with the p99 RNL for NC RPCs always more than 1.5x that of the p99 RNL for PC RPCs. We also see a point pre-Aequitas where NC RNL rose to more than 8x that of the PC RNL. Post-Aequitas, NC never reaches 2.5x higher. However, this only shows better separation in RNL between the 2 priorities.

Table 4 shows that the average, maximum, and standard deviation of PC p99 RNL is decreased post-rollout. While we witnessed a marginal increase in average NC p99 RNL, the maximum and standard deviation both decreased. Thus, Aequitas effectively differentiates between RPC priorities. It also leads to more stability overall with improvement in worst case p99 RNL for both PC and NC. The reductions in standard deviation are also expected as now each priority is mapped to a unique QoS, whereas in the absence of Aequitas the same priority can operate across different QoS.

Aequitas has been deployed to LL storage for more than 3 years whereas the query service has been using Aequitas for over 2.5 years. The results discussed have continued to be true over time, demonstrating the robustness of the scheme.

6 Discussion

Generalizability: As outlined in §2.2, Aequitas uses metadata from each storage system to classify RPCs as BE, NC, or PC. These RPC classes are then mapped 1:1 to the QoS classes QoS$_l$, QoS$_m$, and QoS$_h$, respectively. This is a flexible design in the sense that any available metadata can be used to classify RPCs into the three priority classes. In general, the Aequitas system accepts a set of RPC metadata features $x_0, x_1, ..., x_k$ from the application and uses these features to map the RPC to one of the priority classes.

This also gives a strategy to extend Aequitas to other Google systems; we simply classify traffic from these systems into a finite number of priorities that adhere to an ordering. These priorities are then mapped to QoS queues such that the distribution among the queues maintains a healthy QoS mix as described in §2.3. Similarly, Aequitas can be extended to networks outside of Google. In addition to the above, networks would need the ability to enforce differentiated service levels in the form of switch scheduling support.

Extending Aequitas to the WAN: The current implementation is restricted to RPCs having a source and destination in the same cluster. A promising future direction is to extend the implementation to the WAN but there are several features of WAN traffic that make this implementation more challenging. First, latencies inside a cluster are typically only a small

fraction of total latency. In contrast, network latency between clusters can be orders of magnitude larger, thus dominating the breakdown of total latency. Thus, changing QoS of such an RPC can have a profound affect on its latency. As such, changes that assign traffic to a lower QoS as compared to what they are currently using must be carefully managed.

Second, BwE [27] is responsible for bandwidth enforcement over the WAN. It allocates bandwidth to applications based on priority. From a network user's perspective this is seen as quota for the amount of traffic at a given priority level. In times of congestion, when usage exceeds capacity, traffic may need to be downgraded to a lower priority. Currently, this downgrading does not account for application-level considerations. So an Aequitas-for-WAN extension would have to work with BwE to ensure that the right QoS is set across various applications. Yet in doing so, Aequitas must be careful not to upgrade RPCs in such a way that the total usage at a given priority exceeds its assigned capacity, leading to BwE throttlings. This is an avenue for future work.

7 Related Work

Congestion Control: Typical congestion control algorithms, such as the Additive-Increase Multiplicative-Decrease (AIMD) approaches [33, 34] focus on trying to find a close-to-ideal tradeoff betwen high utilization and low delay. But these schemes wait for loss to occur and then adjust sending rates, adding unnecessary delays as they reach the send threshold. More recent schemes try to avoid loss altogether by inferring congestion from signals in the network: such as setting an indicator when buffers exceed a threshold [5] or using some combination of delay, estimated send time, and bottleneck link capacities to infer when applications are sending at too high of a rate [35–37]. Yet these schemes are reactive in nature, signalling back to clients to throttle their rates as queues start to build up. Recent efforts have accelerated this signalling by utilizing innovations in switch design [38], but still there is a delay between when congestion signals are sent and when they are reacted to. Aequitas takes a more proactive approach by encoding some application knowledge via network QoS. It can be run in conjunction with these schemes, allowing service owners to tune QoS weights to ensure critical traffic meets their SLOs in times of congestion.

Application-Network Integration: Coflow [21–23] was an early application-network integration idea that proposed informing the network of application semantics. However, this abstraction was tailored to the applications of the time and it cannot encode the end-to-end semantics of some of the more modern applications. Other solutions target an application-network API, providing a way for applications to inform the network of changes in sending rates or their SLOs [39–42].

These schemes target application integration across a general set of applications, but there has also been considerable work on optimizations for specific workloads [24–26, 43]. Many of these either require input from users in the form of workload patterns or use some form of offline profiling before sending flows and thus are better suited to long flows. Aequitas aligns to the priorities used by a small number of storage systems but does not require any input from the various services that use these systems[6]. Moreover, there are no additional profiling phases or other delays introduced by Aequitas, making it suitable for flows of all sizes.

Scheduling and Prioritization: There are many works that incorporate scheduling or prioritization schemes, both in the network domain and the wider systems community. SRPT is a scheduling algorithm that schedules shortest jobs first. It has been proven to minimize mean response times [44–46] and often performs very well in practice [6, 7, 47, 48]. Yet, it is often difficult to know flow or RPC sizes a priori. In response, a collection of SMART schemes were developed that approximate SRPT scheduling [49, 50] and others have aimed to separate large and small flows [51–55]. Even some of these techniques assume job/flow sizes are known in advance, or use techniques to estimate them. However, flow size alone is often not a sufficient predictor of a flow's network requirements [14]. Instead, Aequitas uses only the RPC priority to set QoS, without any knowledge of flow size.

8 Conclusion

In this work we detailed our experience of deploying Aequitas in Google's planet scale production network. This implementation of Aequitas is aimed at storage and enforces static mappings from RPC priorities to QoS classes for these systems. We present production examples showcasing that prioritizing through QoS assignment is not a zero-sum game and the ecosystem as a whole can benefit from the right policy. These findings are backed by theoretical analysis. While Aequitas requires no input from users, deploying it at the scale of our systems provides many challenges. We outline these concerns and our use of an incremental deployment approach. While this greatly extended the rollout timeline, the scheme was enabled in a safe manner that gave users confidence in its benefits. We hope that our experience can serve as a framework for QoS-based deployments in other networks, especially when an all-or-nothing approach is not possible.

[6] While rolling out Aequitas was a long process at Google, this was because we wanted to be transparent to users and ensure that Aequitas performed as intended. But for an individual application, a user can simply opt-in and does not need to provide any information to the Aequitas system

Appendices

A QoS Arbitrage

Here we aim to answer the question posed in §2.3: *what are the conditions under which a user should prefer one QoS class over another?* To answer this question we consider a Weighted Fair Queue (WFQ) with k QoS classes QoS_0, ..., QoS_{k-1} having weights w_0, ..., w_{k-1}, respectively. That is, the long run average service rate for QoS_i is $\frac{w_i}{w_0+\ldots+w_{k-1}}$. Note that a WFQ is work-conserving, thus we can assume the queues corresponding to QoS_0, ..., QoS_{k-1} are non-empty.

Without loss of generality, we will relabel the queues so that we consider the queues corresponding to QoS_0 and QoS_1 with $w_0 > w_1$ (note here we assume $>$ and not $\geq$ because if $w_0 = w_1$ then there is no differentiation between the QoS classes). So in this setting QoS_1 represents a lower priority than QoS_0. Now suppose that the current loads on QoS_0 and QoS_1 are λ_0 and λ_1, respectively. Race-to-the-top arises from the belief that for a particular client c, c's traffic on QoS_0 will experience lower delay as compared to c's traffic on QoS_1. This assumption is due to the fact that $w_0 > w_1$, however, we will show that this is not true in all cases, and depends on the load on both QoS classes.

If client c's traffic on QoS_0 experiences lower latency compared to c's traffic on QoS_1 then this is the desired outcome and we denote this by $\text{QoS}_0 \succ \text{QoS}_1$. If on the other hand, c's traffic experiences worse performance on QoS_0, we refer to this as priority inversion, which is denoted by $\text{QoS}_0 \prec \text{QoS}_1$. Let client c's load on QoS_0 and QoS_1 be β_0^c and β_1^c, respectively. Note that $\beta_0^c \leq \lambda_0$ and $\beta_1^c \leq \lambda_1$ as the client's load on a QoS class is lower than the total load on a QoS class.

Define an epoch to be a unit of time in which each QoS class is served in proportion to its weight. If we assume that a client's traffic is independent from the rest of the traffic in the queue[7] then we can reasonably assume that client c's traffic is evenly distributed in the queue[8]. That is, in a period in which QoS_i is served, we can expect $\frac{\beta_i^c}{\lambda_i}$ proportion of that traffic belongs to client c. Then of all the traffic served from QoS_0 and QoS_1 during the epoch the proportion that belongs to client c (regardless of how much traffic is in other QoS bands) is given by

$$w_0 \frac{\beta_0^c}{\lambda_0} + w_1 \frac{\beta_1^c}{\lambda_1} \tag{2}$$

Now suppose that we shift some small amount ε of client c's traffic from QoS_0 to QoS_1. Then the amount of traffic on QoS_0 and QoS_1 now becomes $\lambda_0 - \varepsilon$ and $\lambda_1 + \varepsilon$, respectively. Whereas, the amount of client c's traffic on these two queues is given by $\beta_0^c - \varepsilon$ and $\beta_1^c + \varepsilon$, respectively. Under this new distribution, equation (2) becomes

$$w_0 \frac{\beta_0^c - \varepsilon}{\lambda_0 - \varepsilon} + w_1 \frac{\beta_1^c + \varepsilon}{\lambda_1 + \varepsilon} \tag{3}$$

Note that client c's traffic distribution in the other $k-2$ queues did not change. So if the quantity in equation (3) is larger than the quantity in equation (2), then of all traffic served in the epoch, a larger proportion of this traffic belongs to client c after the redistribution, and thus client c receives better service. That is, more of client c's traffic is served in a given epoch if

$$\begin{aligned}
&w_0 \frac{\beta_0^c - \varepsilon}{\lambda_0 - \varepsilon} + w_1 \frac{\beta_1^c + \varepsilon}{\lambda_1 + \varepsilon} > w_0 \frac{\beta_0^c}{\lambda_0} + w_1 \frac{\beta_1^c}{\lambda_1} \\
\implies & w_1 \left[\frac{\beta_1^c + \varepsilon}{\lambda_1 + \varepsilon} - \frac{\beta_1^c}{\lambda_1} \right] > w_0 \left[\frac{\beta_0^c}{\lambda_0} - \frac{\beta_0^c - \varepsilon}{\lambda_0 - \varepsilon} \right] \\
\implies & w_1 \left[\frac{\lambda_1 - \beta_1^c}{\lambda_1 (\lambda_1 + \varepsilon)} \right] > w_0 \left[\frac{\lambda_0 - \beta_0^c}{\lambda_0 (\lambda_0 + \varepsilon)} \right]
\end{aligned}$$

Note that the last equation precisely matches (2.3) in §2.3. Moreover, $\lambda_0 - \beta_0$ is the total amount of traffic on QoS_0 across all customers excluding client c, and similarly, $\lambda_1 - \beta_1$ is the total amount of traffic on QoS_1 across all customers excluding client c. Also notice that there is an admissible region for equation (2.3): Take $w_0 = 0.6$, $\lambda_0 = 70$Gbps, $\beta_0 = 20$Gbps, $w_1 = 0.1$, $\lambda_1 = 5$Gbps, $\beta_1 = 0.1$Gbps, $\varepsilon = 1$Gbps. Then the left hand side of equation (2.3) simplifies to 0.0163 while the left hand side is 0.0060. Thus, even though $w_0 > w_1$, it is advantageous for the client to transfer a small amount of traffic from QoS_0 to QoS_1, due to the low load on QoS_1 relative to its weight.

B Unhealthy QoS

In this section, we examine the state of QoS in Google storage systems. We are specifically interested in clusters with an unhealthy QoS mix, as defined in §2.3. Aequitas is targeted towards the queues for QoS_l, QoS_m, and QoS_h so that is what we focus on here as well.

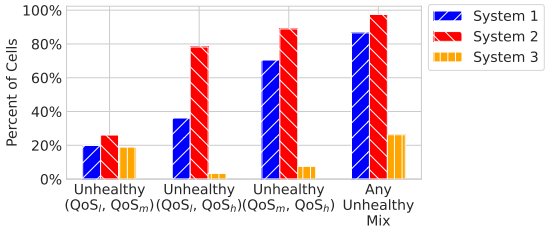
Figure 15 shows the proportion of clusters that have an unhealthy QoS mix across 3 UL storage systems, in the absence of Aequitas. We show the results for the three pairs of QoS classes[9] as well as a column that shows the percentage of cells that have an unhealthy mix between any of the three pairs. The figure contains results for both request and response traffic. For example, in the absence of Aequitas, System 2 request traffic has an unhealthy (QoS_h, QoS_m) mix in 89% of the clusters in which it is located, meaning that System 2's ratio of QoS_h to QoS_m request traffic in 89% of clusters is higher than $w_h : w_m$. Similarly, System 2 request traffic has an unhealthy mix for at least one pair of QoS classes in 97% of the clusters in which it is located.

As can be seen from the figure, a significant proportion of clusters have an unhealthy mix for at least one pair of QoS classes, especially for systems 1 and 2. An unhealthy mix between QoS_h and QoS_m is the biggest culprit, but there are instances of unhealthy QoS across all three pairs. This is in line with the notion of race-to-the-top discussed in [14], which suggests that users gravitate towards higher QoS over time.

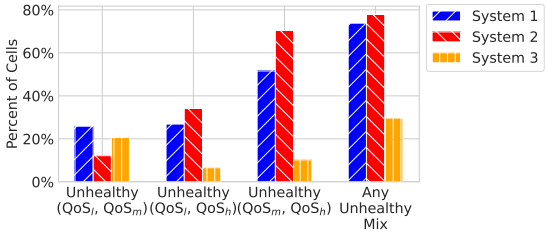
[7] While this assumption does not apply in every scenario, due to Google's scale we can reasonably assume one user's traffic is independent from other traffic in the datacenter

[8] Note that this does not assume that client c's traffic is necessarily smooth over time, it can occur in bursts. This just assumes a relatively small period of time in which client c's traffic is roughly evenly distributed among the rest of the traffic destined to that queue

[9] The QoS classes are naturally ordered by their weights; this also implies an ordering on the pairs



(a) Request Traffic



(b) Response Traffic

Figure 15: Percent of clusters with priority inversion across three UL systems based on (a) request traffic and (b) response traffic

C Client-side vs. Server-side Implementation

As detailed in section 2.2, Aequitas is implemented on the server-side for LL storage, whereas we used a client-side approach for UL storage implementations. The choice of where to implement depends on many factors that were discussed previously. Here we focus on how this affects the rollout process and analysis of the results.

A server-side implementation offers several advantages. First, it facilitates faster rollout and adoption as all traffic using a particular server is affected by Aequitas as soon as the implementation is deployed to the server. Thus the rollout is able to progress at the speed at which the servers are updated with the latest changes. This is generally much faster than client-side updates as the servers are controlled by a small number of teams that can coordinate simultaneous upgrades. Second, as seen in [14] and shown in section 2.3, the performance of traffic using a certain QoS class depends on both the weight of that QoS class and the load of all traffic passing through the same switch queues at that particular QoS. Server-side implementation implies that all traffic using the same server is affected simultaneously. Thus we see large-scale changes with each server updated and the behaviour of the system converges to the Aequitas QoS distribution quickly, making it possible to assess user-level and cluster-level performance changes more easily.

In contrast, for client-side implementations, the rollout process is much slower. It is far more difficult to coordinate simultaneous upgrades across users due to the various teams involved and the different jobs that these users are running. For example, some clients have long running jobs that take on the order of months to complete and thus will not pick up changes until these jobs finish. At the same time, there are other clients that can pick up changes almost immediately. This results in many incremental QoS changes over a long time period, making it difficult to see the impact at a datacenter level. Moreover, for clients who pick up the changes early, their QoS changes as a result of Aequitas can be a small portion of the overall QoS in the datacenter. As a result, it can be difficult to assess the long-term impact for an individual client as most of the datacenter remains unaffected by Aequitas and the client's performance is likely to change as the datacenter QoS distribution changes due to increased adoption of Aequitas. As discussed in §2.2 and seen in §4, this required extra considerations to facilitate a smooth rollout while carefully teasing out the effect of Aequitas.

D Aequitas for SSD LL Systems

In this section, we expand on the results for deploying Aequitas on LL systems previously presented in [14]. The production deployment results explained in [14] were presented for HDD storage traffic between LL and UL systems, wheres since then, we have expanded Aequitas to cover SSD traffic to/from LL systems as well. Here, we present the results related to SSD LL systems performance.

At a high level, $\sim$ 30% of all LL-bound SSD related RPCs were misaligned prior to Aequitas and this number is now $\sim$ 0%[10]. Prior to Aequitas deployment, 34%, 24% and 90% of PC, NC and BE.

The reduction in aggregate misalignment for RPCs, among clusters, varies. There are cluster with close to 100% misalignment, whereas the smallest percentage of misalignment in a single cell, observed during the sampling, is around 10%.

After expanding Aequitas to cover SSD LL system traffic, one of the users with most misaligned RPCs sees significant changes to their PC RPC latency. The average RPC latency is improved by 6.4% while the 99th percentile of RPC latency is improved by 11.2% for this user. Furthermore, we measured improvement of 2.6% and 5.4% for average and 99th percentile of NC RPC latency respectively. This is inline with our goal of having positive overall performance incentive for applications as the corresponding user experiences improvement in both of their latency sensitive RPC priorities.

The aggregated fleet-wide results, also show improvements after full deployment of Aequitas. The average PC RPC latency has reduced by 1.8% and the 99th percentile has reduced by 4.8%. These results, along results in [14] and results presented in rest of this paper for UL storage systems, show the robustness of our learning. That in fact, the correct QoS enforcement holds true consistently across different layers of storage systems stack.

[10]The number of misaligned LL-bound RPCs is $\sim$ 0% as Google has an intricate web of applications and a vast array of jobs running from users around the globe. As a result, while we have completed the Aequitas deployment for LL storage, there can be transient traffic that operates outside of the Aequitas framework

DISC: Backpressure Mitigation in Multi-tier Applications with Distributed Shared Connection

Abstract

Most data-center applications are based on a multi-tier architecture, involving either coarse-grained software components (e.g., traditional 3-tier web applications) or fine-grained ones (e.g., microservices). Such applications are prone to the backpressure problem, which introduces a strong performance coupling between tiers, thus degrading scalability and resource consumption. This problem is due to the fact that, on the response path towards the initial client, a significant fraction of the payloads in the messages exchanged between tiers correspond to "final" data that are simply relayed (i.e., without further modifications) from a backend tier such as a database. This traffic results in additional pressure on the intermediate and frontend tiers.

To address this problem, we introduce DISC, a system allowing several tiers within a multi-tier chain to jointly act as endpoints of the same TCP connection. This enables the selective bypass of one or several tiers on the response path. Unlike existing solutions, DISC is (1) flexible — it accommodates arbitrary multi-tier topologies and heterogeneous application-level protocols, (2) fine-grained — it allows multiple tiers to be involved in the generation and emission of a given response message (e.g., to decouple the network path of the response headers and footers from the path of the response body), (3) and non-intrusive — it requires only minor and localized/modular modifications to the code base of legacy applications and is transparent for external clients. Evaluation results with several micro- and macro-benchmarks show that DISC can reduce the cumulative CPU load on servers by up to 41.5%, decrease the average and tail latencies respectively by up to 74.1% and 5.71×, and also improve the request rate by up to 45%.

1 Introduction

For reasons of modularity and, above all, scalability, Internet services are built in the form of an assembly of components in an architecture formerly referred to as *multi-tier* or more recently as *microservices*. In such an architecture, components are loosely coupled and communicate through messages using protocols such as HTTP, IMAP, gRPC, etc. In the remainder of this paper, we use the terms *"tier"* and *"service"* interchangeably, as our contribution is agnostic to the number and granularity of these components.

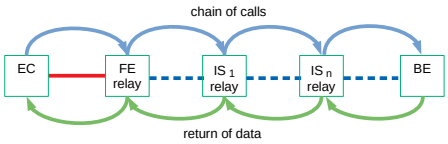

Figure 1: A schematic view of a chain of tiers. Tier BE returns data which is relayed by tiers IS_i, up to FE toward client EC.

Tier *independence* is a fundamental property that makes the popularity of multi-tier architectures. However, this independence is often compromised regarding performance, making it challenging to scale each tier independently. Our contribution aims at reducing redundant data transfers, which are a major impediment to *performance independence* of tiers. As illustrated in Fig. 1, there are redundant data transfers among different tiers involved; a request initiated by an External Client (EC) is received by a first-tier, known as the FrontEnd (FE). FE may require a call to another tier, thus forming a chain of invocations traversing Intermediate Servers (IS) up to a final tier named the BackEnd (BE). Such a chain can be noted as the following: $EC \leftrightarrow FE \leftrightarrow IS_1 \leftrightarrow \ldots \leftrightarrow IS_n \leftrightarrow BE$. In this chain, when BE produces a reply that must be returned to EC without further (read/write) processing by the IS and FE tiers, it still must go up the chain in the reverse order of request calls, generating redundant communications. We refer to such replies as *final data*. An example of final data is the mail (text and attached files) in a (multi-tier) webmail application such as Zimbra [7]. Even if IS and FE tiers only relay the final data, they undergo a load proportional to the activity of BE. Consequently, the performance of IS and FE is strongly coupled with the activity of BE. This is known as the *backpressure* problem [15]. Performance dependency among tiers makes it challenging to manage the scalability of the global application

because of the risk of the FE being the bottleneck (see §2).

For more than 20 years, numerous research works [2, 11, 14, 17, 18, 20, 21, 24, 27] have regularly proposed techniques to overcome this problem, yet with limitations. A first limitation is that these works mainly target 2-tier architectures composed of a load balancer distributing the load between a set of backends whereas applications may include much longer chains. For instance, JEE clustered architectures may include many tiers such as: an HTTP load balancer, a web server, a servlet container, an EJB server, a database load balancer, and a database. We also observed such long chains in the Zimbra clustered email server. The same observation applies to modern applications deployed in data centers, such as LAMP/MEAN stacks and microservices, which rely increasingly on long chains of existing tiers for scalability purposes.

A second limitation of all existing approaches is that they rely systematically on the full transfer of the connection from the EC to the BE, which is analogous to a migration. These solutions are radical as they cannot be generalized; they bring two key constraints. (1) Transferring the connection from a tier T_1 to a tier T_2 requires that the two tiers implement both the same communication protocol (e.g., HTTP) and API. This is why previous works have been limited to a 2-tier architecture. As is generally the case for the scalability of storage services [17], these two tiers comprise only a load balancer and a backend stage. Conversely, a complex multi-tier architecture, such as Zimbra, must generally use different protocols and APIs among tiers and is therefore incompatible with the full transfer principle. (2) Transferring the connection from a tier T_1 to a tier T_2 requires that T_1 can work correctly and efficiently without receiving (after connection transfer) requests/replies, which is only possible for simple and coarse-grained load balancing policies. Modern load balancers are not compatible with such connection transfers as they leverage the metadata included in the headers/footers of requests and replies. For example, to select the target backend, HAProxy [4] uses attributes of the request header and NGINX [5] tracks the return time of the reply header.

In a nutshell, the ideal solution to the backpressure problem is to remove redundant communications of final data. To this end, the following conditions must be fulfilled: (1) allow final data to bypass tiers when required, (2) support heterogeneous protocols (e.g., combining HTTP and IMAP) and APIs in the tier chain (which is not compatible with the full transfer principle), (3) guarantee the correct operation of multi-tier architectures (e.g., prevent inconsistencies when tiers are bypassed), (4) do not require the modification of clients, (5) support secure communication channels (e.g., TLS).

This article presents DISC, the first approach (to the best of our knowledge) that meets all of the above 5 requirements at once. DISC bypasses IS and FE adequately by allowing a BE to directly send the final data to an EC. We design DISC in such a way that the bypass can be applied to any sub-part of a chain of arbitrary depth. To operate seamlessly, DISC disaggregates the reply, which is decomposed into two parts: (i) metadata (i.e., headers/footers), and (ii) payload. DISC lets metadata (generally limited in size) follow the reply path along the chain whereas payloads (generally substantial in size) are subject to bypass IS and FE. DISC can be implemented atop any transport protocol; we chose TCP for our prototype.

Designing DISC has raised 5 major challenges. (C_1) ***TCP sequence number management.*** Since a tier can return payloads directly on the TCP connection established between two other tiers, it is necessary to coordinate the emission of the sequence numbers so that it is transparent to those tiers. DISC allocates and translates the sequence numbers to take into account distributed emitters. (C_2) ***Management of TCP acknowledgments.*** Since the data transmitted comes from different tiers, acknowledgments received from the destination must be propagated to emitters so that they can move forward in the payload transmission process. DISC routes acknowledgments towards the concerned emitter. (C_3) ***Integration into protocol stacks.*** To avoid modifications of the Linux kernel protocol stacks, DISC extensively relies on BPF. (C_4) ***TLS support.*** Many communications over the Internet are secured using TLS. Therefore, all tiers involved in a chain must be able to return encrypted payloads in the same TLS session. To this end, DISC uses a serialization mechanism to ship TLS sessions among emitters. (C_5) ***Modification of applications.*** To minimize the impact of DISC on the code base of the different tiers, we present a pattern allowing to systematically modify applications.

We evaluated DISC using different representative multi-tier and microservice-based applications, in particular: SpecWeb [13], SpecMail [12], Train Ticket [22] and DeathStarBench Social Media [15]. The quantitative results show that DISC can significantly reduce the propagation of pressure in a chain of tiers, thus reducing CPU load on FE and IS but adding CPU load on the BE. Globally, with DISC, the cumulative load on servers is reduced by up to 41.5% and the supported request rate is improved by up to 45%. DISC has no impact on mean latency and can improve tail latency significantly. For instance, on a micro-benchmark with ten IS, DISC reduces tail latencies down to 5.71×. The reduction of the load on the bypassed tiers makes it possible to ensure greater independence of the tiers from the point of view of performance and scalability. With DISC, saturation occurs first at BE up to FE (thus promoting service scalability), whereas without DISC, it is the inverse; saturation occurs first at FE.

The remainder of the article is structured as follows. Section 2 details the motivations for DISC and its position w.r.t. previous works. Section 3 present the main principles of our contribution. Section 4 reports the results of evaluations. We conclude in Section 5. Additional details about the implementation and the evaluation are provided in appendices.

2 Motivation and previous works

The architectural pattern of two common Internet applications, e-commerce web applications and email services (respectively illustrated by the SpecWeb [13] and SpecMail [12] benchmarks), are described in §2.1, and, in §2.2, we evaluate the impact of their inherent redundant communications on server load and application scalability. Finally, we position DISC with respect to state of the art solutions in §2.3.

2.1 Motivating use cases

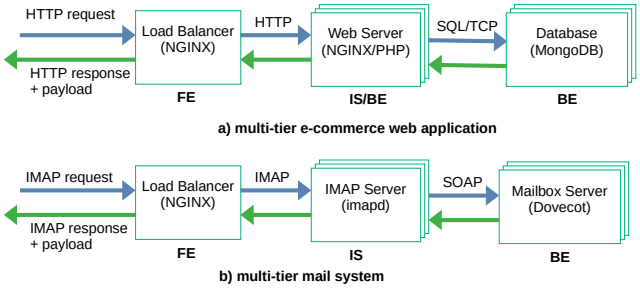

Figure 2: Two typical N-tier applications: e-commerce (SPECweb) and mailing system (SPECmail).

Coarse-grained multi-tier applications remain very popular in many production contexts. For example, according to a study [26], the WordPress content management system [10] is used by 43% of the websites on the Internet. To explain the motivation behind DISC, we use two multi-tier benchmarks due to their simplicity. These two applications involve different protocols such as HTTP, IMAP or SOAP. Notice that, we also demonstrate later how DISC can be beneficial for microservices-based applications (see §4.5 and Appendix B).

E-commerce application. Fig. 2-a depicts a common setup of a 3-tier architecture for an e-commerce application. In this architecture, the FE is a load balancer (NGINX) distributing requests received from EC to a set of web servers. These web servers (NGINX/PHP) can serve as BE, and return static pages (e.g., images). They can also act as IS when executing PHP code that requires database access; in this case, a request is sent to the database (MongoDB), which can in turn serve as BE, and can return dynamic content as final data (e.g., a JSON collection). In our experiments, we used the e-commerce application (and load injector) from SpecWeb [13].

Email serving. Fig. 2-b illustrates a possible deployment setup of a 3-tier architecture for the Zimbra email system. As in the previous application, the FE is also a load balancer (NGINX). It distributes requests received from EC to a set of IMAP servers (imapd). These IMAP servers act as IS, and send requests to Mailbox servers where client emails and folders are managed. The Mailbox servers are implemented using Dovecot [3], and serve as BE. In our experiments, we used SpecMail [12], which provides a load injector.

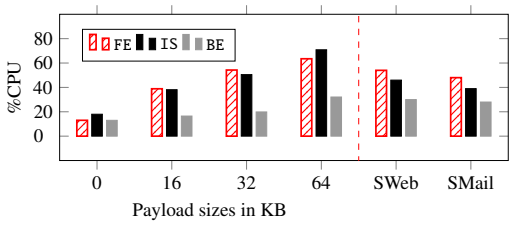

Figure 3: CPU load across each tier (vanilla setting).

2.2 Problem assessment

Final data returned by the BE must go up the chain in the reverse order from tier to tier until it reaches the EC.

Backpressure. To highlight the problem, we study the communications in a traditional multi-tier design (hereafter named *"vanilla"*). We assess the impact, in terms of CPU consumption, of relaying final data on each tier of a 3-tier architecture. We evaluate three applications: a micro-benchmark made of a chain of 3 NGINX servers, SpecWeb, and SpecMail. For the micro-benchmark, the EC submits a constant load to the first tier of the chain (FE), while the payload size of the final data returned by the BE varies from 0KB to 64KB (all the returned data is final). Conversely, for SpecWeb and SpecMail, the amount of final payloads and their sizes vary according to the benchmark instantiated. The detailed setups for these evaluations are provided in §4. At the left of the dashed line on Fig. 3, we show the CPU load on each tier of the chain (i.e., FE, IS, and BE) for the micro-benchmark. We observe a higher load on the FE and IS tiers compared to the BE tier. Furthermore, as the size of the payload returned by the BE increases, the CPU load logically increases on the BE, but it rises more significantly on the FE and IS tiers. This clearly illustrates the issue of backpressure, whereby the increased load on the BE propagates to the FE and IS tiers. Additionally, a payload size of 0 provides an estimate of the CPU load on FE and IS tiers if the payloads were directly returned to EC by the BE, thus bypassing FE and IS tiers. At the right of the dashed line on Fig. 3, we show the results for SpecWeb and SpecMail. We observe similar trends compared to the micro-benchmark.

Scalability. This backpressure problem has a significant impact on the application's scalability. To demonstrate this, we consider the same micro benchmark based on an FE-BE architecture. A load injector (EC) generates requests at a growing rate (+2K req/s every 3 seconds). We start each tier with 2 CPU cores allocated and we double the number of cores of a

tier (FE or BE) when it becomes saturated (vertical scalability). The results are shown on Fig. 4-top (Fig. 4-bottom displays the results achieved with DISC, discussed later in §4.2).

As shown at the left of the solid line on Fig. 4-top, the FE (grey curve) is the first tier to saturate due to the load on the BE that has propagated to its preceding tier. This saturation impacts the average latency measured from the client (dashed curve). At the right side of the solid line on Fig. 4-top, we added 2 cores to the FE, thus allowing the application to scale.

The goal of DISC is to ensure that an increase of the load on the BE (which returns final data to EC) does not propagate to the preceding tiers, and therefore does not lead to a saturation of the FE first, requiring the allocation of additional resources on these tiers. Ideally, an increase of the load on the BE should only lead to an increase of allocated resources on the BE.

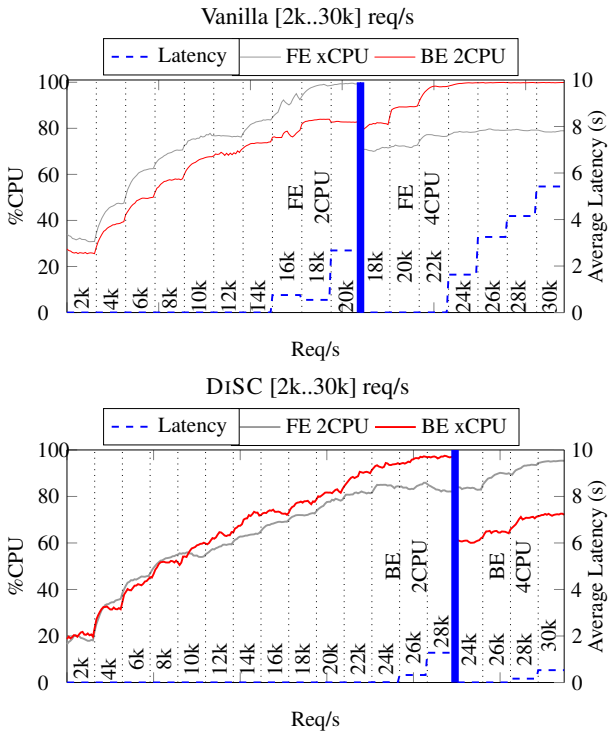

Figure 4: CPU load on the FE and BE and overall latency when increasing the request rate. Vanilla (top) vs DISC (bottom).

2.3 Shortcomings of existing solutions

Over the last decades, several works have partially addressed the backpressure problem [2,17,20,21,27]. They are designed around the *connection handoff* concept [11,18], i.e., the migration of connections between servers. However, existing handoff-based solutions have three major limitations: (i) short depth path, (ii) API lock-in, and (iii) side effects of shortcuts. We also discuss the limitations of QUIC [23], which could falsely appear to be an alternative to DISC. Given our focus on compatibility with existing datacenter applications and infrastructures, we do not discuss data transfer optimizations needing invasive software or hardware modifications [28,29].

Short depth path. The two most recent contributions, CRAB [20] and Prism [17] only support a 2-tier architecture; the FE acts as a load balancer to distribute requests to several BE. As a result, they can only be used to bypass a single server. Moreover, most common n-tier architectures, like those described in §2.1, are based on 3 tiers or more. DISC is independent of the number of tiers, and allows bypassing more than one tier. Besides, unlike Prism, DISC does not require specific hardware support (smart switches).

Application protocol/interface lock-in. Existing solutions rely on connection migration and therefore they require all tiers (FE and BE) to implement the same protocol (e.g., HTTP) and API, which is a strong constraint. As mentioned in §2.1, a multi-tier architecture may involve a combination of different protocols (e.g., HTTP and IMAP). DISC is independent of the application-level protocols and the APIs being used.

Side effects of shortcuts. Connection migration fully bypasses the FE, for both onward and backward traffic. A full bypass may have a significant impact on a FE that acts as a load balancer, which can lead to malfunctioning. This comes from two main reasons: (1) metadata attached to the final data (e.g., header, or footer) may contain information provided by the BE required by the FE to adjust its behavior a *posteriori* (e.g., for feedback-driven load balancing leveraging the request backlog size of each BE). (2) More importantly, receiving responses is an invariant of the execution logic of a multi-tier application. Completely bypassing a tier requires in-depth modifications of its code, which breaks its genericity.

QUIC limitations. QUIC [23] is a transport protocol recently standardized by IETF, implemented in user level and based on UDP. QUIC provides multiple streams within a connection (similarly to HTTP/2, although QUIC does not suffer from head-of-line blocking). It relies on a Connection ID to identify connections instead of IP/port, thus easing connection migration across IP address changes. This way, it provides a mechanism for client-side connection migration, e.g., when a client changes its network connectivity (thus its IP and port) on network handover. Thus, QUIC provides a mechanism equivalent to TCP hand-off. As stated above, hand-off solutions require all servers to implement the same protocol and API (e.g., HTTP) on top of the transport protocol (TCP or QUIC). Besides, some works [25] investigated server-side connection migration in QUIC, especially for migrating to a closer server in an edge computing context. However, such an extension requires modifications both on the server and client sides of QUIC (while DISC is transparent for the client).

QDSR [30] brings the benefits of DSR to QUIC-based L7 load balancers and offloads the responses for distinct streams to different backend servers. This approach also suffers from the limitations discussed in the three previous paragraphs.

3 Our approach: DISC

To operate shortcuts, DISC relies on a new protocol, DISC-PROT. This protocol adds header information to the request and response messages on top of the underlying L4 protocol (TCP). It enables any node in the chain to indicate in a request, which transits through the forward path, that it can be later bypassed, i.e., that it can be skipped in the backward path for the transmission of the final response's payload.

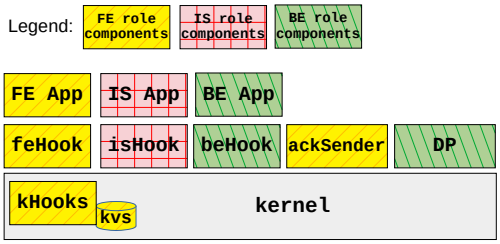

Figure 5: Software architecture of DISC on a server, with components used according to the tier role.

3.1 DISC architecture

A cloud service, invoked by an external client, is made of a set of tiers (hosted by servers in datacenters) structured as a directed acyclic graph that is traversed through request-response invocations following a chain of calls.

Roles. In a chain, depending on whether it is bypassed or not, a tier T_i can play one or the other of the following roles: (i) BE, (ii) EC, (iii) IS, and (iv) FE. T_i acts as a BE (*i.e., it has a backend behavior*) if it sends the final response. T_i acts as an EC (*i.e., it has a client behavior*) if it emits the initial request, and hence is the target of the final response. Usually such a role is taken by the external client, but nothing prevents a tier from having this role if the shortcut occurs in the middle of the chain. T_i acts as an IS (*i.e., it has an intermediary tier/service behavior*) if it is bypassed in the chain, while still receiving the metadata of the final response (without its payload). Finally, T_i acts as FE (*i.e., it has a frontend behavior*) if it is directly connected to the one that acts as an EC. In this particular case, it will ask the first encountered previous BE to send the final response to EC.

Components. DISC is implemented as a kernel extension, and is bundled with several additional components in both the kernel and user space. These components enter in action according to the role played by tiers, i.e., FE, IS, BE (see Fig. 5). Note that to act as an EC, DISC is not required as it is transparent — external clients do not need DISC. However, DISC must be deployed on all servers of the datacenter to perform shortcuts. From a kernel-space perspective, DISC includes two kernel modules: (i) a key-value store, named *kvs*, to register information about in-progress requests, and (ii) a kernel hook called *kHook* for treating incoming/outgoing L4 packets (e.g., connection establishment). From a user-space perspective, DISC provides different hooks (i.e., *feHooks*, *isHook* and *beHook*) to act at the L7 layer (such hooks allow adapting applications) and two user-level modules, noted *ackSender* and *DP*. The former manages the acknowledgment of L4 packets, and the latter takes care of sending the payload to be sent directly from BE to EC (i.e., it performs the shortcut).

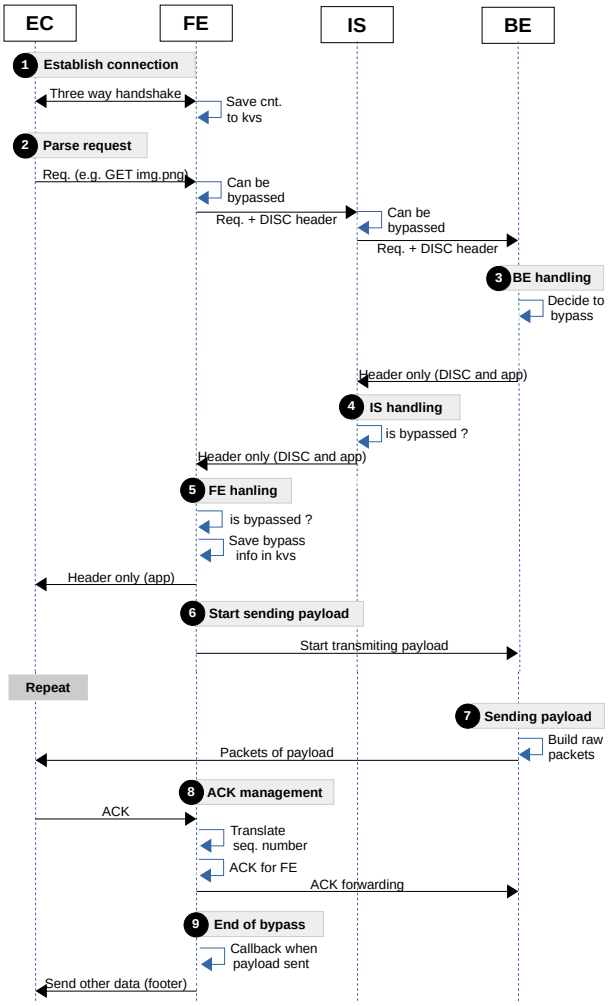

Figure 6: End-to-end coordination with DISC.

DISC shortcut mechanisms. A shortcut is the result of a coordination among FE, IS, BE and EC in 9 phases. Fig. 6 illustrates the different phases in terms of packet sequence

diagram for a scenario where BE sends the final response on the initial connection between FE and EC. The 9 phases are:

(1) Establish connection. When EC connects with FE, kHook intercepts three handshake messages and when the connection is established, it creates a key in kvs that identifies the TCP session. This key is associated with a record `<source IP, source port, ...>` that includes all information required for sending packets to EC and handling acks. Notice that all packets received on that connection are intercepted by kHook, especially acks (detailed in §3.3). As we show in §4, this interception does not impact request latency.

(2) Parse request. When EC sends a request, FE can indicate (*via* feHook, which adds an option in the DISC-PROT protocol) that it can be bypassed for the returned payload (see details in §3.2). Here, feHook is an adaptation in the L7 layer, where any policy can be applied for accepting or not the bypass, depending on the need for that tier to have or not access to the returned payload. Notice here that if FE is bypassed regarding the payload, it will anyway receive the application response header (e.g., IMAP header) and footer (e.g., IMAP footer) that can be used for internal processing. Then, FE forwards the request to IS, which behaves similarly (with its isHook) and forwards in turn the request to BE.

(3) BE handling. BE uses beHook to enable the current tier to decide whether the payload is eligible to bypass the previous tiers. If bypass is enabled, the payload is sent to the DP module, instead of the TCP connection with the preceding IS. At this point, DP generates an identifier (ids) that designates the payload in DP. Then, beHook builds a DISC-PROT header that includes the following options: a flag (*bypass*) saying that the payload is subject to bypass, the previous DP identifier (ids), the size of the payload and the IP address of the BE (allowing the FE to later request from the DP the emission of the payload, thus bypassing other tiers, FE and IS). Then, the BE application-level protocol builds its header, but with a payload size set to zero. Both headers (DISC-PROT and application-level) are included in the response message.

(4) IS handling. On IS, the response message is received and isHook checks the bypass option to skip the reading of the payload if bypassed. IS then handles the response normally and sends the response (including the DISC-PROT header) to its preceding FE, except it omits the payload if bypassed.

(5) FE handling. Like on IS, feHook checks the bypass option to read or not the payload. If the FE is bypassed, then feHook extracts all information about the bypass from the (DISC-PROT protocol) response header and stores them in the kvs entry associated with the associated initial connection. This information includes the IP of BE, the ids of the payload and its size, that will be used later to handle acks. Thus, FE can send the application-level response header back to EC.

(6) Sending the payload on FE. On FE, feHook then invokes (remotely) the DP on BE (it has its IP address) asking the emission of the payload identified with ids. This invocation provides to DP all information required to spoof FE (including TCP sequence numbers to be used), thus sending the payload on the initial connection.

(7) Sending the payload in DP. DP builds raw packets and sends them on the initial connection towards the EC. From that time, FE will receive acks for these packets (as DISC does not modify the Client). To allow the DP to continue emitting the payload (increase its emission window), received acks on FE (related to the payload) are forwarded to the DP.

(8) ACK management. All received acks on FE are intercepted by kHook (the kernel module), analyzed and handled. kHook is responsible for ensuring consistency of TCP sequence numbers. Indeed, the TCP stack on FE is not aware of packets sent by DP, thus kHook has to apply translations on sequence numbers. Also, acks received from EC may acknowledge packets emitted by the TCP stack on FE, or by DP. Acks concerning FE's stack have to be translated and acks concerning DP are forwarded to DP. Every ack concerning DP is stored in kvs and the ackSender process (started on FE) polls kvs to extract acks and forward them to DP. TCP sequence number management is detailed in §3.3.

(9) End of bypass. An application-level protocol may include a header and a footer. This is for instance the case with the IMAP protocol. Therefore FE, which sent on the initial connection its response header and delegated the emission of the payload to BE, may need to send a footer after the payload. In order to provide a means for that to the feHook, we provide an API for registering a callback function. This callback function is called when kHook observes from received acks that the full payload was received by the Client. feHook can then prepare the footer and register a callback function that will send the footer on the initial connection when the payload was totally sent. Notice here that we did not want to address this footer need through a synchronous invocation of the DP (which would have returned when the payload is sent), as it would have affected the threading model of FE. With this callback-based mechanism, the handling of footers is kept asynchronous (without blocking a thread). With DISC, we observe that the capacity to emit on the initial connection is temporarily delegated to BE and gets back to FE for sending the footer or sending the response header of the next request.

3.2 Instantiation

The previous section gave the general principle of DISC in a scenario with a unique shortcut, where a payload sent by BE bypasses IS and FE and is sent directly to EC. Now, we consider a more general example with 4 tiers chained as follow: $T_0 \leftrightarrow T_1 \leftrightarrow T_2 \leftrightarrow T_3$, as depicted in Fig. 7, and with two shortcuts at once; T_0 and T_2 can be bypassed but not T_1. The DISC-PROT protocol includes two options for managing shortcuts in its header: `NB_TIER` and `BYPASSED_TIERS`. The former is a counter initialized to 0 on T_0, incremented each time a request is forwarded to the next hop and decremented each time a response is returned to the preceding hop. It

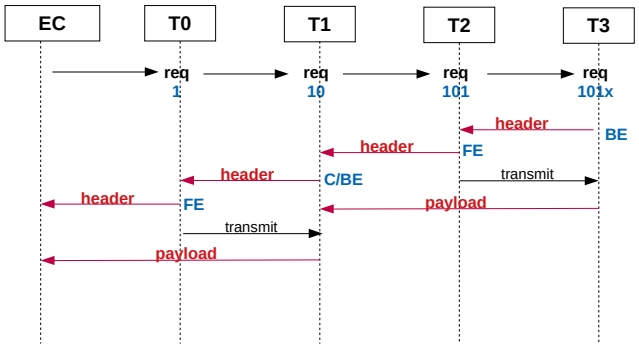

Figure 7: Concrete example of DISC with an external client invoking a chain of 4 tiers. Here, tiers T_0 and T_2 are bypassed.

permits a tier to know its place in the path and to adequately set the bit of the bitmap `BYPASSED_TIER`, indicating whether or not it wants to be bypassed.

Roles. T_3 acts as BE. Bypassing is possible if T_3 wants it for the current payload according to its policy (e.g., payload size greater than 20KB) and if the next tier (i.e., T_2) agrees to be bypassed. To perform a bypass, T_3 splits the final response into two responses and sends (i) one response without payload, i.e., a header and/or a footer, to T_2 to follow the backward path (lightweight forward), and (ii), one response that includes the payload to the local DP (shortcut). Otherwise, if there is no bypass, the final response is sent to T_2 (heavyweight forward).

Regarding T_1 or T_2, they can play different roles depending on whether they accept bypassing. If it does not agree to be bypassed (e.g., T_1), it receives a response that includes a payload. Hence, it plays simultaneously both EC and BE roles. Particularly, it acts as BE from the perspective of the next tier (e.g., T_0), and it acts as EC from the perspective of the previous tier (e.g., T_2). Otherwise, if it agrees to be bypassed (e.g., T_2), it receives a response without payload as it was checked by the tier that sent that response. Then, in this case, if the next tier (e.g., T_1) agrees to be bypassed, it plays the IS role (lightweight forward), otherwise it plays the FE role. In this case, it (e.g., T_2) remotely asks the DP of the first previous BE encountered (e.g., T_3) which held the payload to send it on the connection with the next tier (e.g., T_1). In this latter case, the next tier will receive a final response, acting as EC and BE as seen earlier.

Regarding T_0, if it receives a response with a payload (it plays an EC role), it simply sends it on the initial connection. Otherwise, if it receives a response without payload, it plays the FE role. Accordingly, it remotely asks the DP of the first previous BE encountered (e.g., T_1) that held the payload to send it on the connection of either the next tier (and so on) or the external client if the end of the chain is reached.

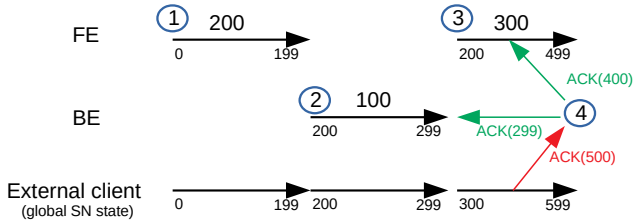

Figure 8: Coordination of TCP sequence numbers.

Bitmaps. In the scenario of Fig. 7, the final value of the bitmap is *101x* (the first bit is the leftmost one). T_3 decides to enable bypass (e.g., based on the payload size). Thus, it plays the BE role. As T_2 agrees to be bypassed (in Fig. 7, the 3rd bit of the bitmap is 1), T_3 sends a response without payload, and the payload is sent to DP. T_2 plays the FE role since T_1 does not agree to be bypassed (in Fig. 7, the 2nd bit is 0). Therefore, T_2 sends a response without payload, but it is sent from T_3 (its DP) to the T_2-T_1 connection. T_1 receives a response with payload, so it plays the EC and BE roles, and since T_0 agrees to be bypassed (in Fig. 7, the 1st bit is 1), T_1 sends a response without payload, and the payload is sent to its DP. T_0 receives a response without payload, and since its predecessor (EC) cannot be bypassed, it plays the FE role, thus sending a response without payload, but the payload is sent from T_1 (DP) on the T_0-EC connection (initial connection).

3.3 DISC atop TCP

First, we stress that DISC's design and implementation do not hinder the characteristics of applications built atop TCP. In particular, DISC is compatible with keep-alive connections, piggybacking (an ACK carries a new request), and request pipelining and does not negatively impact (or remove) TCP's congestion control mechanism. Below, we describe the main challenges introduced by DISC w.r.t. TCP. Implementation details for our DISC prototype are provided in Appendix A.

As we do not want to modify the TCP stack deployed on the servers (DISC pervasiveness), DISC needs to coordinate the TCP Sequence Number (SN) emitted by FE and BE. Indeed, EC is likely to receive TCP packets from multiple sources, such as from FE and BE, so both must send packets with consistent sequence numbers. This is illustrated in Fig. 8 where, for more clarity, we do not present sequence numbers in terms of bytes but in terms of packets. If FE sends 200 packets with SN from 0 to 199 (❶), and thereafter BE sends 100 packets (❷); then the SN for the latter should be from 200 to 299 (BE must be informed about the SN it should use). Now, if FE sends 300 additional packets (❸); from its point of view, the SN will be from 200 to 499 since it is not aware of the packet emissions from BE. Consequently, these SN must be translated to be consistent from the point of view of EC, so they will be from 300 to 599 (instead of 200 to 499).

The management of SN in DISC is implemented in kHook as follows. kHook maintains a global SN state in kvs, considering all emitted packets (from FE and BE). The invocation of BE (especially its DP) to trigger the emission of the final payload takes as an additional parameter the global SN state so that BE can send packets with consistent SN. The global SN state can be updated as we know the payload size (from the DISC-PROT response header). In Fig. 8 at emission (❷), the global SN state is 200, and the global SN state is updated to 299 after emission. Packets emitted by FE are modified by kHook to adapt their SN according to the global SN state. In Fig. 8 at emission (❸) from FE, SN from 200 to 499 are modified and become from 300 to 599. kHook maintains in kvs the emitted SN and the servers (FE or BE) which emitted them. Any packet acknowledgment (ack/sack) received by FE is intercepted by kHook. Its SN is analyzed to either send an ack/sack packet to FE 's TCP stack (and the SN is translated back) or either send an ack/sack packet to BE which emitted it (allowing to resend a packet, free its internal buffers, and adapt its emission window). In Fig. 8, an ack with SN 500 is received (❹) on the initial TCP connection. kHook, according to its internal state, modifies the SN to 400 (since 100 packets were sent by BE) so that the ack is consistent for FE. Moreover, it generates an ack packet for the preceding emission from BE with SN 299.

Last, SN for packets received from EC (e.g., requests) are all handled by the FE and will generate ack/sack towards EC. However, all payload packets emitted by the BE towards EC must include an ack with the last acknowledged received data SN. This SN (that we call the *client SN*) is passed to the DP of the BE when invoked for payload emission so that a proper ack can be added in the emitted packets.

Due to a lack of space, we only briefly discuss the behavior of DISC in the event of failures. Without DISC, in a multi-tier architecture, the failure of one tier generates delays, ultimately leading to a disruption in the connection with the external client. The application code in the tiers is responsible for implementing precise semantics in the event of such failures. Message losses are handled by TCP, thus by DISC. In the case of DISC, sending the payload to the client is delegated to the BE by the FE (recall that the headers follow the normal path). The BE (and its DP) behaves like TCP, meaning that it retransmits lost messages and will stop (and clean up) sending the payload if the connection with EC gets broken.

3.4 TLS support

The integration of TLS in our prototype relies on wolfssl [6]. The design of TLS support extends the work described in [17]. It relies on two functions that behave as serialization primitives: `wolfSSL_tls_export()` (which transforms an `SSL_SESSION object` into an `ASN1` representation) and `wolfSSL_tls_import()` (which performs the reverse operation). In our DISC prototype, feHook and DP are mutually exclusive, i.e., they run on different machines. When feHook invokes the DP to request the emission of a payload, it invokes `wolfSSL_tls_export()` and passes as a parameter the `ASN1` representation of the SSL session. DP receives this representation and then invokes `wolfSSL_tls_import()` to recreate the SSL session. The latter is then associated with the file descriptor used to emit payload chunks directly to the client. Once the full payload has been emitted, DP sends the `ASN1` representation of the SSL session back to the FE. On the FE, kHook receives this representation and restores the SSL session. Note that the encrypted chunks of the payload are buffered in DP so that they can be re-sent if a SACK or DUP ACK is received. The FE cannot emit data toward the client while the SSL session is located on the DP (until the SSL session is returned on the FE).

This main impact of DISC's TLS support is the shift of TLS processing from the FE to the BE. From the datacenter point of view, this is not an overhead but a shift, and this can moreover be seen as a benefit since the FE (which is often a load balancer) can be a bottleneck while the BE is often sharded and replicated for scalability.

3.5 Application integration

We need to modify applications that run on FE, IS, and BE tiers to implement DISC. These modifications are hereafter referred to as feHook, isHook and beHook. In this section, we give pseudo-code, which describes the algorithms of such hooks in the case of HTTP communications. The code has to be adapted to receive and send HTTP responses without payload. As depicted in §3.2, headers (of the DISC-PROT protocol) are added in requests and responses. A DISC-PROT request header indicates whether the current tier can be bypassed, and a DISC-PROT response header indicates whether the payload is present or not.

First, for IS, the program below is a prototype of the code of the IS and its adaptation (in bold). We assume the server has two socket file descriptors: `fdc` and `fds` (respectively towards the client and the server side). This code is executed when a request is received on `fdc` and has to be forwarded to `fds`.

```
1  discprot_req_hdr = receive_discprot_request_header(fdc);
2  update_discprot_request_header(&discprot_req_hdr);
3  send_discprot_request_header(fds, discprot_req_hdr);
4   http_req_hdr = receive_http_request_header (fdc);
5   send_http_request_header (fds, http_req_hdr);
6  payload = receive_http_payload (fdc);
7  send_http_payload(fds, payload);
8    ...
9  discprot_resp_hdr = receive_discprot_response_header(fds);
10 send_discprot_response_header(fdc, discprot_resp_hdr);
11  http_resp_hdr = receive_http_response_header (fds);
12 send_http_response_header(fdc, http_resp_hdr);
13 if (! bypass(discprot_resp_hdr)) {
14       payload = receive_http_payload (fds);
15       send_http_payload(fdc, payload);
16 } else {
17     // NOTHING
18 }
```

Onwards, this program receives the DISC-PROT request header, updates it as described in §3.2, and forwards it (lines

1-3). It then receives and forwards the HTTP request header and payload (lines 4-7). Backward, it receives and forwards DISC-PROT and HTTP response headers (lines 9-12). Then, depending on the information in the DISC-PROT response header (extracted by the `bypass()` function), it receives and forwards the payload if no bypass occurs (lines 13-15).

For FE, the code adaptation is very similar to the above one, with few differences. First, the DISC-PROT request header is not received from the external client but constructed (line 1). Second, when a response is received without a payload (line 17, `NOTHING` comment), FE has to request the emission of the payload by the BE. Here (line 17), FE must execute the following additional code:

```
17    register_range(discprot_resp_hdr);
18    start_transmit(discprot_resp_hdr);
```

`register_range()` registers in the kvs the SN of the packets sent by BE. `start_transmit()` remotely invokes BE (its DP) to start the emission of the payload. The `discprot_resp_hdr` structure includes all the required parameters for these functions.

Finally, for BE, the code below is a prototype of the code of BE and its adaptations (in bold):

```
1   discprot_req_hdr = receive_discprot_request_header(fdc);
2   http_req_hdr = receive_http_request_header (fdc);
3   payload = receive_http_payload (fdc);
4
5   // process request and compute response
6   // (http_response_header and payload)
7
8   discprot_resp_hdr = make_discprot_response_header(discprot_req_hdr);
9   send_discprot_response_header(fdc, discprot_resp_hdr);
10  send_http_response_header(fdc, http_resp_hdr);
11  if (bypass(discprot_resp_hdr)) {
12          dp_send_payload(fd_disc, payload);
13  } else {
14          send_http_payload(fdc, payload);
15  }
```

Onwards, this program receives the DISC-PROT, HTTP request headers, and the request payload (lines 1-3). The application processes the request, and a response is computed. Backward, a DISC-PROT response header is computed (line 8), deciding whether a bypass occurs. The DISC-PROT and HTTP response headers are returned on the `fdc` client socket (lines 9-10). Then, according to information in the DISC-PROT response header (extracted by the `bypass()` function), the payload is either sent to the local DP component[1] (line 12) on a dedicated file descriptor (`fd_disc`) if a bypass occurs or to the preceding tier (line 14) if no bypass takes place.

4 Evaluation

Testbed. We use c220g5 nodes from CloudLab [1]. Each server has 2 Intel Xeon Silver 4114 10-core CPUs at 2.20 GHz, 192GB memory, and a 10GB Intel X520-DA2 NIC. They run Debian server 11 with Linux v5.19. For CPU measurements, in order to concentrate on DISC impact on CPU consumption, each tier is executed on one CPU core unless otherwise specified.

[1] As discussed previously (§3.1), the DP buffers the payload locally and sends it to the EC when it receives a transmission request from the FE.

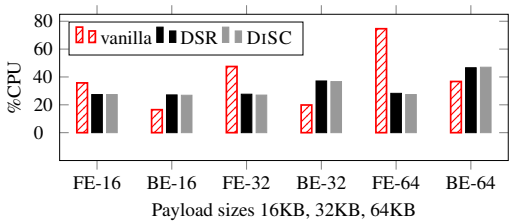

Figure 9: CPU load on each tier in `[FE-BE]` configuration.

Benchmarks. We use one micro-benchmark and four macro-benchmarks to evaluate DISC. The micro-benchmark is a simple N-tier web application that returns static contents of different sizes (16–64KB). The FE and IS tiers only relay requests/responses. We choose the size ranges based on statistics from the Internet/HTTP Archive about typical statistics for HTML pages and images (whose average sizes are respectively 32 and 48KB). It is important to note that the larger the response size, the greater the benefits of DISC.
We use wrk [16] as client, generating 750 req/sec. FE, IS, and BE are implemented with NGINX. Using this micro-benchmark, we can evaluate DISC with various numbers of IS. Concerning the macro-benchmarks, we use SpecWeb [13], SpecMail [12], Train Ticket [22], and Social Media (from the DeathStarBench suite [15]). The first two applications follow a 3-tier architecture (`FE-IS-BE`), presented in §2.1. We use them for the majority of the experiments. We simulate 700 clients. The requested payload sizes are respectively in the [1–64 KB] and [1–100 KB] ranges for SpecWeb and SpecMail. The two other macro-benchmarks, Train Ticket and Social Media, are based on the microservices paradigm. Their characteristics and setups are detailed in §4.5 and §B, respectively.
Goals. We consider five questions: (Q_1) Does DISC effectively offload load from FE and IS, thus addressing the back-pressure problem (§4.1)? (Q_2) What is the impact on scalability (§4.2)? (Q_3) What effect does DISC have on network latency as perceived by the application client (§4.3)? (Q_4) What is the impact of TLS support (§4.4)? (Q_5) What is the impact of DISC on microservices architectures (§4.5)?

We compare DISC with vanilla settings and Direct Server Return (DSR) [19], a standard TCP Handoff [11] solution implemented by many load balancers as stated in §2.3. DSR does not allow fine-grained bypass nor several-tier bypass, and is limited to a single protocol (HTTP). Consequently, we use DSR only for bypassing the FE tier, from its preceding tier which is BE in the `[FE-BE]` architecture or IS in the `[FE-IS-BE]` architecture. Note that, for the 4 macro-benchmarks, we only compare DISC against vanilla because they all are based on architectures featuring multiple protocols and one or several

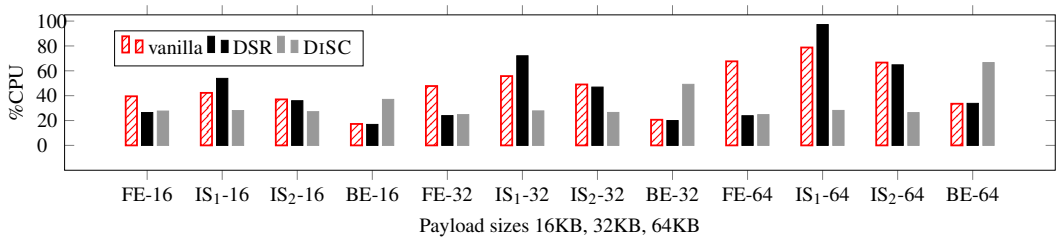

Figure 10: CPU load on each tier in [FE-IS$_1$-IS$_2$-BE] architecture.

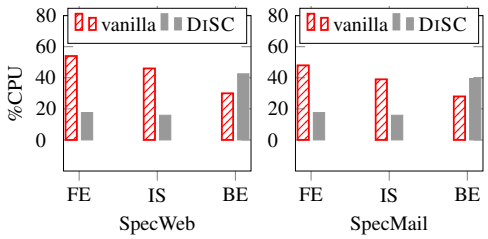

Figure 11: CPU load on SpecWeb and SpecMail tiers.

intermediate tiers.

4.1 CPU load offloading from FE and IS (Q_1)

Micro-benchmark, [FE-BE] architecture. Fig. 9 shows the CPU load for each tier while varying the size of the requested content. With vanilla, FE consumes a significant amount of CPU compared to BE. The gap increases as the content size increases. With DISC and DSR, the load is pushed on BE, where it should since most of the request processing is related to BE. Additionally, with DISC and DSR, as the size of the response increases, the load on FE remains almost constant while the load increases on BE. Overall, DISC and DSR lead to almost the same results. They significantly offload the CPU load on the FE. **DISC efficiently addresses Q_1, it has almost the same results as DSR in a [FE-BE] architecture**.

Micro-benchmark, [FE-IS *-BE] architecture. As explained earlier, DSR can only support a single bypass (of the FE tier). Accordingly, in a [FE-IS$_1$-IS$_2$-BE] architecture, we compare DISC with its vanilla counterpart (with no bypass at all) and with DSR with a bypass of the FE tier only (initiated by IS$_1$). In Fig. 10, we can see that, with vanilla, considerable CPU time is spent on FE and IS, whereas the load on BE does not increase in the same order when we increase the payload size. This is explained by the fact that FE and IS tiers are both receiving, and sending the payload while the BE is only sending the payload. With DISC, the load on FE and IS tiers remains constant. Further, the load is partially pushed on the BE (as it performs additional tasks such as payload buffering and ACK management). For instance, in the micro-benchmark with a 64KB payload size, DISC offloads FE/IS tiers respectively by 63.4% (FE), 64.3% (IS$_1$), 60.4% (IS$_2$), and increases the CPU load on the BE by 98.8%. With DSR, the load on BE and IS$_2$ is the same as vanilla (nothing changed on these tiers), and offload takes place between IS$_1$ and FE. As depicted in Table 1, for the [FE-IS *-BE] 64KB experiment, the cumulative CPU load across all tiers is 246% for Vanilla, 208% for DSR, and 145% for DISC. Thus, a reduction of 41% of the load with DISC compared to vanilla and 30.3% compared to DSR. **In a [FE-IS *-BE] architecture, DISC also efficiently addresses Q_1, it drastically offload load from FE/IS tiers.**

SpecWeb and SpecMail. As shown in Fig. 11, we observed the same trends as above. Overall, DISC achieves a global reduction of the load, about 41% for SpecWeb and 36% for SpecMail (Table 1). **DISC addresses Q_1, we observe a significant offload of the FE/IS tiers, and a limited increase of the load on the BE.**

Scenario	Vanilla	DSR	DISC
[FE-BE] 16KB	52	54 (-3.8%)	54 (-3.8%)
[FE-BE] 32KB	67	65 (3%)	64 (4.5%)
[FE-BE] 64KB	111	75 (32.5%)	74 (33.3%)
[FE-IS*-BE] 16KB	136	132 (2.9%)	120 (11.7%)
[FE-IS*-BE] 32KB	173	158 (8.7%)	128 (26%)
[FE-IS*-BE] 64KB	246	208 (15.4%)	145 (41%)
SpecWeb	130	—	76.11 (41.5%)
SpecMail	115	—	73.06 (36.5%)

Table 1: Cumulative CPU load on all tiers for all our scenarios and reduction percentages with respect to Vanilla.

4.2 Impact of DISC on scalability (Q_2)

Setup. To study scalability of [FE-BE] architectures, we generate requests, with a payload size of 32KB, at a growing rate, i.e., increasing the rate by 2K req/s every 3 seconds. We run this scenario while varying the number of cores on the FE and BE tiers. Initially, each tier is allocated 2 cores. Upon reaching saturation, the number of cores for the saturated tier doubles.

Results, vanilla settings. In Fig. 4-top, using the vanilla settings, we notice that the front-end (FE) is the first tier to reach saturation, primarily because of the load (pressure) propagated from the back-end (BE). It validates the initial findings

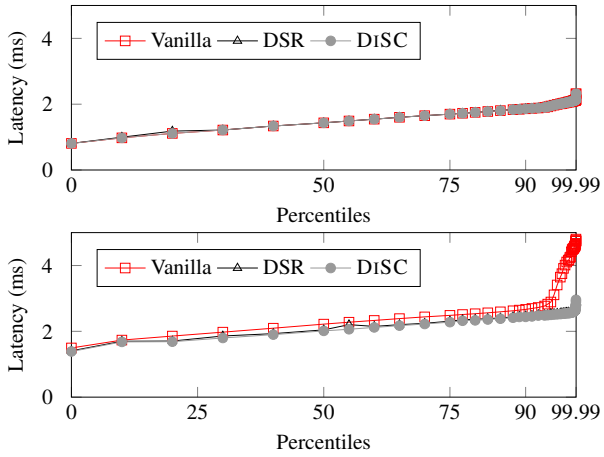

Figure 12: Latency percentiles for the micro-benchmark with the [FE-BE] (top) and [FE-IS$_1$-IS$_2$-BE] (bottom) setups.

presented in §2.2. As soon as the FE saturates, the average request latency raises up, and the doubling of the number of cores is triggered. It appears that with only 2 cores on the FE and BE (on the left side of each sub-figure), tiers achieve a rate of 18K req/s without latency degradation. Having twice the number of cores enables at most a rate of 22K req/s.

Results, DISC settings. In Fig. 4-bottom, using the DISC settings, we observe a notably reduced load on the front-end (FE) in comparison to the vanilla settings. Interestingly, the first tier to reach saturation is the back-end (BE), leading to the increase of: (i) the average latency and therefore (ii) the number of cores (x2). We can observe that with DISC, the tiers achieve a rate of 26K req/s with 2 cores, reaching a plateau at 30K req/s (due to the saturation of the network adapter) with 4 cores.

Compared to the vanilla settings, DISC achieves a significantly higher rate with the same amount of resources: with 2 cores, a rate of 18K for vanilla and a rate of 26K for DISC (an improvement of 45%).

DISC successfully addresses Q_2 by effectively mitigating the backpressure problem. This results in a reduction of the load on tiers preceding the BE, ultimately promoting scalability in the last tiers of a tier chain.

4.3 Impact of DISC on latency (Q_3)

Setup. As previously, the evaluations of latency have been realized with both the micro- and the macro-benchmarks (i.e., SpecWeb and SpecMail). Additionally, we performed evaluation with and without IS tiers involved.

Results, micro-benchmarks. Fig. 12 respectively show the results for zero IS (top) and two IS (bottom) using the micro-benchmarks. From Fig. 12 (top), when no IS is involved, DISC yields nearly identical results to vanilla and

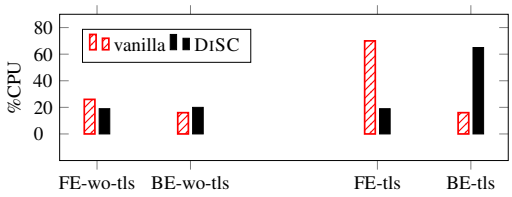

Figure 13: CPU load on each tier in [FE-BE] configuration without and with TLS (micro-benchmark, 32KB payload).

DSR settings. As more IS are involved (Fig. 12 bottom), DISC demonstrates improved latency, with approximately a 0.35ms average difference for 2 IS compared to the vanilla setting and 0.18ms better than DSR. Furthermore, from Fig. 12 (bottom), one can also observe that the tail latency (see the 99.99 percentiles on the figure) is significantly reduced $4.803s \rightarrow 2.959s$. The latency is further improved with more IS tiers, reaching up to $5.71 \times (8s \rightarrow 1.4s)$ for tail latencies with a longer chain of 10 IS (not plotted).

Results, macro-benchmarks. For SpecWeb and SpecMail, we measured that DISC provides a better latency than vanilla by up to 12% in average.

DISC successfully addresses Q_3. It clearly improves latency from the client perspective.

4.4 TLS impact (Q_4)

All the previous experiments were conducted without TLS. To evaluate the impact of TLS, we run the previously used micro-benchmark on a [FE-BE] architecture with and without TLS. Compared to Fig. 9 in §4.1, we reduced the submitted load in order not to saturate CPU with TLS.

As explained in §3.4, when a payload is sent by a BE (when its DP is invoked), the `ssl_session` object is serialized and transmitted from the FE to the DP which deserializes it and uses it for payload encryption. The consequence is that the encryption workload is shifted from FE to BE.

In Fig. 13, we observe the same trend as in previous evaluations. Most of the load is pushed from FE to BE. This is an important benefit for scalability as it prevents FE from becoming a bottleneck. In some way, encryption is part of emission and should be logically handled by the BE without back-propagating the pressure to the preceding tiers.

To answer Q_4, TLS integration in DISC amplifies the mitigation of the backpressure problem.

4.5 Impact on microservices applications (Q_5)

Train Ticket. This macrobenchmark [22] is composed of 43 microservices, which is more complex than the SPEC applications we evaluated above. The microservices communicate with each other via gRPC. An external client request triggers the execution of a specific chain of microservices. The chains vary in length and may involve different sizes of final

data, generated by the database (MySQL). For example, the request corresponding to page `client_adsearch` generates very little final data, which would be irrelevant for DISC. Conversely, the requests triggered by `client_order_list` and several other pages[2] are likely to pull a large amount of final data from MySQL. For our experiments, we focused on the microservices involved in these requests. To illustrate the evaluation of DISC, we use the `client_order_list` request, which involves 4 microservices: `ui` (FE), `gateway` (IS_1), `order` (IS_2), and `mysql` (BE). We keep the default configuration for each service. An important detail to understand the results is that the `gateway` implements traffic shaping, calibrated at 20 req/s.

The modifications made to the application to integrate DISC primarily consisted of extending the SQL language to signal when the return path of a microservice can be bypassed. We also extended the MySQL JDBC driver [9] to handle this SQL extension and implement DISC's DP component.

For this experiment, we use virtual machines (VMs), unlike the previous experiments, which were conducted on bare-metal. This allows DISC to be evaluated in typical application execution environments. Each service is deployed in a separate VM (2 vCPU and 2GB of memory), resulting in a total of 43 VMs. To simplify the interpretation of results, we opted for a setup without microservice replicas. In this virtualized environment, for the `MySQL` VM, the virtual network interface (virtio) is configured with multiple transmission queues, with one queue specifically dedicated to XDP. Using wrk2, we launched 400 clients, each requesting a payload size of 32KB.

Fig. 14 shows the results. We observe that DISC does not significantly reduce the CPU load on the `gateway` compared to other microservices. This is because the `gateway` applies rules to throttle incoming requests upon reception (traffic shaping), which adds computational overhead. To support this, we conducted experiments with a 0B payload and we observed that the CPU load on the `gateway` remains high, indicating that it is primarily driven by the computations from its traffic shaping module. The load on the `gateway` increases with DISC, compared to the vanilla setup, when the payload is 0B because DISC allows the application to receive more traffic, resulting in more traffic shaping processing on the `gateway`. DISC shifts the CPU load from the `order` service (49% reduction w.r.t. vanilla), while moderately increasing it on the MySQL BE (+18.5%).

We also observe that DISC improves both latency and throughput. Average latency decreases by 74.1%, from 3.57 to 0.928 seconds, and throughput increases by 39.8%, from 635.80 to 889.20 req/s.

Social Media. Due to a lack of space, we only provide a brief summary of the results for this macro-benchmark. More details on the benchmark, setup and experiments, are available in Appendix B. Similarly to Train Ticket (§4.5), DISC shifts

[2] `admin`, `admin_travel`, `admin_user`, `client_consign_list`, `client_enter_station`, and `client_ticket_collect`.

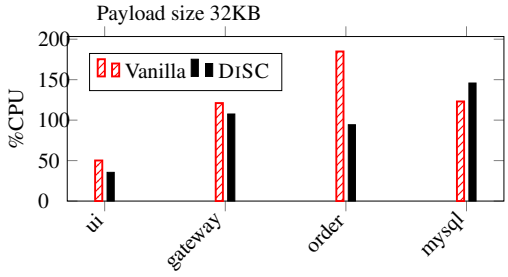

Figure 14: CPU load on the Train-ticket microservices triggered by a `client_order_list` request. `ui` and `mysql` correspond to FE and BE, respectively.

the CPU load from frontend to backend tiers. Compared to vanilla, DISC offloads the frontend tiers by up to 41.7% and increases the backend tier by up to 48.8%. Moreover, DISC reduces the average latency by up to 66.7% by dropping it from 510ms to 221ms, while increasing the throughput by 21.9%, from 80355 req/s to 98009 req/s.

DISC successfully addresses Q_5: its benefits are applicable to coarse-grained as well as to microservices applications.

5 Conclusion

This paper tackles the backpressure problem, which compromises both: (i) the independence of tiers regarding performance, and (ii) the scalability of multi-tier architectures. We presented the drawbacks of state-of-the-art solutions and identified six requirements (flexible, protocol agnostic, transparent, pervasive, consistent, TLS support) that a solution should meet to efficiently address this problem in a holistic manner. We introduced our solution, DISC, which meets all these requirements. With a prototype built atop TCP, we demonstrated that DISC significantly: (i) reduces the CPU load, and (ii) improves tail latencies on heavy-load scenarios.

Note that, like CRAB [20], DISC relies on IP spoofing, which is generally not possible for IaaS tenants. Thus, in the context of public cloud platforms, DISC can only be deployed by cloud providers to complement (or replace) their existing offerings (load balancers and managed applications).

Acknowledgements

We thank our shepherd, Ankit Bhardwaj, and the anonymous reviewers for their insightful comments. Théo Boury, Maxime Bruno, and Adrien Vannson contributed to early versions of the DISC implementation. This work was supported by the French *Agence Nationale de la Recherche* under the ANR projects "PicNic" (ANR-20-CE25-0013) and "PEPR DiVa" (ANR-23-PECL-0004), by the CNRS "MLSN2" International Research Project, and by Inria "Défi OS".

Appendices

The appendices are organized as follows: Appendix A provides implementation details regarding the implementation of the different components of DISC, Appendix B provides additional details regarding the Social Media benchmark, setup and experiments (discussed in §4.5).

A Implementation details

DISC is implemented with a kernel module (kHook, kvs), two user-level modules (ackSender and DP) and a set of L7 hooks to act at the L7 layer (i.e., feHook, isHook, beHook). kHook relies on BPF (extended Berkeley Packet Filter) for intercepting and adapting packets at the L4 layer. kvs is implemented with BPF maps (a generic storage system for sharing data between the kernel and the user space). L7 hooks can be implemented with patches or application extensions when such a support is provided (e.g., NGINX allows the definition of filters). The overall design of DISC is depicted in Figure 5. The implementation details of each component is given below.

kHook. The kHook is activated on each server of the datacenter hosting a tier that may act as FE. kHook is composed of three interceptors called `in_tc`, `out_tc`, and `in_drv`. Both `in_tc` and `out_tc` are implemented in the TC (Traffic Control) layer while `in_drv` is integrated in the NIC driver. kHook could be fully implemented at the TC level, but we introduced `in_drv` for performance reasons (to prevent needless walks in the protocol stack). `in_tc` intercepts incoming TCP connections and initializes kvs with the characteristics of the established connection. All other incoming packets are handled by `in_drv`.

`in_drv` intercepts all packets received from the client after connection. Such packets may either include data or not, and must include an ack. If the packet includes data, then data is transmitted to the stack of FE. But anyway (whether the packet includes data or not), acks must be handled, so that they are consistently (regarding sequence numbers SN) sent to the stack of FE or to DP (which emitted the payload). If there were not any bypass yet, packets are transmitted to the FE stack as is. As soon as a bypass occurred, SN included in acks have to be translated as depicted in §3.3. A map of the SN that were emitted (returned to the client) by the FE stack and the DP is registered in the kvs. This map includes emitted SN ranges and the IP addresses of the emitting servers. Both are kept in the kvs as long as they are not acknowledged by EC. A SN in a received ack that acknowledges data from a range generates an ack which is sent to the emitting server of the range (FE or DP) with the highest acknowledged SN from the range (notice that several ranges may be acknowledged by an ack). If the generated ack is transmitted to FE, the SN is translated back into the SN as sent by the FE. If the generated ack is to be sent to the DP, it is actually stored in kvs and consumed by the ackSender process.

Regarding out_tc, it translates SN sent by FE to the client, taking into account the global SN state (see §3.3) that is returned when DP is invoked (for sending a payload).

lib_kHook. This library provides an API for instantiating kHook within the kernel and for accessing kvs. It provides: (i) setup_khook() to instantiate the hook, (ii) poll_ack() to poll acks from kvs to be sent to DP by ackSender, and (iii) register_range() to register a packet range sent by BE.

register_range() is called by feHook after the reception of the response header that includes in its DISC-PROT header the ids (identifier) of the payload, its size and IP of the BE (location of DP). Those parameters are passed to register_range(), which registers in kvs the packet range associated with the payload and information for handling acks for these packets (IP of BE and ids). register_range() also receives as parameters the SN associated with the registered packet range (deduced from the global SN state and the size of the payload) and also the IP address and port of the client. Notice that register_range() also receives a callback function, invoked by kHook when the client receives the full payload (thus allowing to handle protocol footers, e.g., in the case of IMAP).

lib_comm. This library implements an API for communication between DISC components located on different machines. It provides two key functions: (i) start_transmit() to remotely invoke a DP, and (ii) forward_ack() to forward acks to a DP. start_transmit() takes as parameters the IP of BE and ids of the payload, address of EC (IP and port) and the global SN state to be used for sending the payload.

ackSender. ackSender is a process started on each FE. It relies on poll_ack() from lib_kHook and forward_ack() from lib_comm to extract acks from kvs and send them to DP. Since acks can be any of the following ACK, SACK, DUP ACK and ZERO WINDOW, DP can therefore manage the buffering of the payload (freeing buffers), the re-emission of lost packets and its emission window.

feHook. feHook calls register_range() after the reception of the response header to store in kvs information about the emitted payload. It then calls start_transmit() to request the emission of the payload from DP.

beHook and DP. The implementation of DP relies on two modules called ctr_msg_manager and payload_sender. Both modules include a thread for handling to incoming requests. ctr_msg_manager handles requests issued by FE when either: (i) an ack is forwarded *via* forward_ack(), or (ii) the emission of a payload is requested *via* start_transmit()). payload_sender handles the emission of payloads (i.e., packets on the connection preceding the FE).

When beHook (which acts at the L7 layer of BE) decides to send a payload with bypass, it asks ctr_msg_manager to create a job that is inserted into a red-black tree structure. This job includes a unique identifier (ids) of the payload, and a data structure representing the content of the payload. In our prototype, the content of the payload in a job can be of two types. In the first case (type 1), the payload content is a buffered stream of data sent by the L7 layer of BE. BE starts filling the buffer and blocks until buffers are freed by received acks. In the second case (type 2), the payload content is a file, meaning that emitted packets are directly read from a file. This is equivalent to the sendfile() Linux primitive, which directly copies data from a file descriptor to a socket descriptor.

When feHook (on FE) calls start_transmit() to request the emission of the payload, ctr_msg_manager receives that request, and retrieves the job identified by ids from the red-black structure. It adds in the job the parameters received in the request (IP address and port of the client, SN associated with the payload, size of the reception window of the client) and asks payload_sender to insert a task in its internal task list (a FIFO list of tasks consumed by the handler thread). A task is a request to emit a data chunk. When starting transmission of a payload, the created task corresponds to the emission of a chunk whose size is the reception window of the client. Then, when ctr_msg_manager receives an ACK, DUP_ACK or SACK, it implies that either a chunk has to be re-sent or that an additional chunk within the payload can be sent. Therefore, ctr_msg_manager handles such acks by adding tasks in the task list. The handling of a task reads the chunk either from the buffer or the file (according to the job) and generates a set of packets on the TCP connection preceding the FE (thus DP is spoofing FE).

B DISC with the Social Media benchmark

We perform additional experiments to show how DISC performs with complex microservices. To meet this aim, we modified the Social Media benchmark from the DeathStarBench benchmark suite [15]. The Social Media benchmark comprises 36 services, primarily written in C, C++, Java, and Node.js, communicating through Thrifts RPC [8]. The storage services run MongoDB with caching services that run Memcached or Redis. A client request queries a load balancer, which distributes a client request across Nginx web servers. The request processing chain length depends on the client's request input. Like for Train Ticket (§4.5), to apply DISC, we modify the storage and caching layers and their connectors (MongoDB, Memcached, and Redis) to obtain the microservices that can be bypassed when receiving a read or write request. Consequently, we reduce the load on the intermediate nodes hosting the bypassed microservices.

We deploy our modified version of the Social Media benchmark where each service runs in VMs that have the same size as the ones from Section 4.5 (2vCPU and 2GB memory) and

use the built-in load generator (built atop wrk) to evaluate the impact of DISC. Concretely, we use the load generated to simulate 1000 clients that read randomly previously registered posts for 600 seconds. 1000 clients is enough to stress the frontend tiers cores up to 70% overall. Each client triggers a request every 10ms. We chose this scenario because it is among the scenarios with the longest request processing chain. The input payload size for such a request is 4KB, and the response payload size depends on the requested post, which varies from 64KB to 8.2MB. During the experiment, we record the CPU usage on all microservice nodes. Figure 15 reports the CPU usage on the frontend tier `LB`, the intermediate (IS) tiers `Media frontend, Nginx` and the backend tier `MongoDB`. The caches hit ratio is, on average, 2.8%. Thus, we do not focus on the CPU load on the caching nodes.

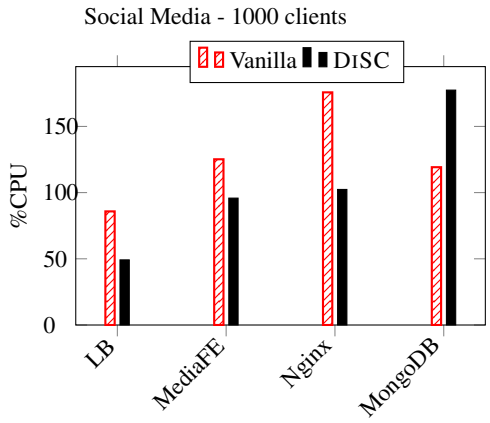

Figure 15: CPU load on the main microservices triggered during the execution of the read post requests performed by 1000 clients during 600s. `LB` correspond to the `FE`, `Media frontend (MediaFE), NGINX` correspond to `IS`, and `MongoDB` correspond to the `BE`.

Similarly to Train Ticket (§4.5), DISC shifts the CPU load from frontend to backend tiers. Concretely, DISC offloads the frontend tiers by up to 41.7% and increases the backend tier by up to 48.8%. Moreover, DISC reduces the average latency by up to 66.7% by dropping it from 510ms to 221ms, while increasing the throughput by 21.9%, from 80355 req/s to 98009 req/s. Thus, DISC efficiently shifts load from FE to BE, improving overall end-end latency and throughput compared to vanilla.

Enabling Silent Telemetry Data Transmission with InvisiFlow

Abstract

Network applications from traffic engineering to path tracing often rely on the ability to transmit fine-grained telemetry data from network devices to a set of collectors. Unfortunately, prior work has observed—and we validate—that existing transmission methods for such data can result in significant overhead to user traffic and/or loss of telemetry data, particularly when the network is heavily loaded.

In this paper, we introduce InvisiFlow, a novel communication substrate to collect network telemetry data, silently. In contrast to previous systems that always push telemetry packets to collectors based on the shortest path, InvisiFlow dynamically seeks out spare network capacity by leveraging opportunistic sending and congestion gradients, thus minimizing both the loss rate of telemetry data and overheads on user traffic. In a FatTree topology, InvisiFlow can achieve near-zero loss rate even under high-load scenarios (around 33.8× lower loss compared to the state-of-the-art transmission methods used by systems like Everflow and Planck).

1 Introduction

Network management and monitoring tasks often rely on fine-grained telemetry data to empower network administrators and systems with insight into current conditions [1–3]. For instance, when monitoring for failures and other network anomalies, switch telemetry enables the detection of unusual traffic patterns, errors, or drops [3–5]. Similarly, when optimizing or provisioning the network, administrators can analyze trends in traffic volume, bandwidth usage, and port utilization to make decisions [6–9].

Recent research has provided compelling arguments in favor of expanding the scope and diversity of collected telemetry data. Rationales vary. Some researchers note a reduction in the timescales of congestion events and its impact on the granularity required to observe them [10–12]. Others propose enhanced measurement capabilities enabled by modern network devices that can capture buffer statistics, sketches, per-QoS counters, and more [13–16]. Still, others advocate for the advantages of per-packet in-band metrics [17–19], and some suggest increasing telemetry to strive for the highest levels of availability and Service Level Objectives (SLOs) [20–22].

Regardless of the reason, high volumes of telemetry data produced at switches are typically collected at machines placed throughout the network that are responsible for processing, collating, analyzing, and storing the gathered data [1,3–5]. The traditional method used to send telemetry reports (*e.g.*, in [23]) routes them as standard data packets that can impact user traffic. For example, in §2, we observe increases in user traffic flow completion time of up to ≈19%, which affects latency-sensitive workloads. Techniques like In-band Network Telemetry (INT) [18], In-situ Flow Information Telemetry [24], and Broadcom's IFA [25] that embed data directly into user packets impose similar overheads [19].

Acknowledging this issue, recent work has tried to reduce overheads on user traffic by sacrificing the completeness of the telemetry data. One approach is exemplified by systems like [19, 26] that reduce telemetry's frequency and/or volume through approximation, saving some bandwidth but at the cost of information loss. When tracing paths of flows, for instance, PINT [19] will miss path changes for small flows (large flows as well under flowlet routing). Even when incomplete/approximate data is sufficient, the data is still eventually transferred across the network, incurring the associated overheads of those transmissions. Another approach is taken by systems like [21, 27–30] that de-prioritize telemetry traffic in favor of user traffic. This solution, however, risks starvation and telemetry loss when links are shared. The loss can affect the accuracy/utility of monitoring applications that rely on the data. For instance, our benchmark of a path tracing utility missed around 11% of paths under this strategy (§2).

In this paper, we aim to design a novel communication substrate for telemetry data that provides both (a) high sustainable throughput (*i.e.*, throughput given the constraint of zero loss) and (b) little-to-no impact on user traffic. We present InvisiFlow, a new mechanism to isolate telemetry data from user traffic. InvisiFlow is agnostic to both the content of the telemetry data and the network's topology; consequently, it can be used as a drop-in replacement for many existing monitoring systems.

The main insight behind our work is that exploring unused network bandwidth using *congestion gradients* maximizes sustainable throughput and minimizes the external impact of telemetry traffic—similar in spirit to water always flowing toward a lower elevation, telemetry packets are sent along the gradient to neighbors with lower congestion and more space in their telemetry buffers. To tackle challenges in applying existing theory on congestion gradients (§3.2) to practical environments, InvisiFlow constructs a pull-based transmission channel in which network switches frequently send low-priority pull requests to their physical neighbors that quantify the amount of telemetry congestion at each node, and utilizes shared pipelines in switches to support the late-binding of egress ports based on telemetry buffer usage.

We implement a hardware prototype[1] of InvisiFlow on a commodity switching ASIC with P4 programmability. With testbed experiments on a leaf-spine topology, we demonstrate that InvisiFlow can efficiently explore available network bandwidth to simultaneously prevent impact on user traffic *and* loss of telemetry data, even under high load. In contrast, baselines based on the communication protocols of state-of-the-art telemetry systems exhibit drop rates of >80% when prioritizing user traffic on the same workload. Simulation results on larger networks and a range of workloads, network applications, and topologies show that InvisiFlow remains resilient and effective across a wide range of scenarios. Specifically, InvisiFlow can improve the accuracy of prior systems in per-flow accounting approximation (*i.e.*, ApproSync [31] with Count-Min sketches [32]) up to 22.5×.

2 Background and Motivation

We begin by briefly summarizing existing telemetry data transmission systems and their limitations.

2.1 Telemetry Data Transmission

Network operators design and deploy systems to collect data from the network, including host/switch counters, flow records, and log information. While some systems ingest and exploit such data locally [8, 33], most of the time, operators need to collect the data at centralized databases/repositories for subsequent processing, storage, and analysis to provide a comprehensive view of the network [34, 35].

These modern telemetry systems—regardless of their target data—share a high-level workflow, depicted in Figure 1. The systems comprise three major components. The *source* can reside on any network device (*e.g.*, switches, routers, or end hosts), encompass any target data (*e.g.*, SNMP port utilization counters, drop notifications, or NetFlow records), and may be generated at any interval, periodic or event-based. A set of *collector sinks* receive, process, and store this telemetry. Monetary incentives typically imply that the number of collectors is small compared to the number of devices (*e.g.*, < 1% as shown in Everflow [28]) and that they must aggregate telemetry data from multiple devices.

Between the above two components is a *transmission channel*, responsible for forwarding telemetry packets from sources to collectors (which is the focus of this paper). We note several requirements for this transmission channel:

(R1) High/full sustainable throughput for telemetry data. As the mechanism responsible for delivering telemetry data, network applications depend on this channel to provide high throughput with minimal loss of data. Finer-grained telemetry data allows network operators to make more informed decisions [10] and provide better services to end users; data loss can result in incomplete or inaccurate insights [30].

[1] Code is available at https://github.com/eniac/InvisiFlow.

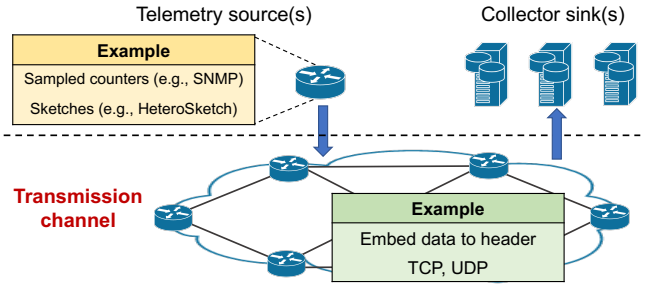

Figure 1: Workflow of a typical telemetry system.

(R2) Minimal impact on user traffic. Telemetry data often shares the same network with user traffic [19, 26, 29] as this can lead to more efficient resource utilization and beneficial fate-sharing properties [21]. While doing so, it is crucial to avoid introducing excessive latency, packet loss, or congestion due to the telemetry data transmission process, which may degrade the quality of service for user applications. As discussed in [19], this overhead can lead to up to 20% degradation of application-level throughput and a corresponding 25% increase in flow completion time.

(R3) ASIC-implemented operation. Finally, while early switches and routers often punted all non-forwarding tasks (including telemetry) to the switch CPU, growing telemetry granularity and ASIC capabilities have led to heavier reliance on data planes to both generate and send telemetry data [19, 27–30]. In particular, data planes can collect and export data at much higher resolution and power efficiency than CPUs. This trend toward data plane implementation is visible in line-rate monitoring systems like INT [18] and Broadcom's IFA [25], but it is also increasingly true for classic, decades-old telemetry systems like NetFlow and sFlow [36, 37].

2.2 Existing Solutions and Limitations

We note that recent work [14, 15, 19, 26, 38, 39] that seeks to reduce the size of collected data at the telemetry source (encompassing techniques like sampling, sketching, and encoding) can mitigate some of the above challenges; however, they are not a panacea. First, these solutions often sacrifice generality for the required bandwidth, limiting their applicability to specific applications and types of telemetry tasks. The approximation can also introduce significant errors in higher-layer analysis [5]. For example, applying PINT [19] to path tracing and the Hadoop workload [40] of §6 can limit bandwidth overheads to <2% compared to a configuration without telemetry but will miss path records for >60% of flows that are too small to track. Finally, regardless of whether the techniques are applicable/acceptable, enhancing the underlying transmission channel can mitigate the degradation in the accuracy of higher-layer applications and its impact on user traffic.

We, therefore, focus on the orthogonal problem of telemetry transmission. In this subsection, we examine the channels used by existing systems in the context of the above requirements. Per R3, we look only at data-plane solutions, of which current systems take one of the following two approaches.

Tx Method	Examples
Default-priority UDP	NetFlow [36], sFlow [42], INT-XD (Postcard) [29]
Low-priority UDP	Everflow [28], Planck [27]

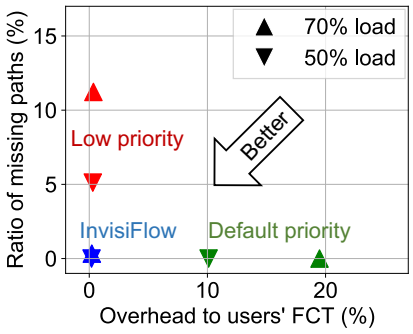

Figure 2: Tradeoffs between different prioritization methods for the telemetry transmission channel under the path tracing application. FCT dilation is an average over applications in the same rack as a collector.

Embedding data into packets. One way to transmit telemetry data is to embed data directly into user packets [18, 19, 26, 41]; end-host receivers are responsible for extracting the telemetry data from these packets and sending it to collectors. Unfortunately, as others have noted and we discussed in R2, embedded data can introduce substantial overheads [19]. For example, for small packets, adding additional data to packets can increase transmission times by a large relative proportion, increasing load on the network. For large packets, reserving header bits or reducing MTU sizes to prevent fragmentation incurs a tax on every packet, regardless of whether real data is embedded or not.

Generating packets and sending them directly. The other approach is to generate dedicated packets that are sent to collectors directly [27–30, 36, 42, 43]. These systems typically layer on top of existing protocols like UDP, which is preferable to TCP due to the impracticality of implementing end-to-end reliability in the data plane [44]. By sending telemetry data as datagrams separate from user packets, these systems can better control the rate and overhead of telemetry data transmission.

However, managing the tradeoff between the throughput of the transmission channel (R1) and its impact on user traffic (R2) can be challenging. Aside from generating less telemetry data, the primary knob to tune the overheads of today's transmission channels is Class-of-Service packet prioritization, where there are two primary options: (a) treat telemetry and user packets equally or (b) send telemetry data with a lower priority than user traffic.

Figure 2 categorizes a few popular telemetry systems along this axis and illustrates the challenge of balancing sustainable telemetry throughput and user-traffic overhead (measured via FCT dilation). Results are presented for a FatTree data center [45] using a Meta Hadoop workload [40] and a range of average utilizations, as detailed in §6.1. We employ a path tracing application similar to [5], where each switch maintains a record of user flows and forwards it to a collector for path reconstruction. As seen in Figure 2, as load increases, network operators are forced to choose between prioritizing telemetry (and increasing the FCTs of collector-collocated applications by 19%) or prioritizing user traffic (and accepting 11% missing paths). As a preview of our results, InvisiFlow can keep both minimal, even in a heavily loaded network.

3 Design Overview

In this paper, we present InvisiFlow, a communication substrate for telemetry data transmission that can minimize the network-wide loss rate of the telemetry data given the constraint of little-to-no impact on user traffic. As previously mentioned, InvisiFlow is agnostic to the content of the telemetry data and the network's topology. It also leaves user traffic transmission untouched. As such, it can be used as a drop-in replacement for many existing monitoring systems.

3.1 Opportunistic Gradient Forwarding

InvisiFlow is driven by two overarching design principles:

1. Prioritize user traffic.
2. Instead, seek out spare capacity, wherever it may be.

For the first principle and to satisfy R2, InvisiFlow keeps telemetry and user traffic separate and ensures that all control and telemetry packets are de-prioritized compared to user packets. Although packet processing and transmission are generally not preemptable in modern network devices, prior work [21, 27] and our results in §6.3 show that proper configuration of priorities at every stage of modern network devices can ensure that overheads are negligible, even when every available gap between user packets is filled with lower-priority packets. With these techniques, InvisiFlow can operate with minimal impact on user traffic.

Instead, InvisiFlow seeks out spare network capacity for telemetry data transmission, aggressively leveraging any such opportunities. Over a decade of measurement studies on large-scale networks have frequently observed low average utilization in modern networks [10, 40, 46–48], with data centers, for instance, sometimes seeing ∼5% average utilization (comprised mostly of small bursts), even for supposedly high-throughput applications like Hadoop and distributed ML training. Telemetry, generally off the critical path of user-facing requests, is a particularly good fit for leveraging the opportunities provided by these gaps in sending.

InvisiFlow's approach to finding spare capacity is based on classic theoretical foundations regarding multicommodity flows and the stability of queuing networks [49, 50]. More formally, given a network and a vector of flows with associated sources, sinks, and arrival rates, a scheduling/routing policy π is said to provide buffer stability if it satisfies the following.

Definition 1 (Buffer Stability). *Let $B(t)$ be the total amount of packets remaining in the buffers at time t. Assume no*

constraints on buffer size. The system is stable under π iff:

$$\limsup_{t\to\infty} \frac{1}{t} \sum_{\tau=0}^{t-1} \mathbb{E}[B(\tau)] < \infty \quad (1)$$

The alternative to buffer stability is a system where buffer sizes grow to infinity. Note that it is often useful to define scheduling policies that are robust to changes in arrival rates. Prior work has termed this a problem of characterizing and maximizing a policy's stability region.

Definition 2 (Stability Region)**.** *Let g be the vector of the packet arrival rates at all telemetry sources. Stability region S_π of policy π is the set of all g for which the system is stable under π.*

Results in *max-weight scheduling theory* [50] have shown that transmission based on the *congestion gradient* can provide an optimal policy that maximizes the stability region and sustainable throughput. The congestion gradient is defined as the difference in telemetry buffer usage between neighboring switches. Unlike traditional forwarding [51], where nodes blindly push packets along the shortest path to the destination, for every pair of neighbors in congestion gradient-based transmission, the one with a larger telemetry buffer usage sends toward the one with a smaller buffer usage. This is similar in spirit to water always flowing toward a lower elevation. These approaches have been found to be robust to diverse topologies and dynamic arrival patterns. As with prioritization, we argue that telemetry, typically amenable to asynchronous and out-of-order delivery, is a particularly good fit for our approach.

3.2 InvisiFlow Architecture

While InvisiFlow is inspired by the simplicity and efficacy of prioritization and congestion gradient forwarding, the theory is, of course, significantly different from practice.

(C1) How do we calculate the gradient over time and address situations where the gradient itself is not known (*e.g.*, because control packets are subject to prioritization behind user traffic)? (C2) How do we address limitations in packet processing pipeline structures for sending telemetry data, *e.g.*, the need to specify an output port before egress availability is known? (C3) How do we handle failures of both network components and telemetry collectors? The primary challenge of InvisiFlow is to develop practical solutions to the above issues and others.

Components. The high-level architecture of InvisiFlow is shown in Figure 3. It contains several types of components:

- *Switches:* To obtain the gradient (C1), every switch in the network, when it has free capacity, will continually generate low-priority pull requests (with its current telemetry buffer usage) and send them to all neighboring switches. Neighboring switches will respond to this per-hop pull request if the other side's buffer usage is lower. The current switch may also send packets if it would otherwise have dropped data. To enable the late binding of egress ports for telemetry data (C2), we store telemetry data in the egress pipeline, which is shared by multiple egress ports, as detailed in §4.1.
- *Collectors:* Telemetry collectors operate similarly to today, ingesting and processing data as it arrives. In InvisiFlow, they also act as true sinks in the congestion gradient, equivalent to having a constant telemetry buffer utilization of zero. This can be implemented by either the collector sending pull requests on its own or via offload to its last-hop switch [43]. In either case, telemetry data is naturally drawn in from surrounding devices. InvisiFlow supports sharding and backups of these devices and can support flow control through an extension of the switch protocol.
- *Available Servers:* Finally, InvisiFlow supports optional usage of spare server memory capacity, similar to [52, 53]. These also extend the per-hop pull protocol of the switches, with their advertised utilization providing a knob for tuning their usage. For example, advertising 80% usage means that they will only be used when nearby switches are >80% full. Configuring these servers is optional but can be beneficial when there is a high load or failures of either network components or telemetry collectors (C3).

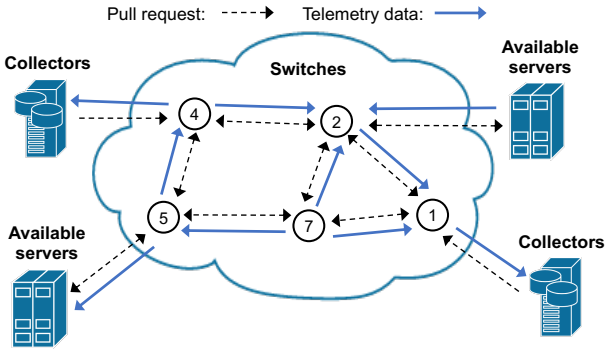

Figure 3: Overview of an InvisiFlow-enabled network.

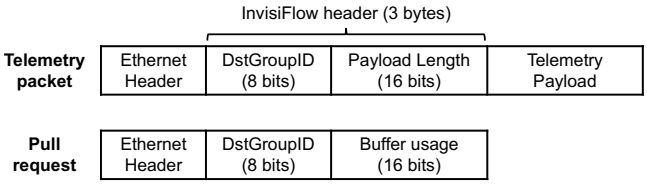
Workflow. InvisiFlow creates a network where switches continually trade pull requests and telemetry data with their neighbors in the gaps between microbursts of user traffic. Through these gaps, InvisiFlow implements a variant of the edge-balancing approach to approximating a maximal-stability-region routing policy. As long as gaps exist, InvisiFlow will leverage them to route telemetry packets. In the rare case that one or both directions of a link are occupied for an extended period, InvisiFlow will leverage congestion gradients to find alternate paths and take risks when appropriate.

While inevitably not a perfect reproduction of the formalisms of results like [50] (*e.g.*, due to the asynchrony of pull requests), our extensive evaluation over a wide range of topologies and workloads in §6 demonstrates that InvisiFlow can—entirely in the data plane (R3)—maximize the sustainable throughput of telemetry data (R1) while incurring little-to-no impact on user traffic (R2).



Ethernet header: *Ethertype* identifies the InvisiFlow header.
DstGroupID: The destinations (collectors) group ID for the packet.
Payload length: The total length of the telemetry payload measured in bytes.
Buffer usage: The number of telemetry packets recorded in the telemetry buffer.
Telemetry payload: The telemetry data provided.

Figure 4: The packet format of InvisiFlow

Ethertype	Egress port
Generated seed packet	Multicast to all neighbors
Pull request	Ingress port
Telemetry packet	Free ports

Table 1: Default routing table used by the ingress pipeline.

4 The InvisiFlow Transmission Channel

In this section, we discuss the design of the InvisiFlow transmission channel in detail. To keep our discussion general, we assume (a) telemetry sources can be placed at arbitrary locations in the data plane and generate arbitrary amounts of data, and (b) one or more collectors are placed in the network, any of which can ingest that data. Note that InvisiFlow can also support differentiated collectors and sharding (*e.g.*, based on hashing over a partition key) through a `DstGroupID` header field and a straightforward extension to parallel transmission channels, but we omit that discussion for simplicity.

Message format. The packet formats of InvisiFlow messages are illustrated in Figure 4. There are two types of packets, both gated by `DstGroupID` as mentioned above. Pull requests are generated periodically and contain the current telemetry buffer usage, which can be scaled to account for heterogeneous buffer allocations. Telemetry data packets are only sent in response to received pull requests or upstream telemetry, and they contain a variable-length payload. Both types of packets are set to the lowest priority at every stage of the pipeline, including the ingress arbiter, traffic manager, and egress arbiter, per [21].

4.1 Switch Operation

The routing table for InvisiFlow's ingress pipeline and the pseudocode for egress pipeline processing logic are provided in Table 1 and Algorithm 1, respectively.

An important building block of this logic is the gap-filling low-priority packet generation mechanism introduced by the OrbWeaver framework [21]. OrbWeaver uses the existing per-pipeline packet generator capabilities of modern switches to generate low-priority packets sent to all ports with configurable frequency and payload, with negligible impact on the average power draw of the switch (<2%) and minimal worst-case impact on pipeline bandwidth (<1.5%). Specifically, it periodically generates 'seed' packets in the ingress pipeline

Algorithm 1: Egress logic for InvisiFlow packets.

```
Input: Packet P
switch Ethertype do
    case generated seed packet do
        Ethertype ← 'pull request';
        Set the buffer usage field;
    case pull request do
        if local.buffer_usage > P.buffer_usage then
            Ethertype ← 'telemetry data';
            Pop telemetry from buffer and append it to P;
        else
            Set the buffer usage field;
    case telemetry packet do
        Store the payload in the local buffer;
        Drop the packet;
```

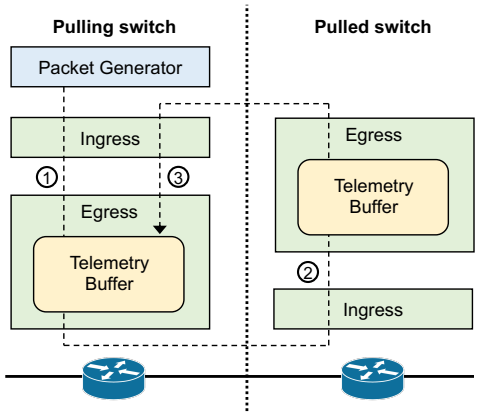


Figure 5: A potential lifecycle of a InvisiFlow packet. Circled numbers correspond to the steps in §4.1.

and then multicasts those seed packets to all egress ports, with additional details in §5 and Appendix A. InvisiFlow uses this mechanism to initiate pull requests, from which the rest of the InvisiFlow protocol stems.

Another building block is InvisiFlow's telemetry buffers in the ingress and egress pipeline of every switch. These telemetry buffers are distinct from the traditional packet buffers used by user traffic and managed by the ASIC; instead, SRAM arrays are easier for data plane programs to manipulate. Note that while both types of buffers are used to store telemetry data, the egress buffer(s) of the pipeline(s) closest to the collector(s) serves as the primary storage location. To see why, consider a system that creates and appends telemetry data to packets in the ingress. Packets must be assigned an egress port in the ingress pipeline, but the fine-grained usage of any given egress port can be difficult to ascertain, especially if multiple pipelines may be sending to the same egress port. Storing data in the egress instead enables late binding—whenever the egress arbiter can schedule a low-priority telemetry packet (destined for any port in the same pipeline), the next chunk of data can be appended immediately before it is placed on the wire. The ingress buffers are only used as a temporary

holding area for data that will eventually be transferred to the egress pipeline.

Given these components, Figure 5 shows one potential lifecycle of an InvisiFlow packet. For this packet:

1. *The pulling switch generates/sends pull requests:* As shown in Table 1, every switch in the network will periodically generate seed packets and multicast them to all neighbors. Before each copy leaves the egress pipeline, it will be converted to a pull request with the current telemetry buffer usage as shown in line 2-4 of Algorithm 1.
2. *The pulled switch replies to the pull requests:* As shown in Table 1, after receiving a pull request, the neighbor switch sets the egress port equal to the ingress port to return telemetry data. In the egress pipeline, the switch compares the telemetry buffer size recorded in the pull request with its local buffer size as shown in line 5-10 of Algorithm 1. If the local buffer size is larger, the switch pops telemetry data from the buffer and sends it back. Otherwise, the switch reflects the pull request back to the sender as its own.
3. *The pulling switch processes the telemetry data:* There are two possible replies from the pulled switch: (1) If the reply is still a pull request, the procedure remains the same as described above. (2) If the reply is a telemetry packet, we store the packet in the telemetry buffer at the egress pipeline as shown in line 11-13 of Algorithm 1.

Example. Suppose a seed packet, denoted as p, is initially generated by $S1$ and multicast to all neighbors in the ingress pipeline. In the egress pipeline of $S1$, p is converted to a pull request, p' with its buffer usage field set to the current telemetry buffer usage (*e.g.*, 10). Upon receiving the pull packet p', the neighbor switch, $S2$, routes it back out the same port. In the egress pipeline of $S2$, if the buffer usage (*e.g.*, 20) of $S2$ is larger than the buffer usage field in the pull request p', $S2$ pops telemetry data from the buffer and sends it back to $S1$. Finally, $S1$ forwards the telemetry packet through free ports and stores it in the buffer at the egress pipeline.

There are several important aspects and possible variations of the above procedure.

Egress port choice and its impact on packet buffers. First, we note that the choice of egress port of Table 1 and their configurations in each branch of Algorithm 1 is deliberate. Pull requests are valid for a single port and are reflected back for egress handling. Because the seed and pulls are regenerated periodically, the loss of these requests is acceptable, and the ASIC-level shared buffers for these packets can be shallow (*i.e.*, enough for only a handful of outstanding requests). Packets containing telemetry data should not be dropped as readily, so InvisiFlow only sends them if capacity is guaranteed. It does so by using free ports (*e.g.*, recirculation ports) that are not typically used by user traffic, as shown in Table 1. The advantage of using these ports is that it leverages higher aggregate bandwidth within the switch and reduces the usage of non-evictable packet buffers in the traffic manager.

Adding a slope to prevent zero congestion gradient. When the network contains only a limited number of telemetry packets, there are potential issues where the congestion gradient remains consistently at zero. Consider the scenario with only one telemetry packet, p, sitting in switch $S1$. A neighbor, $S2$, will pull p because it has lower telemetry buffer usage; however, $S1$ now has less telemetry buffer usage than $S2$, so there is a chance that p can oscillate between these switches.

To address the problem, we add a 'slope' to the congestion gradient. Suppose the buffer usage of switch $S1$ is u_{S1}. Switch $S1$ can pull telemetry data from switch $S2$ if and only if $u_{S1} + \delta_{S1,S2} < u_{S2}$, where $\delta_{S1,S2}$ indicates the slope. In InvisiFlow, we set δ based on the distance to the collector. If switch $S1$ is closer to the collector than switch $S2$ as defined by the routing protocol, then $\delta_{S1,S2} = 0$. Otherwise, $\delta_{S1,S2} = 1$. This approach improves the directness of paths and ensures that even when there is just one telemetry packet, it can efficiently flow toward the collector without getting stuck.

Adjust the pulling rate based on local buffer usage. Adjusting the pulling rate is crucial to avoid pulling excessive telemetry data, which could result in buffer overflow. In the egress pipeline, InvisiFlow randomly drops generated seed packets, with the probability of dropping packets equal to the buffer usage. Moreover, if a switch's buffer usage exceeds a certain threshold (*e.g.*, > 95%), it will revert to blindly pushing out telemetry packets to neighboring switches, as in prior work [54]. While push-based sending carries risks for telemetry packets, extreme buffer usage suggests they would likely have been dropped otherwise. We find that this approach effectively prevents the loss of telemetry data, particularly in scenarios with asymmetric bandwidth usage.

4.2 Server Operation

Two types of servers participate in InvisiFlow: those that collect telemetry data and those that serve as temporary storage.

Collectors. To get telemetry data from switches, collectors simply send pull requests to the network in the same manner as switches. We set the buffer size recorded in the pull request to 0. Based on §4.1, neighbor switches will send any available telemetry packets in response to these pull requests. Note that it also works if there are multiple collectors, and the telemetry data will flow to any one of the collectors.

Note that collectors also have the option to *not* send pull requests if, for instance, they lack sufficient CPU resources or storage bandwidth to keep up with the current inflow. Alternatively, collectors can offload the collection tasks to the last-hop switch as in prior works [43], *i.e.*, the last-hop switch is responsible for generating pull requests and directly writes the telemetry data to servers' memory throughput Remote Direct Memory Access (RDMA).

Available servers. To further minimize telemetry data loss, InvisiFlow can optionally explore available memory/storage in servers to store telemetry packets. We assume that the

Resource	Baseline	Marginal Increase
Gateway	11.46%	2.08%
VLIW Actions	4.69%	0.78%
Hash Bit	5.07%	0.46%
Exact Match Input xbar	3.58%	0.39%
Meter ALU	14.58%	0.00%
SRAM	1.77%	0.00%
Stages	7	0

Table 2: Additional H/W resources used by InvisiFlow. Baseline is the low-priority UDP using OrbWeaver [21] to generate telemetry packets.

memory/storage capacity in these available servers is much larger than that of switches. Similar to collectors, available servers join InvisiFlow by sending pull requests. The difference is that we set the buffer usage in the pull request to a constant value α (*e.g.*, 50%). These available servers can pull telemetry packets from their neighboring switches if the buffer usage of the switch is larger than α. Otherwise, the neighbor switches pull telemetry packets from these available servers. The setting of α determines the usage rate of the memory/storage in available servers and the possibility of data loss as shown in §6.2. A larger α may lead to a larger possibility of data loss but a lower usage rate of the memory/storage in available servers, and vice versa. The available servers can also dynamically adjust α based on their available memory and leave enough space for user applications.

5 Implementation

We implement an InvisiFlow prototype on a testbed with two Wedge100BF-32X switches. Servers are equipped with a Mellanox ConnectX-5 100 Gbps NIC, dual-socket AMD EPYC 7313 16-Core Processor, and 64 GB memory.

InvisiFlow servers. Per §4.2, each InvisiFlow-server (*i.e.*, a collector or a free server) sends out pull requests if there is available space and processes pull requests or telemetry packets from the network. In our testbed, we implement the collectors and free servers using DPDK (v21.11).

InvisiFlow switches. We implement InvisiFlow's switch component in P4-16. Our implementation leverages the built-in packet generation and strict prioritization features present in today's switches. In total, the data plane implementation consists of around 600 lines of P4 code. Our implementation scales to today's multi-pipeline switching architectures.

Egress pipeline register buffer for telemetry packets: Similar to PayloadPark [55], we use an array of registers in the egress pipeline to store telemetry packets. Due to the constraints on the number of stages and the number of bytes read/written per stage, the size of telemetry packets should be small (*e.g.*, <160 B) as in [55]. This amount is sufficient for most applications [5, 27, 28] and even allows for multiple telemetry records within a single packet in many cases. Larger telemetry messages can be handled with per-hop segmentation of telemetry packets. To improve the goodput of telemetry data, we omit the IP and UDP header and include only Ethernet. Different *EtherType*s distinguish different types of packets, *e.g.*, user packets, pull requests, or telemetry packets.

Switch-local teleport of telemetry data: Besides front-panel ports, modern switches also have per-pipeline internal ports for pktgen traffic and recirculation. InvisiFlow consumes the bandwidth of one of these ports to move the telemetry data to the egress pipeline, as discussed in §4.1. Note that InvisiFlow does not recirculate any telemetry packets nor suffer from recirculation overhead. The egress pipeline drops telemetry packets from the ingress pipeline immediately after storing the telemetry data in the egress pipeline register.

Hardware resource usage: Table 2 summarizes the key resources required by our prototype. Compared with low-priority UDP, which uses OrbWeaver [21] to generate low-priority telemetry packets, the additional resource used by InvisiFlow is small: 2.08% additional gateways and 0.78% additional VLIW actions to process the telemetry packets. The ALU and SRAM are mainly used to store and read/write telemetry data in the egress pipeline.

6 Evaluation

We evaluate InvisiFlow using a combination of testbed experiments and large-scale ns-3 simulations [56]. Our evaluation focuses on the following three key questions.

- Can InvisiFlow minimize the accuracy degradation on the telemetry application (R1)?
- Can InvisiFlow simultaneously minimize the overhead of transmitting telemetry data (R2)?
- Is InvisiFlow robust to different settings and workloads?

6.1 Simulation Methodology

Topology and workload. We simulate a FatTree [45] topology with 9 core switches and 4 pods that, combined, have 12 aggregation switches, 12 top-of-rack (ToR) switches and 144 servers. All links have a capacity of 100 Gbps, leading to a 4:1 oversubscription ratio similar to prior work [57–59]. The propagation delay for all links is 1 µs, resulting in a maximum base RTT of 12 µs. Switch buffer sizes are set proportionally to the bandwidth-buffer ratio of Intel Tofino switches [60], following prior research [58, 59]. Specifically, each switch has approximately 2 MB of buffer for up to 600 Gbps of user traffic and 170 KB for up to 50 Gbps of telemetry traffic[2]. These buffers are shared by all ports on the same switch and are fully isolated to prevent any impact on user traffic. For DCTCP, we set $K = 65$ based on [59, 61]. User traffic is load-balanced using ECMP over the 5-tuple.

Experiments are performed with one of two workloads: a Hadoop workload (FB_Hadoop) and a machine-learning (ML) workload. Details of the workloads can be found in Appendix B. Unless otherwise specwified, FB_Hadoop is the default setting.

[2] In experiments, the total telemetry data generated is generally <30 Gbps.

Stressed scenarios. In addition to the default setting, we introduce two other scenarios to test InvisiFlow's robustness.

- *Load imbalance:* We simulate a load imbalance scenario caused by a faulty configuration, where ECMP is configured to hash based only on the destination IP, which causes packets to a single destination to use only one path, leading to high load imbalance, as discussed in prior work [62].
- *Asymmetric topology:* We also stress the collector under an asymmetric topology with failed fabric links [20, 63]. We reduce the capacity of two links to 50 Gbps. These links include a Core-Aggregation link and an aggregation-ToR link, both toward the collector.

Telemetry sources, channels, and sinks. Next, we describe the evaluated configurations of the three components of the telemetry frameworks depicted in §2.1.

Sources: Four telemetry applications run concurrently between 20% and 80% of the simulation time.

- *Path tracing (NetSeer [5]):* Following [5], each switch maintains a record of user flows passing through it. When encountering a new flow, the switch stores the tuple (switch ID, flow ID, TTL value) in its buffer. The collector uses the TTL value to calculate the hop ID of each node and reconstruct the entire path of each flow.
- *Load imbalance detection (NetFlow [36]):* Following [36], every switch records the number of bytes passing through each egress port in the data plane. The switch then stores the tuple (switch ID, port ID, time, # of bytes) in the buffer and reports the results (by default) every 5 µs. The collector aggregates the byte counts to calculate each switch's load. It measures the load imbalance rate as the maximum load relative to the minimum load among switches.
- *Per-flow accounting (ApproSync [31]):* We implement ApproSync [31] with Count-Min Sketch (CMS) [32] to track the size per-flow. In the CMS, we use 3 arrays of 2^{17} counters per array. ApproSync sends sketches to the collector by checking the divergence of each counter in the sketch. Divergence is quantified using relative error, with a threshold based on an expected bandwidth of 10 Gbps.
- *Packet drop notification (NetSeer [5]):* Similar to [5], when a user packet drop occurs, the switch stores the tuple (switch ID, flow ID) in the buffer.

Channels: We compare InvisiFlow (IF) with three communication substrates for telemetry data:

- *Default-priority UDP:* Prior telemetry systems like NetFlow [36], sFlow [42], and NetSight [29] often use default-priority UDP to send telemetry data. We implement default-priority UDP in postcard mode [29]: When there is telemetry data to be sent, the switch generates a telemetry packet using mirroring and sends it to the collector. Telemetry packets are assigned the same priority as user traffic. If multiple shortest paths are available to the collector, we use packet spraying [51] for load balancing.
- *Low-priority UDP:* Some telemetry systems like Everflow [28] and Planck [27] assign low-priority to telemetry packets to avoid impacting user traffic. To implement low-priority UDP, we use OrbWeaver [21] to generate low-priority telemetry packets. These packets are forwarded to the next hop when there is available bandwidth. As before, we use packet spraying if there are multiple shortest paths.
- *Pull-based transmission:* As an ablation study, we include pull-based transmission without using congestion gradients. Each switch generates pull requests only to switches farther from the collector, so that telemetry packets follow the shortest paths. A switch pulls only when its telemetry buffer usage is below 50%. We reserve some buffer capacity to prevent overflow, as there could be locally generated or late telemetry data due to low-priority transmission.

Sinks: In our experiments, one of the 144 servers is always reserved as a collector server. When additional sinks are required, they are taken from other clusters. We assume that every switch is pre-configured with their addresses.

6.2 Telemetry Application Performance

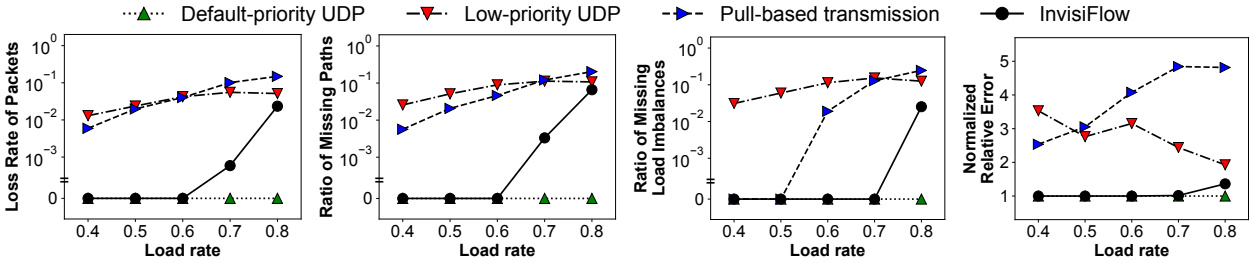
This section compares the impact of InvisiFlow to alternative communication substrates on telemetry applications, highlighting InvisiFlow's ability to minimize accuracy degradation, particularly for low-priority transmissions.

Performance metrics. We consider the following metrics:

- *Ratio of missing paths:* Following [3], the collector reports all paths it receives. If the collector fails to capture one or more switch IDs along a path, we mark the path missed.
- *Ratio of missing load imbalance events:* We calculate the ratio of missing events in core switches for load imbalance detection as in [10]. A missed event occurs when the collector cannot identify a period where the imbalance rate at the core switches exceeds 2.
- *Normalized relative error of the flow size:* As in [31], all core switches estimate the number of packets per flow using sketches before sending them to the collector. To quantify the impact of telemetry loss, we calculate the average relative error of those estimates normalized to the case without loss (i.e., we exclude errors introduced by ApproSync and the Count-Min sketch). The errors for heavy hitters (*i.e.*, $> 10^3$ packets) are shown in §C.

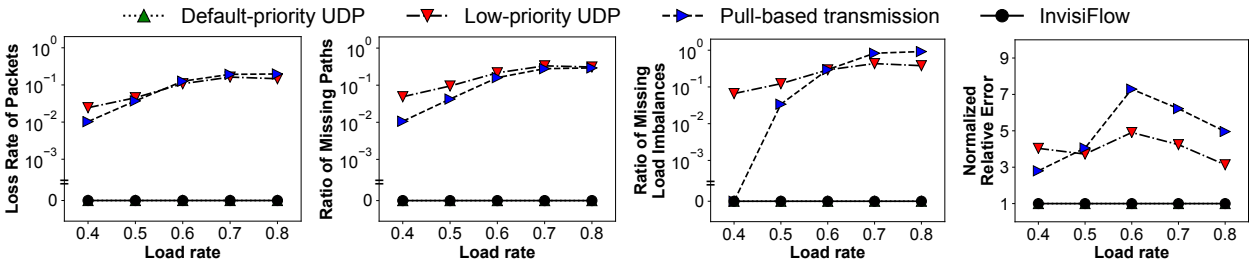
Since user packet drops are rare in our setup, we do not present the loss rate for packet drop notifications. Ground truth results are captured with the help of extensive out-of-band logging in the simulator.

Default setting (Figure 6). Figure 6 illustrates the performance of different telemetry applications under varying load rates. InvisiFlow maintains a zero loss rate for telemetry packets when the load rate is below 70%. Consequently, the ratio of missing paths and load imbalances are also 0, and the normalized relative error is 1 below this threshold. However, InvisiFlow has to drop telemetry packets when the load ex-



(a) Telemetry packet loss (b) Path loss for NetSeer (c) Imbalance loss for NetFlow (d) Flow error for ApproSync

Figure 6: Default setting. InvisiFlow maintains a zero loss rate when the load rate is below 70%.



(a) Telemetry packet loss (b) Path loss for NetSeer (c) Imbalance loss for NetFlow (d) Flow error for ApproSync

Figure 7: Load imbalance. InvisiFlow maintains a zero telemetry packet drop rate even under an 80% load, whereas the loss rates of low-priority UDP and pull-based transmission increase compared to the default setting.

ceeds 70% due to limited available bandwidth for low-priority transmission, which could be smaller than the generation rate of the telemetry packets. The performance of pull-based transmissions deteriorates under heavy loads compared to low-priority UDP because it cannot fully utilize the buffer and bandwidth when the available bandwidth is insufficient for the telemetry data throughput. Default-priority UDP does not drop packets even under 80% load, but increases the FCT by approximately 26.4%, as discussed in §6.3.

At a 70% load, InvisiFlow's ratio of missing paths is approximately 33.8× and 36.3× lower than that of low-priority UDP and pull-based baselines, respectively. The gap between them narrows under an 80% load, as there is limited room to reduce loss due to insufficient available bandwidth for low-priority packets at such a high load rate. However, InvisiFlow still shows a 1.6× and 3.1× improvement over low-priority UDP and pull-based baselines, respectively. Regarding the relative error of all flows, InvisiFlow at a 70% load exhibits a reduction of approximately 2.4× and 4.8× compared to low-priority UDP and pull-based baselines, respectively. Normalized relative errors may decrease with higher load rates due to increased error in the original Count-Min sketch caused by higher traffic volumes.

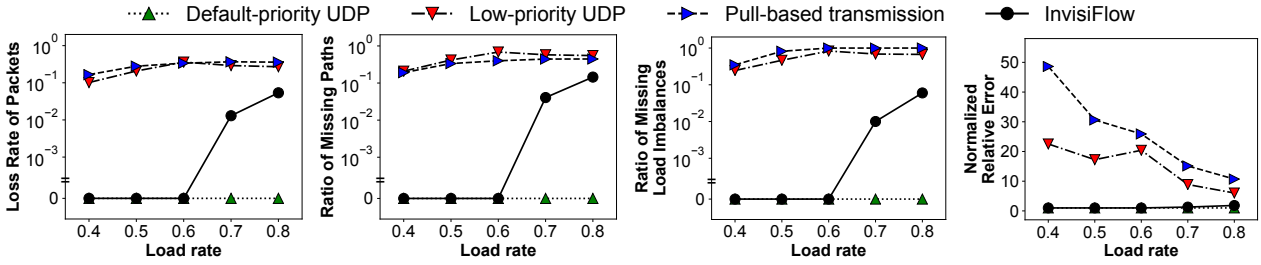
Load imbalance (Figure 7). In this scenario, InvisiFlow maintains a zero telemetry loss rate even under an 80% load, whereas the loss rates of low-priority UDP and pull-based transmission increase compared to the default setting. This is because the load imbalance reduces the throughput of user traffic, potentially leaving more available bandwidth for telemetry data. However, low-priority UDP and pull-based baselines fail to fully utilize this additional bandwidth as they remain constrained to the shortest path.

At a 70% load, the ratio of missing paths for InvisiFlow is 0, while it is 33.2% and 27.9% for low-priority UDP and pull-based baselines, respectively. Furthermore, the normalized relative error of all flows for InvisiFlow is 1, while it is 4.2 and 6.2 for low-priority UDP and pull-based, respectively.

Asymmetric topology (Figure 8). In an asymmetric topology, the loss rates of low-priority UDP and pull-based transmission experience significant increases. In contrast, InvisiFlow only drops telemetry packets when the load rate exceeds 70%. Specifically, the ratio of missing paths for low-priority UDP often exceeds 40%, and for the pull-based baseline, it often exceeds 30%. Furthermore, the normalized relative error of all flows for low-priority UDP and pull-based baselines can reach up to 22.5 and 48.6, respectively.

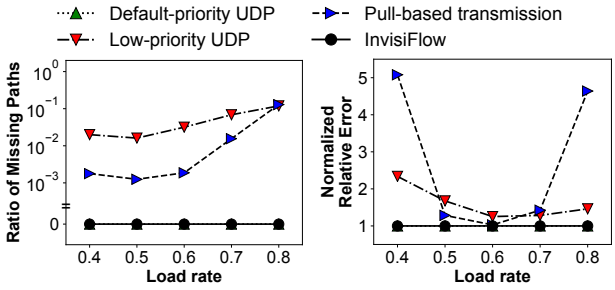
ML workloads (Figure 9). In ML workloads, InvisiFlow has a zero telemetry packet drop rate even under an 80% load, while low-priority UDP and pull-based transmission lose approximately 11.9% and 12.9% of paths at an 80% load, respectively. Furthermore, at a 70% load, the relative error of all flows for InvisiFlow is approximately 1.5× and 4.6× lower than that of low-priority UDP and pull-based, respectively.

Different buffer sizes (Figure 10). In addition to the default buffer size of 170 KB, we experiment with different buffer sizes under the default setting. We observe that InvisiFlow achieves a 0% loss rate when the buffer size exceeds 400 KB, because the congestion gradient-based transmission efficiently utilizes all available telemetry buffers across the network. In contrast, low-priority UDP and pull-based transmission lose around 5.8% and 9.8% of paths, respectively, even with a 500 KB buffer. With a 500 KB buffer,



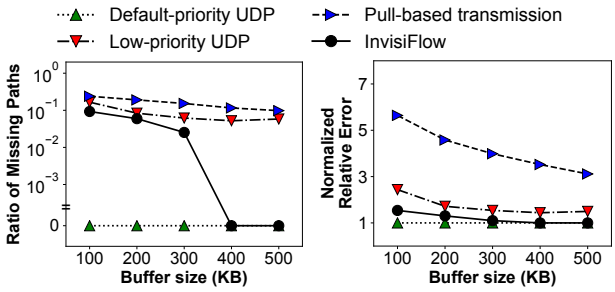
(a) Telemetry packet loss (b) Path loss for NetSeer (c) Imbalance loss for NetFlow (d) Flow error for ApproSync

Figure 8: Asymmetric topology. InvisiFlow only drops telemetry packets when the load rate exceeds 0.7. The ratio of missing paths for low-priority UDP often exceeds 40%, and for the pull-based baseline, it often exceeds 30%.



(a) Path loss for NetSeer (b) Flow error for ApproSync

Figure 9: ML workload (Default setting).



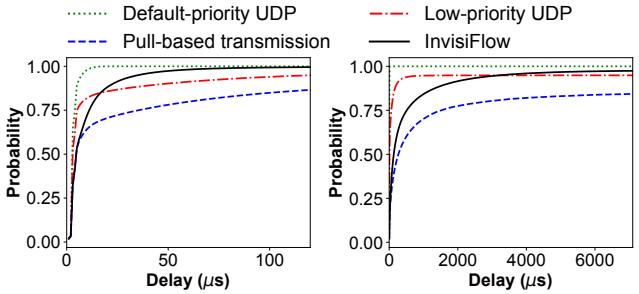
(a) Path loss for NetSeer (b) Flow error for ApproSync

Figure 10: Different buffer sizes (80% load).

the relative error of all flows for InvisiFlow is approximately 1.5× and 3.1× lower than that of low-priority UDP and pull-based baselines, respectively.

CDF for delay of telemetry packets (Figure 11). Figure 11 illustrates the end-to-end delay of the telemetry packets. We calculate the delay by subtracting the timestamp at which the collector receives the packet from the timestamp at which the telemetry packet is generated. In case of packet loss, we consider the delay infinite. Notably, InvisiFlow significantly improves tail latency compared to other low-priority transmissions. Under a 40% load, the 99% latency of InvisiFlow is approximately 80 μs, which is around 3.4× and 10.9× lower than that of low-priority UDP and pull-based baselines, respectively. Under an 80% load, InvisiFlow increases the delay to avoid both telemetry packet loss and impact on user traffic, with a 99% latency of around 4.9 ms.

Using multiple servers (Table 3). Using multiple collectors or additional available servers as temporary storage can further reduce telemetry data loss. When using two collectors,



(a) 40% load rate. (b) 80% load rate.

Figure 11: Delay of telemetry packets (Default setting).

telemetry data can be directed to any available collector, enabling a 0% loss rate. When using one available server, the threshold of the buffer usage determines the storage usage in available servers and the data loss rate. A higher threshold increases the risk of data loss but reduces the storage usage in available servers, and vice versa. Setting the threshold to 25% allows zero loss rate while utilizing up to 13.63 MB of storage for telemetry packets under the default setting. Unlike using multiple collectors where telemetry data can be distributed, using available servers results in all telemetry data being sent to the single designated server without further aggregation.

6.3 Impact on User Traffic

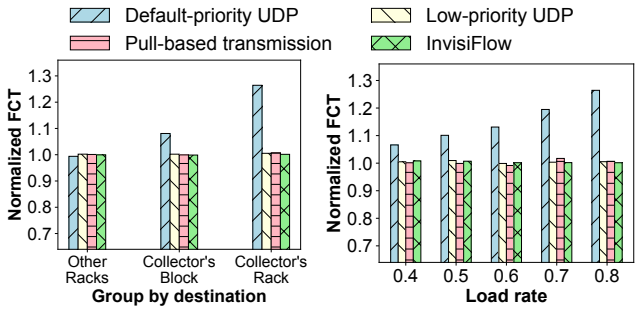
In this section, we compare InvisiFlow with other communication substrates and show that InvisiFlow achieves near-zero overhead to user traffic. The experimental setup is consistent with that in §6.2.

Metric. We evaluate the flow completion time (FCT) of user traffic initiated between 20% and 80% of the simulation time (*i.e.*, when the telemetry applications are running). The FCT is normalized to the case where no telemetry data is generated.

Default setting (Figure 12). In Figure 12a, we group the FCT by the destination of the user traffic and calculate the ratio. We find that user traffic destined for the rack of the collector is primarily influenced by the telemetry data under the default setting. Assigning telemetry data default priority results in an FCT increase of ∼26.4% under an 80% load. In contrast, InvisiFlow and low-priority baselines exhibit minimal overhead, often <1%. Figure 12b shows the ratio under different load rates, showing that the overhead of InvisiFlow and

Default Setting	Telem. Loss	Peak Avail. Util
1 Collector	2.34%	N/A
+ 1 Collector	0.00%	N/A
+ 1 Available Server *Threshold: 50%	1.94%	2.27 MB
+ 1 Available Server *Threshold: 25%	0.00%	13.63 MB
Asymmetric topology	**Telem. Loss**	**Peak Avail. Util**
1 Collector	5.38%	N/A
+ 1 Collector	0.00%	N/A
+ 1 Available Server *Threshold: 50%	1.79%	10.92 MB
+ 1 Available Server *Threshold: 25%	0.00%	25.83 MB

Table 3: Telemetry packet loss rate and peak storage utilization of available servers when using multiple servers for telemetry data collection. We evaluate the default and asymmetric topologies under 80% load.



(a) 80% load rate. **(b) In Collector's rack.**

Figure 12: Normalized FCT (Default setting).

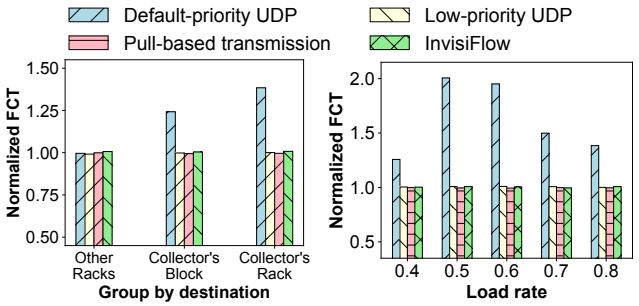
low-priority remains minimal, while the overhead of default-priority UDP increases with higher load rates.

Asymmetric topology (Figure 13). As depicted in Figure 13a, user traffic not only to the rack but also to the block containing the collector is significantly influenced by telemetry data under the asymmetric topology. For default-priority UDP, the FCT of user traffic to the rack increases by ∼38.4%, and the block by ∼25.2%. In contrast, InvisiFlow and low-priority baselines maintain near-zero overhead (<1%). Figure 13b illustrates that under a 50% load, the FCT of user traffic is doubled. The normalized FCT may decrease with increasing load rates due to user traffic causing more congestion.

6.4 Testbed Experiments

Topology (Figure 14a). We emulate a 2-tier leaf-spine topology in our testbed. With two physical switches, similar to [11], we divide one 128-port physical switch into four virtual leaf switches and the other into two virtual spine switches. The virtual switches are connected with 10 Gbps links. In the data plane, every logical switch has its isolated buffer of telemetry packets and runs InvisiFlow independently.

Setup. We emulate the case that a link to the collector is fully



(a) 80% load rate. **(b) In Collector's rack.**

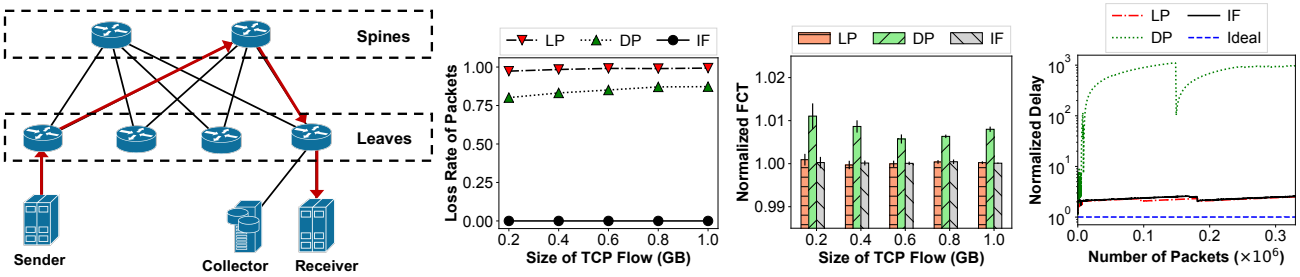
Figure 13: Normalized FCT (Asymmetric topology).

occupied by user traffic. Specifically, as shown in Figure 14a, we build a TCP connection between two servers and send traffic. Then, we measure the statistics in the right spine switch, which is the main bottleneck for telemetry data transmission. We use the load imbalance detection as the application and compare InvisiFlow (IF) with the low-priority UDP (LP) and the default-priority UDP (DP) as above.

Loss rate of telemetry packets (Figure 14b). In Figure 14b, we measure the loss rate of telemetry data in the right spine switch. We can find that the loss rate for low-priority UDP is higher than 97%. Because the only shortest path to the collector is fully occupied by the user traffic, low-priority UDP can hardly send telemetry data. In contrast, the loss rate of InvisiFlow is always 0 because InvisiFlow can find other available paths to send telemetry data. Note that the loss rate of default-priority UDP is also higher than 80% and increases over the size of TCP flows. It may be due to the switch architecture, *i.e.*, mirroring could fail when the corresponding egress port is fully utilized by user traffic.

Impact on user traffic (Figures 14c and 14d). In Figure 14c, we measure the ratio between the flow completion time (FCT) of user traffic with telemetry data against that without any telemetry. The overhead incurred by low-priority UDP and InvisiFlow is negligible (<0.1%), while the overhead of the default-priority UDP is higher (≈0.8%). The overhead of the default-priority UDP is mitigated because the switch already drops over 80% of telemetry packets when user traffic fully utilizes the link, as illustrated in Figure 14b.

In Figure 14d, we measure the delay of user packets within the right spine switch over time. Specifically, we calculate the switch delay by subtracting the timestamp at the egress pipeline from the timestamp at the ingress pipeline. The ideal delay in the figure represents the delay without any telemetry data. We can find that the default-priority UDP will gradually increase the delay of user packets over time, leading to the queue becoming full and subsequent packet drops. The delay for default-priority UDP could be up to $10^3\times$ larger than the ideal delay. Conversely, the delay of low-priority UDP and InvisiFlow is similar, which keeps around $2\times$ as the ideal delay. In other words, the delay of default-priority UDP could be up to $500\times$ larger than that of InvisiFlow. The reason for the additional delay ($1\times$ more normalized delay) in low-



(a) Testbed topology. (b) Telemetry packet loss. (c) Flow completion time. (d) Queuing delay.

Figure 14: Testbed experiments.

priority UDP and InvisiFlow might be that the switch will start strict prioritization only after there is a user packet waiting in the queue. However, it will not influence the overall flow completion time as shown in Figure 14c.

7 Discussion

Limitations of InvisiFlow. We note that InvisiFlow, in its effort to minimize the impact on user traffic, may result in drops and arbitrary delays of telemetry packets, particularly if all ports of the switch are fully utilized by user traffic. Under an extreme case where none of the switches have available bandwidth, all low-priority transmissions, including InvisiFlow, would have to drop packets. However, such scenarios are rare in modern high-speed networks. As demonstrated in §6.2, even under 80% load, InvisiFlow can reduce missing paths by around 1.63× and 3.08× compared to low-priority UDP and pull-based baselines, respectively. If a portion of telemetry traffic is essential, it can always fall back on standard transport mechanisms. InvisiFlow may also struggle with networks that need a large number of distinct collector types, as it requires the use of a separate buffer allocation for every type. Switching ASICs with more flexible memory access patterns may alleviate this limitation [64, 65].

Low-latency transmission. In some cases, telemetry reports may only be valuable if collected in a timely manner. Heretofore, InvisiFlow was presented as a framework that minimizes loss but does not bound the latency of reports. To support time-sensitive reports, we can adapt InvisiFlow by restricting sending to only hops that are strictly closer to the eventual destination. Packets would have fewer options for forwarding, but prior work on progressive routing has shown that adaptive routing policies like InvisiFlow's are still very effective [66].

Generality to other applications. InvisiFlow's abstraction to exploit network-wide under-utilized bandwidth is also applicable to other application amenable to low-priority transmission. As discussed above, InvisiFlow cannot (1) guarantee the delivery and (2) support too many distinct destinations. To address these problems, we can (1) ask the above application to handle delivery or add a layer above InvisiFlow to guarantee delivery as TCP and (2) group multiple destinations into one for simplicity, similar to how we group multiple IP addresses into an IP prefix. We leave the extension to user applications as future work.

8 Related Work

Applications of congestion gradients. Congestion gradients (*i.e.*, max-weight scheduling) have mainly been studied in a theoretical context [49, 50]. The mathematical optimality properties of congestion gradients have motivated experimental demonstrations of its use on wireless sensor networks [67, 68]. Some work [69] also applies it to urban traffic networks. However, these works focus on entirely different scenarios, so they need to consider many different factors (*e.g.*, lossy links in wireless networks) and implement the systems on different platforms (*e.g.*, CPU in sensors).

Per-packet multi-path routing. A commonly studied per-packet multi-path routing technique is packet spraying [51]. However, as shown in §6.2, the loss rate of low-priority UDP remains high even when utilizing packet spraying. This is because packet spraying assumes symmetry topology, while the available bandwidth for low-priority transmission is often asymmetric and varies largely over time. Furthermore, there are also some other per-packet multi-path routing protocols proposed [70, 71], primarily for wireless networks. As discussed above, they focus on entirely different scenarios and are mainly designed to achieve different objectives (*e.g.*, energy efficiency, security, and reliability).

Explore external memory in servers. Prior work has suggested system architectures that allow switches to utilize external memory on servers [52, 53]. The switches can directly access DRAM on servers via RDMA. However, similar to default-priority UDP, such a way is not friendly to achieve near-zero overhead on user traffic. In addition, [52, 53] need to pre-define the memory allocated in servers, while InvisiFlow can dynamically adjust the size of the memory needed.

9 Conclusion

Existing transmission methods for telemetry data often have to choose between overhead to user traffic and sustainable throughput of telemetry. To achieve both, we introduce InvisiFlow, a low-priority communication substrate utilizing opportunistic sending and congestion gradients. Our experimental results show that InvisiFlow can support high sustainable throughput with minimal impact on user traffic across multiple different applications and settings.

A Background of OrbWeaver

OrbWeaver [21] is a framework designed for the opportunistic transmission of data within modern programmable networks. As detailed in its paper, OrbWeaver imposes a negligible impact on user traffic, the computational/state resources of participating switches, or their power consumption.

Instead of "measuring" the utilization of each port, OrbWeaver continually generates a stream of low-priority packets. Leveraging the behavior of priority queues, when there are no high-priority user packets in the queue, the low-priority packets produced by OrbWeaver can effectively utilize the available bandwidth and are transmitted to neighboring switches. Essentially, OrbWeaver fills these bandwidth gaps based on the characteristics of the priority queue.

OrbWeaver also supports the amplification (*i.e.*, multicast) of low-priority packets, as demonstrated in its paper. In InvisiFlow, we require only one multicast group to multicast pull requests to all neighboring switches. For Intel Tofino switches, the multicast group ID can be configured in the control plane, enabling the data plane to utilize this ID for multicasting packets.

B Workloads

Our evaluation workloads are configured as follows.

Hadoop workload (FB_Hadoop). By default, we adopt the FB_Hadoop workload [40]. In this workload, around 60% of the flow sizes are smaller than 1 KB, and the flows arrive according to a Poisson process as in previous work [17, 19].

Machine learning workload (ML). We emulate an ML workload to demonstrate InvisiFlow's performance under different traffic patterns and distributions. In this workload, all flows are large (1 MB each), and multiple ML jobs are running concurrently. We randomly select eight servers for each ML job and these servers periodically exchange data with each other, as described in [72, 73]. The duration of the period is calculated based on the load rate.

C Flow Error for Heavy Hitters

This section shows the normalized relative error of the flow size for heavy hitters with more than 10^3 packets.

The results are similar to the relative error of all flows shown in §6.2. Under the default setting, InvisiFlow at a 70% load exhibits a reduction of approximately 1.6× and 4.9× compared to low-priority UDP and pull-based baselines, respectively. In the asymmetric topology, the normalized relative error of all flows can reach up to 14.4 for low-priority UDP and 54.8 for pull-based baselines.

Unlocking ECMP Programmability for Precise Traffic Control

Abstract

ECMP (equal-cost multi-path) has become a fundamental mechanism in data centers, which distributes flows along multiple equivalent paths based on their hash values. Randomized distribution optimizes for the aggregate case, spreading load across flows over time. However, there exists a class of important *Precise Traffic Control* (PTC) tasks that are at odds with ECMP randomness. For instance, if an end host perceives that its flows are traversing a problematic switch/link, it often needs to change their paths before a fix can be rolled out. With randomized hashing, existing solutions resort to modifying flow tuples; since hashing mechanisms are unknown and they vary across switches/vendors, it may take many trials before yielding a new path. Many other similar cases exist where precise and timely response is critical to the network.

We propose *programmable ECMP* (P-ECMP), a programming model, compiler, and runtime that provides precise traffic control. P-ECMP leverages an oft-ignored feature, ECMP groups, which allows for a constrained set of capabilities that are nonetheless sufficiently expressive for our tasks. An operator supplies high-level descriptions of their topology and policies, and our compiler generates PTC configurations for each switch. End hosts can reconfigure specific flows to use different PTC policies precisely and quickly, addressing a range of important use cases. We have evaluated P-ECMP using simulation at scale, and deployed one use case to a real-world data center that serves live user traffic.

1 Introduction

ECMP (equal-cost multipath) is foundational to modern data centers, for distributing traffic stochastically along multiple paths. ECMP is widely adopted not only because Fat-tree topologies [12, 26] naturally expose equivalent paths, but also because of its ease of implementation. The flow hashing mechanism at its core is efficiently realizable in ASICs and is widely available in commodity off-the-shelf switches.

Randomized flow hashing has turned out to be a simple yet effective mechanism. In data center networks, traffic patterns are hard to predict and they fluctuate over time. ECMP embraces this observation and optimizes for the aggregate. Individual flows might still fall victim to unfortunate choices of randomness (e.g., hash collisions between large flows); however, given enough flows, and when considering a long timespan, this randomness produces a good traffic spread and utilizes the underlying network efficiently. All production data center networks that we are aware of make use of ECMP.

However, strong aggregate performance does not remove the pitfalls of randomness in specific scenarios. In particular, we have identified a set of *Precise Traffic Control* (PTC) scenarios where rapid and precise response to network anomalies is key but randomness hinders it. Consider the case of switch/link failures that render an ECMP path unavailable or unstable [49, 56, 66]: it is then critical to quickly redirect network traffic off this path before we roll out a fix. In the presence of ECMP, this is no easy task: state-of-the-art solutions (e.g., Google's PLB [49] or PRR [56]) resort to random modification of flow tuples (e.g., by varying TCP ports), hoping that it would eventually yield a new path. This trial-and-error process could take minutes to complete [49]. Likewise, network monitoring systems [28, 31, 32] often need to quickly probe all paths to localize a fault; with randomness, we again need repeated flow modifications until all paths are covered. What these PTC scenarios have in common is the need to 1) exert precise control over traffic paths 2) against the backdrop of ECMP—the latter is equally important, as we cannot afford to *disable* ECMP, even if momentarily. In other words, the majority of network traffic should still be subjected to ECMP, while we seek a way to impose precise control *over* ECMP.

We propose to achieve this by carefully leveraging a commodity switch feature, ECMP groups, which is as simple, efficient, and widely available as basic ECMP itself. Basic ECMP maps a flow f to a preconfigured list of outgoing ports $l = [p_0, p_2, \cdots, p_n]$ based on the range that $hash(f)$ falls into. ECMP groups allow a flow to carry a selector s in its packet header, where each s maps to a its own port list l_s. Operators

*Equal contribution.

can configure the default ECMP group, say $\langle s = 0, l_{s=0} \rangle$, in conjunction with other $\langle s, l_s \rangle$ in an ECMP *matrix*. By doing so, operators could ensure, for instance, paths in l_s and $l_{s'}$ are always disjoint, and that precise control can be achieved by a single modification to the packet header field s. By leveraging this long-overlooked feature, we could instantiate ECMP matrices for each switch, so that traffic can enter/exit random modes of control by the end hosts toggling a packet header.

We call our key design *programmable ECMP* (P-ECMP), which does not require fanciful features (e.g., P4 programmability [29, 35, 39, 62]) but only exposes a restricted amount of reconfiguration for ECMP. The key challenge is to develop the 1) programming model, 2) compilation support, and 3) update mechanism for P-ECMP. While we could ask the operator to handcraft an ECMP matrix for each switch in her network, this is a tedious and error-prone undertaking. Instead, the operator describes her network in a topology matrix T, her PTC policies in control matrix C, and our compiler generates the ECMP matrices across the topology to realize precise control—while taking into account SRAM constraints across heterogeneous switches. Our consistent update mechanism further provides atomic transactions within and across switches, whether to repopulate the ECMP matrices or to dynamically change the selectors while traffic is still in flight.

We demonstrate a set of P-ECMP use cases that were previously difficult to achieve due to the lack of precise control:

- Network failover: End hosts can precisely re-path their flows to avoid perceived failures, whether silent packet drops or link flaps along an existing ECMP path.
- Failure localization: Network monitoring systems can precisely cover a set of underlying paths with their probes, e.g., to localize failures efficiently.
- Load imbalance: When skewed traffic patterns lead to performance degradation, end hosts can act upon congestion signals (e.g., ECN) to re-path select flows.
- Multipath protocols: With multipath protocols (e.g., MPTCP [50], MPRDMA [40]), we can ensure that each flow traverses a disjoint path for best performance.
- Packet spraying: Workloads that are resilient to network reordering [24] can spray packets across multiple paths for higher fairness and efficiency [21].
- Segment routing: Hosts can even precisely dictate all or parts of the forwarding paths for their flows, e.g., so that they traverse specific middleboxes.

The last use case, segment routing, points to the upperbound flexibility of P-ECMP in exerting precise control: over the entirety of a network path. The first use case, network failover, has been deployed and evaluated in a live data center network at scale. At the same time, all use cases are deployable in commodity data centers with legacy devices, and traffic that does not trigger PTC policies will continue to be handled by ECMP. Our evaluation with simulation and testbed experiments shows the effectiveness and low overhead of P-ECMP.

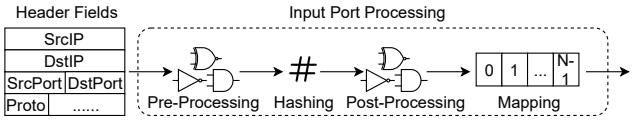

Figure 1: Four stages of ECMP processing.

2 Motivation

Many equal-cost paths exist in Clos topologies [12, 26], offering a natural opportunity for ECMP-based load balancing. When a packet arrives at an ingress port, relevant headers such as IP addresses and protocol types are parsed for further processing, including routing decisions and ECMP. The SAI (switch abstraction interface) [7] standard defines ECMP processing in four stages: pre-processing, hashing, post-processing, and mapping, as shown in Figure 1. During pre-processing, the switch performs bit-wise operations to obtain the flow ID, *e.g.,* the five-tuple <src_ip, dst_ip, src_port, dst_port, protocol>. The flow ID is then hashed by the hashing stage using ASIC functions (e.g., CRC) and reduced to a small integer. The post-processing stage also performs bit-wise operations, usually fixed in their logic, on the hash outputs. Finally, the mapping stage bins the hash output into one of the next hops $\{0, 1, \ldots, N-1\}$ for forwarding. All four stages are simple to realize in ASIC, so ECMP is widely available in commercial off-the-shelf switches.

2.1 The Pitfalls of Randomness

Since ECMP decisions are determined by the flow ID and the hash functions, across many flows the spreading pattern is essentially random. Furthermore, this randomness is difficult to predict or control, since switch vendors might employ different hash functions and their details are opaque to the network operator. While the pitfalls of ECMP regarding hash collisions resulting in (temporary) load imbalance are well-known, we have identified a more severe class of problems that, once they manifest, produce a more persistent issue inside the network.

Example: Network failover by re-pathing flows. Timely response to network failures is critical for high availability and service-level objectives (SLOs). Network failures can stem from a variety of issues, including hardware malfunctions in switches, software bugs, or configuration errors. While many of these failures can be addressed by the network control plane – for example, by using protocols like BFD to quickly detect failures and reroute traffic – others are more challenging. Failures such as silent packet drops, whether caused by misconfigured ACLs, routing blackholes, or errors in CRC computation, often affect only a subset of traffic and evade timely detection by traditional control-plane mechanisms.

In these cases, applications will perceive the failures earlier and the traditional wisdom is to produce a faster response from the end host side before the control plane fixes come in. Google [56] and Alibaba [66] have proposed using additional

header fields to modify the hash input used in network path selection, effectively tricking ECMP into recalculating the path. Applications can therefore re-path affected flows to bypass failures [56, 66]. Figure 2(a) shows an example where Flow B successfully avoids the failure encountered by Flow A on the original path.

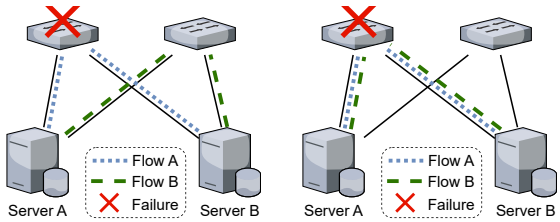
Problem: Lack of precise control. Since ECMP makes random decisions, and hash functions are opaque to operators, this re-pathing effort is essentially a trial-and-error process. It is common to encounter multiple failed re-pathing attempts due to hash collisions [56]. Figure 2(b)[1] illustrates a failed re-path attempt, where the re-pathed flow (Flow B) is mapped to the same path as the original flow (Flow A), encountering the same failure at Switch A.

Quantification of Failed Attempts. Quantitatively, the probability that either the "to" or "from" path of a new flow is mapped to a healthy path under ECMP is $\frac{N-1}{N}$, where N is the total number of equal-cost switches in the network tier where the failure occurs. The probability that the flow successfully circumvents the failure on its first re-path attempt, *i.e.,* both "to" and "from" paths avoid the failure point, is therefore $p = \frac{(N-1)^2}{N^2}$. If the flow fails to circumvent the failure on the first attempt, both "to" and "from" paths need to be re-selected randomly. Each re-path attempt is independent of the previous attempts and has the same probability of encountering the network failure as before, *i.e.,* $\frac{1}{N}$. Let T be the number of re-paths needed for successful failover. Then T has a geometric distribution with parameter p, where $P(T=k) = p(1-p)^{k-1}$. The expectation of T is given by:

$$\mathbb{E}[T] = \frac{1}{p} = \frac{N^2}{(N-1)^2}. \quad (1)$$

While the average number of new flows needed for a successful failover is relatively low, with T being at most 4 when $N = 2$ and decreasing when $N > 2$, its long-tail distribution can lead to extremely slow failovers for critical flows, resulting in SLA violations. For example, privious study [49] has shown that during a link failure, random re-pathing can cause certain flows to be disabled for 1-2 minutes due to unlucky failed re-pathing. This may further lead to unstable loads on other links for more than 20 minutes. Another proposal from Google is to re-path flows relying on TCP's RTO signal to indicates failures [56], where RTO's duration is influenced by RTT and subject to exponential backoff. Without a maximum limit on RTO and with a success probability $p \leq 0.5$, the average time for failure recovery using PRR cannot converge. Fortunately, RTO typically has an upper bound, and $p > 0.5$ when there are three or more switches in the ECMP group. Despite this, the recovery time in such setups is significantly longer compared to situations where failover is guaranteed to succeed on the initial attempt.

[1]For the sake of simplicity, examples in Figure 2 assume that the flow's "to" and "from" paths are identical. However, in reality, the "to" and "from" paths of the same flow may be different, as the flow identifier, *i.e.,* five-tuple header fields, is different when the source and destination are reversed.



(a) Succeeded case. (b) Failed case.

Figure 2: Demonstration of (a) succeeded and (b) failed failover by flow re-pathing or multi-path protocols.

2.2 Precise Traffic Control

Re-pathing is not an isolated case where the lack of precision causes operational challenges. In fact, there are many scenarios where precise traffic control (PTC) is critical.

Network failure localization. ECMP also hinders network failure localization, a crucial function for maintaining and ensuring high availability in modern data centers. Many data centers employ systems similar to Pingmesh [28], where servers regularly send ping (ICMP) packets to probe network availability. However, due to the randomness of ECMP, these probes are randomly distributed across available paths, without guaranteed coverage of all network hops (i.e., switches). As a result, achieving full path coverage requires an excessive number of probe packets, often exceeding the number of actual paths between any two servers. Further, the randomness in ECMP limits monitoring tools' ability to effectively identify localized network issues. While it can detect regional problems, it lacks the granularity needed to precisely pinpoint failures at the switch or link level [54].

Load imbalance. The goal of ECMP is to distribute flows based on their five-tuples, achieving an even spread. However, as the traffic loads are generally long tailed, the randomness in ECMP may lead to imbalances in real-world workloads, or even exacerbate congestion hotspots [13, 34]. To mitigate this, Google introduced a method called PLB, where applications re-path their flows upon detecting congestion signals – such as a few ECN-marked packets from switches – thereby improving load balancing [49]. However, addressing load imbalance in this way can lead to failed attempts. At certain cases, flows can be disrupted for 1-2 minutes due to unlucky attempts, destabilizing load distribution across other links for over 20 minutes, as reported by Google's PLB [49].

Multi-flow applications and multi-path protocols. Applications may initiate multiple flows for their transfer, and some transport protocol such as MPTCP [16] or MPRDMA [40] are inherently multipath. By exposing path diversity, we can leverage multiple paths for transmission, identify best paths, and achieve better balance in terms of path utilization – assuming that paths are independent. However, multi-flow applications and multi-path protocols do not interact well with ECMP. Its randomness may mean that paths could be overlapping. This could lead to (sub-)flows being routed along the same path,

diminishing the benefits of using multiple paths.

Packet spraying. Packet spraying is a technique that distributes packets across multiple available paths on a per-packet manner. This is particularly useful for flows that do not require strict packet ordering – such as UDP flows or networks with reordering-resilient network stack [24]. Previous results show that packet spraying can greatly improve network fairness and efficiency [21]. Unfortunately, the randomness in ECMP routing also undermines the effectiveness of packet spraying, as it prevents precise distribution of packets across paths, leading to potential hotspots and imbalance.

Segment routing. Finally, segment routing is a network function that enables the sender (host machines) to specify all or part of the forwarding path for packets. It is widely employed in wide-area networks (WANs) to support traffic engineering [44]. In data center networks, applications can benefit from segment routing such as diverting specific packets to designated middleboxes. However, segment routing is a network function that demands precise control, which is not compatible with the randomness of ECMP.

In all of these cases, we need a solution that enables the majority of the traffic to still use ECMP, while temporarily allowing certain flows or applications to exert precise control over ECMP. One solution is to implement these use cases in programmable switches, so that certain flows are processed differently when they traverse the network. However, this requires a universal deployment of programmable switches inside data center networks. Another solution is to use out-of-band mechanisms, as proposed in RePaC [66], which precomputes the mappings between inputs and outputs of the hash algorithm in ECMP and distributes these mappings to host machines. This allows host machines to exercise precise control of relative path (offset). However, this assumes uniform switch configurations within the data center network, whereas operators often source equipment from multiple vendors to avoid vendor monopoly and increase resilience against single-product flaws.

2.3 Idea: Leverage ECMP Groups

To support PTC use cases on commodity switches, our key observation is that ECMP has a certain amount of flexibility that we have not fully used. This is signaled by the fact that a significant portion of the SRAM memory resources reserved for ECMP routing remains underutilized. Indeed, the abundant ECMP table capacity is primarily designed to support ISP use cases, where asymmetric topologies and a large number of destination sets are common. However, this is not the case in DCNs which have symmetric topologies and thus require fewer ECMP groups at normal times. Our measurement of the commodity switches in a production DCN revealed that, while hardware providers (e.g., Trident5 ASIC) allocate space for 4 pipelines (e.g., uplink or downlink), with 8K ECMP groups

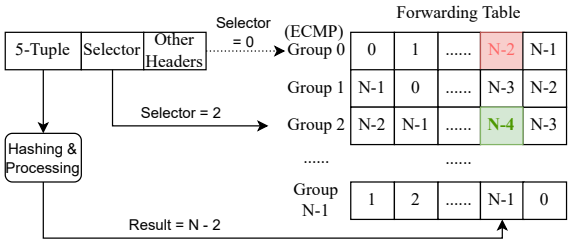


Figure 3: An example of PTC of path offset by P-ECMP where the selector is 2 and the outcome of the ECMP processing is $N-2$. By redirecting the ECMP group by 2, P-ECMP re-directs the forwarding port from $N-2$ to $N-4$.

and 64K ECMP members per pipeline, current switches use only up to 8 groups (0.1%) and 512 members (<1%) at most (spine switches). ToR and leaf switches use only one group (0.01%) and up to 64 members in uplinks (0.1%). Our idea is to extend the basic ECMP mechanism both *horizontally* and *vertically* leveraging *ECMP groups*, a common feature in ECMP-capable switches.

In basic ECMP, the hash value of a flow tuple $Hash(f)$ is used as the index into an array to determine the output port. The ECMP group feature allows for multiple such arrays as depicted in Figure 3. These multiple (M) ECMP groups transform the forwarding table from a simple array (with only group 0) into a matrix C. The selection of an ECMP group can be driven by an additional field in the packet header, referred to as the selector s. As a result, the forwarding decision is based on the tuple $< s, Hash(f) >$, where s determines the row, and the hash of the flow's selected field $Hash(f)$ determines the column. That is, the final output port is given by $C[s, Hash(f)]$. This extended flexibility in the forwarding table enables us to tune the C matrix for precise control.

Horizontal: Let us first consider only one ECMP group, with C being a one-dimensional array $[0, 1, \ldots, N-1]$. This already allows for extending the forwarding behavior by inserting, deleting, or replacing items in this array. For instance, by adjusting the number of entries in the table according to specific rules, we can implement weighted ECMP, where the weight of each next hop reflects its proportion in the table. If the array contains only a single entry, this effectively achieves precise control, eliminating randomness so that packets are always forwarded to the same next hop.

Vertical: Considering multiple ECMP groups provides further flexibility, in two dimensions: (i) multiple ECMP policies can coexist simultaneously, allowing applications to select a policy on demand, and (ii) it introduces an additional layer of determinism on top of the inherent randomness of ECMP. Specifically, applications can embed a value in a custom header field to specify which row of the matrix to use. The row selection is deterministic, while the column selection within each row (*i.e.,* the ECMP routing) remains random.

2.4 P-ECMP contributions

The contributions we made in developing *programmable ECMP* (P-ECMP) are as follows.

Programming model. Our first contribution is a systematic study and exploration of the inherent flexibility in ECMP, upon which we distill the abstraction of ECMP *programmability*. Specifically, we categorize the programmability of ECMP into three sets of intent: (i) PTC of path offset, (ii) PTC of the exact next hops, and (iii) Weighted-Cost Multi-Path (WCMP). Since our approach to WCMP aligns with previous work [29], this paper focuses on the first two intents.

Compiler. We also develop a compiler that automates the process of generating ECMP forwarding tables for all switches in the network. The compiler takes the programmability intent, along with the network topology and resource constraints, as inputs. This streamlines the development and deployment of ECMP programmability, making it intuitive and easy for network operators to implement and manage.

Runtime updates. A challenge with ECMP programmability lies in ensuring consistency during deployment. Specifically, when deploying ECMP forwarding tables on commodity switches in production DCNs, issues can arise. For example, a host machine might have an outdated database and send a packet with a flag corresponding to an invalid ECMP policy, or in-flight packets might not be able to adjust their embedded flags and thus hit an invalid policy at next switches. This could lead to packet loss or out-of-order delivery. Given the constant high volume of traffic, an inconsistent update could have a significant impact. To address this, we propose a distributed transaction scheme that ensures consistency during updates, preventing packet loss or reordering issues.

Rich use cases. P-ECMP enables a range of PTC tasks, such as the ones motivated before. We evaluate these use cases and report our experience in testing the network failover use case in a production data center at scale.

3 System Design

3.1 Where Can We Program ECMP?

To better understand the potential programmability residing in commodity switches, let us first trace back to the architecture of commodity switches and its forwarding process. In the ECMP processing described above, three elements can be modified: the input fields, the hashing algorithm, and the mapping stage. Below, we explore whether modifying each of these components can alter the output port and enable programmability. Table 1 summarizes the analysis.

First, modifying the input fields in ECMP processing enables the generation of a different hash output, which in turn determines a different output port. This approach has been employed in several studies, such as PLB [49] for improved load balancing, and PRR [56] and RePaC [66] for network failover. These studies introduce an additional header field as an input to ECMP, beyond the standard five-tuple flow definition. This allows for changing the forwarding output port by adjusting the value of the extra header field without disrupting ongoing flow sessions.

Table 1: Programmability potential of commodity switch at different forwarding stages.

Stage		PTC of Offset	PTC of Hop	Compatibility	Practicality
	Input	Yes*	Yes*	Yes	No
	Hashing	No	No	No	No
Mapping	Member Redirect	No	Yes	No	Yes
	Group Redirect	**Yes**	**Yes**	**Yes**	**Yes**

However, if the hashing algorithm used by the switches is unknown, this modification may result in random outcomes, thereby limiting programmability. When the hashing algorithm is known in advance, such as what was assumed in RePaC [66], it is possible to deterministically adjust the value of the extra header field to achieve the desired output port. Specifically, let f represent the selected flow fields for hashing, and $Hash(f)$ denote the hashing result. RePaC deterministically alters the output port by modifying the input fields with a difference $\Delta \in \{0x0...01, 0x0...10, \ldots, 0x1...00\}$, *i.e.,* the output becomes $Hash(f+\Delta)$. Leveraging the linearity of hashing algorithms, we have $Hash(f+\Delta) = Hash(f) + Hash(\Delta)$. This gives that $Hash(\Delta)$ can be used to control the output port offset. However, programmability can still be constrained by the significant heterogeneity of switches. For example, in heterogeneous environments where ToR, leaf, and spine switches employ different hashing algorithms [61], finding a suitable value for the additional header field may become infeasible due to the diversity of hashing functions across switches. For further details, please refer to Appendix A. In summary, RePaC only enables PTC of offsets in limited scenarios. Thus, it is not feasible for production deployment.

A second approach involves changing the hashing algorithm to generate different outputs for different input packets. However, this requires specialized switch chips capable of selecting the hashing algorithm based on a specific header field value in incoming packets. In our data center, only a small fraction of switches support such modifications, making this approach impractical. Additionally, changing the hashing algorithm does not necessarily guarantee that a different output port will be selected, as different algorithms may still produce the same output port for certain inputs (see Appendix B). Even when successful, this method demands extensive computation of all possible input-to-output mappings to achieve the desired network functions by selecting appropriate selectors. Moreover, the range of possible functions is constrained by the limited number of available hash functions.

The final approach involves modifying the mapping stage, which can be done in two ways: (i) redirecting the packet to a different member within the same ECMP group or (ii)

redirecting it to a different ECMP group while keeping the member fixed. However, the first approach faces compatibility issues. Many switches do not support performing arbitrary mathematical operations on the post-processing results; the only feasible modification is to replace the post-processed result with a predefined value (such as selector s). This limitation reduces programmability, allowing only PTC of hops but preventing the use of the hashing process to support PTC of offset. As a result, we discard this approach.

On the other hand, the second approach of redirecting the packet to a different ECMP group is more feasible and aligns well with our goals. Therefore, we choose this method as the foundation for P-ECMP.

3.2 Programming Model and Use Cases

Let $l = [p_0, p_1, \cdots, p_{N-1}]$ represent an ECMP group, where each p_i ($i \in [0, N-1]$) corresponds to an output port, and N is the total number of available ports. For each ECMP group, the port selection for a flow f is determined by a hashing function, $Hash(f)$. P-ECMP generalizes this by using multiple (M) ECMP groups instead of just one, transforming the forwarding table into an ECMP matrix, referred to as the control matrix C, whose dimension is $M \times N$. We assume that users can select a specific ECMP group by embedding a selector s in the packet header, i.e., l_s. If the selector value exceeds the total number of ECMP groups ($s > M$), it will be taken modulo M, i.e., $s \bmod M$. As a result, the port selection for flow f becomes an item selection in the matrix, $C[s \bmod M, Hash(f)]$.

Next, we demonstrate how PTC can be implemented. We categorize two types of PTCs, each associated with a different control matrix C. For simplicity, we will describe each type individually before addressing how to support them concurrently in § 3.3.

Precise traffic control of path offsets. A useful form of PTC involves adding an offset to the existing randomness introduced by ECMP. Specifically, let us assume a default selector s_0 and a custom selector s. The desired property is that the output port selection shifts by a constant offset corresponding to the difference between s_0 and s for a given flow. Formally, this means $F[s, Hash(f)] - F[s_0, Hash(f)] = G(s) - G(s_0)$, where G is a linear function. Taken $G(x) = x$, we have $F[s, Hash(f)] - F[s_0, Hash(f)] = s - s_0$. In this way, the randomness of ECMP is maintained, *i.e.,* with $Hash(f)$ used for column selection, while PTC of path offset is achieved through the selector $s - s_0$.

The control matrix that satisfies this property can be constructed by recursively copying the last available ECMP group and shifting each subsequent group by one position, either to the right or left. For example, if the first ECMP group is $l_0 = [p_0, p_1, \ldots, p_{N-1}]$, the next group would be $l_1 = [p_{N-1}, p_0, \ldots, p_{N-2}]$. This process continues until all N ECMP groups are generated, with the final group being $l_{N-1} = [p_1, p_2, \ldots, p_{N-1}, p_0]$, as illustrated in Figure 3.

The PTC of offset supports various use cases:

- Network failover. Google has proposed randomly re-routing flows upon detecting a network failure signal, such as an RTO [56], by adding a random value in the IPv6 header to alter the ECMP hash outcome. However, this approach is prone to re-pathing failures caused by hash collisions, where the re-pathed flow may still be mapped to the same failed path.

  In contrast, the ability to perform packet forwarding with precise offset control enables deterministic re-pathing, ensuring successful failover. For example, assume the default selector is $s_0 = 0$. When a flow needs to be re-pathed, it can select any s that is not equal to the default selector and does not result in the same path, i.e., $s - s_0 \not\equiv 0 \bmod M$.

  In practice, the value of M (the number of ECMP groups) may not be knowledgeable to applications, and there could be multiple values of M corresponding to different layers of switches in the network. A robust solution is to adopt a sufficiently large prime number for M, which works across any network topology. In most modern data centers, a prime number greater than 16 is typically adequate.

  Another concern is that re-pathed flows should ideally remain load-balanced. We provide a detailed discussion on selector selection to realize this in Appendix C.

- Load imbalance. Similar to network failover, Google proposed PLB [49], which randomly re-path flows to avoid congestion points. In contrast, PTC of offsets allows applications to re-path flows with a specific offset that ensures they will not be mapped to the original path, guaranteeing successful flow re-pathing. The selector value used is the same as in the network failover scenarios.

- Multipath protocols. PTC of offset can also enhance multipath protocols by ensuring that no sub-flows are mapped to the same path, thereby improving resilience against network failures or congestion.

  Unlike flow re-pathing, multipath protocols using P-ECMP should assign increasing integers starting from 0 as the selector s[2]. For instance, if an MPTCP flow creates 4 sub-flows, the selectors s should be $0, 1, 2, 3$, respectively. When all network tiers have at least 4 equal-cost paths, each sub-flow will be mapped to a distinct path with no overlap. However, if a network tier has fewer than 4 available paths, two sub-flows may overlap at one hop, reducing MPTCP's effectiveness. This limitation is not due to P-ECMP but is an inherent consequence of the pigeonhole principle. Determining the optimal number of sub-flows requires analysis of the network topology and workloads, which is beyond the scope of this study.

[2] A native implementation of MPTCP uses random port numbers for its sub-flows, which makes assigning increasing integers starting from 0 as the selector s ineffective. Instead, we have implemented a custom MPTCP protocol where sub-flows are distinguished based on the selector s.

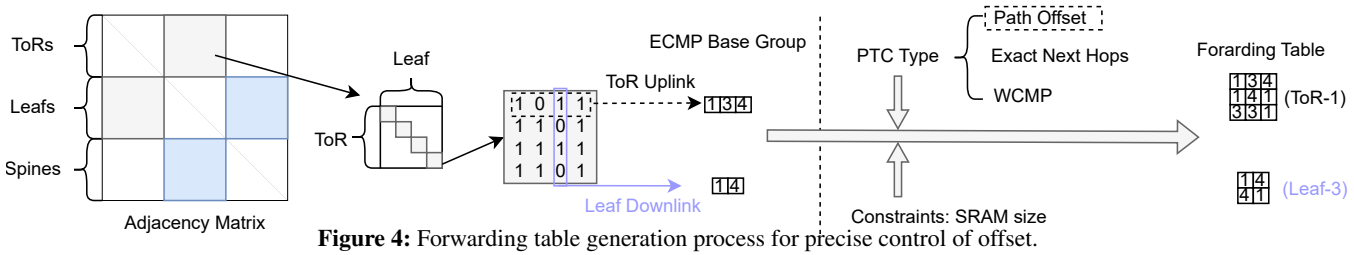

Figure 4: Forwarding table generation process for precise control of offset.

Precise traffic control of exact next hops. P-ECMP can achieve greater precision by removing the hashing process. This can be done by either setting all output ports in an ECMP group to the same port or reducing the number of output ports to just one (i.e., making $l_s = [p_s]$), allowing the output port to be determined entirely by the selector s. At different network tiers, commodity switches can use different packet headers or different bits of the same header field as the selector. As a result, multiple selectors can be configured by the sender, enabling precise control over the entire network path.

This also supports various use cases:

- Failure localization. Existing network failure localization tools, such as Pingmesh [28], need to generate an excessive number of probe packets to cover all paths due to the inherent randomness in ECMP routing. To overcome this limitation, systems like NetBouncer [54] employ IP-in-IP encapsulation to systematically probe all possible paths, providing more accurate and fine-grained failure localization at the cost of incurring additional overhead due to the encapsulation technique. In contrast, P-ECMP offers an optimized alternative for network failure localization, allowing for precise control over all paths without the overhead associated with IP-in-IP encapsulation.
- Packet spraying. Previous approaches to packet spraying have typically followed a random manner [21], relying on ECMP routing. In contrast, P-ECMP enables deterministic packet spraying, enhancing efficiency and fairness beyond what can be achieved through random packet distribution.
- Segment routing. Commodity switches used in today's data centers do not genuinely support segment routing natively, which contributes to its limited adoption. As a workaround, segment routing is often achieved using techniques like IP-in-IP encapsulation [47], though this comes with the tradeoff of increased header size.

  By leveraging the ability to specify the exact output ports with P-ECMP, segment routing can be implemented without the need for IP-in-IP encapsulation. In this approach, the selector s serves as an indicator of the intended path, and together with coordinated forwarding tables across different network tiers realizes the segment routing.

3.3 Compilation Support

To deploy the aforementioned PTC, operators must offload the control matrix as forwarding tables into every switch in the data center network. Manually performing this task would be highly labor-intensive and prone to errors. Instead, we propose automating this process using a compiler. At a high level, the compiler takes as input the type of PTC (as described in § 3.2), the network topology, and the SRAM constraints of the heterogeneous switches. The output of the compiler is the forwarding tables for all switches in the network.

Figure 4 shows the network's adjacency matrix for a topology with switches organized into three tiers: top-of-rack (ToR), leaf, and spine. While P-ECMP can adapt to any topology, here we assume a fat-tree topology with partial connectivity for simplicity. The adjacency matrix is sparse due to the absence of interconnectivity within the same tier (e.g., between ToR switches). We omit sections of the matrix where all values are zero and focus on the portion where ToR switches connect to leaf switches. By scanning each row, we can identify the ECMP base group, representing the available next hops for each ToR switch. In Figure 4, the first ToR switch connects to all leaf switches except the second, resulting in an ECMP base group of $[1,3,4]$ for its uplinks. Similarly, scanning each column reveals the ECMP base group for the leaf switches' downlinks. Note that these numbers represent the global switch IDs across the entire data center. During forwarding table deployment, translating the global switch IDs to the corresponding output ports on each switch is needed.

After determining the ECMP base group for each switch, the next step is to incorporate additional inputs, such as the desired PTC type and the SRAM constraints of each switch, to generate the forwarding table. The process for generating the forwarding table for each PTC type is straightforward, as outlined in § 3.2. The control matrices for different PTC types can be concatenated, with the matrix for precise control of offset appended after the base ECMP group being preferred. This is because the default ECMP group is also part of the control matrix for precise control of offset. We discuss the design of the selector bits in Appendix E.

Note that the PTC of offsets does not necessarily require knowledge of the network topology, whereas the PTC of hops does. When both types of PTC are supported concurrently, servers need to be aware of the network topology and the mappings between selectors and specific PTC policies.

3.4 Update Mechanism

The dynamic nature of data center networks, such as topology changes, requires updates to the forwarding tables in switches.

However, these updates can lead to inconsistencies between the PTC policies in the switches and the host machines, potentially causing packet drops or unintended forwarding behavior for a short period. Given the high bandwidth in data centers – often in the tens or hundreds of Gbps – even brief periods of inconsistency, or no delay but with packets already in transit, can significantly impact data. For instance, at 100 Gbps, a 10 ms disruption may affect 125 MB of data per link. The impact will be significantly larger considering the entire data center network.

To mitigate this issue, we propose a transactional runtime update mechanism that ensures global consistency inspired by previous work [45, 60, 64]. Specifically, we treat the forwarding tables as versioned entities, where each version corresponds to a specific range of selectors. When an update is imposed at runtime, instead of modifying the current version of the forwarding table during an update, a new version is created. This ensures that the existing forwarding table remains unchanged during runtime. Once the new version of the forwarding table is ready, servers update their selectors to align with the new version, guaranteeing a smooth runtime update without forwarding glitches.

In practice, we divide the SRAM space at switches into two symmetric halves, with each half occupying equal space. One half stores the current version of the forwarding table, while the other holds the new version during updates. For instance, if the SRAM can accommodate up to M ECMP groups, ECMP groups 0 to $\lfloor \frac{M-1}{2} \rfloor$ would represent the current version, while groups $\lfloor \frac{M-1}{2} \rfloor + 1$ to $M-1$ would represent the new version. When the new table is in place, servers update their selectors by adding $\lfloor \frac{M}{2} \rfloor$ to adapt to the new version. Once all servers have transitioned, the new version becomes the active one, freeing the 0 to $\lfloor \frac{M-1}{2} \rfloor$ range for the next update cycle.

It is important to note that updates to PTC policies are only necessary for addressing stationary topology changes, such as network expansion, reconstruction, or long-lasting failures and maintenance. These updates are not required for transient failures, such as temporary congestion or brief hardware/software glitches, which are short-lived and self-resolving. As a result, compiling a new version of ECMP groups is not a time-critical task. Nevertheless, our system is capable of compiling the new configurations and offloading them to all switches in the production network within a few milliseconds.

4 Implementation

Switch. We have implemented the aforementioned functionalities across all switches used in our production data centers, primarily including various series of Trident and Tomahawk. Our implementation is built on SONiC [9], where we ensure each operation at a switch – such as adding, replacing, or deleting ECMP groups and their members – is atomic by using locks. Additionally, when making network-wide changes, we utilize the transactional runtime update mechanism (§ 3.4) to maintain consistency across the entire network.

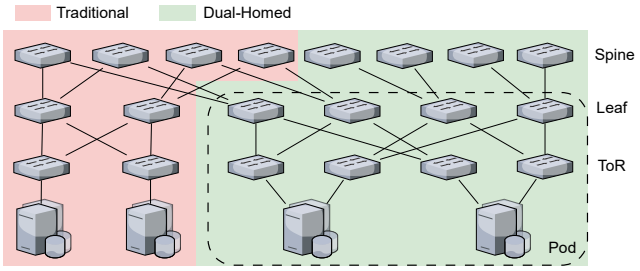

Figure 5: Comparison of traditional and dual-homed data center network architectures.

Host machine. When a host machine needs to invoke the various network functions supported by P-ECMP, such as re-pathing flows after detecting a failure, it populates the selector s in the packet header with the appropriate value corresponding to the desired network function.

Several prior works have explored different methods for encoding the selector s within the packet header. For example, FlowBlender [34] uses the VLAN tag, while PLB [49] and PRR [56] leverage the IPv6 Flow Label. Both of these fields are compatible with P-ECMP. However, in our implementation within the production network (§ 5.3), we avoid both options because (*i*) VLAN tags has been used for other purposes in our production network, and (*ii*) IPv6 Flow Labels are not useful for IPv4 traffic, which is still prevalent on the Internet and in our data centers. Instead, we select the Differentiated Services Code Point (DSCP) in the IP header to encode the selector s value. This is reasonable as DSCP is intended to be used for classifying and managing network traffic, and providing quality of service (QoS) in modern IP networks [27]. it also avoids conflicts with other packet or flow-related operations in our data center. Note that DSCP, VLAN, and Flow Label are not the only viable options – data center operators should select the appropriate header field for carrying the selector s based on their specific environment and requirements.

There are various approaches for modifying the DSCP value. For instance, one can modify the DSCP at the kernel level using eBPF [3] or by introducing a loadable kernel module [4]. Alternatively, one can modify the DSCP at the application level by calling `SetSocketOpt` [8], a function provided by the Unix socket interface, to set the desired value. We adopt the last approach in our implementation.

Note that the focus of this paper is on exploring the programmability of ECMP forwarding on commodity switches, rather than addressing when and how specific network functions should and can be applied, such as how to detect silent packet drops or congestion. For these aspects, we simply rely on state-of-the-art approaches. For instance, in network failover using deterministic re-pathing, we follow PRR [56] by using TCP RTOs as indicators of silent packet drops. For load

balancing, we adopt PLB's approach [49], using a fixed number of packets with ECN marks to detect network congestion. Additionally, our implementation supports application-level signals that can be customized based on user requirements.

Multi-homed server. As a leading cloud provider, we have built and been managing multiple large data centers. Nevertheless, we adopted a different approach when constructing them. One critical revision is that we adopt a dual-homed server bonding architecture where each server connects to two ToR switches. As illustrated in the green section of Figure 5, the numbers of ToR, leaf, and spine switches are hence doubled compared to the standard fat-tree topology. The dual-homed server bonding provides several benefits, including improved network resiliency and reduced downtime. It has also been adopted by other providers recently [48].

Given our dual-homed setup, it is essential for host machines to support similar functionalities provided by P-ECMP-enabled switches across different network interface cards (NICs) as well. A common and convenient practice is to bond multiple NICs to a single logically bonded interface, which allows flows to be distributed across different NICs and paths [5]. However, bonding often relies on hashing algorithms, which introduce randomness as ECMP.

Instead, we adopt a design approach similar to our switch-based solution. Specifically, we add the selector value to the output of the hashing algorithm and perform modulo calculations afterwards. This ensures deterministic path selection and avoids any randomness or the need to modify the hashing algorithm itself. Our approach can be implemented by a hot patch to the NIC bonding driver, making the support for multi-homed networks easy and light.

5 Evaluation

We begin by evaluating the compilation and update mechanism of P-ECMP (§ 5.1). Next, we demonstrate the effectiveness of utilizing P-ECMP to address various critical network corner cases (§ 5.2). Most experiments in § 5.1 and § 5.2 are done using the NS3 simulator [6]. Finally, we share our experience deploying network failover enabled by P-ECMP's PTC of path offset capability in our production network (§ 5.3).

5.1 P-ECMP Compilation and Update

We first present the resource requirements for deploying P-ECMP after compilation. We evaluate multiple topologies, as listed in Table 2, including whether dual-homed architecture is adopted, the number of leaf and spine switches (determined by the product of the number of spines per plane and the number of planes, where the number of planes equals the number of leaf switches per pod), and the resulting maximum number of paths between two servers. Among them, the largest topology #12 is the same as our production network.

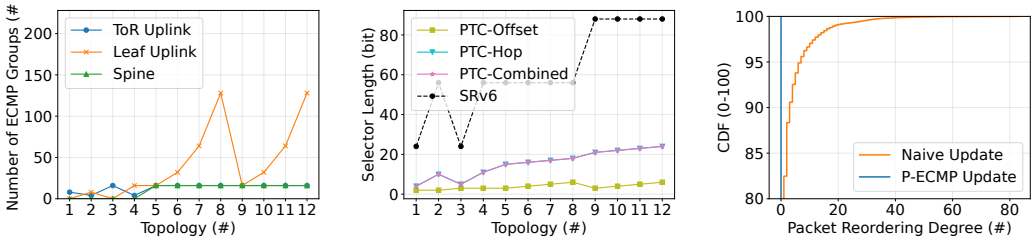
Table 2: Topologies for evaluation. OSR stands for oversubscription ratio.

Topo	Dual-Homed	# Leaf Per Pod	# Spine	OSR	Max # Paths Between Servers
#1	N	4	N/A	N/A	4
#2	Y	4	N/A	N/A	8
#3	N	8	N/A	N/A	8
#4	Y	8	N/A	N/A	16
#5	N	8	8×8	8:1	64
#6	N	8	16×8	4:1	128
#7	N	8	32×8	2:1	256
#8	N	8	64×8	1:1	512
#9	Y	8	8×8	8:1	128
#10	Y	8	16×8	4:1	256
#11	Y	8	32×8	2:1	512
#12	Y	8	64×8	1:1	1,024

Figure 6(a) shows the number of ECMP groups required for P-ECMP across different switches under various topologies, with both PTCs enabled. At the ToR uplink, between 4 and 16 ECMP groups are needed. For leaf switches (uplink), the SRAM resources range from 4 to 128 ECMP groups, except in cases where spine switches are not available, requiring 0 groups. For both ToR and leaf switches, the available SRAM resources are more than sufficient to accommodate P-ECMP. At spine switches, the SRAM resources required range from 4 to 16 ECMP groups per pod. However, it is important to note that this number must be multiplied by $(x-1)$ for a network with x pods. Given that the Trident 5 ASIC provides 8K ECMP groups and accounting for our transactional update mechanism – which halves the available ECMP space – P-ECMP can support networks with up to 512 pods based on ECMP considerations. Nevertheless, the actual number is capped at 128 due to the spine switch's 128-port limit. In other words, P-ECMP's consumption of SRAM is not the bottleneck. Notably, when using either the PTC of offset or hop, the number of required ECMP groups is halved (see Figure 11 in Appendix D).

We move on to the bit length of selector s. As shown in Figure 6(b), when only the PTC of offset is required, the selector ranges from 2 to 6 bits, making a 6-bit DSCP sufficient. If the PTC of path is needed, whether combined with the offset PTC or not, the selector will require more bits. For single-homed topologies (up to topology #8), fewer than 20 bits are needed, making the 20-bit IPv6 FlowLabel a suitable option for carrying the selector. For larger and dual-homed topologies, up to 24 bits may be required, necessitating the use of multiple header fields or other headers not covered in § 4. Nevertheless, compared to SRv6 or IP-in-IP (which incurs even higher overhead than SRv6 but is not depicted in Figure 6(b) for clarity), P-ECMP reduces the header overhead by 3x to 6x.

Next, we evaluate our transactional runtime update mechanism. At each switch, updating ECMP groups typically takes less than 2ms. While updating a single switch is atomic, updating all switches without our transactional update mechanism (§ 3.4) can result in packet reordering due to inconsistencies



(a) Number of ECMP groups. (b) Bit length of selector. (c) Packet reordering degree.

Figure 6: Evaluation of P-ECMP compilation and update mechanism.

across switches and in-flight packets using outdated P-ECMP selectors. We generate a Hadoop workload [10, 51] on topology #4 to assess the packet reordering degree at the receiver, defined as the number of packets arriving earlier or later than their expected sequence position. As illustrated in Figure 6(c), without our transactional update mechanism, the reordering degree can reach up to 83, with a 99th percentile of 19. Depending on the receiver's tolerance for packet reordering, such high levels of reordering may lead to performance degradation, or even packet loss in severe cases.

5.2 Network Functions

Next, we evaluate the support of various network functions by P-ECMP. We use topology #12 for all experiments below.

Network failover. We begin by evaluating the failure recovery of P-ECMP with a single flow. Specifically, we initiate a flow at full rate and introduce a network failure later. We follow PRR [56] to use TCP RTO as the indicator for network failures. We also change the RTO calculation following PRR to better adapt to data center networking scenarios, where RTO $\approx$ RTT + 5ms and has a cap of 1 second. It is noteworthy that the indicator for network failure and the trigger for flow re-path operation is up to user customization, which can react faster or slower than in our experiment.

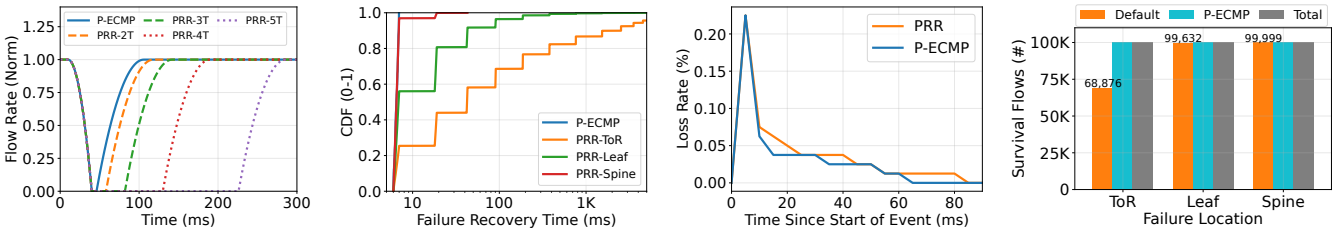
Figure 7(a) compares the performance of P-ECMP to PRR as a representative of random re-pathing. The failure occurs at 10ms. After that, the host takes roughly 6ms to detect the failure and trigger flow re-path. If the first re-path fails, the flow will pause and wait for another RTO, which grows exponentially, before attempting another re-path. In this experiment, P-ECMP succeeds in the first re-path attempt, resulting in full flow recovery at 106ms. However, PRR or other random re-pathing may require two (PRR-2T), three (PRR-3T), four (PRR-4T), or more attempts, resulting in flow recovery at 118ms, 142ms, 190ms, or even later.

We repeat the experiments for 10,000 times. Figure 7(b) presents the CDF of the failover duration for P-ECMP and PRR under different failure scenarios: at the ToR switch (PRR-ToR), at the leaf switch (PRR-Leaf), or at the spine switch (PRR-Spine). The results demonstrate the long-tail distribution of flow recovery duration by PRR (note that X-axis is in log scale). Failures at the ToR switch have the most significant impact on flows, requiring a median recovery duration of 42ms and 95th percentile recovery duration of notably over 4.5s. Failures at the leaf switch have an intermediate impact, with a median recovery duration of 7ms and a 95th percentile recovery duration of 91ms. Note that in practice, failures indeed mostly occur at ToR or leaf layers. Finally, failures at the spine switch have the smallest impact, with only a slight chance ($\sim$3%) of failure during the first re-path attempt. In contrast, P-ECMP always succeeds in re-pathing the flow in the first attempt regardless of the failure location, and hence realizing a stable flow recovery duration of 6ms.

We further present a case study of link failure between a ToR and a leaf switch. Prior to the failure, we initiated data flows of varying sizes mimicking web search workloads [10, 15] from each host machine to randomly selected destination machines. Figure 7(c) illustrates the packet loss rates over time, starting from the onset of the failure. Both PRR and P-ECMP rapidly decrease loss rates, with PRR reducing the loss from over 0.2% to 0% within 85ms. Notably, P-ECMP surpasses PRR in reducing loss rates, achieving failure mitigation within 65ms – a 24% improvement over PRR. Although our current data limitations prevent a similar emulation to more outage events presented in PRR report [56], we expect that P-ECMP will consistently outperform PRR across various scenarios, owing to its PTC capability.

Load imbalance. Next, we evaluate P-ECMP's performance against load imbalance. For each host machine, a destination is randomly chosen, and we generate flows with sizes following web search and Hadoop workload [10, 14, 15, 51]. We compare P-ECMP to PLB [49], a leading load balancing scheme leveraging random flow re-pathing. We incorporate PTC of offset by P-ECMP into the re-pathing phase of PLB [49], and employ the same parameters as PLB.

Table 3 presents the total number of flow re-paths and normalized flow completion time (FCT) results. Our analysis shows that P-ECMP requires fewer re-paths in half of the cases, while in the other half, it incurs a marginally higher number of re-paths (1% to 3%) compared to PLB. This does not indicate that P-ECMP fails to re-path flows on the first attempt; rather, the timing of successful re-paths (e.g., P-ECMP succeeding in the first attempt while PLB requires multiple attempts) can alter the workload distribution across remaining paths and influence the overall network dynamics. What is more important is that P-ECMP achieves significant improvements across various metrics, including p50 FCT, p99



(a) Single-flow recover example. (b) Single-flow recovery duration. (c) Failover from a link failure event. (d) MPTCP enhancement.

Figure 7: Use case evaluation of P-ECMP.

Table 3: Normalized flow completion time with load balancers. LF stands for last flow (*i.e.,* 100th percentile).

Trace	LB Scheme	30% Load				50% Load				80% Load			
		p50	p99	LF	#RePath	p50	p99	LF	#RePath	p50	p99	LF	#RePath
Web Search	PLB	1	21.5	33.0	1x	1	**22.5**	214.3	1x	1	54.9	366.7	**1x**
	P-ECMP	**0.90**	**8.1**	**13.6**	**0.96x**	**0.91**	23.1	**182.4**	**0.93x**	**0.92**	**45.0**	**189.0**	1.01x
Hadoop	PLB	1	147.2	334.0	**1x**	**1**	212.4	4,700.0	1x	**1**	41.9	1,278.3	**1x**

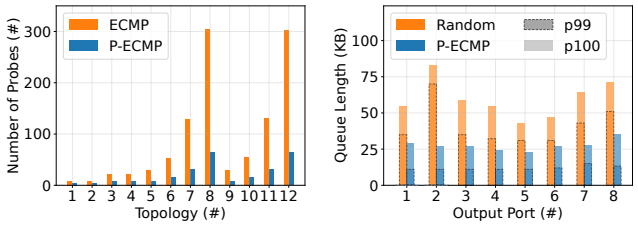
FCT, and last flow (LF) completion time, in most scenarios. Notably, under high network load, P-ECMP nearly halves the last flow completion time, highlighting its effectiveness in addressing the randomness and delays associated with PLB.

Multi-path protocol. We then evaluate P-ECMP's enhancement to the robustness of multi-path protocols. We have implemented a custom MPTCP based on P-ECMP, where subflows are distinguished using the P-ECMP selector. We generate 100K MPTCP flows between two servers, with each MPTCP flow consisting of four subflows, resulting in a total of 400K subflows. A subflow fails if either direction (uplink or downlink) is affected by a switch failure, but an MPTCP flow fails only when all its subflows are lost. Our results show that spine failure barely affects the results. When a leaf switch fails, less than 400 MPTCP flows fail because all their sub-flows are mapped to the same failed leaf switch out of four available leaf switches. When a ToR switch fails, more than half of the MPTCP flows fail because there are only two equal-cost ToR switches. These results match the theoretical expectation[3] and demonstrate the vulnerabilities of multi-path protocols to network failures, especially at the ToR level. In contrast, when P-ECMP is enabled, all MPTCP flows survive regardless of where the failure occurred, demonstrating the effectiveness of P-ECMP in enhancing the robustness of multi-path protocols.

Failure localization. Figure 8(a) illustrates the number of probes required to cover all available paths between a pair of host machines across various topologies. Previous ECMP-based mechanisms (such as Pingmesh [28]) unfortunately require 2x to 5x more probes compared to P-ECMP which enables the PTC of next hops. There are also proposals to use techniques like IP-in-IP to achieve similar functionality.

[3]Assume there are N switches at the network layer where failure occurs. That leaves $N-1$ healthy hops. As mentioned in § 2.1, the probability that a subflow avoids the failure is $\frac{(N-1)^2}{N^2}$, so its failure rate is $1-\frac{(N-1)^2}{N^2}=\frac{2N-1}{N^2}$. Assume there are K subflows. Given that an MPTCP flow fails only if all subflows fail, the survival rate of an MPTCP flow is $1-\frac{(2N-1)^K}{N^{2K}}$.



(a) Failure localization. (b) Packet spray.

Figure 8: More use case evaluation of P-ECMP.

However, these approaches incur significantly higher packet header overhead compared to P-ECMP (see Figure 6(b)).

Packet spraying. We evaluate packet spraying using a 30% Hadoop workload, monitoring ToR switch output queue lengths. Figure 8(b) reveals that random spraying causes uneven packet distribution at a microscopic level, with 99th percentile queue lengths ranging from 31KB to 70KB, likely degrading performance in low-latency environments. This imbalance worsens at the 100th percentile. In contrast, P-ECMP's PTC capability ensures a more balanced queue length distribution across ports, with most queues measuring 11KB at the 99th percentile and a maximum of only 15KB. This demonstrates superior load balancing. Further results confirm that P-ECMP consistently outperforms random spraying in terms of FCT, as detailed in Appendix D.

Segment routing. Finally, we address segment routing. Previous approaches to implementing segment routing on commodity switches typically rely on IP-in-IP or SRv6 protocols, both of which introduce significantly higher (3x-6x) header overhead compared to P-ECMP, as shown in Figure 6(b).

5.3 In Production

Over the past year, we have incrementally deployed P-ECMP's PTC with offset across multiple data centers. The rollout was seamless, with P-ECMP coexisting with existing workloads without disrupting or interfering with live traffic.

Application Recovery. We focus on Cloud Block Storage

Table 4: CBS application performance with P-ECMP (numbers before slashes) and without P-ECMP (numbers after slashes) under different network failures and configurations. #MDS refers to the number of Metadata Service daemons.

Failure Type	#MDS	IO Jitters				IO Hang

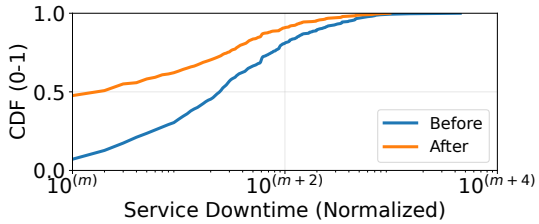

Figure 9: The distribution of service downtime by network failures in our production networks, before and after deploying P-ECMP.

(CBS) to illustrate the effectiveness of P-ECMP. CBS is a high-performance application that transmits large chunks of data across data center storage nodes. CBS may spawn multiple flows at the same time, and the completion of a CBS IO task usually incorporates a series of transport-layer flows. When a network failure occurs, CBS may encounter IO jitters or IO hang, *i.e.,* all the ongoing flows are lost, multiple times through its lifetime as the new flows spawned may be unfortunately mapped to the path with failure.

Before P-ECMP is introduced, the network failure recovery for CBS relies on FullPingmesh, a custom service similar to Pingmesh [28], and a custom socket-level failure detection and reconnection mechanism. FullPingmesh is able to detect and locate network failures within 20s. In addition, our custom socket-level failure detection for CBS can detect potential network failures by sending heartbeat packets and monitoring the socket buffer. When CBS considers that a network failure occurs and starts flow re-pathing by creating new TCP flows with different port numbers. According to our production log, the failure detection takes on average 1s.

Table 4 presents the CBS application performance with and without P-ECMP under different network failures and configurations, *i.e.,* different numbers of Metadata Server (MDS) daemons [1], where more MDS daemons generally help to serve larger workloads [2]. For each configuration and failure type, we repeat the experiments for 50 times. The results show that P-ECMP improves the application performance in most scenarios. Specifically, P-ECMP reduces the IO jitters minimum, median, and maximum durations by up to 80%, 36%, and 40%, respectively. P-ECMP also reduces the occurrence of IO hang by up to 16%, and the recovery duration for IO hang as well. The results demonstrate the effectiveness of P-ECMP in enhancing service availability.

Overall Impact. Our data centers have implemented and integrated multiple standalone solutions to detect and localize network failures, including active and passive probing, as well as data plane telemetry. Figure 9 shows the distribution of service downtime caused by network failures in our data centers. Many network failures can be mitigated within one minute. However, some failures such as hardware failures, take orders of magnitude more – *e.g.,* tens of minutes or even hours – to recover, which falls short of our needs. For example, the switches may encounter optical module failures. This requires the on-site operator to manually inspect and replace the optical module. This may take hours or even days depending on the availability and schedules of the on-site operators. In the worst case, the monthly occurrence of such failures could surpass ten times per pod, lasting for more than 20% of the total operational time.

After deploying P-ECMP in our data centers, the overall downtime due to network failures significantly decreased, as shown in Figure 9. Most downtimes were reduced to within one minute, and tail downtimes were also significantly improved. It is noteworthy that the figure still shows some long downtimes after P-ECMP is deployed. This is because these failures are multi-point or global network failures, *e.g.,* campus electricity outages, and are out of the capacity of P-ECMP or any flow re-pathing signals. Overall, P-ECMP is effective in production and meets our expectations.

6 Discussion

Dual-homed server bonding architecture. We adopted a dual-homed server bonding architecture as in § 4. It is noteworthy that this is not a strict requirement for P-ECMP, as P-ECMP can work with any topology. Instead, the dual-homed server architecture guarantees that a failure-free path is always available in case of any single-point failures in the network, and thus allows obtaining full benefits from P-ECMP. Indeed, when there is only one ToR connected to the host machines, P-ECMP cannot help in the presence of a ToR failure.

PTC policy with asymmetric topologies. When only the PTC of path offset is enabled, P-ECMP functions effectively in any topology, as long as there is more than one equal-cost output port available at each switch (otherwise P-ECMP is not useful). Appendix C details how to select the appropriate selector value for arbitrary topologies. However, enabling PTC of next hops introduces additional complexity. So far, our

discussion is restricted to tree-like topologies. P-ECMP can handle tree-like topologies with varying numbers of switches in different tiers. However, for non-tree-like topologies, such as mesh networks, hypercube topologies, or random graphs, where the concept of "network tiers" may not be as clear, the PTC policy requires more careful design. We leave further exploration of these scenarios to future work.

Interaction between P-ECMP and switch's local failover. For network failover issues, we note that commodity switches are often equipped with built-in local failover mechanisms, such as rapid link failure detection and fast reroute (FRR) protocols [17]. These mechanisms enable switches to quickly reroute traffic to alternative paths when a link or port failure is detected, often within milliseconds. As a result, not all failures require intervention from P-ECMP, which operates as an application-layer failover mechanism. However, certain types of errors fall outside the capabilities of commodity switches' local failover (though programmable switches can resolve some of these issues [23, 55]). Examples include silent packet drops and gray failures [31, 32], which are difficult to detect and mitigate using traditional failover mechanisms. Furthermore, P-ECMP addresses a broader range of scenarios beyond failover, such as congestion avoidance and load balancing. By operating at the application layer, P-ECMP complements the switch's local failover and provides a more comprehensive solution for ensuring network reliability and performance.

7 Related Work

ECMP and host-based path control. To defend against the randomness of ECMP and enable host-based path control, previous studies have mainly focused on removing ECMP, typically by redesigning or using different routing protocols [30, 33, 54]. For instance, XPath [30] identifies all end-to-end paths, compresses them, and pre-installs them into the IP TCAM tables of commodity switches. However, this approach requires a large number of forwarding table entries, which becomes impractical at the scale of data centers. More recently, programmable switches provides another solution for explicit host control. Nevertheless, their deployment in production networks remains limited so far.

Other studies attempt to work within the constraints of ECMP. For example, Volur [65] uses a centralized controller to collect routing information from switches, predict network behaviors, and send these predictions to servers. However, this approach faces two major issues: limited scalability and inaccurate predictions. RePaC [66] leverages the linearity of hashing functions to achieve relative path control. Unfortunately, this method assumes uniform switch deployment, making it impractical in production environments with diverse switches and hashing functions.

Our approach, P-ECMP, aligns more closely with the second group of studies. However, we leverage a different feature – additional ECMP groups – to extend ECMP's capabilities, allowing for precise traffic control. P-ECMP requires acceptable resources at switches and adapts to heterogeneous switch environments. Notably, P-ECMP has been successfully deployed in production.

Data center network failure. Existing proposals for network failure detection are mostly based on active or passive probing [11, 19, 20, 28, 42, 63], or data plane telemetry monitoring and analysis [18, 22, 25, 38, 41, 46, 52, 68, 69]. After detecting and locating the network failures, data center operators then need to mitigate the failures. Various automated failover solutions have been proposed based on SDN [36, 37, 43, 53, 58, 59, 67].

Nevertheless, the first-detection-then-mitigation fashion of failover is inherently slow. To speed up this process, another line of work proposes to mitigate the failures before accurately locating them. For instance, NetPilot [57] proposes to rely on the data center redundancy and blindly apply mitigation methods. Fast failovers can also be done by the host machines alone. For example, MPTCP [16] or MPRDMA [40] can be employed to address the network failures in data centers [50] by actively adjusting its sub-flows to circumvent network failures. In single flow scenarios, PRR circumvents the failure by re-pathing the flow leveraging the ECMP capability of data center networks [56]. Nevertheless, all the above solutions are vulnerable to hashing collisions. P-ECMP enhances fast failover, multipath protocols, and many other network functions by enabling precise traffic control.

8 Conclusion

This paper introduces programmable ECMP (P-ECMP), a programming model that achieves precise traffic control (PTC) by reconfiguring ECMP groups on commodity switches. P-ECMP enables PTC for both path offset and exact next hops, extending its support to multiple use cases, from network failover to segment routing, without disrupting the majority of traffic flowing through standard ECMP forwarding. Our evaluations demonstrate that P-ECMP requires minimal resources at switches and outperforms several existing approaches across various use cases. P-ECMP has been deployed in production for network failover, where it has proven effective in significantly reducing failover duration.

Acknowledgements

We sincerely thank our shepherd Kaihui Gao and anonymous reviewers for their insightful comments. We also thank software engineers at Tencent for their support in deploying P-ECMP in production. Figure 10: Required Δ's length to cover 64 paths.

A Evaluation of RePaC In Production

RePaC [66] introduces modifications to header fields by XORing a n-bit Δ. This generates a *pathmap* of 2^n entries where each possible Δ corresponds to an offset $Hash(\Delta)$. The output offset is subject to the number of available next hops. Assume the number of next hops is 2^m, then $Hash(\Delta)$ has a length of m bits. Let O be the matrix of all the outputs with n-bit Δ as input, where each $O_{i,j}$ represents the value of jth index of $Hash(\Delta_i)$ for $i \in [1, 2^n]$. To control the offset across all possible alternative paths, it requires $\text{rank}(O) = m$, meaning the hash results of all n-bit Δ must cover all 2^m possible paths. When there are multiple K layers of switches in the network with $2^{m_1}, 2^{m_2}, \ldots, 2^{m_k}$ switches per layer, then it requires $\text{rank}(O) = \sum_{i=1}^{K} m_i$, ensuring coverage of all possible path offsets across all switch layers.

We evaluated this requirement in a heterogeneous environment using all commonly used hash algorithms in commodity switches, including 8 variants of CRC-8, 8 variants of CRC-16, and 8 variants of CRC-32. We used topology #12, which mirrors our production network, with the same type of switches within each layer (e.g., ToR, leaf, or spine) but different switches across layers. We tested all permutations of hash algorithms across layers, totaling permutation(24,3)=12,144 settings, with different hashing algorithms assigned to different network layers.

Figure 10 shows the CDF of the required Δ's bit length n to cover all available paths across three network layers. The minimum bit length of Δ is 10 (1 bit needed for 2 ToR switches per server, 3 bits for 8 leaf switches per pod, and 6 bits for 64 spine switches). While 20 bits suffice in most settings, in 608 out of 12,144 (roughly 5%) switch permutations, no suitable Δ exists to cover all paths (tested with up to 1024-bit inputs, *i.e.,* $n = 1024$). In other words, RePaC fails if the deployed switches use hashing algorithms from these 608 settings. If switches are purchased randomly, there is a 5% chance that RePaC will not work. Moreover, if heterogeneity across pods

Table 5: Hashing collision rate between different hashing algorithms. Three numbers in each cell represent collision rates when there are 2, 4, and 8 equal-cost next hops, respectively.

Collison Rate (%)	Pearson	CRC	XOR	Random
Random	50.00 / 25.00 / 12.50	49.99 / 25.00 / 12.49	50.01 / 24.98 / 12.50	-
XOR	50.00 / 25.00 / 12.50	50.00 / 25.00 / 12.50	-	
CRC	50.01 / 24.97 / 12.50	-		
Pearson	-			

Table 6: The obtained maximum path load using selected selector set and the differences between it and the optimal (D.O.) or P-ECMP-allowable optimal (D.D.O) loads for an arbitrary network with a maximum of 4 equal-cost next hops.

$n\backslash p$	5	7	Maximum Path Load (%) Obtained	D.O.	D.D.O.
2	1	1	50	0	0
3	2	1	66.67	0	0
4	1	3	66.67	8.33	0

is considered, it will require longer Δ and increase the number of switch settings where no suitable inputs exist.

B Alternative of Changing Hashing Algorithm

We investigate the four most common hashing algorithms used in ECMP [66]: random-based, XOR, CRC, and Pearson hashing. The input to the hashing algorithms in ECMP is usually the five-tuple <Src_IP, Dst_IP, Src_Port, Dst_Port, Proto>, which includes 104 bits. However, given the huge input space, *i.e.,* 2^{96} possibilities for 104-bit inputs, we only select a random set of four-tuple inputs. We then feed them into the hashing algorithms respectively, and check whether the outputs would be the same. If two hashing algorithms produce identical outputs for the same input, switching between them would not alter path selection, rendering it incapable of achieving PTC of offset.

Table 5 illustrates the probabilities that two different hashing algorithms produce the same outputs for a random set of five-tuple inputs, *i.e.,* the re-pathing failure rates. The results show that the re-pathing failure rates are substantially high – 50%, 25%, and 12.5% when there are 2, 4, and 8 equal-cost next hops, respectively. This means that the PTC of offset cannot be guaranteed by swamping among any of these common hashing algorithms.

C Load balance After Flow Re-Path

Here, we discuss how to maintain load balancing for flows after they are re-pathed for failover, leveraging P-ECMP's PTC

Table 7: The obtained maximum path load using selected selector set and the differences between it and the optimal (D.O.) or P-ECMP-allowable optimal (D.D.O) loads for an arbitrary network with a maximum of 8 equal-cost next hops.

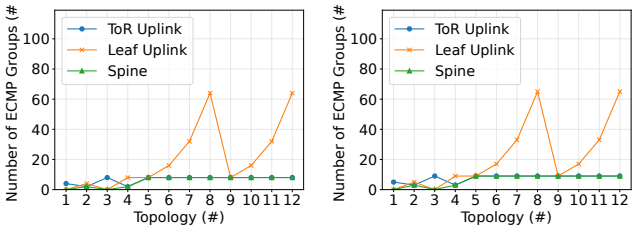
$n\backslash p$	11	13	17	19	23	29	Maximum Path Load (%) Obtained	D.O.	D.D.O.
2	1	1	1	1	1	1	50	0	0
3	2	1	2	1	2	2	60	6.67	6.67
4	3	1	1	3	3	1	66.67	8.33	0
5	1	3	2	4	3	4	75	5	5
6	5	1	5	1	5	5	60	23.33	6.67
7	4	6	3	5	2	1	85.71	0	0
8	3	5	1	3	7	5	75	12.5	5

of offset capability. We assume that the PTC of next hops is not simultaneously supported, and that servers have limited knowledge of the network topology. Otherwise, servers could simply select from the remaining available paths evenly, ensuring that all re-pathed flows are distributed uniformly across the paths.

First, if the bit efficiency of the selector s is crucial and the network topology follows a symmetric Clos-like structure – which is adopted by most data centers –, the servers should select selector s from the set of positive odd numbers less than the largest ECMP group size in the network. For instance, if the spine tier has 8 switches, then the selector s should be selected from the set $\{1,3,5,7\}$ with equal probability. In this case, selector s needs only three bits, providing good bit efficiency. It also guarantees that the load will be balanced across half of the remaining available switches in each network tier. It is important to only select odd numbers because the other network tiers may contain switches of even numbers, *e.g.,* 2 or 4, and selecting an even number could result in failed re-pathing at some network tiers.

Second, if the network topology is asymmetric/less structured, the host should select selector s from at most $N-1$ prime numbers greater than N, where N is the largest ECMP group size in the network. For example, if $N=8$, then the selector s should be selected from the set $\{11,13,17,19,23,29\}$ with equal probability. In this case, selector s occupies 5 bits, providing the capability to avoid any single-point failures and *good* load-balancing performance on most network tiers with a size equal to or less than N. We detail more analysis below.

We assume an arbitrary ECMP network where the largest ECMP group size is N. If the ability to circumvent single-point network failure is desired, then it means that there might be network tiers with the ECMP group size n to range from 2 to N, *i.e.,* $n \in [2,N]$. In such a network, our goal is to find a set of selector S that satisfies two conditions: (i) the re-pathing succeeds circumventing the network failure on the old path, *i.e.,* $\forall s \in S, p \bmod n \neq 0$; and (ii) good load balance is achieved after the flow re-pathing. Note that the minimum ECMP group size is 2 because we assume a dual-homed architecture (§ 4). If a traditional fat-tree topology is adopted,



(a) PTC of offset only. (b) PTC of hop only.

Figure 11: Number of ECMP groups with either PTC type.

the minimum ECMP group size is 1 at the ToR switch tier, meaning that flow re-pathability cannot ensure a successful failover from a ToR switch failure or link failure between the server and the ToR switch.

To quantify the second condition, let $D_n = \{s \bmod n, \forall s \in S\}, \forall n \in [2,N]$. A perfect load balance after flow re-pathing based on S means that $\forall n \in [2,N], D_n$ needs to be perfectly balanced, *i.e.,* every possible element has the same frequency. This might involve a large selector set S. In fact, the minimum size of S to achieve perfect load balance is the least common multiple of all prime numbers ranging from 2 to N. For example, with $N = 8$, the minimum $|S| = 2 \times 3 \times 5 \times 7 = 210$. To achieve a perfect balance an ECMP group of size n requires the number of selectors $|S|$ to be the product of its group size and any positive integer, *i.e., kn* where $k \in \mathbb{Z}^+$. If n is not a prime number, then it is the product of several prime numbers smaller than it. As long as $|S|$ can achieve perfect balance for its prime factors, $|S|$ can achieve perfect balance for n.

To find the set S for perfect load balance, one should start with the set of smallest prime numbers that are greater than N, *e.g.,* $\{11,13,17,\ldots\}$ if $N = 8$. This set should contain $|S|$ prime numbers. It follows that $\forall n \in [2,N], D_n$ can be calculated accordingly. If D_n is not balanced, then one should adjust the prime numbers in the set. The above process should be repeated until S is found. Some intuition might be helpful to optimize the prime number adjusting, but we do not go into details here as we do not deem the perfect load balance after flow re-pathing to be necessary given its high cost.

Rather, it may be more practical to target a smaller selector set to ensure *satisfactory* post-re-pathing load balance, rather than striving for perfection. This trade-off allows for a "good enough" load balance outcome while mitigating the high costs associated with the above prime number searching.

To achieve this objective, we propose a straightforward approach: simply select the subsequent $N_1 - 1$ prime numbers that are greater than N for the selector set, where N_1 represents the largest prime number less than or equal to N. For instance, when N is 8, the highest prime number fitting this criterion is $N_1 = 7$. Consequently, we arrive at $S = \{11,13,17,19,23,29\}$ where $|S| = 6$.

Assuming that load balance is established prior to the occurrence of any failure — meaning that all paths have identical loads — we define the degree of post-re-pathing load balance by examining the maximum load on each path. Employing the example provided, $D_4 = \{3,1,1,3,3,1\}$. In the scenario where one path becomes unavailable, its load is evenly distributed across two other paths. This results in the maximum load on each path reaching 66.67%.

For a state of perfect load balance, implying that the load on the failed path can be evenly redistributed across all other paths, the maximum load on each path can be up to 75%. Consequently, the disparity between our solution and the optimal path load equates to 8.33%.

However, it is crucial to acknowledge that the value 2 can never be attained via modulo 4 with any prime numbers. Consequently, we introduce the concept of P-ECMP-allowable degree of load balance by eliminating paths that cannot be derived through the modulo operation involving prime numbers. Returning to the aforementioned case, two paths can be re-pathed using P-ECMP. Hence, the difference between our solution and the optimal P-ECMP-allowable path load is 0%.

Table 6 and 7 illustrate the post-re-pathing load balance where N is 4 and 8, respectively. Overall, we find that the above straightforward approach demonstrates a good enough post-re-pathing load balance that meets our use case requirements adequately, with the disparity between the obtained and the optimal P-ECMP-allowable maximum path load remaining under 6.67%.

It is noteworthy that unlike RePaC which requires a central server to calculate the comprehensive path map and subsequently distribute it across all data center servers, the algorithm outlined above for ascertaining the optimal selector set S can be executed on any local server. Furthermore, each local server retains the freedom to determine its own desired properties, such as pursuing a state of perfect load balance or settling for a reasonably good load balance. More crucially, RePaC struggles to address scenarios involving an asymmetric network topology. In contrast, P-ECMP demonstrates the capacity to handle arbitrary network topologies and offers varying levels of load balance that can be fine-tuned against the size of the selector set.

D Additional Evaluation of P-ECMP

Figure 11 presents the number of ECMP groups with either PTC type.

Table 8 shows the normalized FCT with random packet spray and with P-ECMP.

E Selector Length

We examine the length of the selector when supporting either PTC type or both concurrently. For the sake of simplicity, we assume a small topology with one ToR switch connected to each server, four leaf switches, and two spine switches. Figure 12 shows the ECMP groups and members when different PTCs are supported.

Table 8: Normalized flow completion time with packet spray. LF stands for last flow (*i.e.,* 100th percentile).

Trace	LB Scheme	30% Load			50% Load			80% Load		
		p50	p99	LF	p50	p99	LF	p50	p99	LF
Web Search	Random Packet Spray	1	11.4	45.7	1	57.8	412.8	1	54.8	1,155.4
	P-ECMP	**0.98**	**10.0**	**45.1**	**0.84**	**56.0**	**396.7**	**0.98**	**47.5**	**1,071.8**
Hadoop	Random Packet Spray	1	57.8	412.8	1	166.5	2,062.1	1	27.8	475.2
	P-ECMP	**0.84**	**56.0**	**396.7**	**0.81**	**151.2**	**2,049.0**	**0.99**	**27.1**	**340.5**

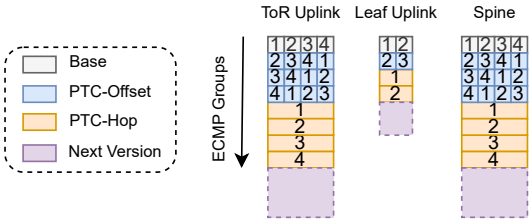


Figure 12: Forwarding table design.

When only the PTC of offset is required, the selector can range from 0 to 3 (for more details, see Appendix C). This value is effective across all network hops. For example, when $s = 1$, the flow will be re-pathed through a different leaf, spine, and another leaf switch in a different pod. As a result, the selector length is 2 bits. Our transactional update mechanism (§ 3.3) doubles the required space, increasing the selector length to 3 bits.

When only the PTC of next hops is needed, the situation changes, as different selector values are required at different switches. Without ECMP groups for PTC of offset, we find that 5, 3, and 5 selector values are required at the ToR, leaf, and spine switches, respectively, to specify the exact next hops. Therefore, the selector length is $\lceil \log(5) \rceil + \lceil \log(3) \rceil + \lceil \log(5) \rceil = 8$ bits. Including the transactional update, the selector length increases to 9 bits.

When both PTC types are supported, we again evaluate each switch individually. This results in 8, 4, and 8 selector values needed at the ToR, leaf, and spine switches, respectively. Thus, the selector length is $\lceil \log(8) \rceil + \lceil \log(4) \rceil + \lceil \log(8) \rceil = 8$ bits. Accounting for the transactional update, the selector length remains 9 bits, the same as when only the PTC of next hops is supported.

Enabling Portable and High-Performance SmartNIC Programs with Alkali

Abstract

Trends indicate that emerging SmartNICs, either from different vendors or generations from the same vendor, exhibit substantial differences in hardware parallelism and memory interconnects. These variations make porting programs across NICs highly complex and time-consuming, requiring programmers to significantly refactor code for performance based on each target NIC's hardware characteristics.

We argue that an ideal SmartNIC compilation framework should allow developers to write target-independent programs, with the compiler automatically managing cross-NIC porting and performance optimization. We present such a framework, Alkali, that achieves this by (1) proposing a new intermediate representation for building flexible compiler infrastructure for multiple NIC targets and (2) developing a new iterative parallelism optimization algorithm that automatically ports and parallelizes the input programs based on the target NIC's hardware characteristics.

Experiments across a wide range of NIC applications demonstrate that Alkali enables developers to easily write portable, high-performance NIC programs. Our compiler optimization passes can automatically port these programs and make them run efficiently across all targets, achieving performance within 9.8% of hand-tuned expert implementations.

1 Introduction

SmartNICs [3, 11, 15, 33, 34, 36] have become a popular platform for hosting various tasks in datacenters [5, 10]. They enhance traditional NICs by incorporating programmable compute units, a memory hierarchy, and (in some cases) domain-specific accelerators (*e.g.,* crypto engine). These additional resources enable the NICs to serve various functionalities, spanning network functions [10, 26], transport offloads [4, 50, 59], and non-network infrastructure processing [19, 25]. Many works have also offloaded application-specific computation onto the NICs (*e.g.,* data analytics [29, 31], RPC orchestration [14, 28, 58] and serverless [7]).

However, despite growing popularity, effectively programming SmartNICs remains challenging for two key reasons. First, NIC architectures vary significantly, so each vendor offers a custom language or SDKs tailored to its hardware architecture. They only provide architecture-specific low-level programming primitives, such as customized instruction sets to access memory and accelerators. At the same time, NIC programs often involve complex processing logic, *e.g.,* intricate control flow and stateful computations. Implementing such complex logic using vendor-provided low-level programming primitives is challenging—it essentially requires developers to have expertise with each vendor's hardware.

Second, even if one can implement them, optimizing program performance is challenging. The performance depends on numerous factors, such as identifying ideal parallelism and effectively using heterogeneous memory specific to a target NIC. Developers must manually tweak programs based on their understanding of detailed target-specific hardware characteristics which is arduous and error-prone.

Trends indicate that SmartNICs from different vendors or generations from the same vendor exhibit significant variations in hardware parallelism and memory interconnects to cater to the diverse needs of cloud infrastructures, applications, and workloads. Thus, as datacenter operators upgrade or change their NIC hardware the above challenges become even more pronounced requiring not only (re)writing programs but also (re)tuning performance for each new SmartNIC iteration. Existing NIC programming frameworks, including P4 extensions and recent proposals [6, 26, 44, 56] while extremely valuable, are narrowly built for a single type of architecture – thus, they do not offer the much-needed portability.

We present Alkali, a compilation framework enabling portable and high-performance NIC programs. With Alkali, developers use high-level languages (*e.g.,* a subset of C) to write a single-threaded, run-to-completion NIC program. Then, our compiling toolchain transforms the program into an optimized, pipeline- and data-parallel program aligned with

*Both authors contributed equally to the paper.
†Author's contributions were made while at UT Austin.

the target NIC's hardware characteristics.

Our paper makes the following contributions to realize Alkali and showcase its benefits:

• **An IR targeted at SmartNICs:** Inspired by existing compiler frameworks like LLVM [22] that recognize the importance of an intermediate representation (IR) for supporting multiple targets, we design an IR called α*IR* aimed at SmartNICs, their architectural nuances and SmartNIC programs' common structures. α*IR* generalizes and captures how the inherent parallelism in NIC programs' computations and salient aspects of their memory access patterns map across diverse SmartNICs. To this end, α*IR* uses the *stateful parallel network handler graph* abstraction (§4).

• **A two-phase iterative algorithm for parallelism optimizations:** Translating the α*IR* into parallel code that optimally leverages the underlying hardware is challenging. This is due to the large space of potential parallelization – *e.g.,* the many ways of splitting NIC programs into pipeline stages, replication options per stage, possible mappings between replicas/stages and compute units, and placements of different replicas'/stages' state onto the target's memory hierarchy. To efficiently navigate the space and identify good parallelization plans, we model the problem as a two-phase iterative optimization (§5). The first identifies suitable pipeline stages via a novel weighted min-cut formulation to determine the places to partition programs (in α*IR*) into pipeline stages. The second employs an SMT solver alongside a simple NIC performance model to determine the number of replicas of each stage and the placement of replicas and state (onto compute cores and memory layers, respectively) to maximize performance.

• **Open-source prototype:** We present a full end-to-end implementation of the Alkali compiler toolchain including a C frontend, a mid-end, and multiple backends that support four types of NIC targets–on-path SoC NICs (Agilio [36]), off-path SoC NICs (BlueField-2 [34]), FPGA NICs [3], and specialized ASIC SmartNICs (PANIC [30]). We open-source the prototype [2].

Our evaluation using a wide range of NIC applications demonstrates that our framework enables developers to easily write portable, high-performance NIC programs. The compiled programs run efficiently across different NIC targets - their performance is competitive with experts' implementations, showing less than a 9.8% gap.

2 Background and Motivation

SmartNICs can be viewed generally as comprising a *subset* of three types of components: (1) programmable compute units, (2) a memory hierarchy, and (3) reconfigurable match-action table (RMT) pipelines. Of these, RMT pipelines have received substantial attention from a programming point of view, with P4 [55] being a framework ideally suited to it, with important P4-based NIC programs already used in many production settings today [24, 27, 42, 57].

The architecture of the remaining "non-RMT" components has significant heterogeneity (Figure 1): (1) *Programmable compute units* have substantial differences in micro-architecture and degrees of parallelism. For instance, the BlueField-2 DPU has 8 ARM cores, while Agilio boasts 48 micro-engines, Pensando's Elba contains 256 MPUs, and FPGAs can have hundreds of hardware modules running in parallel; (2) *Memory hierarchies* have distinct sharing scopes, sizes, and access latency. For example, Agilio has CAM, CLS, CTM, and EMEM [37], Elba has SRAM and TCAM [11], while FPGAs have SRAM, BRAM, and DRAM [3]. They are software-managed, non-coherent, and require careful selection for placing stateful program objects.

2.1 NIC Programming Challenges

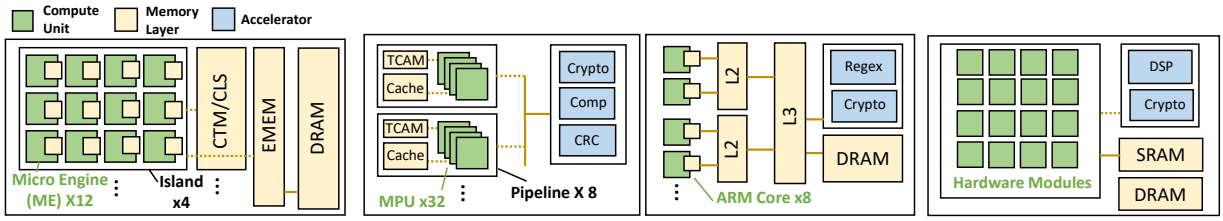
Programmability is a key driving factor of the broader adoption of SmartNICs. However, programming today's SmartNICs remains arduous and time-consuming. First, the NICs' hardware complexity and low-level programming interfaces create a steep learning curve. Second, hardware heterogeneity exacerbates the challenge, making programming and learning efforts non-portable across different NICs.

2.1.1 Target-specific Primitives

NIC vendors today provide a language and toolchain tailored to their NIC. For example, developers use Verilog for FPGA NICs, DOCA SDK for BlueField-2 [38], Micro-C (a subset of C++ with the vendor-provided library) for Agilio [37], and a mixture of customized P4 with hand-coded assembly for Elba [11]. They offer low-level target-specific primitives that are tightly coupled with the NIC architecture. For example, when writing the network transport offload (Flextoe [50]) on Agilio (the program logic shown in Figure 2), developers need to break down a sequence of packet processing tasks into fine-grained micro threads and determine how to replicate and map these micro threads onto 48 micro engines across 4 compute islands [37, 50]. Then, since the transport offload maintains a flow table, developers need to explicitly define which memory layer this table's content is placed in using the customized C++ macro (*e.g.,* `__declspec(emem)`). A similar tedious programming process is needed for FPGA NICs [26] and Elba NICs [5].

2.1.2 Lack of Portability

Portability between different NIC targets is essential for reducing vendor lock-in and allowing network operators to switch between NIC targets as workloads evolve. However, today, developers must follow a two-step transformation process to adapt architecture-dependent low-level programs across different NICs, making portability challenging.



(a) **Netronome Agilio [36]** (b) **Pensando Elba [11]** (c) **NVIDIA BlueField-2 [34]** (d) **AMD Alveo [3]**

Figure 1: **An abstract view of different SmartNICs' architecture.**

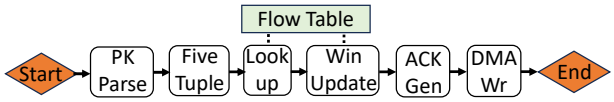


Figure 2: **FlexTOE's packet processing flow graph [50].**

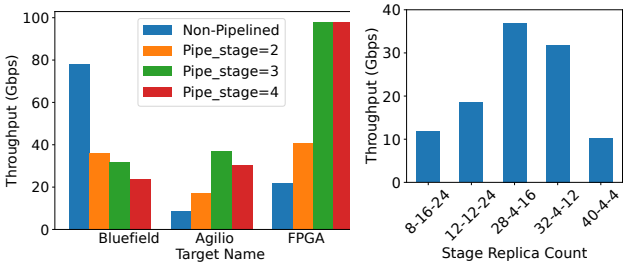

(a) **Impact of pipeline parallelism.** (b) **Per-stage replica count.**

Figure 3: **Different parallelism influences FlexTOE [50]'s performance on different arch. Using 16 connections with 256B packets.**

Step 1: Translate primitives. Developers must resolve the impedance mismatch between different NICs' low-level hardware primitives. For example, the Figure 2's packet processing logic will be implemented as a thread on an ARM core on BlueField-2, whereas on FPGAs, it will be implemented using combinational and sequential logic on LUTs. Similarly, the flow table can be implemented in CAM on Agilio but will be implemented as a hash table on BlueField-2 due to the lack of CAM hardware support. When performing primitive translation, developers need to find primitives that provide the same or equivalent functionality. Such translation may not always exist because of target-specific functional constraints (*e.g.,* supported accelerators and hardware interfaces).

Step 2: Refactoring. Developers also need to significantly refactor and re-optimize their code to make it run fast based on the target NIC's hardware characteristics:

(1) Change code parallelism. SmartNICs are designed with extensive hardware parallelism, making them ideal for highly parallel network tasks. NIC programs usually leverage two forms of parallelism: data parallelism, where the same code block runs across multiple compute units with packets or flows distributed via RSS [35], and pipeline parallelism, where the code is divided into stages that communicate in a pipelined fashion. The optimal parallelism strategy varies across NICs, requiring developers to adjust the code's parallelism when porting. This involves determining (1) the number of pipeline stages and (2) how many replicas to use per stage.

To illustrate the need for such refactoring, we implemented FlexToe [50] in Figure 2 on three platforms - BlueField-2, Agilio, and FPGA - using two approaches: (1) a non-pipelined data parallel-only version, where the entire program is replicated across all compute units and packets are steered to compute units using flow steering, and (2) pipelined versions, where the program is divided into stages, and each stage is replicated independently.

Figure 3a shows that the optimal number of pipeline stages varies by architecture. On Agilio and FPGA, three pipeline stages yield the best performance, while on BlueField-2, the non-pipelined version performs better. These differences arise because Agilio and FPGA both (1) have more compute units, allowing pipeline stages to fully utilize available units when the active flow number limits data parallelism; (2) have specialized hardware queues to reduce the communication overhead between pipeline stages, and (3) are more sensitive to data locality - memory access latencies vary more across their memory layers, and pipelining helps improve locality.

Figure 3b shows that with pipeline parallelism, developers must also optimize the number of replicas per stage. For example, on Agilio, replicating a three-stage pipeline to optimally occupy its 48 micro-engines boosts performance up to 3.7×.

(2) Change state mapping. Many NICs [3, 11, 36] come with a memory hierarchy, and developers must select the appropriate memory level for storing states. This includes analyzing each program state's size and access patterns to place frequently accessed states in faster, lower-capacity memory layers. For example, our experiments showed that placing Figure 2's flow table into the fastest memory layer (CAM) resulted in an over 8× throughput improvement compared with placement in the slowest layer (EMEM).

2.2 Limitation of Existing Frameworks

An ideal SmartNIC programming framework should allow developers to write target-independent programs and let the compiler automatically port these programs across various NICs. However, existing frameworks [26, 44, 45, 56] fail to achieve this for the following reasons:

(1) Non-reusable compiler infrastructure and optimizations: Existing frameworks are usually only narrowly built

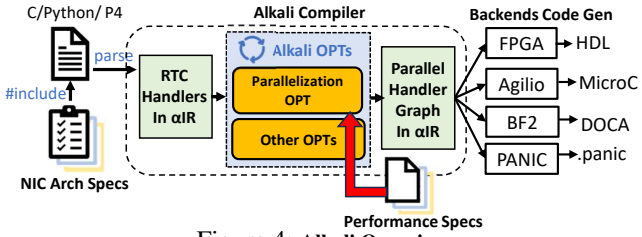

Figure 4: **Alkali Overview.**

for a specific NIC. For instance, Floem [44] is built for on-path SoC NICs; ClickNP, and Flowblaze [26,45] target FPGA NICs; P4 and its backend compilers [41,56] target RMT-like SmartNICs. Compiler optimizations in these frameworks are often not reusable across different NICs. For example, P4 backend compilers' optimizations focus on packing resources into constrained, fixed, line-rate RMT-like pipelines but lack performance-oriented optimizations such as pipeline stage replication and state mapping, which are crucial for SoC and FPGA NICs as shown in Figure 3.

(2) Lack of automatic parallelization: These compilers still require developers to manually define the degree of parallelism and cannot automatically change the program's pipeline/data parallelism degree when compiling programs to different NICs. For example, Floem requires developers to determine the program's pipeline stages and replication counts and rewrite the program when porting to another SoC NIC with different core counts.

These limitations stem from the tight coupling of programs and optimizations to specific NIC targets, which restricts portability across different architectures.

3 Alkali Overview

Overcoming the above limitations requires decoupling NIC programs (written in various languages) from a specific NIC architecture. Drawing inspiration from the role of intermediate representations (IR) in conventional software compilers, which bridge high-level code and architecture-specific implementations, we introduce α*IR*, a new IR tailored for NIC programming. α*IR* serves as a bridge between target-agnostic NIC programs and target-specific code generation.

Building on α*IR*, we develop Alkali, a multi-target SmartNIC compilation framework that (1) allows developers to write NIC programs in high-level languages, (2) uses α*IR* to translate between languages and vendor-specific code seamlessly, and (3) employs novel compiler optimization techniques to automatically port programs for high performance across various targets.

Figure 4 illustrates the workflow of Alkali. First, developers import the target NIC's architecture specification provided by NIC vendors, which specifies high-level architectural functionality constraints of the target NIC. They then write single-threaded, run-to-completion NIC programs (*e.g.,* Figure 6a) using high-level languages (*e.g.,* a subset of C). This interface frees programmers from having to manage hardware parallelism or memory hierarchies, enabling simpler and more portable code. These input programs are parsed and translated into α*IR* where the compiler performs parallelization optimizations that transform the single-threaded program into a highly optimized, pipeline- and data-parallel program based on the target NIC's characteristics. The parallelization optimization is guided by a simple performance specification provided by the NIC vendor. Finally, the backend takes the optimized α*IR* program and generates target-specific code.

3.1 Design Challenges and Ideas

Here, we describe the main design challenges in Alkali:

C1: IR design. An IR for NICs must preserve the parallelism inherent in NIC programs while also abstracting the details of their execution on diverse NIC hardware. Directly reusing a general-purpose IR like LLVM IR [22] will not work well since it is too low-level to suitably capture/express the semantics of SmartNICs' parallel execution patterns and memory hierarchies. This makes developing NIC-specific optimization passes hard. Creating an IR specific to a single type of NIC (*e.g.,* FIRRTL IR for FPGA [16], P4 IR for RMT NICs [55,56]) fails to represent other architectures adequately.

C2: Identifying parallelization plans. Transforming single-threaded NIC programs into pipeline-/data-parallel programs is challenging because there are numerous ways to divide a program into pipeline stages and replicate them. Parameters include the location of stage boundaries, the number of stages, and the stages' replication counts. Also, NIC programs are usually stateful, and careless parallelization can compromise state consistency and correctness. Alkali must efficiently navigate this expansive design space to find optimal solutions while maintaining the program's semantics.

To solve these challenges, we employ the following ideas:

I1: Stateful handler graph IR (§4). We observe that although NICs come with huge compute and memory heterogeneity (Figure 2), their architectures and program execution typically involve two main types of parallelism (pipeline and data) and three kinds of state access (local value, persistent table, and context state). Based on this, we propose the *stateful handler graph IR* that enables flexible compiler optimizations.

I2: Iterative mapping-then-cut search (§5). To manage the vast search space of parallelization plans, Alkali's optimizer mimics a developer's fine-tuning process: starting with a data-parallel, non-pipelined program, developers iteratively identify bottlenecks and apply pipeline cuts to increase stages and boost performance. Similarly, Alkali's optimizer operates in an iterative loop between two modules: (1) the *mapping engine* (§5.1), which determines optimal data parallelism strategies for the current pipeline and identifies bottleneck stages, and (2) the *cut engine* (§5.2), which splits the bottleneck into additional pipeline stages to improve throughput. The updated

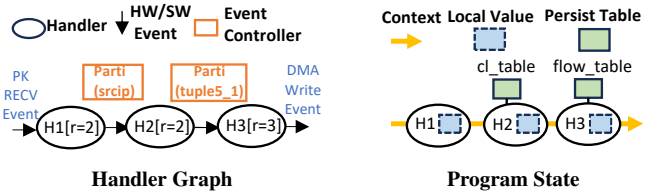

Figure 5: **Visualised αIR structure for Figure 6b.**

pipeline is then returned to the mapping engine for further refinement. Throughout this process, both modules carefully analyze program states to ensure that all cut and replication plans preserve program correctness.

4 Alkali IR

We design αIR with two goals: (1) Providing a general representation of the program's execution on heterogeneous architecture, capable of abstracting various types of computational parallelism and state access, and (2) Enabling the compiler to realize a broad set of architecture-agnostic transformations/optimizations. This section explains how αIR achieves them with an example input C function that implements connection limiter and transport [50] detailed in Figure 6a.

4.1 Abstracting Parallelism with Handlers

Observation. SmartNICs have a massive set of parallel compute units. Each compute unit can be viewed as an inseparable hardware block that logically executes code in sequence, such as Agilio's micro-engines, BlueField-2's ARM cores, and FPGA's hardware modules. NIC programs typically leverage two types of parallelism on these units: data parallelism and pipeline parallelism.

IR design. We propose to abstract a NIC program as a *handler graph* to capture parallelisms, in which each handler abstracts a code block running inside a single compute unit. In Figure 6b, the IR contains three handlers: H1 (line 4), H2 (line 15), and H3 (line 23), and Figure 5a visualizes the handler graph. Each handler can be replicated, and a number of replicas is specified in the IR (*e.g.,* [r=2] in line 4). Handlers use *events* to trigger another handler's execution (*e.g.,* lines 9 and 18 in Handlers H1 and H2). The start node of the graph is triggered by hardware events (*e.g.,* packet receive, host MMIO doorbell, etc.), and the end node generates hardware events (*e.g.,* network packet send, DMA operations; see Line 31 in Handler H3). Each handler has an event controller (line 14) that defines how incoming events are ordered and partitioned between a handler's replicas. The handler graph captures both data and pipeline parallelism: events spreading across replicas represent data parallelism, while events flowing through handler chains represent pipeline parallelism.

Enabled optimizations. This representation facilitates parallelism optimizations, allowing the compiler to adapt and transform the graph for different hardware. As discussed in §5, the compiler can split a handler into two pipelined handlers to enhance pipeline parallelism or adjust the number of replicas per handler to increase data parallelism.

4.2 State-based Memory Abstraction

Observation. SmartNICs have multiple memory layers, each with different sharing scopes across compute units. Memories shared by fewer units typically offer better performance but have smaller capacity. Optimal memory placement for program states and variables depends on the state's sharing scope, lifetime, and access pattern.

IR design. We abstract NIC memory accesses into three types of state: local value, persistent table, and context state (Figure 5b), each with distinct sharing scopes, lifetimes, and access patterns. Local values are temporary variables accessed by a single handler replica and live only during a single event's execution. Persistent table state, like the connection limiter's table in Figure 6b's line 1, persists across events and is accessed via lookup/update operations (lines 16 and 18). Context memory is used to pass data along the handler chain, passing data by reference across handlers, unlike events copied by value between handlers. For example, in Figure 6b's line 9, the `payload` value is stored in the context memory, and the reference (`ctx_1`) is passed to H3.

Enabled optimizations. This representation enables various memory optimizations, such as partitioning tables between handler replicas to avoid synchronization and improve data locality (§5.1) and optimizing data flow between handlers using context memory to avoid copies (§5.4).

5 Parallelization Optimizations

Initially, the input run-to-completion, single theaded C function is converted into a single handler without pipeline or data parallelism. As shown in Figure 7, the goal of the parallelization optimization is to transform this single handler into replicated, pipelined handlers based on the target NIC's hardware characteristics.

The total search space for all possible pipeline and data parallelization plans is enormous,[1] and exploring it exhaustively is NP-hard. To manage this complexity, Alkali reduces the search space while ensuring that the generated plan is both correct and near-optimal. To achieve this, Alkali decomposes the search problem into two modules: a mapping engine, which determines the handler replication plans, and a cut engine, which splits handlers to increase pipeline stages. Alkali uses an iterative "Mapping-Then-Cut" loop between these two modules to guide the search.

[1] A program with just a hundred lines of code can have over a million possible plans.

```c
#include <alkali.h> // Alkali library
#include <agilio_spec.h> // Arch Spec

// Connection limiter table, key=src ip
ak_TABLE(64,int,int) cl_table;
// Transport flow state table, key=5 tuple
ak_TABLE(64,five_tuple_t,
        flow_state_t) flow_table;

// _net_recv event defined by agilio_spec
void _net_recv(hdr_t hdr, buf_t payload) {
    /* Generate 5-tuple */
    five_tuple_t tuple5;
    tuple5.srcip = hdr.srcip;
    // ... assign dst ip, ports and proto

    /* Connect Limiter: count pk per srcip */
    int i = ak_tb_lookup(cl_table, hdr.srcip);
    i += 1;
    ak_tb_update(cl_table, hdr.srcip, i);
    // ... check i, drop packet if necessary

    /* Transport: flow state update */
    flow_state_t fs = ak_tb_lookup(flow_table,
                                   tuple5);
    fs.dma_pos += hdr.len;
    // ... update window, OoO detection
    ak_tb_update(flow_table, tuple5, fs);

    // _dma_write defined by agilio_spec
    _dma_write(payload, fs.dma_pos);
}
```

  "ak.genevent"(payload,dma_pos_1){target=dma_send}
}
```

(b) **Optimized αIR for the C program. Red texts are αIR operators. αIR is static single-assignment (SSA) based, thus each value is assigned once. As shown in the IR, after optimizations, the C program is transformed into three replicated handlers.**

Figure 6: **From Alkali source program to optimized αIR.**

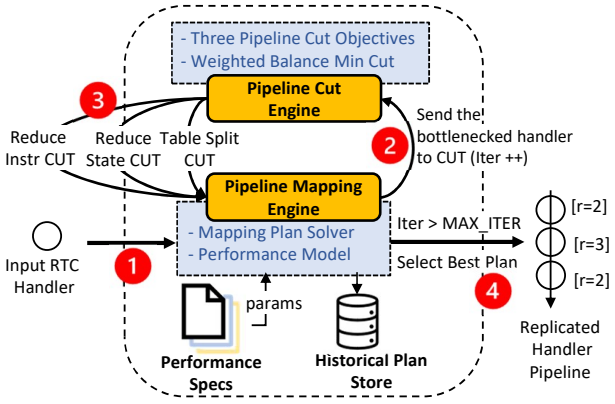

Figure 7: **Parallelization Optimization Overview**

1. **The Pipeline Mapping Engine** takes a non-replicated handler pipeline and uses the SMT solver to search for a replication plan that maximizes the pipeline's throughput within the target NIC's hardware constraints. The solver compares different searched plans' throughput using a cross-target performance model, whose parameters are customized based on the vendor-provided performance specifications. Once the optimized replication plan for a pipeline is found, it is stored in the plan store, and the bottleneck handler in the pipeline is sent to the cut engine (Step 2 in Figure 7).
2. **The Pipeline Cut Engine** improves the bottleneck handler's throughput by splitting the handler into two pipeline stages. It uses a Weighted Balanced Min-Cut algorithm with three criteria: (1) reducing the handler's state size to improve state locality, (2) lowering the handler's instruction count to increase throughput, or (3) splitting persistent tables into different stages to enable a handler's replication. Newly produced increased-staged pipelines are sent back to the mapper (Step 3 in Figure 7).

The loop continues until the predefined maximum number of iterations is reached, which is 100 in our implementation.

5.1 Pipeline Mapping Engine

The pipeline mapping engine takes a non-replicated handler pipeline as input and tries to find a mapping plan – *i.e.,* the number of replicas per handler and the memory placement for each program state – that maximizes its throughput on a given NIC. Our main innovation lies in formulating mapping as an SMT problem. Using a solver and a *cross-target performance model*, our engine searches for a mapping that, given the *hardware resources* and *handler replication constraints*, achieves the highest model-estimated throughput.

The solver retrieves parameters such as the number of compute units, memory hierarchy, and sizes from a "performance

specification" (Table 1). Alkali requires NIC vendors to provide these (simple and brief) specifications.

Mapping plan. The solver searches for two parts of a plan:

The *computational mapping plan* defines the assignment of handlers to compute units on the target NIC. Let the NIC have n compute units, and the handler pipeline have K handlers. The plan $M_1, \ldots, M_n$ ($0 \leq M_i \leq K$) specifies the assignment of handlers to compute units. $M_i = 0$ indicates that no handler is assigned to compute unit i. $M_i = M_j = X$ means that the handler X is replicated on both compute units i and j.

The *state mapping plan* specifies the memory layer to which each persistent table or context memory state is mapped. Let the program have states $S_1, \ldots, S_m$ and the target NIC have X memory layers. The state plan $L_1, \ldots, L_m$ ($1 \leq L_i \leq X$) defines the assignment of a memory layer to each state.

Resource constraints. Mapping plans must account for:

1. **Memory capacity**: For all states mapped to the same memory layer, the sum of the sizes of these states must be smaller than the capacity of memory layer.
2. **Memory sharing scope**: If the handler H is mapped to compute unit C, and if H's state S is mapped to memory layer L, then C must be able to access L.

Replication constraints. Care must be taken when replicating stateful handlers in NIC programs (as noted in [18] in the network functions context). Crucially, replicating a handler with a persistent state may have correctness issues because sharing such states among parallel handler replicas can lead to race conditions. For example, in Figure 6b, when handler H2's replicas run concurrently, a race between the connection limiter table's lookup and update operations can cause the state to become inconsistent.

To avoid race conditions, we can either synchronize handler replicas or disable replication for handlers, but both approaches can significantly and needlessly degrade performance. Fortunately, because tables are indexed by keys, we can partition table state across handlers as long as we ensure that all events accessing a specific key are steered to the same replica [18, 43]. For example, the connection limiter table in H2 (Figure 6b) can be partitioned between replicas when events are steered based on the source IP by the event controller (line 14).

Thus, we add the following constraints during mapping:

1. A handler without any persistent tables or with read-only persistent tables can be replicated.
2. A handler with non-read-only persistent tables can be replicated only if: (1) All lookup and update operations on non-read-only tables use the same key (which can be identified through data flow analysis) and (2) the key is present in the input event parameters, which allows the event controller to use it to steer events (*e.g.,* in Figure 6b, the source IP is H2's input event parameter and is used by the event controller for steering in line 14).

Cross-target performance model. The performance model estimates each pipeline stage's performance using the handler's throughput multiplied by its replication count, and the overall pipeline performance is determined by the slowest pipeline stage. It uses a general formula whose parameters are customized based on performance characterization metrics – also included in the NIC performance specification (Table 1).

Parameter	Description	Usage
$InstrTimeFn(\{\text{op}\})$	A function that returns the instruction execution time for a set of IR operators.	Perf Model
$MemTimeFn(l, b)$	A function that returns memory access latency for layer l when b bytes are accessed.	Perf Model
$CommTimeFn(i, j)$	A function that returns interconnect communication time from compute unit i to j.	Perf Model
CU Count	Number of compute units on the NIC.	Map Constraints
Mem Layers	Total memory layers and how these memories are shared between compute units.	Map Constraints
Mem Sizes	The size of each memory layer.	Map Constraints

Table 1: **Parameters provided by the performance specification. Performance parameters can be derived from offline microbenchmarks.**

The throughput of a handler H's replica is calculated as:

$$T(H) = \frac{1}{Exec_{Time}} = \frac{1}{Time_{Instr} + Time_{Mem} + Time_{Comm}}$$

That is, $T(H)$ depends on:

1. $Time_{Instr}$**:** The handler's instruction execution time is estimated by *InstrTimeFn*, as defined in Table 1. Each backend can provide its own implementation of *InstrTimeFn* through Alkali's interface. The current implementation uses a simple model that sums up the cycle latencies of individual IR operators. In future work, the *InstrTimeFn* interface could be extended to integrate with more detailed or ML-based models for improved accuracy.
2. $Time_{Mem}$: The total memory access time for the handler's states, calculated by summing the memory access latencies of all mapped states. The latency for accessing each state is calculated based on the $MemTimeFn$ in the performance specification.
3. $Time_{Comm}$: The time of sending events to the next pipeline stages through on-chip interconnects. If this handler has M replicas and sends the event message to the handler on compute unit j, the communication time is $\sum_{i \in M_Replicas} CommTimeFn(i, j)$, which models the message incast overhead that scales linearly with concurrent senders. This term penalizes mappings with excessive handler replications that cause significant communication overhead when pushing data to the same destination.

It is important to note that precise mapping-performance estimates are not critical. The primary objective is to comparatively rank and assess different mapping strategies. This design philosophy allows our performance model to remain general and cross-target, accommodating various hardware configurations.

Lock-free execution. Alkali's replication algorithm produces lock-free programs by avoiding synchronization among compute units (*e.g.,* Alkali replicates a handler only when

its state can be partitioned). This design is driven by two factors. First, locking overhead is typically prohibitive in high-throughput NIC data paths, and many NIC programs can operate without synchronization when sufficient hardware parallelism is available. Second, accurately estimating locking and synchronization overhead in the performance specification is challenging.

5.2 Handler Cut Engine

The handler cut engine aims to improve the throughput of a bottleneck handler by splitting its instructions into two chained pipeline handlers. Similar to prior work [9], the basis of our approach is to construct a flow network based on the data dependencies of handler instructions which allows us to model the problem of partitioning instructions into pipeline stages as selecting cuts in the flow network. Our innovations lie in devising a Weighted Balanced Min-Cut formulation showing how different performance objectives map to this modeling and ensuring and proving the correctness of the cut when the handler has persistent NIC program states.

Construct flow network. Figure 8a shows the flow network graph constructed for the H1 handler in Figure 6b. Each gray node (L5–L10) represents an IR statement from lines 5 to 10 of Figure 6b, while each white node corresponds to the value defined by a statement. For every statement S that defines a value V, we add a *definition edge* (S,V) with a weight equal to V's byte count, representing the cost of transmitting V between pipeline stages. Additionally, for each statement S that uses V, we add a *usage edge* (V,S) with infinite weight.[2]

As shown in the figure, by finding a cut that divides the nodes into disjoint subsets, we can split the H1 handler into two pipelined handlers. The figure shows a possible cut where the first pipeline stage contains statements L5 and L6, while the second stage includes statements L7–L10. The communication cost between stages is equal to the sum of the weights of the cut edges (79B in this example).

Uncuttable region for persistent table. Cutting access to persistent tables across pipeline stages can lead to correctness issues due to inconsistent operations. For instance, Figure 8b illustrates the flow network for the H2 handler in Figure 6b, showing a cut that separates the table's lookup operation ($L16$) from its update operations ($L17$ and $L18$) into two pipeline stages. In this scenario, when two packets enter the pipeline sequentially, with the first packet in stage 2 and the second packet in stage 1, the second packet's table lookup may occur before the first packet's table update, which can be incorrect.

We prevent such cuts as follows: we first add a UNCUT node (Figure 8b) for each persistent table and add bidirectional infinite-weight edges from the lookup (L16) and update (L17) statement nodes to the UNCUT node. This ensures that all statements involved in reading or writing the same persistent table remain within the same pipeline stage.

Weighted balanced min cut. We now consider where to cut the flow graph to most effectively improve the handler's performance. We develop a weighted balanced min-cut algorithm that extends the traditional balanced min-cut approach [9, 61] with specialized weight functions tailored to our performance objectives. The balanced min-cut algorithm starts by finding a min-cut of the graph and then iteratively applying the min-cut process to the larger side of the flow graph until it identifies a balanced cut that satisfies $|W - \overline{W}| \leq \beta$, where W and $\overline{W}$ represent the sum of node weights on the left and right sides of the cut, respectively. β is the imbalance tolerance threshold.

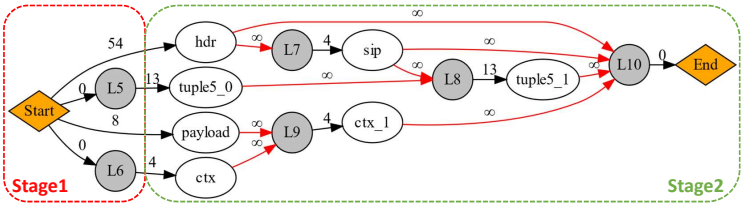
We note three main sources of speedup from pipelining a handler, which guide our node weight functions' design:

1. **Reducing handler state**: By partitioning the handler state equally into two stages, the state size within each handler is decreased. This allows the handler state to be allocated in a local, faster but smaller memory layer in the next mapping iteration. If the handler's performance is memory-bound, throughput can be improved. *Weight function:* Based on this, we assign weights equal to the byte count to all value nodes (white nodes in Figure 8a) and assign a weight of 0 to all other types of nodes.
2. **Reducing instruction counts**: Equally partitioning the handler's instructions into two stages decreases the instruction count in each handler. If the handler's performance is compute-bound, this can improve throughput. *Weight function:* Thus, we assign a weight of 1 to all statement nodes (gray nodes in Figure 8a) and assign a weight of 0 to all other node types.
3. **Splitting tables to enable handler replication**: As discussed in §5.1, a handler cannot be replicated if it contains multiple persistent tables with different keys. By splitting tables with different keys into different pipeline stages, each handler becomes replicable, allowing the program to utilize more compute units in the next mapping iterations. *Weight function:* First, we group tables with identical keys and add a UNCUT node for each "table group" to prevent splitting same-key tables across different stages. Then we assign a weight of 1 to each table group's UNCUT node and 0 to all other node types. This weight assignment encourages the weighted balanced min-cut algorithm to split tables with different keys into different stages while keeping the same key tables in the same stage.

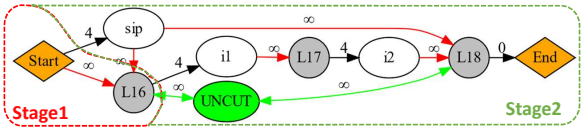
5.3 End-to-end Example and Properties

Figure 9 shows a simple example that puts these components all together. In iteration 1, the input RTC handler A is mapped by the mapper. Since it has multiple tables with different keys, A can only have a single replication. Next (iteration 2), A is sent to the cut engine, which generates three 2-stage han-

[2]The infinite weight ensures that cuts happen only on *definition edges* – this is because the weights of the cut edges should reflect a value's transmission cost, which depends on its defined size rather than the number of uses.



(a) **Constructed flow network graph of Figure 6b's H1 handler. It shows a cut that splits the handler into two pipelined handlers, with L5 and L6 in the first pipeline stage, and L7-L10 in the second pipeline stage.**



(b) **Flow network graph of Figure 6b's H2 handler. This cut shown in the figure is incorrect since it split the table lookup operation (L16) with the update operation (L18) into two stages. By adding the UNCUT node we can prevent this cut.**

Figure 8: **Constructed flow network graph.**

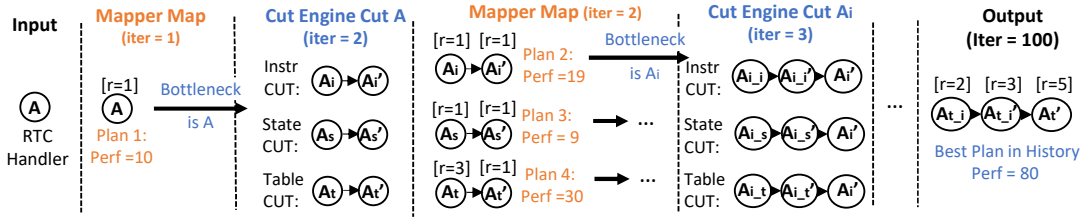


Figure 9: **End-to-end example.**

dler pipelines based on three performance objectives. These pipelines are mapped, which calculates the replication number for each handler within each pipeline. Compared to iteration 1, the program's performance may increase or decrease after the cut. In subsequent iterations, the mapper identifies the bottleneck handler for these three pipelines and sends it to the cut engine to generate 3-stage pipelines. This loop continues until the predefined max. iterations is reached, after which the optimizer selects the plan with the best performance from the history plans.

Search optimality vs. efficiency. It is important to note that Alkali does not guarantee optimality; in rare cases, the search algorithm may overlook better parallelization plans. However, Alkali is not designed to find the absolute best plan. Instead, its goal is to efficiently generate correct, competitive plans that closely approximate expert implementations. By employing domain-specific heuristics, Alkali filters out suboptimal plans, which narrows the search space and reduces reliance on an exact performance model.

Correctness. In §A.2, we show that after optimization, the replicated handler pipeline P_a is semantically equivalent to the original RTC handler P_b; that is, *after executing the same input event sequence, P_a and P_b will generate the same output event sequence and end in the same persistent state.*

5.4 Other Optimizations

After the parallel optimizations, Alkali performs a pass of four other optimizations:

1. Traditional optimizations. These include peephole optimizations [1], control flow reduction, and elimination of common expressions [8] and dead code [20].

2. Event controller generation. After replicating handlers, the compiler generates event controllers to dispatch events between replicas of handlers based on the table keys.

3. Context memory conversion. α*IR* supports two methods to pass variables along the handler chain: *Pass-by-event* and *Pass-by-context* (§4). Context memory conversion optimization determines when to use pass-by-context based on the variable's size and lifetime. If a variable is large or needs to persist across multiple handlers, Alkali opts for pass-by-context to avoid redundant data copying.

4. Saving context memory. This optimization further minimizes context memory allocations. Each handler pipeline analyzes the temporal overlap in the lifetimes of data stored in the context. It then tries to reuse memory for data with non-overlaspping lifetimes (detailed example relegated to §A.1) thereby saving overall context memory.

6 Programming Frontend, Architecture Spec

Our prototype supports programs written in C, using a subset of the language that is expressive enough for a wide range of NIC programs (§8.1). For example, developers can use conditional branches (if-else) and bounded loops, but pointer operations and unbounded loops are not currently supported. Since Alkali programs are written as single-threaded executions, concurrency primitives such as mutex locks are also not supported. Additionally, developers must include `alkali.h`, which provides built-in data structures (*e.g.,* tables, packet buffers) and library functions for common operations such as table lookup/update and buffer extract/emit. Looking ahead, we plan to extend Alkali to support additional languages, including Python and P4.

Because network traffic distribution affects program performance, developers can annotate their code to make Alkali's compiler optimizations workload-aware. For instance, they can limit the maximum number of table replications based on active flow counts, allowing the SMT solver to use this as a replication constraint. Additionally, developers can specify branch probabilities to enhance the performance model's accuracy in estimating handler execution efficiency. Below are examples:

```
1  annot_MAX_REPLICA(3)    ak_TABLE(64,int,int) ftable;
2  annot_BRANCH_PROB(0.7)  if(a){...};
```

Each NIC vendor provides an "architecture specification", which is included as a header file in the Alkali program (*e.g.,* line 2 in Figure 6a). The specification defines the high-level interfaces for supported hardware events on the target NIC, enabling developers to write functions to process and generate these events. For example, Figure 6a's C function processes `net_recv` events and generates `dma_write` events and is defined by the specification as follows:

```
1  // Event processed by programmer
2  void _net_recv(hdr_t hdr,buf_t data){}
3  // Event processed by hardware
4  void _dma_write(buf_t data,long addr){return;}
```

This event-based interface hides NIC micro-architectural details, enhancing program portability: a single Alkali program can be compiled for NICs with the same event types.

7 Backends and Compiler Implementation

We implement four distinct NIC backends, each representing a different type of SmartNIC architecture: Agilio [36] (on-path SoC NICs), BlueField-2 [34] (off-path SoC NICs), Alveo [3] (FPGA NICs), and PANIC [30] (a prototype of an ASIC NIC).

Each backend takes the optimized αIR and generates target-specific executables. The Agilio backend produces a NFP Micro-C code [37], while the BlueField-2 backend converts the αIR into LLVM IR, generating ARM binaries linked to the DPDK runtime. The Alveo backend outputs Verilog code, and the PANIC backend produces bare-metal RISC-V binaries with scheduler configurations.

The backend translates the IR objects into architecture-specific components (Table 5). For instance, in the Agilio NIC, handlers run as micro-engine threads, while on FPGAs, handlers are implemented as hardware modules with parallel, pipelined LUTs (FPGA backend details are in Appendix B).

Because handler replicas running on parallel compute units can reorder events due to variable processing times (*e.g.,* smaller packets finishing before larger ones), the αIR event controller ensures proper event ordering by default. It reorders events from the previous stage's handler replicas before dispatching them to the next stage. Each backend generates different code to handle event sequencing (*e.g.,* the FPGA generates a reorder buffer, while Agilio generates code that invokes a hardware sequencer). For programs that tolerate out-of-order processing [7, 28], programmers could add annotations to disable event ordering, allowing backends to use FIFO queues, not sequencers.

We implement the C frontend, Alkali compiler, and backends using the MLIR framework [23], totaling 20K lines of C++. We also developed runtime libraries for each NIC target, totaling 4K lines of code, providing features such as dynamic memory allocation, event steering, and inter-compute unit communication queues. Since Alkali centralizes most optimization and mapping in a common compiler mid-end, adding support for new backends is streamlined. *e.g.,* the BlueField-2 backend was developed in a week using 1107 lines of code.

8 Evaluation

We evaluate Alkali by answering the following questions:

1. Does it help easily write portable NIC applications (§8.1)?
2. Does Alkali programs perform well across targets (§8.2)?
3. Does the mapping-then-cut loop find good plans (§8.3)?
4. Does the mapping engine find optimal computational and state mapping plans (§8.4)?
5. How do other optimizations improve performance (§8.4)?

Testbed: Our testbed comprises five commodity servers with two Intel Xeon Gold 6258R 28-core CPUs and 256GB of RAM. We use one server equipped with a Mellanox ConnectX-6 DX NIC to generate DPDK traffic to four SmartNIC servers. Each SmartNIC server is equipped with one of these four SmartNICs: (1) a 100GbE AMD Alveo U280 [3], atop which runs the generated FPGA program at 250MHz; (2) PANIC's FPGA prototype [30] (configured to have 32×250MHz RISC-V cores); (3) a 40GbE Netronome Agilio CX [36] (equipped with 48×800MHz micro engines); and (4) a 100GbE BlueField-2 DPU (8×2.5GHz ARM A72 cores and 16GB DRAM).

8.1 NIC Applications Implemented with Alkali

Table 2 lists five NIC applications implemented using Alkali. For the L2 forwarding [40], JSQ RSS [17], and FlexTOE [47], we re-implemented in Alkali-C based on their open-source implementations to ensure functional equivalence. For the NF chain and RPC message reassembly applications, where no open-source implementations were available, we asked a graduate student with SmartNIC expertise to write them using BlueField-2's DOCA API as our baseline.

Table 2 compares the lines of code (LoC) between Alkali programs and their baseline implementations. The Alkali implementations are 5–10× smaller, as Alkali allows developers to focus on core logic while abstracting away target-specific details. All Alkali-C programs can be compiled for different NICs with no modification, demonstrating Alkali's portability.

Application	Description	Alkali LoC	Original Impl LoC (Target NIC)
L2 Forward [40]	Swaps the Ethernet source and destination addresses and echoes packets back to the network.	28	128 (Agilio)
Flextoe Transport [47]	Flextoe's RX pipeline (same as Figure 2), it validates the packet header, performs OoO detection, and looks up and updates the **flow table**. It then generates ACKs and DMA payloads to the host.	224	1264 (Agilio)
NF Chain	A chain of three network functions to offload a stateful firewall, a connection limiter, and a L4 load balancer. The chain has **six tables**: four use the 5-tuple as the key, while two use src and dst IP addresses as the key.	289	780 (BlueField-2)
RPC Message Reassembly	It drops OoO packets, looks up the **flow assemble buffer table** to get the assemble buffer for this flow, and appends the **incoming packet's payload** to this buffer and update table. It sends assembled msg to host.	120	467 (BlueField-2)
JSQ RSS [17]	Implements Ringleader's request steering [28]. NIC uses a **worker load table** to track the inflight request count on 32 host cores and steers incoming requests to the least-loaded core.	126	1312 (FPGA)

Table 2: **Application description. The last two columns compare LoC when using Alkali and vendor-provided SDK.**

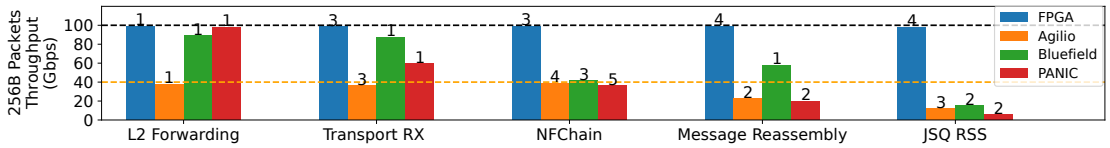

Figure 10: **Performance of Alkali programs on NIC targets. The number over the bar shows the number of pipeline stages in the generated code.**

	Throughput (Gbps)		Latency	LUTs
	64B Packet	128B Packet	(ns)	Usage
Ringleader	64 Gbps	100 Gbps	64ns	208K(1.6%)
Alkali	64 Gbps	100 Gbps	84ns	247K(1.9%)

Table 3: **Alkali's JSQ RSS performance compared to Ringleader's original implementation on FPGA.**

8.2 Performance on Heterogeneous Targets

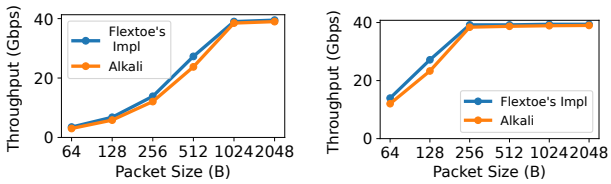
We evaluate the above applications' performance on different targets and compare them with experts' implementations.

Alkali program performance. Figure 10 shows the end-to-end throughput of five applications across four targets, measured with 256B packets. The L2 forwarding application achieves the line rate on all NICs. FlexTOE also reaches line-rate performance on all NICs except PANIC, where the low-frequency RISC-V cores become a bottleneck. FlexTOE's flow table satisfies replication constraints and can be partitioned across multiple handler replicas, enabling data and pipeline parallelism to sustain high throughput.

The NF chain application, consisting of six tables, achieves the line rate on the FPGA and Agilio NICs. Alkali's cutting algorithm efficiently splits the NF chain's tables into pipelined handlers, ensuring that tables in each handler share the same key and can be replicated. On BlueField-2, performance is limited to 50 Gbps due to high inter-core communication overhead, which degrades pipeline efficiency.

Message reassembly operates below line rate on Agilio (22 Gbps), BlueField-2 (57 Gbps), and PANIC (19.73 Gbps) due to the costly buffer aggregation operation, which involves copying the entire packet payload to the reassembly buffer. This overhead significantly reduces throughput on SoC NICs.

JSQ RSS has limited throughput on Agilio, BlueField, and PANIC. It uses a small load table to track in-flight packet counts per core. Upon receiving a packet, it looks up each core's load, selects the least loaded one, and updates its count. Since the table lookup and update operations use different keys, handler replication is impossible, creating a bottleneck.



(a) **Single Flow Throughput** (b) **16 Flows Throughput**

Figure 11: **Alkali compiled FlexTOE's performance compared to its original implementation on Agilio.**

The FPGA achieves line-rate performance because the table is mapped to local registers, allowing both operations to complete within two cycles and ensuring high throughput.

Comparison with experts' implementations. We evaluated and compared Alkali generated program performance with FlexTOE [50]'s open-source Agilio implementation and Ringleader [28]'s FPGA implementation. We also compared the message reassembly and JSQ RSS application with NIC expert's Bluefield implementations.

Figure 11 shows that Alkali closely matches FlexTOE with a 10% performance gap. Both achieve line rate for packet sizes larger than 1KB with a single flow or for packets larger than 256B with 16 flows. The gap is mainly due to Alkali's mapping engine searched replication count for a pipeline stage being not optimal when running on real hardware.

Alkali's JSQ RSS performance matches Ringleader's implementation. The generated Verilog achieves comparable throughput to an FPGA expert's design since the compiler automatically breaks the program into pipeline stages. Alkali has 30% higher latency and 18% higher resource utilization due to the backend inserting registers between dependent operations to avoid timing issues. A future backend could remove unnecessary registers when timing allows.

We then asked a NIC expert to port this JSQ RSS program and implement the message reassembly program on Bluefield. The result in Appendix C shows that Alkali's performance lags 0.6% to 9.8% behind the expert implementations. Notably, the expert spent 14 hours implementing the fine-tuned

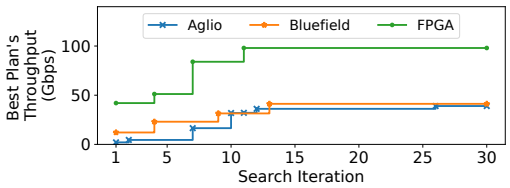


Figure 12: **The best-searched parallelization plan's throughput under different iteration counts.**

applications, whereas Alkali compiled from unmodified code.

8.3 Effectiveness of Mapping-Then-Cut

We use the NF chain application to demonstrate how Alkali's mapping-then-cut loop searches for an optimal parallelization plan. Figure 12 shows that as the number of search loop's iterations increases, the performance of the historical best plan improves. In different iterations, Alkali tries different cutting methods, gradually dividing the program into multi-stage pipelines, which improves performance. Eventually, performance plateaus as finer-grained parallelism no longer adds benefits. The performance saturation point varies by architecture. For Bluefield, the optimal plan is found with a 3-stage pipeline (at iteration 13), while for Agilio, it is found with a 4-stage pipeline (at iteration 26).

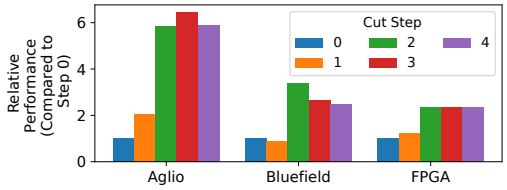
We provide a walk-through of how the program is cut into pipelined handlers. For each NIC, we present the cut history for the 5-stage pipelines that perform best. Figure 13's bar graph shows throughput changes after each cut step; the table below details the cut type, the replication count per handler, and the identified bottleneck. The results show: (1) different cut methods improve performance in different steps. For example, the table cut improves performance in Agilio's Steps 1 and 2, while in Step 3, the state cut does. This highlights the importance of Alkali trying all three cut methods per iteration; (2) the bottleneck handler shifts after each cut, emphasizing the need to iteratively identify bottlenecks before applying further cuts; and 3) a cut does not always guarantee improved performance. For example, Bluefield's performance decreases after the first cut, but improves after the second. This shows the importance of Alkali maintaining the plan history and continuing the search to avoid getting stuck in the local optima.

8.4 Effectiveness of the Mapping Engine

We now evaluate whether the mapping solver can identify good handler replication and state mapping plans.

Handler replication plan. We evaluate whether Alkali can effectively determine handler replications. We did an exhaustive manual search of all possible replication plans[3] for the

[3]Since the NF chain achieves line-rate on Agilio, we restricted the application to a single island (12 micro-engines) to observe throughput variations across different mapping plans.



Cut Step	[Cut method], replication count of each stage		
0	1	1	1
1	[table] 21	[table] 31	[table] 41
2	[table] 722	[table] 322	[table] 212
3	[state] 3222	[state] 2221	[instr] 1212
4	[instr] 32222	[state] 12221	[instr] 12121

Figure 13: **Cut traces of the best performing 5-stage pipelines on three NICs. Use the NF chain application. In the table, the number sequence represents the per-stage replication count. *e.g.*, 22 indicates a 2-stage pipeline with 2 replicas per stage. The bottleneck stage is shown in red.**

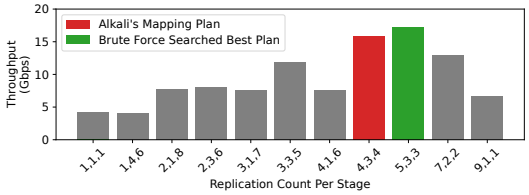


Figure 14: **Alkali mapping plan's performance compared with the brute-force searched plans. Measured on Agilio using NF chain.**

State Placement	FlexTOE Perf	NF Chain Perf
Place into EMEM	1.05 Mpps	0.86 Mpps
Place into CLS	2.06 Mpps	3.34 Mpps
Alkali solver's plan	6.28 Mpps	4.43 Mpps

Table 4: **Comparison of the solver's state placement plan's performance with the other two naive plans.**

NF chain application's 3-stage pipeline and measured the performance of these plans on the Agilio NIC. We compared these plans' performance with the one generated by Alkali's mapping solver (Figure 14). The results show that Alkali finds the second best plan in the search space, whose performance is 8.4% below the best replication plan. Alkali did not find the best plan because of the simplicity of the performance model, which estimates computational cost by summing the execution latencies of individual IR operations. Nonetheless, the results suggest that this model is adequate for automatically finding practical mappings.

Alkali's solver can identify the optimal replication plan for both FPGA and BlueField-2. For FPGA, Alkali's performance model can accurately estimate the handler's throughput, as the execution cost (initial interval) of each IR operation type is predictable when running on the hardware.

State placement. Alkali's mapping solver strategically places program states in the fastest available memory tier based on the state's sharing scope and size. For FlexTOE and NF chain, we compare Alkali's state placement plan with two other naive mapping strategies on Agilio: (1) placing all states into the global memory hierarchy (EMEM) and (2) placing all states into the cluster local scratch memory (CLS).

Table 4 shows that, compared to the naive placement strategies, Alkali's state placement yields a 1.32× to 6× improvement in throughput. Alkali achieves better performance by utilizing all of Agilio's memory layers (CAM, fast local memory (LMEM), CLS, and EMEM). Alkali places frequently accessed, small states in CAM and LMEM, while storing infrequent, larger states in CLS and EMEM.

Performance model sensitivity. We found that Alkali's performance model is robust to parameters in performance specification. Even with parameter errors up to 50% of the accurate value, the mapping result performs only 1.3% lower than when using accurate values.

Effectiveness of other optimizations. We studied the benefits of other compiler optimizations (Section 5.4) and measured the throughput of the FlexToE program on BlueField-2, Agilio NICs, and PANIC. Our results show that traditional compiler optimizations yield performance improvements of 5%–20%. Context conversion results in gains of 6%–113%, while context reduction provides improvements of 6%–137%.

9 Limitations and Future Work

Handling dynamic workloads. Alkali currently depends on program annotations to enable workload-aware compile-time optimizations (see §6). However, this approach has limitations, as it does not account for workload shifts occurring at runtime. In the future, integrating Alkali with a dynamic runtime workload profiler could enable automatic recompilation and adaptation in response to changing workloads.

Detailed performance specifications. Alkali's performance model relies on functions defined in the performance specification. Our prototype utilizes simple functions (*e.g.,* summing instruction cycles for *InstrTimeFn*) to estimate performance. While this approach achieves good results, as demonstrated in our evaluation, future work will incorporate more detailed, potentially ML-based, per-hardware models. These enhanced models will account for additional factors such as memory contention, cache hierarchies, and out-of-order execution, further improving the accuracy of parallel optimization.

Support for locking. As mentioned in §5.1, Alkali currently does not support locking due to the challenges of accurate model contention overhead. In the future, with a more detailed performance specification that models locking costs, Alkali could enable handler replication for non-partitionable shared states by automatically generating locks to safeguard critical sections where the shared state is read-then-modified.

10 Related Work

Compilers for programmable switches. Programmable switch compilers such as Domino [52] partition C code into pipeline stages, while Gallium [62] and Lyra [12] distribute programs across switches and servers. Unlike Alkali, these compilers are designed for switches with fixed line-rate pipelines, focusing on pipeline partitioning and resource packing. In contrast, NICs support pipelining and data parallelism without a fixed rate, which requires Alkali to explore multiple dimensions of parallelism with extensive performance optimizations.

IR for accelerators. Prior work has developed domain-specific IRs for hardware accelerators, including GPUs [22, 54] and FPGAs [32, 49]. However, α*IR* is distinct in that it is specifically designed to abstract the unique architectural features of NICs, such as parallel event processing and memory hierarchies. It also supports key functionalities commonly used in NIC programs, including persistent tables, flow steering, and context states.

SmartNIC performance prediction. Many tools have been developed to predict the performance of NIC programs [13, 39, 46, 51]. Clara [46] transforms NIC programs into LLVM IR and uses ML models to predict the program's performance on various SoC NICs. Pipeleon [60] adopts a profiling-based approach to predict the performance of the P4 program. HLSPredict [39] and LEAPER [51] forecast FPGA program throughput and latency. Alkali can integrate these models for parameter estimation in the performance specification. For example, Clara could take α*IR* as input and estimate its execution latency on a given target, which can be integrated with Alkali's performance model (*e.g.,* through the *InstrTimeFn* interface).

Network programming languages and IRs. Many existing works have developed high-level programming languages for network hardware devices, such as Lucid [53], Click [21, 26], Floem [44], and λ-NIC [7]. Alkali is complementary to these efforts and can be extended to support these programming languages. NetASM [48] provides an IR for network programs using an assembly instruction set. However, it lacks automatic parallelization optimizations for heterogeneous targets.

11 Conclusions

We present Alkali, a multi-target NIC compilation framework that introduces a novel intermediate representation to abstract the compute parallelism and state access of NIC programs. Alkali uses an iterative parallelism optimization algorithm that automatically transforms single-threaded programs into highly optimized ones. Our prototype effectively compiles five NIC applications across four distinct NIC architectures. The compiled programs run efficiently on all targets, exhibiting a performance gap of less than 9.8% compared to expert implementations.

(a) **Without Opt** (b) **With Opt**

Figure 15: **Context memory optimization.**

A Additional Design Details

A.1 Context Memory Reduction Example

Figure 15 shows how context memory optimizations reduce context memory allocations. Consider a program with a call chain handler 1 $\rightarrow$ handler 2 $\rightarrow$ handler 3. The context state passed through the chain has three fields: A1 (16 bits), A2 (16 bits), and A3 (32 bits). Figure 15a shows the allocation of context memory without the optimization. It allocates 64b to store A1, A2, and A3. However, from the figure, we can see that A3 has a non-overlapping lifetime with A1 and A2, as A1 and A2 are used only by handlers 1 and 2, while A3 is used only in handler 3. With context memory optimization, for each handler call chain, the compiler analyzes the lifetimes of context fields and attempts to reuse buffer slots for context fields with non-overlapping lifetimes. As such, the compiler can allocate only a 32b context memory, allowing A3 to reuse the memory slots of A1 and A2 (Figure 15b).

A.2 Proof of Parallelization Optimizations Correctness

We prove that the transformed pipelined, parallelized program is fully equivalent to the original run to completion (RTC) program. We define the equivalence using as following:

Theorem 1. *With the same starting persistent state, after executing the same input packet sequence, a run-to-completion program P_a and a transformed pipelined, parallelized program P_b would generate the same sequence of external events and ends up in the same persistent state.*

Proof. The proof is based on the following property of αIR transformation implementation:

Prerequisite 1. *αIR transformation does not break data dependency.*

Prerequisite 2. *αIR transformation does not reorder dependent table and event generation operations, as we convert the ordering constraint into data dependency in αIR.*

We first prove that the program state and generated event values are equivalent after transformation after execution of a single packet. In case of single packet execution, the order of generate events is Thanks to the αIR's simplified memory model and operations, the only program state is table value. We need to prove

Lemma 1. *After executing a single packet, in P_a and P_b, for any table T and any key k, the value $T[k]$ will be the same; for any generate command, the content of the generated event is the same.*

Proof. We reason about the value of operations. There are two types of operations in αIR. First, all operations except table access operations in αIR are pure operations, whose value is only decided by its parameter values, and not related to any system state; Second, Only table operations $lookup, update$ and event $generate$ operations are non-pure operations. which table operations will change system state and event generation will change the external state.

Based on that, We further prove all operation output values remain unchanged after the transformation by reduction. Based on **pre-assumption 1**, All of our transformations reserve the data dependency for non-pure operations: which means that for all pure operations we do not change the input parameters, thus the output values are the same. For the values produced by $non-pure$ operation, we use reduction to prove they are not changing. We prove the following For any table T and key k, if we perform the same sequence of operations, we will end up in the same system state. We prove by reduction on **sequence length**. For the first-ever non-pure operation in the data dependency graph (in topological order), all its input parameters must be pure values, it holds in this case. At any sequence l, as all system state and values are all the same, the parameter for input $l+1$ is also the same, and we will get same output value and system states. □

After understanding the case for single packet, We could easily get the following conclusion based on the proof: 1. Reschedule of pure operations with both pre-assumption hold will not change the output value of them. 2. P_a and P_b is equivalent when a sequence of packets are executed in order without parallelism.

Next, we reason about the case when multiple packets could be executed in pipeline- or data-parallelism, based on the following properties:

Prerequisite 3. *A packet will be processed by only one single handler out of multiple replicated handlers.*

Prerequisite 4. ***Key Partition***. *For a partition P and parallel handlers H_i after the partition, if any table operation with key k happens in H_k, all table operations with key k must happen in H_k.*

Prerequisite 5. ***Event Reorder***. *The order of generated events in parallel handler for any input packet sequence is the same as if the sequence is executed without parallelism. This is achieved with reorder buffers.*

	Event	Handler	Controller	State		
				Local	Context	Persistent Table
Agilio	Inter-ME msg	A hardware thread on ME	HW Sequencer	ME local registers	Mem pool in CLS/EMEM	Table in TCAM/CLS/..
Bluefield	Inter-ARM core msg	A thread on a ARM core	Reorder queues	Stack var in DRAM	Mem pool in DRAM	Table in DRAM
FPGA	Inter-module msg	Pipelined LUTs	Reorder Buffer	Intra-module datastream	Inter-module datastream	Table in BRAM/TCAM
PANIC	Inter-RISCV core NoC msg	Instructions on RISCV core	Centralized Sche queues	RISCV core local mem	NoC msg metadata	Local State Only

Table 5: **How αIR's concept maps to different hardware targets.**

We now reason about the case that P_a and P_b is the same with multiple packets executed in parallel. We first prove that the value of table and generated events is equivalent:

Theorem 2. *For a partition P and parallel handlers H_i. For any sequence of packets, the table state change (For any table T, P_a and P_b, for any key k, the value $T[k]$ is the same for parallel (multiple RTC in parallel on different H_i) and single packet execution.*

Proof. Considering each different k is executed independently in the same sequence, leveraging Pre-assumption 3. Similarly, for a multi-partition-stage pipeline, we can prove by reduction if the **input event sequence** is the same for each partition stage, the program is identical to the original program. □

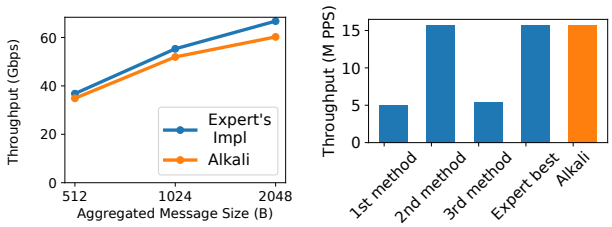
Also, based on Pre-assumption 5, the order of generated event is identical. P_a and P_b generate same event sequences, as the order and value of each event in the sequence is identical. So for any input event sequence, the transformation keeps **generated events** and **program state** unchanged. □

However, in real scenarios, we often do not want the program to be fully equivalent: for example, sometime the order of generated events do not matter to both system state and external state, and leveraging this information could lead to further performance optimizations. Thus, we leave this choice to the user: if the user believes that there is any system state (i.e, a table for counting the number of packets) that does not need to be updated in order or there are external *generate* events that do not need to happen in order, user could annotate the corresponding table and generating operations and Alkali will leverage the information to optimize the generated code.

B Additional Implementation Details

Table 5 shows how different Alkali concepts maps to heterogeneous hardware backends.

FPGA Backend. Compared to CPU architectures, FPGAs exhibit unique computational characteristics. They support massive parallelism and can be thought of as having thousands



(a) **RPC message ressaambly** (b) **JSQ RSS porting process**

Figure 16: **Compare to expert's implementation on Bluefield.**

of micro-cores operating concurrently. To fully leverage this parallelism, the backend exploits both coarse-grained parallelism at the handler level and fine-grained parallelism within each handler.

The backend first exploits coarse-grained parallelism where each handler and its replicas are mapped to an independent hardware module, ensuring that handlers can execute in parallel. Within each handler, the backend exploits fine-grained parallelism by mapping each IR operator to a dedicated hardware execution unit (*e.g.,* subtractor, adder, CAM) and converting IR's SSA values into pipelined FIFO queues that interconnect these execution units. This design maximizes parallel execution by enabling continuous data flow between IR operators.

The FIFO queues between IR operators ensure that the generated hardware design meets timing constraints. While this approach may introduce some redundant pipelining structures, we observe that the additional resource usage remains minimal compared to the available FPGA resources. Future work will focus on optimizing resource utilization to further improve efficiency.

FPGA mapping constraints (Table 1) differ from those of SoC-based NICs. We do not impose a limit on the number of compute units in the FPGA. For memory layers and sizes, we set the constraint based on the total available BRAM and DRAM on the FPGA.

C Additional Evaluation Results

Compare with a BlueField expert's implementation. We compare Alkali's message reassembly and JSQ RSS performance with a BlueField expert's implementation. The expert takes 14 hours to implement these two programs and tuning performance as much as possible. Alkali adopts the unmodified source as for other backends. As shown in Figure 16, Alkali's message reassembly performance is slightly lower than the expert's implementation (5.4% to 9.8%), this small gap is because the expert smartly chooses to reuse the buffer for the first packet in a message to store the aggregated data, avoiding allocation overhead. This buffer reuse is a BlueField backend-specific optimization that could be supported in the future. For the JSQ RSS, the NIC experts tried multiple versions of the program to test different mappings and pipelining methods, while Alkali generated code automatically generates the pipeline and achieves a performance comparable to the expert's best implementation.

Scaling IP Lookup to Large Databases using the CRAM Lens

Robert Chang[1] Pradeep Dogga[1] Andy Fingerhut[2] Victor Rios[1] George Varghese[1]

[1]*University of California, Los Angeles* [2]*Cisco Systems*

Abstract

Wide-area scaling trends require new approaches to Internet Protocol (IP) lookup, enabled by modern networking chips such as Intel Tofino [35], AMD Pensando [2], and Nvidia BlueField [55], which provide substantial ternary content-addressable memory (TCAM) and static random-access memory (SRAM). However, designing and evaluating scalable algorithms for these chips is challenging due to hardware-level constraints. To address this, we introduce the CRAM (CAM+RAM) lens, a framework that combines a formal model for evaluating algorithms on modern network processors with a set of optimization idioms. We demonstrate the effectiveness of CRAM by designing and evaluating three new IP lookup schemes: RESAIL, BSIC, and MASHUP. RESAIL enables Tofino-2 to scale to 2.25 million IPv4 prefixes—likely sufficient for the next decade—while a pure TCAM approach supports only 250k prefixes, just 27% of the current global IPv4 routing table. Similarly, BSIC scales to 390k IPv6 prefixes on Tofino-2, supporting 3.2 times as many prefixes as a pure TCAM implementation. In contrast, existing state-of-the-art algorithms, SAIL [83] for IPv4 and HI-BST [65] for IPv6, scale to considerably smaller sizes on Tofino-2.

1 Introduction

For many, Internet Protocol (IP) lookup is considered a challenge of the past. With over 40 years of research and hundreds of papers (e.g., [7, 19, 21, 22, 29, 45, 65, 83, 89]) focused on supporting IP lookup at scale, numerous schemes have been developed—some of which have been in practical use for two decades. However, these classical approaches are *single-resource* solutions, designed for conventional switch chip architectures that provided either specialized hardware like ternary content-addressable memory (TCAM) or commodity random-access memory (RAM), such as on-chip static RAM (SRAM) coupled with off-chip dynamic RAM (DRAM), but not both. TCAM enables parallel searches across wildcarded entries in a single clock cycle but requires three times more transistors per bit than SRAM and consumes hundreds of watts [5]. RAM-based approaches are cheaper but require additional complexity and memory compared to pure TCAM solutions. Thus far, commercial switch chip vendors have scaled these *single-resource* solutions by increasing hardware resources.

In this paper, we contend that it is important to reconsider IP lookup due to the continued growth of lookup tables and a recent inflection point in network hardware. A slew of new application-specific integrated circuits (ASICs), such as Intel Tofino [35], AMD Pensando [2], and Nvidia BlueField [55], have transformed the networking chip market [58]. These chips are built on two modern packet processing architectures—Reconfigurable Match-Action Tables (RMT) [9] and disaggregated RMT (dRMT) [15]—which consist of match-action processors with access to large amounts of *both* TCAM and SRAM. We review these architectures at the start of §2. This leads us to our central question: *How can we leverage modern networking chips, utilizing both TCAM and SRAM, to develop new IP lookup algorithms that scale to larger databases than classical single-resource solutions?*

Two main challenges make designing scalable algorithms for RMT and dRMT chips difficult: **(1)** Lack of an abstract model for evaluating and comparing algorithms. Chip-specific arcana such as memory allocation, metadata storage, and action bits must be carefully considered. **(2)** Large but finite resources. While TCAM, SRAM, and pipeline stages are available in substantial amounts, they require careful algorithm design to scale effectively.

Solution: We introduce the CRAM (CAM+RAM) lens, an abstract model of modern packet processing architectures, such as RMT and dRMT, paired with a set of optimization idioms. The CRAM model enables us to estimate algorithm scalability using higher-order space and time metrics, without requiring simulation of ASIC-specific details such as TCAM block sizes, SRAM page sizes, and per-stage memory. The CRAM model goes beyond classical models such as random-access machine (RAM) [23] and parallel RAM (PRAM) [41] by adding TCAM operations and using match-action dependencies to measure time complexity. The optimization idioms provide eight strategies for designing scalable algorithms.

CRAM can be generalized to other hardware architectures, such as smart network interface cards (SmartNICs) [2, 32, 55] and field-programmable gate arrays (FPGAs) [3, 34], and applied to broader network applications like packet classification [30, 44, 74] and in-network machine learning (ML) [73, 91, 93]. However, this is not the focus of our paper. For completeness, we briefly discuss these extensions in §2.4 and §2.5. Instead, we concentrate on applying CRAM to *IP lookup* because of the following observations:

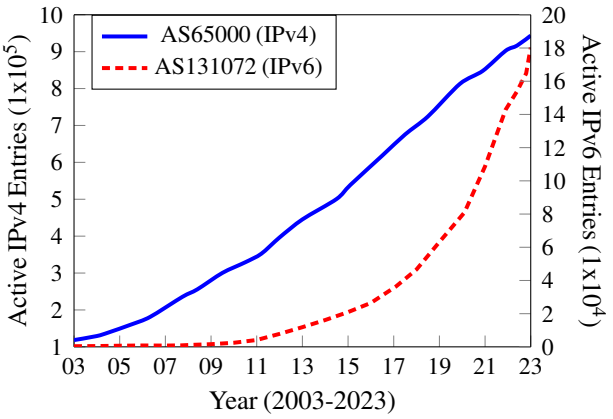


Figure 1: BGP routing table size over the past two decades

O1. Continued IPv4 growth: Over the past two decades, the global IPv4 routing table has grown *linearly* [26, 27], doubling in size every decade (Figure 1). If this trend continues, the IPv4 table could reach two million entries by 2033.

O2. Rapid IPv6 deployment: In the same period, the global IPv6 routing table has grown *exponentially* [25, 28], doubling every three years (Figure 1). Even if growth slows to a linear rate, the IPv6 table could still reach half a million entries by 2033. IPv6 prefixes are also four times wider, though typically, only the first 64 bits are used for global routing.

O3. Virtual private networks (VPNs): Some routers maintain hundreds of VPN routing tables. On such devices, publicly available routing tables account for only a fraction of the total capacity required.

O4. Other tasks: Routers need table memory for additional tasks such as network address translation (NAT) and firewalls. Minimizing the memory used for forwarding allows more features to fit on a chip.

CRAM enables us to rethink pre-existing IP lookup schemes, such as SAIL [83], DXR [89], and multibit tries, to develop new algorithms that scale to larger databases. We start with the best-of-breed algorithms from three classic IP lookup approaches—search on prefix *lengths*, search on prefix *ranges*, and trie-based search. We derive new algorithms using the optimization idioms (§2.2) and predict their scalability with the CRAM model (§2.1). Each new algorithm—rethinking SAIL (RESAIL), Binary Search with Initial CAM (BSIC), and MASHUP—offers unique strengths for different settings.

We chose Intel Tofino-2, an RMT switch chip, for our experiments because we had access to its development environment. While Intel recently announced it will not develop new Tofino models, it remains committed to supporting Tofino and Tofino-2 [53]. We expect our results to hold for dRMT, as RMT is a stricter version of dRMT with additional access restrictions.

This paper makes the following contributions:

1. IP Lookup Algorithms: Three new scalable IP lookup algorithms—RESAIL, BSIC, and MASHUP.

2. CRAM Model: An abstract model for quickly estimating the scalability of packet processing algorithms before detailed implementation.

3. Optimization Idioms: Eight design strategies for minimizing TCAM, SRAM, and pipeline stages.

4. Evaluation: Simulations and Tofino-2 implementations achieve 9X (IPv4) and 3X (IPv6) improvements over pure TCAM solutions, enabling scalability for the next decade.

The remainder of this paper is organized as follows. §2 introduces the CRAM model and optimization idioms, followed by an overview of the idioms in action. It also briefly explores other hardware architectures, broader network applications, and algorithmic requirements. We design three new IP lookup algorithms in § 3, § 4, and § 5. § 6 presents simulation and implementation results, followed by scalability experiments in §7. §8 evaluates the predictive accuracy of the CRAM model, and §9 surveys related work. We conclude in §10.

2 The CRAM Lens

We now formally introduce the CRAM model, list eight optimization idioms, and preview the idioms in action. Additionally, we briefly discuss how CRAM can be generalized to other hardware architectures, applied to broader network applications, and adapted to algorithmic requirements.

The CRAM model abstracts two modern packet processing architectures, RMT [9] and dRMT [15]. Figures depicting both can be found in Appendix A.1. A list of known RMT and dRMT implementations is provided in Appendix A.2.

RMT: RMT is a sequential pipeline architecture of match-action stages. TCAM and SRAM are partitioned among stages such that a stage cannot access the memory of other stages.

dRMT: In contrast, dRMT features programmable processors that execute match-action operations in any order. It disaggregates memory from processors by relocating TCAM and SRAM into a shared external pool.

2.1 The CRAM Model

The CRAM model adds two extensions to the RAM model [23]: first, the ability to perform an SRAM *or* TCAM table lookup; second, an explicit dependency structure between steps (as in RMT compilers [37]) that models the ability to execute multiple steps in parallel. Our goal is for the memory and run time measures of a CRAM model program to be within a small constant factor of the measures for actual hardware implementations.

Thus, a CRAM model program is parameterized by:

- A register size w, and a set R of (w-bit) registers. Let C denote the set of w-bit integers in the range $[0, 2^w - 1]$.
- Sets of unary ($Uops$) and binary ($Bops$) operators on w-bit values, e.g., $Uops = \{+, -, \sim, !\}$ and $Bops = \{+, -, <<, >>, ==, !=, <, \leq, >, \geq, \&, |, \hat{}, \&\&, ||\}$, with behavior as defined in languages like Java and P4 [58].

A CRAM model program consists of a parser P, a deparser D, and a directed acyclic graph G comprised of *steps*. A state S is a function from R to C. P is a function from all bit sequences representing packets to an initial state. D is a function from a final state back to all bit sequences representing packets.

A *step* may optionally begin with a single table lookup operation. A table t consists of a match kind (exact or ternary), a key selector function K_t, a maximum number of entries n_t, and a default value Z_t. K_t's result is a sequence of k_t bits, each representing a chosen bit position within one register of R. An entry e contains a key and associated data, with the d_t bits of associated data stored in a set of w-bit registers A_t.

For an exact match table, the key is a k_t-bit integer. A special case arises for exact match tables with $n_t = 2^{k_t}$, in which the key does not need to be explicitly stored, as it can be used to directly index into the table. For a ternary match table, the key is a pair of k_t-bit integers, a value v_e and a mask m_e, plus an integer priority p_e. All keys in the same table must be distinct.

A step consists of an optional table t followed by a sequence of statements in the form $if(cond) : dest = expr$. Here, *dest* is an element of R, *expr* contains a single unary or binary operator with operands from $R \cup A_t \cup C$, and *cond* is a potentially nested expression with operands from $R \cup A_t \cup C$. No data dependencies are allowed within this sequence, i.e., for any statement in the sequence that assigns a value to $r \in R$, r may not appear in *cond* or *expr* of any later statements. This enables all statements within a step to be executed in parallel.

A step reads register r if any bit of r appears in the output of its key selector function K_t, or as part of *cond* or *expr* in any of its statements. A step writes register r if r appears as *dest* in any of its statements.

For all steps u and v in G, if u writes r and v reads or writes r, then there must be a directed path (u,v) or (v,u). This prevents u and v from being executed in parallel. This condition must hold for all registers. A directed path (u,v) indicates that step u must be executed before step v. If there is no directed path between two steps, they may be executed in parallel.

The CRAM model introduces a set of higher-order space and time metrics. The memory footprint of a CRAM model program is evaluated by calculating the total TCAM and SRAM bits across all tables t in G. In a ternary (exact) match table, the memory used for the keys is $n_t k_t$ TCAM (SRAM) bits. For ternary match tables, we only count the v_e component of the key, as these are the logical bits involved in the match. For both types of tables, the memory used for the associated data is $n_t d_t$ SRAM bits. To compute the overall TCAM and SRAM totals, simply sum the bits used across all tables. The latency of a CRAM model program is evaluated by determining the number of steps (nodes) in the longest directed path in G.

2.2 Optimization Idioms

The following idioms can be applied together in various combinations to achieve different space-time trade-offs:

I1. Compress with TCAM: Entries containing wildcards must be expanded to fit into SRAM. For example, the prefix 1** would be stored as 100, 101, 110, and 111. However, by utilizing TCAM, these four SRAM entries can be compressed into a single TCAM entry (1**), thus saving nine bits.

I2. Expand to SRAM: In the dual of *I1*, replace a TCAM block with SRAM if the expanded forms of its prefixes are less than a small constant factor c of the original TCAM entries. We choose $c = 3$ because TCAM requires three times more transistors per bit than SRAM [82].

I3. Compress with SRAM: Despite their high memory cost, directly indexed data structures such as next hop arrays are used because they avoid the extra instructions needed for hashing. However, since most RMT and dRMT ASICs are designed with the cost of performing SRAM-based lookups—whether by hashing or direct indexing—being exactly the same, it is often more advantageous to use compressed forms of SRAM storage such as hash tables instead.

I4. Strategic Cutting: If several entries at a given node share a common prefix, we can save memory by strategically cutting at the bit position where the shared prefix ends, storing only one copy of the repeated bits. While this is how multibit tries [70] work, we extend the concept to TCAM nodes.

I5. Table Coalescing: To reduce memory waste, minimally populated logical tables can be coalesced in shared physical TCAM blocks or SRAM pages. They can be differentiated with tag bits [66]. Although tagging increases the lookup key width, it minimizes physical TCAM and SRAM fragmentation.

I6. Look-aside TCAM: IP lookup schemes are often optimized around common cases such as 24-bit IPv4 prefixes. As a result, uncommon entries (e.g., extremely short or long prefixes) tend to require undue computational or storage costs. We address this by moving the special prefixes into a separate look-aside TCAM that can be trivially searched in parallel.

I7. Step Reduction: A program's number of steps can be reduced by leveraging match-action unit (MAU) parallelism to consolidate data-independent lookups into a single stage.

I8. Memory Fan-out: In traditional RAM model architectures, a lookup table can be accessed multiple times per packet. However, many RMT and dRMT chips restrict each table to one memory access per packet. To address this limitation, we split the original table by fanning out its contents and storing entries accessed by different lookups in separate tables.

2.3 Idioms in Action

We briefly preview the idioms in action for three fundamental classes of IP lookup: search on prefix *lengths*, search on prefix *ranges*, and trie-based search.

From SAIL to RESAIL: Search on prefix *lengths* [10, 21, 40, 77, 83] splits IP lookup into two sub-problems: finding the *length* of the longest match and retrieving the *next hop*. SAIL [83], the best performing IPv4 lookup scheme in hardware settings with fast on-chip SRAM

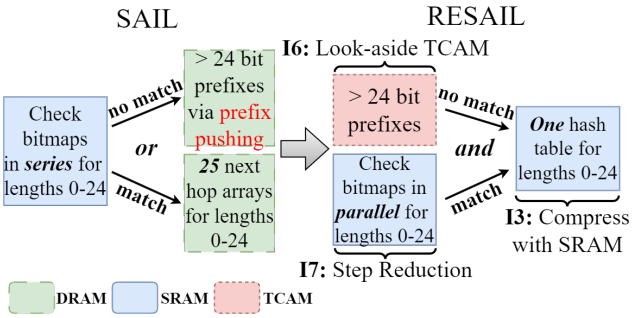

Figure 2: From SAIL to RESAIL via CRAM idioms

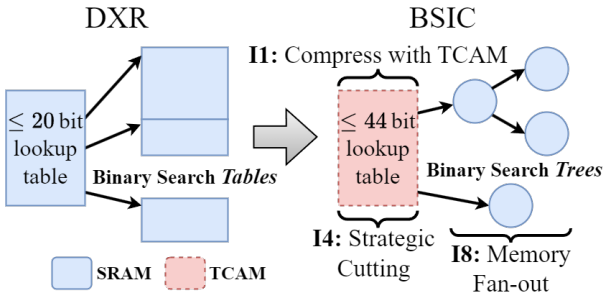

Figure 3: From DXR to BSIC via CRAM idioms

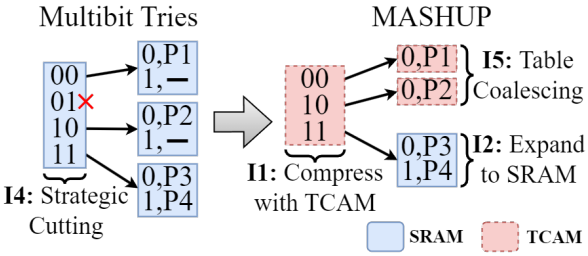

Figure 4: From multibit tries to MASHUP via CRAM idioms

and cheap off-chip DRAM, uses a bitmap of length 2^L to determine whether there is a matching prefix of length L. This works well for prefixes of up to length 24 (the vast majority); for prefixes longer than 24 bits, SAIL uses a complex scheme called pivot pushing that requires excessive prefix expansion [70]. In Figure 2, to obtain RESAIL (rethinking SAIL), we: *I6)* Move the small number of prefixes longer than 24 bits into a separate look-aside TCAM. *I3)* Compress all the next hop arrays into a single hash table using a standard encoding trick [76]. *I7)* Use MAU (stage) parallelism to reduce the number of steps by performing the bitmap lookups in parallel.

From DXR to BSIC: Search on prefix *ranges* [29,45,72,85,89] represents prefixes as range endpoint pairs (e.g., 0**→[000, 011]). Finding the longest matching prefix becomes equivalent to finding the smallest range that encompasses the lookup key. DXR [89], the fastest IPv4 software implementation of range-based searches, uses an initial lookup table to split the search space into multiple smaller binary search tables. In Figure 3, to obtain BSIC (Binary Search with Initial CAM), we: *I1)* Replace the SRAM-based initial lookup table, which supports up to 20-bit prefixes due to direct indexing, with a TCAM-based table that can store prefixes of up to 44 bits (Tofino-2 TCAM block width). *I8)* Replace each binary search *table* with a binary search *tree* that can be fanned out across stages. *I4)* Strategically cut the initial lookup table to balance TCAM required against binary search depth.

From multibit tries to MASHUP: For trie-based search [7,8,19,22,31,54,70], we specifically focus on multibit tries—tries that examine multiple bits, known as a stride, per lookup. We do not consider state-of-the-art *compressed* trie schemes like Poptrie [7] and Tree Bitmap [22], because in the CRAM model, one can directly compress with TCAM without the extra computational and storage costs of bitmap compression. Figure 4 shows a standard multibit trie for the prefixes P1 = 000*, P2 = 100*, P3 = 110*, and P4 = 111*, with a 2-bit stride at the root and a 1-bit stride at the next level—chosen by strategic cutting *(I4)* to minimize the number of downstream pointers. In Figure 4, to obtain MASHUP (mashup of CAM and RAM nodes), we: *I1)* Replace the SRAM root node with a TCAM node to eliminate the empty 01 entry, and do the same for the two upper-right nodes. *I2)* Leave the bottom-right node as SRAM, as it has no wasted space. *I5)* Coalesce the two upper-right TCAM nodes using tag bits (not shown). While the improvement is minimal in this simple example, § 5.1 demonstrates significant gains for large databases.

Although the CRAM versions of these classical schemes may seem simple, they require new algorithms to determine, for example, where to make strategic cuts and which nodes to coalesce. We elaborate on these details when describing RESAIL, BSIC, and MASHUP in §3, §4, and §5, respectively.

2.4 CRAM for other Hardware Architectures

CRAM can be generalized to hardware architectures beyond RMT and dRMT as follows: the space and time metrics of an algorithm specified in the CRAM model serve as lower bounds on the corresponding costs in any implementation, whether in programmable switch ASICs [16, 35, 52, 56], SmartNICs [2, 32, 55], FPGAs [3, 34], or purpose-built fixed-function ASICs designed solely to execute that algorithm. A faithful implementation of a CRAM algorithm achieves a minimum latency equal to that of the longest (critical) path in its directed acyclic graph. While an implementation may have a longer latency, it cannot be shorter. Similarly, the number of bits required may match or exceed the amount specified by the CRAM model, but it cannot be less.

2.5 CRAM for broader Network Applications

Although this paper focuses on IP lookup, we believe CRAM applies to other memory-intensive network applications. These include packet classification (with Access Control Lists (ACLs) and Quality of Service (QoS) as specific

instances), measurement algorithms (such as sketching), regular expression matching, and in-network ML.

In packet classification [30, 44, 74], packet headers are matched against a classifier, where the highest-priority match determines whether to allow or deny traffic, enforce a QoS policy, or apply a custom action. Measurement algorithms [17, 42, 68, 87], by contrast, dynamically build and update a stateful database that tracks network statistics such as per-flow counters, traffic volume, or frequency estimates. Regular expression matching [43, 50, 78] compares unstructured data streams against a database of predefined patterns, often represented as finite automata [14], to detect keywords, signatures, and anomalies. Lastly, in-network ML [73, 91, 93] performs inference by matching a feature vector against a classification model database, which contains decision rules mapping extracted feature values to inference labels.

In practice, these applications often rely on combinations of common data structures, such as decision trees, Bloom filters [11], tries, hash tables, and bitmaps, many of which we demonstrate how to optimize with CRAM. Consequently, our optimization idioms naturally extend beyond IP lookup. For example, the careful balancing of TCAM compression (*I1*) and SRAM expansion (*I2*) used in MASHUP to create a hybrid trie, can similarly be applied to packet classification [47, 67] and in-network ML [39, 79] algorithms that rely on decision trees. Likewise, the look-aside TCAM (*I6*) in RESAIL, which captures longer prefixes, can serve a similar role in offloading other specialized cases, such as multi-field wildcard classification rules [30], heavy-hitter flows with rare protocols [68], multi-line attack patterns [78], and fast-patch updates for classification models [92]. A more in-depth exploration of CRAM's broader applicability is left for future work.

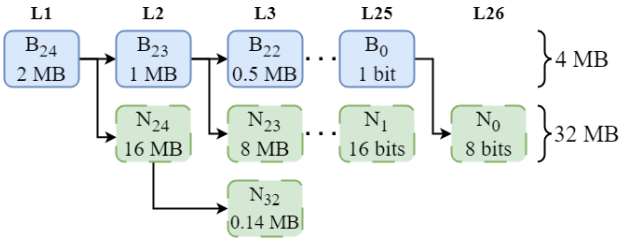
2.6 Other Algorithmic Requirements

Certain algorithmic requirements introduce additional considerations. We briefly examine how CRAM applies to algorithms that require atomic memory updates, stateful data plane operations, and pseudo-random keys.

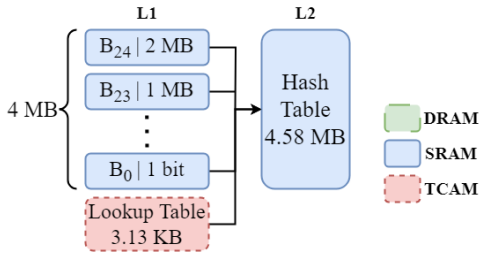
Atomic memory updates: CRAM neither facilitates nor hinders an algorithm's ability to support atomic updates [14, 46, 61]. The CRAM model provides an abstraction to estimate *performance*, not an execution model to predict *implementation feasibility*. If an algorithm requiring atomic updates can be implemented, the CRAM model should accurately predict latency and memory.

Stateful data plane operations: P4 register arrays are the primary mechanism for stateful operations in the data plane, as used in [6, 13, 68]. Stateful operations can be incorporated into the CRAM model by introducing a new SRAM-based register match table, and counting these memory bits separately alongside regular TCAM and SRAM bits.

Pseudo-random keys: For algorithms with pseudo-random keys [12, 36, 86], the efficacy of some CRAM optimization idioms is clearly reduced, as uniformly distributed random bytes are difficult, if not impossible, to compress. In contrast, other idioms are unaffected by key distribution. Specifically, table coalescing (*I5*), look-aside TCAM (*I6*), step reduction (*I7*), and memory fan-out (*I8*) can still be applied. Nevertheless, the benefits of the CRAM model are likely to be significantly diminished, as lack of compression eliminates a major source of optimization.



(a) CRAM model representation of SAIL



(b) CRAM model representation of RESAIL (*min_bmp*=0)

Figure 5: SAIL vs RESAIL for IPv4 prefixes in AS65000

3 RESAIL

By applying the optimization idioms to SAIL [83], we create a new IPv4 CRAM lookup algorithm called RESAIL. Refer to Figure 2 for the intuition to which we now add details.

SAIL Review: SAIL designates 24 as a pivot level and divides the forwarding information base (FIB) into short prefixes ($\leq$24) and long prefixes (>24). SAIL determines whether there is a length-i match for $i \leq 24$ by consulting a bitmap B_i of size 2^i in which bit p is set if and only if p is a length-i prefix in the FIB. Since the total memory footprint of the bitmaps is 4 MB, they are stored in on-chip SRAM. If a match is found in B_i, the next hop is retrieved by directly indexing into a next hop array N_i of size 2^i located in off-chip DRAM. SAIL handles prefixes of length $i > 24$ by using a complex scheme called pivot pushing that expands [70] them to 32-bit entries in N_{32}.

3.1 Applying the Optimization Idioms

We show the CRAM derivation of RESAIL using the IPv4 AS65000 BGP routing table (Sep 2023). Start with the CRAM model representation of SAIL in Figure 5a. To obtain RESAIL in Figure 5b, use the idioms as follows:

Entry	Prefix (Ternary)	Output Port
1	010100**	A
2	011*****	B
3	100100**	C
4	100101**	D
5	10010100	A
6	10011010	B
7	10011011	C
8	10100011	A

Table 1: Example routing table

Index	Key	Value
0	1001001	C
1	0101001	A
2	0111000	B
3	-	-
4	1001011	D

Table 2: Hash table for Table 1 (pivot level = 6)

1. Observe a large number (26) of data dependencies between the bitmaps and next hop arrays. This makes sense in the RAM model as it enables early exits which reduce average execution time. However, these are false dependencies because their lookup keys can be computed in parallel. Therefore, we apply step reduction (*I7*) to reduce all the bitmap and next hop array lookups into a single step. The next hop can then be determined by taking the highest priority result.

2. SAIL relies on a significant amount of DRAM (32 MB) for its directly indexed next hop arrays. Since DRAM is not available in CRAM, we replace the next hop arrays with a more compact data structure by either compressing with TCAM (*I1*) or compressing with SRAM (*I3*). Since the 25% memory penalty of d-left hashing [10] is less expensive than TCAM's 3X higher area cost, we compress with SRAM by replacing the next hop arrays with a single SRAM-based hash table.

3. SAIL uses a special next hop array N_{32} for prefixes of length >24, which are very uncommon. Its entries are prefix expanded to 32 bits. In the worst case, a single prefix may be expanded into 2^8 duplicate next hops. We address this memory inefficiency by replacing N_{32} with a look-aside TCAM (*I6*) that can store prefixes of length >24 without additional expansion.

4. The number of bitmaps serves as a trade-off between the amount of parallelism required and the hash table's memory footprint. For RESAIL, we introduce a parameter *min_bmp* that represents the smallest bitmap available. In Figure 5b, *min_bmp* is 0 which means there are a total of 25 bitmaps from B_{24} down to B_0. Increasing *min_bmp* reduces the number of parallel lookups at the cost of increased SRAM usage.

3.2 Building the Data Structures

Look-aside TCAM: Given a routing database, add all prefixes longer than 24 bits to the look-aside TCAM. Since there are very few IPv4 prefixes of length >24, little TCAM is used.

Bitmaps: For $i = 24$ down to $i = min_bmp$, construct a bitmap (B_i) of length 2^i such that every prefix of length i in the routing database is marked as a 1 at the corresponding index. If *min_bmp* is not equal to 0, use prefix expansion [70] to combine B_0 to B_{min_bmp-1} into B_{min_bmp}. Start with length min_bmp-1 prefixes and work down linearly to length 0. A bit in B_{min_bmp} is flipped from 0 to 1 only if the bit is already a 0. This prevents incorrectly overwriting longer prefixes.

Hash Table: We use d-left [10] for the hash table because it has a low probability of collision even when the ratio of entries to memory is as high as 80%. Hashing the matched prefix directly would require a separate hash table for each length from *min_bmp* to 24, greatly fragmenting memory. Instead, RESAIL uses a standard trick [76] we call bit marking that enables us to generate hash keys of a fixed length. When an entry is added to bitmap B_i, its unique 25-bit hash key is produced by appending a 1 and left shifting by $24-i$ bits. Each hash key is paired with its next hop and inserted into the hash table. The boundary of each prefix can be determined by scanning from the right for the first 1. In effect, bit marking removes the need for multiple hash tables.

Table 2 shows a hash table using 7-bit hash keys for Table 1. For simplicity, this example assumes a pivot level of 6 and a maximum prefix length of 8. Since entries 5-8 from Table 1 are longer than the pivot length, they are not placed into the hash table (they are in the look-aside TCAM instead). The hash table has a size of 5 due to d-left's 25% memory penalty. 011, a 3-bit entry, is appended with a 1 and left shifted 3 times, thus resulting in the hash key 0111000.

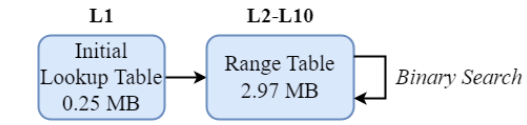
3.3 Performing Lookups

Start by performing two sets of lookups in parallel: **(1)** In the look-aside TCAM, perform a longest prefix match with the full 32-bit IPv4 address. **(2)** From B_{24} ($i = 24$) down to B_{min_bmp}, perform exact match lookups using the first i bits of the destination address to directly index into B_i.

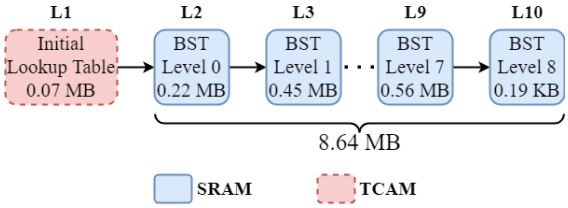
If a match is found in the look-aside TCAM, return its associated next hop. Otherwise, take the longest match across all bitmaps and generate its 25-bit hash key by bit marking.

At this step, either the next hop for a prefix match greater than 24 bits has been found or the final hash key has been created. In the latter case, use the hash key to perform an exact match lookup into the hash table to retrieve the next hop.

Algorithm 1 in Appendix A.5 contains pseudocode for RESAIL lookups. Appendix A.3.1 describes incremental updates, deletions, and insertions in RESAIL.



(a) CRAM model representation of DXR (k=16)



(b) CRAM model representation of BSIC (k=16)

Figure 6: DXR vs BSIC for IPv4 prefixes in AS65000

4 BSIC

By applying the optimization idioms to DXR [89], we create a new CRAM lookup algorithm called BSIC, capable of supporting both IPv4 and IPv6. Refer to Figure 3 for the intuition to which we now add details.

DXR Review: Inspired by [29] and [45], DXR performs binary search on range endpoints using a range table (binary search table). To reduce the depth of binary search, DXR uses an initial lookup table directly indexed by the first k bits of the address. The lookup table returns a pointer to the subsection of the range table in which binary search will be performed. DXR adds two optimizations: **(1)** Merging neighboring ranges that point to the same next hop. **(2)** Discarding right endpoints.

4.1 Applying the Optimization Idioms

We show the CRAM derivation of BSIC using the IPv4 AS65000 BGP routing table (Sep 2023). Start with the CRAM model representation of DXR in Figure 6a. As recommended by [89], set $k=16$ (D16R) for the best IPv4 results. To obtain BSIC in Figure 6b, use the idioms as follows:

1. Since DXR's initial lookup table relies on direct indexing, leaving many entries unused, we compress with TCAM (*I1*). Replacing the SRAM-based initial lookup table with a TCAM-based one reduces its memory consumption by over 3X, from 0.25 MB of SRAM to 0.07 MB of TCAM.

2. In DXR, the range table is repeatedly accessed during binary search. Since lookup tables are limited to a single access per packet in the CRAM model, the range table must be split up. We do so through memory fan-out (*I8*). By converting the range table into multiple binary search trees (BSTs) and distributing search levels across separate tables accessed at different steps, we ensure each table is visited at most once per packet. However, this greatly increases the amount of memory needed because every internal node has to store up to two pointers. In Figure 6, DXR's range table uses only 2.97 MB of SRAM while BSIC's BST levels use 8.64 MB of SRAM—a 2.9X increase. Although costly, memory fan-out is essential because duplicating the entire range table for each search level would require an infeasible amount of SRAM (26.73 MB).

Key	Value	BST Entries (for reference)
0101	Pointer to BST 1	00**
011*	Next Hop B	-
1001	Pointer to BST 2	00**, 01**, 0100, 1010, 1011
1010	Pointer to BST 3	0011

Table 3: Initial lookup table for Table 1 ($k=4$)

3. The parameter k is a strategic cut (*I4*) that balances memory usage in the initial lookup table against the number of required BST levels. Due to the high memory cost of direct indexing, DXR's SRAM-based lookup table is limited to $k<=20$. For example, if $k=24$, DXR's initial lookup table would consume 64 MB of SRAM. To effectively support IPv6, which has longer prefixes, a larger k value is required. Since TCAM can store wildcard entries without prefix expansion, BSIC's TCAM-based initial lookup table can use much larger k values, up to the underlying TCAM block width ($k=44$ for Tofino-2).

4.2 Building the Data Structures

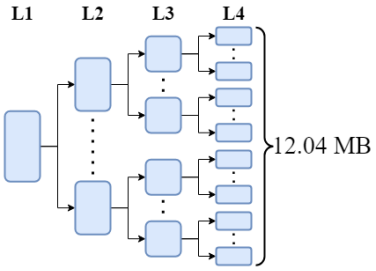
Initial Lookup Table: Given a routing database and a slice size k, populate the initial lookup table by storing all prefixes as unique k-length slices. Duplicate slices are condensed into one entry. Three cases arise when adding a prefix p of length l:

1. If $l < k$, pad p with $k-l$ wildcard (*) bits. Its associated table value is p's next hop.
2. If $l == k$, do not modify p. If there are longer prefixes that share the same k-length slice as p, its associated table value is a pointer to the corresponding BST's root node. Otherwise, its associated table value is p's next hop.
3. If $l > k$, trim p down to k bits. Its associated table value is a pointer to the corresponding BST's root node.

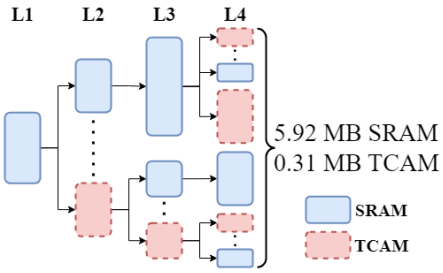
Table 3 shows an initial lookup table with k=4 created using Table 1. The maximum prefix length is 8. The Key column contains all the k-length slices while the Value column stores the associated pointers and next hops. The BST Entries column shows the prefix segments that are pointed to by the slices. Since entries 3-7 in Table 1 share the same k-length slice, they are condensed into a single key 1001 that points to BST 2.

Binary Search Trees (BSTs): To create a BST for a given lookup table entry, identify all prefixes in the database that match the entry up to the kth bit. For all such prefixes, store the remaining bits and next hops as tuples in a list. Take the list of tuples and perform the range expansion and optimizations described in [89]. We defer these details to Appendix A.4.

Use the resulting list of left endpoints to construct a BST in which every node contains four fields: pointers to the left and



(a) CRAM model representation of multibit trie (16-4-4-8)



(b) CRAM model representation of MASHUP (16-4-4-8)

Figure 7: Multibit trie vs MASHUP for IPv4 prefixes in AS65000

right child, the next hop, and the left endpoint itself. Repeat this process for all lookup table entries containing pointers.

4.3 Performing Lookups

Start in the initial lookup table by performing a longest prefix match using the first k bits of the destination address. If either a next hop is returned or a miss occurs, search terminates. If a pointer to a BST is returned, follow the pointer to the corresponding root node and form the next search key by extracting the remaining bits of the destination address. Once at a node, perform standard binary search using the search key.

Algorithm 2 in Appendix A.5 contains pseudocode for BSIC lookups. Appendix A.3.2 describes incremental updates, deletions, and insertions in BSIC.

5 MASHUP

By applying the optimization idioms to multibit tries [70], we create a new CRAM lookup algorithm called MASHUP, capable of supporting both IPv4 and IPv6. Refer to Figure 4 for the intuition to which we now add details.

Multibit Trie Review: Multibit tries are search tries that examine multiple bits per lookup, known as a stride. Reducing the number of strides decreases the number of worst-case memory accesses, but increases prefix expansion and memory usage. We assume each tree level has exactly one stride.

5.1 Applying the Optimization Idioms

We show the CRAM derivation of MASHUP using the IPv4 AS65000 BGP routing table (Sep 2023). Start with the CRAM model representation of a multibit trie in Figure 7a. We find strides 16-4-4-8 yield the best IPv4 results (§6.3). To obtain MASHUP in Figure 7b, use the idioms as follows:

1. For each trie node, we consider both compressing with TCAM (*I1*) and expanding to SRAM (*I2*). If the increase in memory due to prefix expansion [70] is less than 3X, we use SRAM. Otherwise, we use TCAM. This results in a hybrid trie with both TCAM and SRAM nodes, as seen in Figure 7b.

2. Once the trie is hybridized, apply table coalescing (*I5*) by merging partially filled nodes[1] of the same memory type into super-tables, compactly mapping them onto contiguous TCAM blocks or SRAM pages with minimal fragmentation. This requires prepending entries with a tag [66] to distinguish between logical tables. A tag of width x can coalesce 2^x logical tables into one super-table. The combination of node hybridization and table coalescing reduces SRAM usage from 12.04 MB to 5.92 MB at the cost of 0.31 MB of TCAM (Figure 7).

3. The set of strides is a parameter that serves as a strategic cut (*I4*). For a given set of strides, the trie's memory overhead is directly proportional to the number of internal pointers. A simple method for choosing strides, explained in §6.3, is to analyze the database's prefix length distribution.

We omit standard algorithms for building the MASHUP trie, as the process is identical to constructing a multibit trie, which has been extensively studied in prior work [70, 76].

5.2 Performing Lookups

Let S_i represent the i-th stride. Start in the root node by performing a lookup with the first S_0 bits of the destination address. If the current node is TCAM, perform a longest prefix match. Otherwise, perform an exact match. If a miss occurs, terminate the search. If a hit occurs, three values may be returned: a next hop, a pointer to the next node, and a unique tag. If a next hop is returned, save it. Form the lookup key for level i by extracting the next S_i bits of the destination address and prepending the current tag. Repeat the lookup process until either a leaf node is reached or a miss occurs. Upon termination, return the saved next hop.

Algorithm 3 in Appendix A.5 contains pseudocode for MASHUP lookups. Appendix A.3.3 describes incremental updates, deletions, and insertions in MASHUP.

6 Results

In this section, we introduce the databases, target implementations, and parameter values that we selected for our experiments. We use the CRAM metrics to determine the

[1] For MASHUP in §6.4, we greedily fill the largest tables with the smallest ones. This approach is easy to implement, but possibly suboptimal.

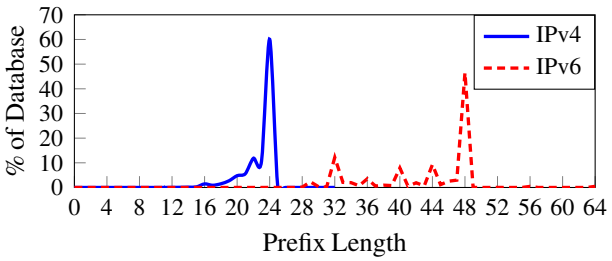


Figure 8: IPv4 and IPv6 prefix length distributions in AS65000 and AS131072, respectively, for September 2023

best IPv4 (RESAIL) and IPv6 (BSIC) algorithms *before* implementation. We then compare the resource utilizations of the best CRAM algorithms with those of state-of-the-art IP lookup schemes *after* implementation.

6.1 Databases

For IPv4, we used the AS65000 BGP routing table (Sep. 2023) [27] which has close to 930k IPv4 prefixes. For IPv6, we used the AS131072 BGP routing table (Sep. 2023) [28] which has close to 190k IPv6 prefixes. Figure 8 shows their prefix length distributions. We identify three key patterns:

P1. Prefix distributions have major and minor spikes. For IPv4, there is a major spike at length 24 and minor spikes at lengths 16, 20, and 22. For IPv6, there is a major spike at length 48 and minor spikes at lengths 28, 32, 36, 40, and 44.

P2. The majority of IPv4 prefixes are longer than 12 bits.

P3. The majority of IPv6 prefixes are longer than 28 bits.

6.2 Target Implementations

We obtained results for two different targets: an ideal RMT chip and Intel Tofino-2 (also RMT). Since RMT is a stricter variant of dRMT with additional access restrictions, we expect our RMT results to be reproducible on a dRMT chip.

Ideal RMT Chip (Simulation): We define an ideal RMT chip to be an RMT chip with Tofino-2 specifications (same memory, number of stages, etc.) [57] that can achieve 100% SRAM utilization and perform at least two dependent ALU operations per stage. The resource utilization for an ideal RMT chip is obtained through simulation by using Tofino-2 SRAM page (128x1024b) and TCAM block (44x512b) sizes. If the number of TCAM blocks or SRAM pages used by a table exceeds the amount available in a MAU (stage), the table is simply partitioned across multiple MAUs. Since Tofino-2 has 20 MAUs, results that require over 20 are considered infeasible.

Intel Tofino-2 (Implementation): The resource utilization for Tofino-2 is obtained through implementation. We implement the best CRAM algorithms using P4 and compile them with the Intel P4 compiler. P4 Insight [33] then outputs detailed resource mappings and visualizations specific to Tofino-2.

Scheme	TCAM Bits	SRAM Bits	Steps
MashUp (16-4-4-8)	0.31 MB	5.92 MB	4
BSIC (k=16)	0.07 MB	8.64 MB	10
RESAIL (min_bmp=13)	3.13 KB	8.58 MB	2

Table 4: CRAM metrics for IPv4 prefixes in AS65000

Scheme	TCAM Bits	SRAM Bits	Steps
MashUp (20-12-16-16)	0.32 MB	0.77 MB	4
BSIC (k=24)	0.02 MB	3.18 MB	14

Table 5: CRAM metrics for IPv6 prefixes in AS131072

6.3 Parameter Values

We choose parameter values based on observations from §6.1.

RESAIL's key parameter is min_bmp, the smallest bitmap available. We choose $min_bmp = 13$ because there are so few IPv4 prefixes shorter than 13 bits **(P2)**, thus minimizing the amount of prefix expansion needed.

BSIC's key parameter is k, the initial slice size. As recommended by [89], for IPv4, we choose $k = 16$. For IPv6, we choose $k = 24$ because most IPv6 prefixes are longer than 28 bits **(P3)**. Therefore, a k value that is close to but smaller than 28 can compress over 190k prefixes into just 7k TCAM entries. We briefly explore other choices of k for IPv6 and examine potential latency-memory trade-offs in Appendix A.6.

MashUp's key parameter is its set of strides. Intuitively, we want to select strides that mirror the distribution spikes **(P1)** seen in Figure 8 because they will minimize prefix expansion. For IPv4, we choose 16-4-4-8 (spikes at 16, 20, 24). For IPv6, we choose 20-12-16-16 (spikes at 32, 48). We do not select 32 as the first stride because it is too wide—especially for the root node which may contain many entries. Therefore, we decompose 32 into separate strides of 20 and 12.

6.4 Comparisons *before* Implementation

Recall that CRAM metrics enable quick estimation of algorithm scalability *before* implementation.

We present IPv4 and IPv6 CRAM metrics in Table 4 and Table 5, derived from the optimization steps in §3.1, §4.1, and §5.1, for the IPv4 and IPv6 BGP tables, respectively.

For IPv4, RESAIL outperforms BSIC in all three CRAM metrics. Between RESAIL and MashUp, RESAIL wins in TCAM and steps but loses in SRAM. However, MashUp requires 100X more TCAM than RESAIL, whereas RESAIL requires only 1.4X more SRAM than MashUp. Therefore, we determine RESAIL to be the best CRAM IPv4 algorithm.

For IPv6, we choose between BSIC and MashUp. BSIC wins in TCAM but loses in SRAM and steps. MashUp requires 16X more TCAM than BSIC, while BSIC requires roughly 4X more SRAM and steps than MashUp. As before, we prioritize TCAM because it is more expensive and limited

Scheme	TCAM Blocks	SRAM Pages	Stages
MashUp (16-4-4-8)	235	216	10
BSIC (*k*=16)	74	558	16
RESAIL (*min_bmp*=13)	2	556	9

Table 6: Ideal RMT mapping for IPv4 prefixes in AS65000

Scheme	TCAM Blocks	SRAM Pages	Stages
MashUp (20-12-16-16)	178	47	8
BSIC (*k*=24)	15	211	14

Table 7: Ideal RMT mapping for IPv6 prefixes in AS131072

than SRAM—for example, Tofino-2 contains 19X more SRAM than TCAM. Although BSIC uses more steps than MashUp, this is due to BSIC's use of BSTs, which have a high initial step cost. Therefore, we determine BSIC to be the best CRAM IPv6 algorithm *for Tofino-2*. However, for more stage-constrained ASICs, MashUp is likely better.

To verify the validity of the CRAM metrics, we explicitly map each CRAM algorithm to an ideal RMT chip and present its resource utilization in Table 6 and Table 7. This mapping, which accounts for Tofino-2 TCAM block sizes, SRAM page sizes, and per-stage memory, is precisely the complicated process that the CRAM model seeks to relieve algorithm designers of. Comparing Table 4 with Table 6 and Table 5 with Table 7, observe that the CRAM metrics accurately predict a target algorithm's resource utilization and potential scalability.

6.5 Comparisons *after* Implementation

The previous subsection compared our three new algorithms *before* implementation using CRAM metrics. Here, we compare the best CRAM algorithms *after* implementation on Tofino-2 against the best pre-existing IPv4 and IPv6 schemes.

6.5.1 Baseline Selection

We select four single-resource baselines: SRAM-only for IPv4 and IPv6, and TCAM-only for IPv4 and IPv6.

SRAM-only for IPv4: We choose SAIL [83] as our SRAM-only IPv4 baseline due to its on-chip memory bound for short prefixes, which enables it to scale very well. Although IPv4 schemes like Poptrie [7] and DXR [89] use less memory, they require too many memory accesses and stages.

SRAM-only for IPv6: We choose Hi-BST [65] as our SRAM-only IPv6 baseline because it is the most memory-efficient IPv6 lookup algorithm to date [90]. It uses a treap data structure that maps each prefix to a unique node.

TCAM-only for IPv4 and IPv6: We choose a logical TCAM as our TCAM-only IPv4 and IPv6 baseline because, although TCAM-oriented schemes exist for reducing power consumption [48] or merging multiple FIBs [51], none focus on scaling IP lookup for a single database.

Scheme	TCAM Blocks	SRAM Pages	Stages	Target Chip
RESAIL (*min_bmp*=13)	17	750	16	Tofino-2
RESAIL (*min_bmp*=13)	2	556	9	Ideal RMT
SAIL	-	2313	33	Ideal RMT
Logical TCAM	1822	-	76	Ideal RMT
Tofino-2 Pipe Limit	480	1600	20	-

Table 8: Baseline comparison for IPv4 prefixes in AS65000

Scheme	TCAM Blocks	SRAM Pages	Stages	Target Chip
BSIC (*k*=24)	15	416	30	Tofino-2
BSIC (*k*=24)	15	211	14	Ideal RMT
Hi-BST	-	219	18	Ideal RMT
Logical TCAM	762	-	32	Ideal RMT
Tofino-2 Pipe Limit	480	1600	20	-

Table 9: Baseline comparison for IPv6 prefixes in AS131072

6.5.2 IPv4 Comparison

Table 8 compares the ideal RMT resource utilization of RESAIL with the IPv4 baselines. RESAIL requires 911X fewer TCAM blocks than the logical TCAM and approximately 4X fewer SRAM pages and stages than SAIL. Although SAIL's memory scales efficiently, its high upfront cost makes it impractical for RMT-like chips. RESAIL outperforms the logical TCAM, which only supports IPv4 databases of up to 245,760 entries—about 3.8X smaller than the current IPv4 BGP table.

Table 8 also compares RESAIL on an ideal RMT chip and on Tofino-2. While RESAIL fits on Tofino-2 for AS65000, it requires nearly 1.4X more SRAM pages and 2X more stages than on an ideal RMT chip. This is because Tofino-2 reserves bits in each SRAM word for identifying actions, limiting the maximum SRAM utilization to 50%. The increase in TCAM is due to extra ternary bitmask tables needed for extracting bits.

6.5.3 IPv6 Comparison

Table 9 compares the ideal RMT resource utilization of BSIC with the IPv6 baselines. BSIC uses less SRAM and fewer stages than Hi-BST, at the cost of 15 TCAM blocks. Both BSIC and Hi-BST support the current IPv6 BGP table, whereas the logical TCAM only supports up to 122,880 entries—about 1.6X smaller than the current IPv6 BGP table.

Table 9 also compares BSIC on an ideal RMT chip and on Tofino-2. Our ideal RMT chip assumes each stage can perform at least two dependent ALU operations. However, in practice, a Tofino-2 stage can execute only one level of ALU logic. Consequently, each BST level requires two stages: one for comparing the search key and another for performing the P4 action. This creates a repeating pattern where an SRAM-intensive stage is followed by a stage with minimal

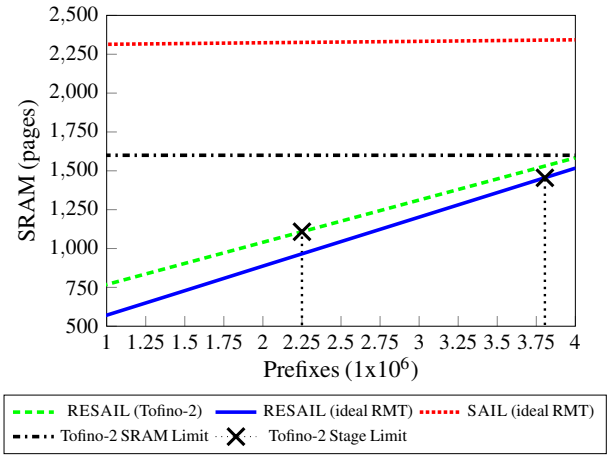

Figure 9: RESAIL vs SAIL scaling (IPv4)

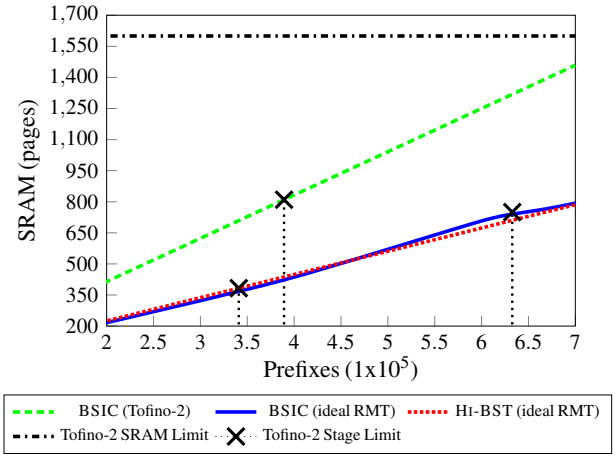

Figure 10: BSIC vs Hi-BST scaling (IPv6)

SRAM usage. Although BSIC on Tofino-2 requires 30 stages (ten over the Tofino-2 pipe limit), we successfully fit BSIC for AS131072 by recirculating each packet. However, this effectively halves the number of available switch ports.

7 Scalability

While §6 presents results for *current* BGP tables, this section presents scalability analysis for RESAIL and BSIC on larger *synthetic* routing databases. We omit scalability analysis for MashUp because it requires too much TCAM (for Tofino-2).

7.1 IPv4 Scaling

Figure 9 shows IPv4 scalability results for RESAIL and our SRAM-only IPv4 baseline, SAIL. We did not generate synthetic prefixes because the resource utilization of RESAIL and SAIL depends on the distribution of *prefix lengths* rather than the distribution of the prefixes themselves. From the perspective of memory usage, RESAIL and SAIL do not distinguish between prefixes of identical length. Therefore, we use a simple scaling model that applies a constant scaling factor to all prefix lengths. For the ideal RMT results of RESAIL and SAIL, we use the steps described in §6.2 to calculate their new utilization. For the Tofino-2 results of RESAIL, we update the corresponding P4 table sizes to reflect the larger databases.

For ideal RMT, SAIL is infeasible because its SRAM cost far exceeds the Tofino-2 SRAM limit. At any given database size, RESAIL for Tofino-2 uses more SRAM than RESAIL for ideal RMT. This is expected since Tofino-2 does not allow 100% SRAM utilization. Notably, RESAIL on an ideal RMT chip scales to around 3.8 million prefixes, 4X larger than the current IPv4 BGP table. RESAIL on Tofino-2 scales to around 2.25 million prefixes, 2.3X larger than the current routing database and significantly beyond SAIL's capacity.

7.2 IPv6 Scaling

Figure 10 shows IPv6 scalability results for BSIC and our SRAM-only IPv6 baseline, Hi-BST. For BSIC, we generated synthetic prefixes because its resource utilization depends on the distribution of prefixes and sub-prefixes. To obtain worst-case scalability results, observe that the first three bits of IPv6 prefixes in AS131072 are 000—forming an *IPv6 universe*. We use different combinations of these bits to generate significantly larger synthetic databases from AS131072, an approach we call *multiverse scaling*. Multiverse scaling assumes that the distribution of all prefix lengths scales uniformly. In practice, customer scaling causes some prefixes (e.g., /48s) to scale more rapidly than others (e.g., /24s). However, this stresses only the BSTs and not the initial TCAM, unlike multiverse scaling which models worst-case results for TCAM, SRAM, and stages. For Hi-BST, we use the memory calculation provided in [65].

As seen in Figure 10, both instances of BSIC are able to out-scale Hi-BST. For an ideal RMT chip, Hi-BST only scales to around 340k prefixes, 1.8X larger than the current IPv6 BGP Table. Even though Hi-BST is the most memory efficient IPv6 lookup scheme, it requires too many stages. Comparing the two instances of BSIC, we see that BSIC for ideal RMT scales to around 630k prefixes, 3.3X larger than the current routing database. Since BSIC for Tofino-2 uses over 2X more stages, it scales to around 390k prefixes—2X the size of the current IPv6 BGP table.

8 CRAM Model Evaluation

How predictive was the CRAM model? §6.4 showed that the CRAM model accurately predicted RESAIL and BSIC as the best algorithms for IPv4 and IPv6, respectively. We now examine the CRAM metrics in more detail.

Table 10 and Table 11 show results for RESAIL and BSIC on three models: the CRAM model, an ideal RMT model, and a Tofino-2 implementation. The three models form a hierarchy

Scheme	TCAM Blocks	SRAM Pages	Steps (Stages)	Model
RESAIL (*min_bmp*=13)	1.14	549.12	2	CRAM
RESAIL (*min_bmp*=13)	2	556	9	Ideal RMT
RESAIL (*min_bmp*=13)	17	750	16	Tofino-2

Table 10: Predictive accuracy of CRAM for RESAIL (IPv4)

Scheme	TCAM Blocks	SRAM Pages	Steps (Stages)	Model
BSIC (*k*=24)	7.45	203.52	14	CRAM
BSIC (*k*=24)	15	211	14	Ideal RMT
BSIC (*k*=24)	15	416	30	Tofino-2

Table 11: Predictive accuracy of CRAM for BSIC (IPv6)

of abstractions with increasing detail. We scale the CRAM metrics found in Table 4 and Table 5 from raw bits to TCAM blocks and SRAM pages to allow for uniform comparisons. The three models can be understood as follows:

CRAM model: Using the CRAM metrics (raw bits and dependent steps), an algorithm designer can quickly predict scalability *without* seeing the product data sheet.

Ideal RMT model: This model allows for more precise predictions but requires a *basic* understanding of the data sheet, specifically the general organization of memory and stages.

Tofino-2 implementation: This is the most accurate model but also the most complex to develop. It accounts for low-level details that are hard to glean from data sheets, such as action bits and ALU operations per stage. This often requires an *expert* with intimate knowledge of the product.

Consider the predictive accuracy for RESAIL in Table 10 as we move from CRAM to ideal RMT. The TCAM and SRAM measures reflect small rounding errors due to unit conversion. However, the latency increases significantly from 2 steps to 9 stages because, unlike dRMT, RMT stages provide *both* memory and processing—to support 556 RAM pages, more stages are required even when no additional processing is needed.

Next, consider the predictive accuracy for RESAIL in Table 10 as we move from ideal RMT to Tofino-2. There is a small additive increase in TCAM blocks due to extra ternary tables required for implementing RESAIL in P4. Additionally, SRAM pages increase by a factor of 1.35, and stages increase by a factor of 1.78. As discussed earlier in § 6.5.2, this is because the maximum achievable SRAM utilization on Tofino-2 is 50%, necessitating more SRAM pages and stages.

The predictive accuracy for BSIC in Table 11 can be interpreted similarly. The key difference is that the ∼2X increase in SRAM pages and stages from ideal RMT to Tofino-2 is due to the fact that implementing 3-way branching on Tofino-2 requires two stages for each BST level.

Based on our limited experience, the CRAM model provides a useful, easily computed initial model for estimating algorithm scalability. Although its measures of space and time are off by small constant factors, this is no different from Big O notation.

9 Related Work

Models of Computation: Abstract models like RAM [23], PRAM [41], and Turing machines [62] are widely used to analyze algorithms. The RAM model abstracts sequential computers, while the PRAM model abstracts shared memory multiprocessors. Our CRAM model abstracts network processors with two types of memory, parallelism, and programmability.

Combinations of CAM and RAM: Earlier CAM and RAM combinations optimize different metrics. CoolCAM [88], cooler TCAM [49], and EaseCAM [60] all reduce power consumption. Liu [48] compacts routing tables to reduce cost, power consumption, and thermal dissipation. Luo [51] merges FIBs in virtual routers to reduce TCAM usage. Compaction and merging are orthogonal to our ideas. Other hybrid approaches [38, 69, 75, 84] target tasks such as packet classification. In summary, no existing solution optimizes scalability for IP lookup by leveraging *both* TCAM and SRAM.

10 Conclusion

Our paper introduces new algorithms for IP lookup made possible by strategically leveraging *both* CAM and RAM. These algorithms address the scaling challenges of global routing tables and are well-suited to the architectures of modern network processors. For these processors, the CRAM lens provided a fresh perspective on algorithm design. Much like the RAM [23] and PRAM [41] models, CRAM offers metrics for quickly evaluating algorithm feasibility *before* implementation. Using the CRAM model, we developed three new IP lookup algorithms: RESAIL, BSIC, and MASHUP. RESAIL and BSIC scale to much larger databases than the best existing IPv4 and IPv6 lookup schemes, respectively, while MASHUP excels in stage-constrained hardware environments.

We aim to establish CRAM's generality by applying it to other hardware architectures (§ 2.4) and network applications (§ 2.5)—helping to "cram" more packet processing power into each unit of chip area. Ultimately, our findings underscore a simple insight for networking chip vendors: *a little TCAM goes a long way. Adding small amounts of TCAM to supplement SRAM can significantly improve scalability.*

Acknowledgments

We thank our shepherd, Xiaoqi Chen, and the anonymous reviewers for their valuable feedback. We are also grateful to David Maltz and Vladimir Gurevich for their guidance. This research was supported in part by NSF grant CNS-2333587.

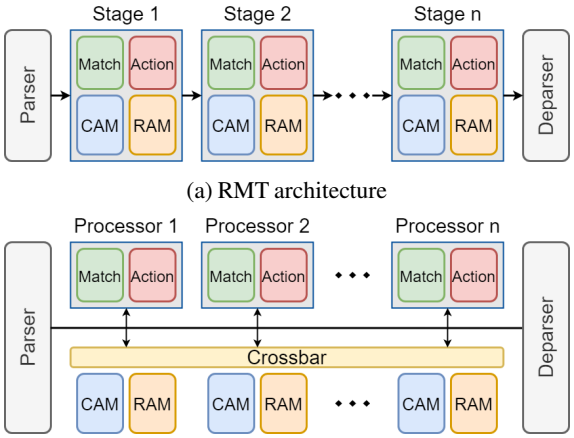
A Appendix

A.1 Packet Processing Architectures



(a) RMT architecture

(b) dRMT architecture

Figure 11: RMT vs dRMT

A.2 RMT and dRMT Implementations

Product	Architecture	Type	Sources
Intel Tofino-2	RMT	switch ASIC	[4, 18, 35]
Intel Mount Evans (E2000)	RMT	SmartNIC	[32, 71]
AMD Pensando DSC-100	RMT	SmartNIC	[2, 24, 63]
Fungible F1/S1	RMT	SmartNIC	[1]
FlowBlaze	RMT	FPGA	[59]
FlexCore	dRMT	switch ASIC	[80]
Nvidia BlueField-3	dRMT	SmartNIC	[20, 55, 81]

Table 12: Summary of known implementations

While we cannot verify all details in some cases, it is evident that TCAM, SRAM, parallelism, and programmability are present in the sources for the products listed in Table 12.

A.3 Updates, Deletions, and Insertions

A.3.1 RESAIL

Incremental updates, deletions, and insertions for RESAIL are efficient, following the same process as lookups but with modifications to the target entry. For prefixes of length *min_bmp* or greater, only two memory accesses are required (bitmap and hash table). For prefixes shorter than *min_bmp*, the operations are more costly because of prefix expansion. Update operations for prefixes longer than 24 bits are much simpler in RESAIL than in SAIL because we have eliminated pivot pushing.

A.3.2 BSIC

For BSIC, incremental updates, deletions, and insertions are costly and complex due to inherent dependencies between binary search tree levels. A separate database with additional prefix information is needed for rebuilding data structures [89]. If fast update operations are important, RESAIL and MASHUP are better choices.

A.3.3 MASHUP

Incremental updates, deletions, and insertions for MASHUP are nearly identical to lookups, except they modify the target entry. These are standard algorithms [76] for multibit tries that have been well studied. Maintaining a sorted TCAM table under these changes is non-trivial, but effective algorithms exist [64].

A.4 Range Expansion and Optimizations

Range	Next Hop
0000 - 0011	C
0100 - 0100	A
0101 - 0111	D
1000 - 1001	-
1010 - 1010	B
1011 - 1011	C
1100 - 1111	-

Table 13: Range expansion for slice 1001 (Table 3)

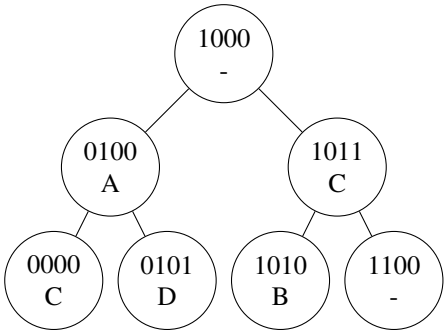


Figure 12: BST for slice 1001 (Table 3)

As in DXR [89], convert all the prefix substrings into ranges by generating their endpoint pairs. Use the endpoint pairs to create sorted, contiguous, and non-overlapping intervals that cover all possible bitstrings of the maximum length. Intervals that are added to complete the full range will "inherit" the next hop of the current lookup table entry's longest prefix match. This is necessary because it is possible for a destination address to be incorrectly directed by the initial lookup table to a BST that does not contain a legitimate match. Therefore, in the case of such a mistake, the search key will land in an interval containing the correct next hop. A simple example of range expansion for slice 1001 from Table 3 is shown in Table 13. Note that the intervals 1000-1001 and 1100-1111 were added to complete the full range. Since there are no valid longest prefix matches for slice 1001, its intervals are assigned a default value of -.

After the full range is created, merge neighboring intervals with the same next hop to reduce the number of nodes required. Discard the right endpoints as they can be inferred from the left ones. Use the remaining left endpoints to create the BST. Figure 12 shows a sample BST for slice 1001.

A.5 Pseudocode

Algorithm 1: RESAIL Lookup ($addr$, min_bmp)

Input : $addr$, IPv4 address
Input : min_bmp, smallest bitmap available
Output : hop, next hop

```
hop ← lookup_table.match(addr)
if hop ≠ None then
    return hop
for i ← 24 ; i ≥ min_bmp ; i−− do
    if B_i.match(addr ≫ (32-i)) == 1 then
        key ← (addr ≫ (32-i)) ≪ (25-i)
        key ← key + (1 ≪ (24-i))
        hop ← hash_table.match(key)
        break
return hop
```

Algorithm 2: BSIC Lookup ($addr$, k)

Input : $addr$, IPv4 or IPv6 address
Input : k, initial slice size
Output : hop_{best}, next hop

```
level ← 0
len ← 32 if IPv4, 64 if IPv6
hop_best,index
  ← lookup_table.match(addr ≫ (len−k))
if hop_best ≠ None then
    return hop_best
while index ≠ None
    hop, left, right, prefix ← bst_level.match(index)
    if prefix == ((addr ≪ k) ≫ k) then
        return hop
    else if prefix < ((addr ≪ k) ≫ k) then
        index ← right
        hop_best ← hop
    else
        index ← left
    level ← level + 1
return hop_best
```

A.6 Latency-memory trade-offs

A natural question is: *are there latency-memory trade-offs for CRAM algorithms that we can exploit to free up pipeline stages for other processing tasks?* Examining the basic CRAM model, there appears to be a clear trade-off: reducing dependency steps at the expense of increased memory or computation can lead to lower latency.

Unfortunately, on real platforms like Tofino-2, *steps* cannot be conflated with *stages* because, in RMT, stages provide a fixed amount of both memory and computation. Therefore, large lookup tables require multiple stages. While a latency-memory trade-off exists for *steps* versus memory in our three CRAM algorithms, no corresponding trade-off exists for *stages* versus memory. Instead, there is an optimal number of stages, beyond which *both* memory and latency increase.

To see this, consider Figure 13 for BSIC (IPv6), in which the only tuning parameter is k—the width of the initial TCAM table. While a latency-memory curve exists, decreasing latency by increasing k actually *increases* the number of stages required. As k grows, the number of stages needed for the initial TCAM table rises significantly, outweighing the reduction in stages gained from decreasing BST depth. In contrast, the basic CRAM model predicts reduced latency as k increases. Unfortunately, this larger TCAM table requires more *stages* but not *steps*.

As shown in Figure 13, the optimal value of k is 24, with both smaller and larger values yielding worse results. Thus, no trade-off exists between stages and memory. This is also the reason we use $k=24$ in our experiments for IPv6.

Similarly, with MASHUP, the strides are the primary tuning parameter. Again, we did not find a useful memory-latency trade-off when considering stages. Finally, RESAIL consistently requires only two steps, with no latency-memory trade-off whatsoever in either the CRAM or ideal RMT models.

Algorithm 3: MASHUP Lookup ($addr$, $strides$)

Input : $addr$, IPv4 or IPv6 address
Input : $strides$, set of strides
Output : hop_{best}, next hop

```
hop_best ← default
table ← root
tag ← None
index ← 0
level ← 0
while table ≠ None
    key ← addr[index:index+strides[level]]
    hop, next_table, tag ← table.match(tag, key)
    if table.hit() then
        if hop ≠ None then
            hop_best ← hop
        index ← index + strides[level]
        level ← level + 1
        table ← next_table
    else
        break
return hop_best
```

While there is no useful latency-memory trade-off for a *fixed* database size in our three algorithms, an obvious trade-off emerges as the database size *increases*: the number of stages (latency) must increase, at least to provide more memory. This is implicit in the linear trade-off curves shown in Figure 9 and Figure 10. Notably, the y-axes in these figures represent SRAM pages. However, since more SRAM requires proportionally more stages, Figure 9 and Figure 10 can be rescaled to (instead) depict stages versus database size, maintaining exactly the same curve shapes.

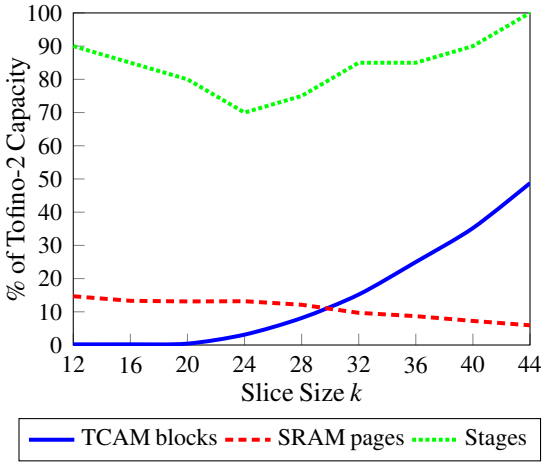

Figure 13: BSIC IPv6 latency-memory trade-off on an ideal RMT chip for AS131072 (Sep 2023)

Quicksand: Harnessing Stranded Datacenter Resources with Granular Computing

Zhenyuan Ruan Shihang Li [†] Kaiyan Fan Seo Jin Park [+] Marcos K. Aguilera [‡]
Adam Belay Malte Schwarzkopf [†]
MIT CSAIL [†]*Brown University* [‡]*VMware Research by Broadcom* [+]*USC*

Abstract. Datacenters today waste CPU and memory, as resources demanded by applications often fail to match the resources available on machines. This leads to stranded resources because one resource that runs out prevents placing additional applications that could consume the other resources. Unusable stranded resources result in reduced utilization of servers, and wasted money and energy.

Quicksand is a new framework and runtime system that unstrands resources by providing developers with familiar, high-level abstractions (*e.g.,* data structures, batch computing). Internally Quicksand decomposes them into *resource proclets*, granular units that each primarily consume resources of one type. Inspired by recent granular programming models, Quicksand decouples consumption of resources as much as possible. It splits, merges, and migrates resource proclets in milliseconds, so it can use resources on any machine, even if available only briefly.

Evaluation of our prototype with four applications shows that Quicksand uses stranded resources effectively; that Quicksand reacts to changing resource availability and demand within milliseconds, increasing utilization; and that porting applications to Quicksand requires moderate effort.

1 Introduction

It is rarely the case that the resources demanded by applications (*e.g.,* compute, memory, etc.) exactly match those available on machines in a datacenter. This mismatch wastes performance and capacity, because as one resource becomes a bottleneck, others are left idle, a notion referred to as *resource stranding* [8, 21, 23, 35, 40, 53]. In an ideal world, applications would use exactly the resources they need without being constrained by their physical availability on each machine.

One idea that could help solve this problem is memory disaggregation—the ability to allocate memory from a common pool that spans across machines. Unfortunately, memory disaggregation forces programmers to give up control of whether they are accessing local or remote memory, which sacrifices performance. This problem is severe enough that cloud providers currently limit their use of memory disaggregation to only the coldest memory pages [32].

Recent granular programming models, by contrast, give the programmer control over where resources are consumed. They decompose applications into granular *units* that bundle together portions of compute and memory, referred to as "proclets" [49], "components" [19], "actors" [39], and "functions" [29]. Each unit resides entirely on a specific machine, so it is guaranteed that state contained within it remains local. Units communicate with each other via the network using remote procedure calls (RPCs), so it is clear to programmers when a memory access could be remote. In some systems, units migrate across machines in response to resource pressure [49]. But this fails to address resource stranding, as the migratable units still couple different resources. Granular programming is also often hard to adopt, as programmers must manually decompose their programs into small units.

Quicksand is a new framework and runtime system that unstrands resources by providing a more performant alternative to disaggregation and offers familiar, high-level programming interfaces to application developers. Quicksand takes inspiration from the idea of granular programming, but crucially lets applications allocate resources of different types largely independently across a rack of machines. Quicksand unstrands resources through three key ideas.

First, Quicksand introduces *resource proclets*, a new abstraction that helps developers specify the use of different resource types in a fine-grained and independent manner. Resource proclets are categorized by the type of resource they primarily use and their functionality: a *compute proclet* handles threads of computation, while a *memory proclet* manages data structures and heap data. Resource proclets can be independently scheduled across machines and efficiently communicate with each other via a low-latency, high-bandwidth datacenter network (e.g., 400 GbE). Compute proclets can efficiently access data from remote memory proclets through prefetching, minimizing the performance impact of cross-machine data access. This allows applications to exploit stranded resources wherever they are available.

Second, Quicksand manages the size of resource proclets so they can be efficiently migrated through the network to rebalance resource use across machines. If a resource proclet becomes too large, it impedes fast migration; and if it becomes too small, communication and metadata overheads will dominate. To address this issue, Quicksand *splits* and *merges* resource proclets to keep them granular: splitting a memory proclet partitions its state into two shards (*e.g.,* by key range of a hash table), and splitting a compute proclet breaks up its work (*e.g.,* loop iterations) into two parts. Merging does the reverse and combines resource proclets, so the right number of proclets emerges dynamically.

Finally, Quicksand provides developers with familiar, high-level libraries while internally managing fine-grained resource allocation through resource proclets, freeing developers from

having to reason about low-level resource management. Developers use these libraries in the same way they use familiar data structures and compute abstractions, such as C++ STL containers and MapReduce-style parallel programming. The libraries internally decompose these high-level constructs into resource proclets. Consequently, Quicksand occupies a sweet spot: its libraries control how applications are decomposed and where memory will be accessed locally by leveraging semantic information. This not only hides the complexity of managing low-level granular primitives but also helps avoid unnecessary and costly remote memory accesses.

To illustrate the power of Quicksand, consider a machine learning pipeline, running on datacenter GPUs shared across applications—a common scenario today [28, 57, 61]. The pipeline preprocesses batches of raw images on CPUs in stages (resizing, noise reduction, etc.) before training a model on the GPUs. We want to keep GPUs fully utilized because they are expensive [31, 37, 38], use CPU and memory wherever available as needed, without having to overprovision them for pre-processing stages. Quicksand's resource proclets enable the pipeline to use stranded resources (*e.g.,* denoise images in memory on another server). To keep GPUs saturated, Quicksand splits and merges resource proclets to adapt its CPU and memory use to changing GPU availability.

Quicksand targets rack-scale environments where machines are typically connected with an overprovisioned network that offers high full-bisectional bandwidth. We prototyped Quicksand, and ported four applications to it: an image processing pipeline for machine learning, a latency-critical service from the DeathStarBench suite [17], a data-intensive sorting tool, and a serverless video encoding system from ExCamera [16]. Experiments show that Quicksand achieves 2–8× better performance than Hermit [45], a state-of-the-art memory disaggregation system, and 2–3× better throughput than Nu [49], a prior granular programming system. Additionally, Quicksand enables millisecond-scale fast reaction to changing load and resource availability by splitting and merging proclets, increasing utilization by 25%–60% compared to baselines that necessitate overprovisioning. Application developers enjoy these benefits with moderate programming effort.

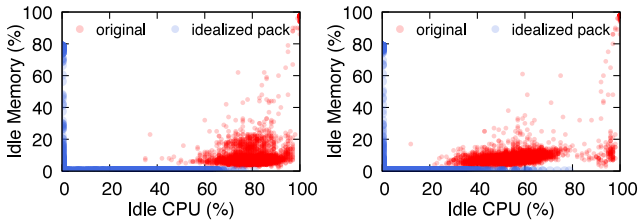
Our prototype has some limitations. It implements only compute and memory proclets, but we envision proclet support for other resource types (e.g., SSDs). Resource proclets are also not inherently fault-tolerant, although existing techniques for fault-tolerant granuluar computing apply [49].

2 Background and Motivation

2.1 Resource Stranding in Datacenters

Resource stranding occurs when hardware resources on machines are underutilized due to a mismatch between the resources demanded by applications and those available, resulting in wasted capacity [8, 21, 35, 40, 53].

We investigate resource stranding by analyzing traces from an Alibaba datacenter [23]. Alibaba colocates batch tasks with high-priority online services to increase utilization. The workload has a strong diurnal pattern [23], so we analyze a demand trough (at t = 500k seconds) and a demand peak (at t = 540k seconds). Figure 1 shows a scatterplot of idle CPU and memory, with each red point representing a specific machine. Even at peak load, machines have an average of 56% idle CPU and 10% idle memory. These idle resources exist because operators overprovision to handle uncertainty about the resources the online services will consume, the first source of stranded resources. This is especially critical for memory, as running out of it leads to crashes. Even though Alibaba already overcommits resources, this approach fails to utilize all available resources, as the level of idle resources is hard to predict and varies over time.



(a) At t = 500k seconds (load trough). **(b)** At t = 540k seconds (load peak).

Figure 1: Resource stranding in an Alibaba datacenter, shown by red points (*original*), arises from overprovisioned resources to accomodate load bursts of online services. Even with theoretically maximal binpacking of batch tasks based on perfect future resource predictions (blue points, *idealized pack*), stranding remains as batch task demands mismatch with available machine resources.

Resource stranding persists even in an idealized scenario without resource overprovisioning. To illustrate this, we simulate an ideal (but impractical) setting where Alibaba can perfectly predict resource needs and densely pack additional batch tasks to maximize utilization. This simulation iteratively fills each machine with batch tasks that have resource requirements and execution times equal to the averages of existing batch jobs in the trace. This continues until no more tasks can be added without exceeding the machine's CPU or memory capacity. This approach is unrealistic because it assumes perfect knowledge of future resource usage, including anticipating load spikes from online services.

Even in this hypothetical setting, some resources remain idle, as shown by the blue points (*idealized pack*) in Figure 1. For instance, under peak load (t = 540k), an average of 14% idle CPU and 3% idle memory persist on machines. These points, clustering along the axes, indicate machines with surplus of one resource type but scarcity of the other. This results from the mismatch between the CPU/memory demand ratios of batch tasks and the availability ratios of those resources on machines, another source of stranded resources.

Resource stranding is a widespread phenomenon: for instance, Microsoft reports up to 30% stranded memory in Azure [8], and Google's datacenters see wasted compute resources because best-effort jobs placed to fill spare compute

encounter out-of-memory events [54].

2.2 Memory Disaggregation

Memory disaggregation can alleviate resource stranding by exposing memory over the network, either from another server or a shared memory pool. Disaggregation can be supported at the kernel layer through paging (*e.g.,* Infiniswap [22], FastSwap [2], Hermit [45]) or at the bus layer through cache coherence (*e.g.,* GenZ [18], CXL [11, 34], LegoOS [51]). Bus-level solutions require new hardware that has not yet been deployed at the time of writing.

Memory disaggregation is appealing as it can be adopted without application changes. However, it faces two major limitations. First, while memory disaggregation facilitates pooling memory across machines, it does not extend this capability to CPUs. Hence, it fails to effectively utilize stranded CPU resources. Second, the transparency of memory disaggregation comes at a performance cost. Any memory access could be local or remote, and remote accesses may introduce delays that stall the CPU. This lack of awareness poses challenges for code optimization, especially problematic when compute intensity (*i.e.,* CPU cycles per byte of data access) is low. For example, Hermit [45] (a state-of-the-art memory disaggregation system) delivers only 9%–11% of the non-disaggregated throughput for a web service application (§7.1).

2.3 Granular Computing Systems

Recent cloud programming trends suggest decomposing applications into granular units, such as "actors" in Ray [39], "proclets" in Nu [49], and "components" in ServiceWeaver [19]. This evolution aligns with the increasing adoption of serverless and microservices paradigms in cloud development. Granular programming can utilize stranded CPU and memory by distributing small, granular units across machines. Unlike transparent memory disaggregation, granular programming explicitly defines unit boundaries; memory accessed within a unit is local, and memory can be accessed remotely only deliberately through remote procedure calls. Hence, developers can optimize their programs by structuring them to operate on local memory when compute intensity is low and exploit remote memory when it is high.

Among granular computing systems, Nu enables fast unit migration across machines to achieve *fungibility*—the ability to use resources interchangeably across machines [49]. However, Nu has major limitations: it still bundles different resources (such as CPU and memory) and fails to avoid resource stranding. Additionally, developing applications in Nu is hard, as developers must manually decompose the application into units and maintain their granularity. Developers may compose units with incorrect granularity, or create initially-granular units that become large over time (*e.g.,* due to memory growth). Improper sizing results in slow migration and imbalanced load, which impacts utilization and performance.

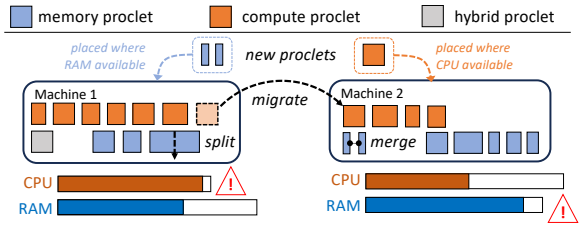


Figure 2: Quicksand places resource proclets where they are available: *e.g.,* memory proclets (blue) on machine 1 with available RAM; and compute proclets (orange) on machine 2 with spare CPU. Quicksand splits, merges, and migrates resource proclets as they grow, shrink, and as resource pressure develops.

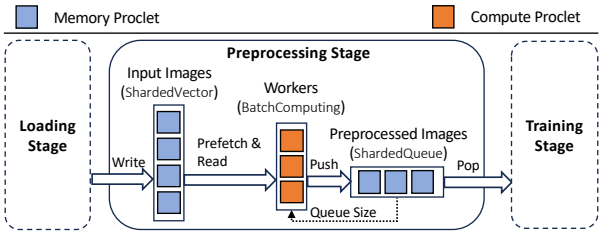
3 Quicksand Overview

Quicksand integrates the principles of resource disaggregation and granular computing in a new system. Quicksand reclaims stranded resources by decoupling resources and aligning allocation with actual use, while making it easy for application developers to use resources wherever they are available.

To dissect the use of different resources, Quicksand introduces *resource proclets*, granular abstractions categorized based on functionality. A compute proclet manages a set of computing threads, while a memory proclet manages megabytes of heap data. Both types of proclet can be dynamically split and merged to ensure a granular size. Each resource proclet functions as an independent unit, with Quicksand's runtime scheduling and migrating it based on application resource demands and availability. Resource proclets efficiently communicate with each other via the datacenter network (when remote) or a fast local data path (when local).

Quicksand places resource proclets on machines based on resource availability. Proclet sizes may change over time. For example, in Figure 2, the application is inserting data into its memory proclets on the left machine, and removing data from its memory proclets on the right machine. Quicksand reacts by dynamically splitting and merging resource proclets to maintain their granularity. In situations where a machine becomes oversubscribed, such as when the left machine's CPU capacity is nearly depleted, Quicksand migrates compute proclets to the right machine where additional CPUs are available. Similarly, Quicksand migrates memory proclets from machines nearing full to those with available space. Additionally, Quicksand supports hybrid proclets (as depicted on the left machine) for scenarios that require a combination of CPU and RAM. These hybrid proclets are also migratable, but resource proclets are easier for Quicksand to schedule because they only require a substantial amount of one resource.

To simplify the use of resource proclets, Quicksand offers developers familiar high-level programming abstractions, freeing them to focus on application logic without thinking about decomposing applications, maintaining granularity, or manually managing resources. Applications link with Quicksand's libraries that provide high-level abstractions: data structures, batch-parallel computations, and building blocks for stateless and stateful services.



```
void preprocessing_stage(qs::ShardedVector<Img>& inputs,
                         qs::ShardedQueue<Img>& outputs) {
 auto f = [outputs](Img i) { outputs.push(preprocess(i)); };
 auto scaling_policy = qs::batch::MinimizeQueue(outputs);
 qs::batch::ForAll(inputs, f, scaling_policy);
}
```

Figure 3: An example of an ML training pipeline illustrating the decomposition of the application into resource proclets using Quicksand's high-level abstractions. It highlights the preprocessing stage, where distributed workers process input images read (with prefetching) from a sharded vector and output to a sharded queue. Quicksand's batch computing framework dynamically scales the number of workers based on the output queue size to match the training stage's consumption rate.

Internally, these libraries provide their functionality by orchestrating resource proclets through a common auto-sharding layer, which dynamically splits and merges resource proclets to keep them granular. This layer is built on resource proclets to decouple state and compute, and leverages Quicksand's runtime to promptly respond to changes in resource demand and availability. Crucially, all of this resource management happens transparently to the application developer, who interacts only with the high-level abstractions.

4 Design

We now discuss how developers create Quicksand applications using its high-level abstractions (§4.1); describe the libraries in Quicksand that support these abstractions (§4.2); explain Quicksand's auto-sharding layer, which Quicksand libraries use to map high-level constructs into resource proclets (§4.3), and finally explain resource proclets in depth (§4.4).

4.1 Quicksand Applications

Application developers write a Quicksand program without worrying about how it is decomposed into resource proclets or how resources are managed. Quicksand handles resource allocation, scaling, and load balancing transparently, freeing developers from manual resource management. It facilitates this by offering three high-level abstractions with familiar APIs: sharded data structures, batch computing, and stateless and stateful services. These abstractions allow developers to focus on application logic while Quicksand's runtime efficiently manages the underlying resources.

The sharded data structures provide in-memory distributed data storage, while exposing APIs akin to C++ STL containers. For example, application developers use `emplace_back` to insert data into a sharded vector and use iterators to traverse the vector. The batch computing abstration enables distributed computing over sharded data structures, exposing declarative API functions such as `Map`, `ForAll`, `Reduce`, etc. The service abstraction offers wrappers for building elastic stateless and stateful services. Developers register a handler function for stateless services, or a class that implements application-specific stateful logic for stateful ones.

To showcase Quicksand's high-level abstractions, let's examine an ML training pipeline that runs on shared datacenter GPUs, which often experience changing availability [28, 57, 61]. As shown in Figure 3, the pipeline has three stages: loading, which loads input images from storage into memory for training; preprocessing, which preprocesses the loaded images; and training, where GPUs train a model on the preprocessed images.

Since input images may consume significant memory, the loading stage utilizes Quicksand's `ShardedVector` to efficiently distribute images across machines using sharding, where each shard is associated with a memory proclet. During preprocessing, the pipeline leverages Quicksand's batch computing abstraction, deploying compute proclets across machines to preprocess the images in parallel. Quicksand might schedule compute and memory proclets into different machines to combine their available resources, and it employs transparent prefetching of the vector to efficiently access remote memory. The pipeline then pushes the preprocessing outputs into a sharded queue for consumption by GPUs. This design might increase network traffic between stages, but it allows Quicksand to decouple compute and memory resources, resulting in better resource utilization and scalability.

If too few compute proclets are provisioned, the GPU can be starved for data, resulting in underutilization of expensive GPU resources. Conversely, provisioning too many compute proclets wastes CPU resources and increases memory usage, as the queue will grow if images are preprocessed faster than the GPU can consume them. To strike this balance, Quicksand dynamically scales the number of compute proclets in the preprocessing stage based on the queue length, aiming to keep the queue shallow while ensuring image production matches the GPU's consumption rate (details in §4.2).

Implementing the core logic of the preprocessing stage requires only a few lines of code (Figure 3). This code has no mention of resource proclets or sharding, the developer does not need to think about resource decomposition.

4.2 Quicksand Libraries

Quicksand offers high-level abstractions via a collection of libraries that applications link to. Each library is dedicated to a specific abstraction, mapping high-level constructs into granular resource proclets through its default policies and mechanisms for splitting and merging. The auto-sharding layer (§4.3) initiates the actual splitting and merging, calling upon these policies and mechanisms accordingly. These libraries abstract away the complexities of resource proclet management, allowing developers to focus on application logic rather than resource allocation and decomposition.

```
void emplace_back(T value)
T& at(size_t index)
size_t size()
```
```
void seal()
  - Seals the vector, making it immutable and iterate-able.
void unseal()
  - Unseals the vector, allowing modifications.
const_iterator cbegin(), cend()
  - Provides read-only iteration with prefetching.
```

Figure 4: Quicksand's sharded data structure API (e.g., a subset of the `ShardedVector` shown above) mirrors C++ STL interface, with additional methods to support efficient iteration with prefetching.

```
void ForAll(ShardedDS& input, F f, Policy p)
  - Applies f to all items of a sharded data structure in parallel.
```
```
ShardedDS Map(ShardedDS& input, F f, Policy p)
  - Transforms input items with f in parallel.
```
```
T Reduce(ShardedDS& input, F f, T init, Policy p)
  - Reduces input items with f and init in parallel.
```

Figure 5: A subset of Quicksand's batch computing API for parallel computation over sharded data structures, with support for custom scaling policies via an optional argument.

The sharded data structure library offers general-purpose data structures, including all common C++ STL container types, with an interface similar to the C++ STL. For instance, Figure 4 shows a subset of the `ShardedVector` API.

Leveraging Quicksand's auto-sharding layer, the library distributes data structures' contents across memory proclets based on a data structure-specific sharding key. For instance, the `ShardedVector` shards over vector indices, such that each memory proclet holds data for a contiguous range; a `ShardedMap` shards into ranges of the map's key space, with each memory proclet managing key-value pairs for a designated key range. The library supports iterators with prefetching for efficient traversal.

The memory proclets of a data structure enforce lower and upper bounds on their heap sizes. Upon element insertion, the auto-sharding layer checks if the shard becomes too large (or too small on element removal). In such cases, the library splits the memory proclet or merges it with a neighboring one.

The mechanisms to split and merge are data structure-specific. For example, the `ShardedQueue` in Figure 3 only supports insertion at the back (`push`), so only the last memory proclet can grow. Consequently, a split always occurs at the tail proclet, generating a new, empty memory proclet for subsequent insertions. By contrast, a sharded map is partitioned by key range and any of its proclets can grow. When a proclet goes above its size threshold, it splits its key range in half and selectively moves key-value pairs to the new proclet.

The batch computing library provides common parallel batch computing operators (*e.g.,* `ForAll`, `Map`, `Reduce`) over input and output stored in sharded data structures, see Figure 5. The computations are internally performed by compute proclets that split and merge via the auto-sharding layer to dynamically adjust parallelism based on available resources or user-specified policies.

```
StatelessServ Register(F handler)
  - Registers a stateless service.
StatefulServ<ID> Register<ID>(F handler, State& s)
  - Registers a stateful service with a client ID type and state.
void Invoke(StatelessServ& s, Args args)
  - Invokes a stateless service with arguments.
void Invoke(StatefulServ<ID>& s, ID id, Args args)
  - Invokes a stateful service with a client ID and arguments.
```

Figure 6: Quicksand's service library API for registering and invoking stateless and stateful services.

Recall the ML training example in Figure 3. The program uses the `ForAll` function to parallelize image preprocessing. Initially, it creates a single compute proclet, responsible for processing the entire range of the input `ShardedVector` by applying `f` to each element. When there are idle CPU cores in the cluster, the library splits the input range of the compute proclet, creating a new compute proclet to handle the other half. By iteratively splitting compute proclets, the library can utilize all available CPUs in the cluster. The batch computing library supports custom scaling policies, such as the `MinimizeQueue` policy in Figure 3. Every two milliseconds, it checks the queue length: if below a small threshold, it adds compute proclets. Otherwise, it adjusts the number of compute proclets by a proportional factor of the queue's shrinking rate, aligning production with consumption speed.

The completion time of compute proclets may vary, due to data skew or slow machines. Upon the completion of a fast compute proclet, the auto-sharding layer detects an idle core and reactively subdivides an ongoing proclet. This process effectively automates the mitigation of stragglers.

The service library facilitates the creation of elastic low-latency services, whether stateless or stateful, capable of dynamically responding to fluctuations in load. Figure 6 shows its API for application developers.

The stateless service uses compute proclets through the auto-sharding layer. Each invocation request from clients implicitly has a random 64-bit number, which Quicksand internally uses as the sharding key in the auto-sharding layer to evenly distribute the requests among compute proclets.

The stateful service uses pairs of compute and memory proclets managed by the auto-sharding layer. Each client request explicitly comes with a per-client or per-session identifier, which Quicksand uses as the sharding key to implement sticky routing through the auto-sharding layer.

Internally, both stateless and stateful services parallelize client interactions to scale out by dispatching requests to different compute proclets based on sharding keys.

Both service types adopt the same policy: Quicksand monitors the CPU utilization of each compute proclet at two-millisecond intervals. If the average usage exceeds one core, the library splits it into two, enabling services to scale up in response to load increase. Conversely, a service winding down from a load spike may have compute proclets that underutilize CPU resources; the library reactively merges proclets, adapting a service's resources to its current load. This two-

```
class VectorShard<T> : std::vector<T> {
  using Key = size_t; using Val = T;
  std::pair<Key, VectorShard<T>> Split() { /*...*/ }
  void Merge(VectorShard<T>& other) { /*...*/ }
};
using MyShardedVector<T> = qs::ds::ShardedDS<VectorShard<T>>;
```

Figure 7: A user can implement their own sharded vector by creating a wrapper (`VectorShard`) around `std::vector`, specifying the types of the sharding key and value, and implementing the split/merge functionality for the vector data.

millisecond interval strikes a balance between reactivity and stability. A shorter interval could lead to frequent, unnecessary adjustments due to transient load spikes, while a longer interval might delay responses to real workload changes. When splitting and merging a stateless service's proclets, the library splits or combines the key ranges they are responsible for. For a stateful service, the application developer provides `Split` and `Merge` functions over the service's internal state stored in proclets.

4.2.1 Extensibility

While Quicksand's libraries cover common use cases for cloud applications, users (*i.e.,* developers) can extend them for additional functionality. For instance, they could augment the sharded data structure library with new data structures, or the batch computing library with new operators (*e.g.,* flatmap, joins, or streaming-based transformations). The service library likely needs no extension as its stateless and stateful APIs cover all intended use cases, with applications supplying the business logic.

The interface of Quicksand libraries facilitates this extensibility. For example, a user can implement their own version of sharded vector in a few lines of code, as shown in Figure 7. The user wraps `std::vector`, adding type definitions for the sharding key and value, and provides implementations for `Split` and `Merge`, which split a vector shard's elements and combine two vectors' elements, respectively. Then, the user defines a new, application-facing type (`MyShardedVector`) by aliasing to the `ShardedDS` class provided by Quicksand's auto-sharding layer, parameterized with the shard implementation (`VectorShard`).

4.3 The Auto-Sharding Layer

Quicksand's libraries use the auto-sharding layer to shard high-level programming constructs into resource proclets and maintain their granularity. The auto-sharding layer accomplishes three tasks: (1) it keeps track of how sharding keys correspond to shards encapsulated within resource proclets, (2) it directs the execution of a given function to the appropriate shard, and (3) it splits or merges shards based on a user-supplied policy using the shard-specific split or merge functionality.

The auto-sharding layer is implemented by Quicksand's `AutoSharder` class, which requires a sharding key type, a proclet type to be sharded, and two policy functions `ShouldSplit` and `ShouldMerge`. These functions assess whether a shard's current state calls for splitting or merging. In turn, `AutoSharder` provides a `Route` method to direct a function invocation to the right shard, given a sharding key, a hint, and the function lambda. The hint indicates whether the shard might need merging or splitting.

Internally, `AutoSharder` keeps a map from sharding key ranges to resource proclets. This map is centrally stored in a mapping proclet, but each `AutoSharder` instance caches it to reduce load. The `Route` method checks the local map and dispatches the lambda to the appropriate shard. If the local cache is stale, the shard rejects the dispatch, in which case `Route` consults the central map and retries. After executing the lambda, the `Route` method uses the hint in combination with `ShouldSplit` or `ShouldMerge` to possibly split or merge the proclet shard using the shard-specific functions.

As an example, the sharded vector in Figure 7 can be built with `AutoSharder` using the vector index as the sharding key and memory proclet as the proclet type. The `ShouldSplit` and `ShouldMerge` functions check that the shard's heap size falls within a desired range. The sharded vector's `push_back` method routes execution of `std::vector`'s `push_back` to the last shard, while the `at` method routes execution to the appropriate shard based on the index key.

4.4 Resource Proclets

Quicksand defines three resource proclet types. The intent is that each resource proclet type primarily consumes one type of resource (compute, memory, etc). The actual definitions of resource proclets are based on their functionality: a compute proclet executes computations through a lambda API, while a memory proclet stores state through a read/write API. §7.4.1 shows that these abstractions in practice indeed meet the intent of using a single resource: compute proclets have a CPU-to-memory ratio greater than 0.1 core per MiB, so they mainly consume CPU; and memory proclets have a ratio of less than 0.001 core per MiB, so they mainly consume memory. Quicksand's runtime monitors the resource usage of resource proclets, issuing warnings if usage exceeds the thresholds. Quicksand also defines a hybrid proclet that provides both compute and memory functionality to support colocation of compute and memory when necessary for performance; it has a more balanced CPU-to-memory ratio (between 0.001–0.1 core per MiB). Appendix §A.2 shows the full API.

4.4.1 Compute Proclet

Compute proclets are conceptually akin to computing threads; developers use them to implement an application's computational logic. A compute proclet still consumes some memory to hold thread stacks and a small heap for temporary data. To create a compute proclet, Quicksand provides two functions: `MakeCompProc(Fn)` simply executes a given function, and `MakeCompProc(Range, Fn)` runs the function over a specified range of data. The range variant is useful for splitting (and merging similarly): upon splitting a compute proclet, the range is split into half, and the new compute proclet takes over the other half. Like popular serverless platforms, the compute

proclet API enables developers to execute computations without thinking about server infrastructure or locality. Unlike serverless functions, compute proclets can split, merge, and migrate during their execution, enabling Quicksand applications to utilize idle CPUs and react to compute pressure.

Compute proclets support both ephemeral and long-running computations. A compute proclet can create more compute proclets and wait for their completion. However, a compute proclet cannot directly access another compute proclet's memory. Instead, compute proclets communicate with memory proclets (via the network or the local data path) to share computation results, which we discuss next.

4.4.2 Memory Proclet

Memory proclets are conceptually akin to small heap regions (a few MBs); developers use them to keep application data. A memory proclet may consume a small amount of CPU to read and write data. Quicksand offers the `MakeMemProclet` function to create a memory proclet encapsulating a user-defined shard. This function returns a smart pointer to the memory proclet that exposes the `Read` and `Write` functions. Quicksand's libraries use these functions (and their asynchronous counterparts) to operate on the memory proclet's contents. As memory proclets can be remote, `Read` returns a copy of the indexed element.

Quicksand supports *sealing* memory proclets to make them read-only. Sealed memory proclets allow for efficient runtime prefetching, as there is no risk of reading stale data even with concurrent accesses. When a memory proclet is sealed and code invokes `Iterate` on it, the Quicksand runtime leverages the semantic information provided by the high-level abstractions to predict access patterns. It then prefetches subsequent elements in the background, effectively hiding access latency for remote data. Finally, memory proclet supports splitting and merging by invoking the `Split` and `Merge` functions of the encapsulating shard.

4.4.3 Hybrid Proclet

Hybrid proclets colocate a computing thread with heap data, providing compute-data locality for applications with low compute intensity. However, a hybrid proclet offers the least placement flexibility, as it may consume both nontrivial amounts of CPU and memory resources. Consequently, Quicksand discourages the use of hybrid proclets via constrained APIs. A hybrid proclet cannot be created directly; it can be realized only by promoting an existing memory proclet using an explicit `Hybridize` call. Once hybridized, it provides the `Offload` method to execute a C++ lambda within the hybrid proclet (computation shipping). A hybrid proclet can be demoted to a memory proclet by calling `Dehybridize`.

5 Implementation

Our Quicksand prototype has 10k lines of C++ code, which implement resource proclets atop Nu [49].

We co-designed the Quicksand runtime with resource proclets, leveraging information from the thread scheduler and slab memory allocator to precisely monitor per-proclet resource usage, with minimal overhead (<1%). Each machine's runtime periodically reports resource usage and idle resources to Quicksand's centralized controller, facilitating centralized decision-making on proclet placement and migration.

To safely and efficiently support resource proclet splitting and merging, we employ RCU locks [36]. Proclet access operations acquire the RCU reader lock, while splitting/merging events acquire the writer lock. This design minimizes the impact on application performance by shifting most synchronization overheads to infrequent splitting and merging events.

Initiation of splitting and merging, managed by the auto-sharding layer (§4.3), involves updating the sharding mapping stored in the centralized mapping proclet. Stale clients efficiently discover updates by fetching the latest mapping from an append-only log at the centralized proclet. This log sequentially records all changes made to the mapping.

We optimized our data structure library (§4.2) to minimize network overhead. For instance, our sharded data structures offer batching, grouping mutations (*e.g.,* `push_back` operations in `ShardedVector`) locally before flushing to memory proclets using large network packets. This significantly improves the performance of small-object operations. In addition, the library supports concurrent flushing, adapting parallelism to align with the application's production rate. Similarly, it supports concurrent prefetching for iterating over data structures.

6 Application Case Studies

We now describe our experience implementing and porting four applications for Quicksand. They cover batch and latency-critical applications, a range of compute intensities, memory usage, and resource proclet usage (Figure 8). Thanks to Quicksand's high-level abstractions, all applications required moderate programming effort, in terms of lines of code and development time; porting existing applications (social network and video encoding) involved modifying 3%–5% of the code and building new applications (ML training and sorting) required adding about 20 Quicksand-related lines of code. Figure 3 illustrates the decomposition of the ML training application, while Figure 9 presents the others. Sorting is the only application that uses hybrid proclets.

ML training pipeline. We implemented the compute-intensive batch application in Figure 3 as an OpenCV-based pipeline with a data loading stage, a CPU-based preprocessing stage, and a GPU-based training stage. We use images from the ImageNet ILSVRC2012 dataset [50] as our training data (35.3 GiB). Our implementation has 300 LoC, of which 20 LoC relate to Quicksand. We leverage Quicksand's `ShardedVector` to store input images, `ShardedQueue` for preprocessed images, and the batch computing library for parallel preprocessing. The batch computing abstraction dynamically scales workers based on the output queue size, matching the training stage's consumption rate. Since our testbed lacks GPUs, we simulate the training stage by consuming images at a rate of 0.2 milliseconds per image, based on the reported

Apps	Type	Dataset	Comp. Intensity	Mem. (GiB)	Abstractions Used	# resource proclets: comp.+mem.+hybrid	QS-related LoC/ Total LoC	Development Time (days)
ML Training	Batch	ILSVRC 2012 [50]	High	35.3	`Sharded{Queue, Vector}` `BatchComputing`	158 + 1,340 + 0	21 / 307	1
Social Network	Latency-critical	soc-delicious [13]	Low	33.4	`ShardedMap` `StatelessService`	91 + 19,034 + 0	98 / 1800	2
Sorting	Batch	TritonSort [46]	Low	112.0	`ShardedPartitions` `BatchComputing`	182 + 4,108 + 4,108	22 / 98	1
Video Encoding	Batch	bunny_480p [9]	High	17.5	`ShardedVector` `BatchComputing`	168 + 625 + 0	203 / 6083	4

Figure 8: Our four case study applications leverage (different) high-level abstractions provided by Quicksand, resulting in moderate porting and development efforts. Their memory usage and the number of resource proclets vary over time, with peak values reported.

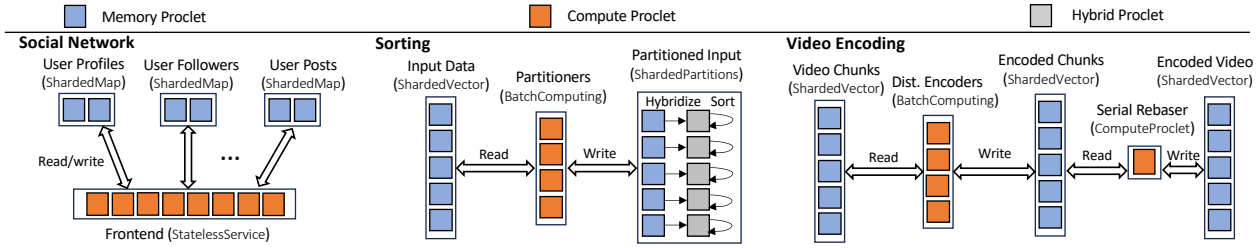


Figure 9: Quicksand's high-level abtractions automatically decompose applications into resource proclets and maintain their granular sizes.

rate of image classification models [14, 44].

Social Network. We ported the SocialNetwork application from DeathStarBench [17]. This is a latency-critical, Twitter-like web service, originally built using twelve microservices. It has a low compute intensity and uses 33.4 GiB memory. The original implementation employs an NGINX web frontend for processing client requests, which accesses user data stored in Redis. This architecture naturally separates CPU-intensive (frontend) and memory-intensive (data store) components, aligning well with Quicksand's model of resource decoupling. Consequently, it is straightforward to port this application to Quicksand, and gain benefits such as resource fungibility and elasticity that are not present in the original implementation.

Our port structures the application into a stateless front-end service layer and several stateful key-value stores, using Quicksand's `StatelessService` and `ShardedMap` abstractions. The stateless service wraps all the business logic originally handled by the microservices, while the sharded map stores user data originally handled by Redis. Our port has 1.8k LoC compared to the 6.8k LoC in the original application. This reduction is primarily due to the elimination of boilerplate code required for interacting with frameworks like gRPC, Redis, etc., which were used in the original implementation. In our port, 98 LoC are Quicksand-related, while the remaining code is application logic. By contrast, an already-granular implementation with Nu [49] (2.2k LoC) required developers to manually implement substantial functionality (such as decomposition, shard resolution, etc.) in the application code. Quicksand provides this functionality out-of-the-box and adds extra functionality (such as load-adaptive dynamic sharding) despite reducing the code size by 20%.

Sorting. We built an in-memory distributed sorting tool that sorts 400 million 100B key-value pairs, similar to TritonSort [46]. This is a batch application with low compute intensity and uses 112 GiB of memory. Our implementation has 307 LoC, of which 21 LoC are Quicksand-related. As depicted in Figure 9, our implementation uses Quicksand's batch computing library and custom data structures. It has two stages: *(i)* shuffling input data into key-based ranges; *(ii)* parallel sorting of these ranges. The first stage uses the batch computing library to concurrently read input data from a `ShardedVector` (with prefetching) and insert them into a `ShardedPartitions` data structure. This data structure uses the input as the sharding key and maintains an unordered vector of key-value pairs within each shard. Upon splitting, it uses the quickselect algorithm [25] to evenly partition these pairs into two ranges. After shuffling, sorting each partition (*i.e.,* the data of each shard) produces the final result. Given the low compute intensity of sorting, we improve locality by promoting memory proclets into hybrid proclets for fast in-place sorting, rather than sorting using compute proclets.

Video encoding. We ported the distributed video encoder from ExCamera [16], a batch application with high compute intensity designed for serverless platforms like AWS Lambda [6]. ExCamera has two stages: 1) a parallel encoding stage that encodes all video chunks, and 2) a sequential rebasing stage that stitches all encoded chunks together in sequence. Since ExCamera's code is no longer maintained or runnable, we created a faithful baseline implementation. Our port, as shown in Figure 9, utilizes Quicksand's `ShardedVector` and batch computing abstractions. It initially loads video chunks from the `bunny_480p` dataset (with a memory footprint of 17.5 GiB) into the input `ShardedVector`. It then uses the batch computing library to read chunks in parallel from the input vector, encodes them, and writes the outputs into another `ShardedVector` for encoded chunks. Finally, a single

compute proclet rebases all chunks from the encoded vector into the final encoded video. The port changes 203 LoC of the application's total 6k LoC.

7 Evaluation

Our evaluation focuses on answering following questions:

1. Does Quicksand unstrand resources better than existing disaggregation and granular programming systems (§7.1)?

2. How does Quicksand respond to changes in resource availability (§7.2) and resource demand (§7.3)?

3. Does the resource proclet abstraction effectively separate the use of different resources (§7.4.1)?

4. Does Quicksand's rapid scaling and fine granularity improve utilization and performance (§7.4.2 and §7.4.3)?

Setup. Our testbed has eight machines, each equipped with an Intel Xeon E5-2680 v4 CPU and 64 GB memory, connected by a 100 GbE network, running Linux kernel v5.10. One machine hosts Quicksand's cluster controller. For the ML pipeline experiments, we use one machine as the GPU server and the remaining six machines as the CPU servers (for preprocessing). For the social network experiments, one machine serves as the load generator and the remaining six machines as servers; and for the sorting and video encoding experiments, all seven machines run the application.

7.1 Using Stranded Resources

We first investigate how Quicksand performs on machines with stranded resources (*e.g.,* servers with ample free CPU but little memory or vice-versa). We use the ML training pipeline, which has high compute intensity, and the social network application, whose compute intensity is low. To comprehensively evaluate Quicksand's ability to handle various cases of stranded resources, we divide the same amount of total resources between machines in different ways (Figure 10). In the *CPU-unbalanced* setup, three machines have few available CPU cores, but memory is equally distributed; in the *memory-unbalanced* setup, three machines have little memory, but available cores are equally distributed; in the *both-unbalanced* setup, three machines have few CPU cores and plenty of memory, while others have plenty of available CPU cores, but little available memory.

We compare Quicksand to two existing systems: Hermit [45], a state-of-the-art memory disaggregation framework, and Nu [49], a recent granular programming framework. Hermit is not designed to scale past the CPU resources of one machine (§2.2). To overcome this limitation, we give Hermit an advantage by running one Hermit instance per machine and evenly distributing tasks among them. This requires extra programming effort that counteracts Hermit's transparency promise. We compare the performance of all systems on the unbalanced setups to an ideal, balanced setup, where the aggregate resources are the same but distributed over only three machines, each with ample CPU and memory. Since Hermit is designed for memory disaggregation, we also evaluate it on a *memory-disaggregated* setup, which partitions the same amount of total resources into three CPU servers with minimal memory and three pure memory servers.

	Machine 1-3		Machine 4-6	
	# CPUs	RAM (GiB)	# CPUs	RAM (GiB)
Ideal	26	12	N/A	N/A
CPU-unbalanced	6	6	20	6
Mem-unbalanced	13	1	13	11
Both-unbalanced	6	11	20	1
Mem-disaggregated	26	1	0	11

Figure 10: To create resource stranding, we partition resources (78 CPUs, 36 GiB memory) in different ways: CPU-unbalanced, memory-unbalanced, and both-unbalanced. We also consider a memory-disaggregated setup and an ideal balanced setup.

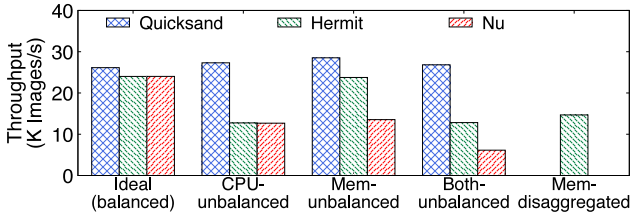

Figure 11: The ML pipeline on Quicksand combines resources from different machines, achieving throughput similar to the ideal scenario. Quicksand has 1.2–2× higher throughput than Hermit in unbalanced setups, as Hermit cannot use stranded CPU resources and suffers from kernel paging overheads when combining memory resources; and Quicksand's throughput exceeds Nu's by 2–4× in unbalanced setups as Nu always bundles CPU and memory resources.

A good result for Quicksand would show performance similar to Hermit and Nu on the ideal (balanced) setup, and better performance than these systems in the unbalanced setups. With high compute intensity, a strong result would show Quicksand coming close to the ideal setup's performance; while when compute intensity is low, resource proclet network's overheads dominate, and a good result would show limited performance loss compared to the ideal setup.

Figure 11 shows the results for the compute-intensive ML pipeline. In the ideal setup, each machine uses all 26 cores and ≈11 GiB memory, achieving throughput of 26k images/sec. In unbalanced setups, Quicksand achieves similar throughput despite the resource imbalance[1], thanks to its effective semantic-based data prefetching mechanism. Hermit and Nu achieve 92% of the throughput of Quicksand in the ideal setup—the overhead arises because they spawn a large number of compute threads, causing lower cache locality and extra context switches. By contrast, Quicksand splits and merges compute proclets to adapt to the available CPU resources. In the mem-unbalanced setup, Hermit combines stranded memory resources across machines through paging, but paging is expensive and limits Hermit to 83% of Quicksand's throughput. Hermit cannot combine stranded CPU resources, as its modified baseline evenly distributes tasks; Quicksand therefore achieves 2× higher throughput in the CPU-unbalanced

[1] In fact, Quicksand's throughput in unbalanced setups is up to 10% *above* the ideal setup; this is an artifact of lighter last-level cache contention.

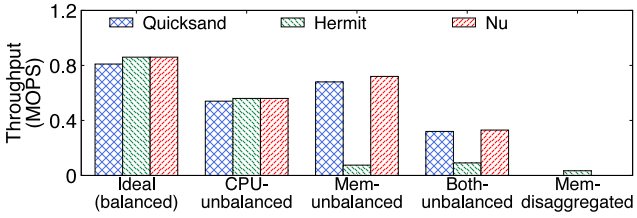

Figure 12: The social network application's low compute intensity poses a challenge in using stranded resources. Yet, Quicksand attains 40%–84% of the ideal throughput in severely imbalanced setups, outperforming Hermit, which achieves only 4%—11% due to poor locality from paging. Nu matches Quicksand's performance as it allows developers to control memory placement to optimize locality.

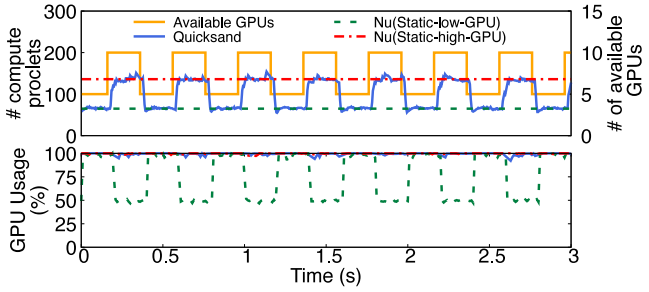

Figure 13: Quicksand quickly adapts the ML pipeline's preprocessing rate to the changing GPU availability by scaling the number of compute proclets. Compared to two Nu-based baselines that statically provision CPU resources, Quicksand achieves either 25% higher GPU utilization or uses 25% fewer CPU cores.

and both-unbalanced setups. Nu cannot combine stranded CPU and memory, as its proclets bundle different types of resources; Quicksand therefore outperforms Nu by 2–4×.

Figure 12 shows the results of the social network application with low compute intensity, where it is challenging to hide the overhead of accessing data on remote machines. In the ideal setup, each machine uses all 26 cores and ≈11 GiB memory, and all three systems achieve similar throughput (810k ops/sec). Quicksand's performance is slightly lower than the baselines as its auto-sharding layer adds a ≈6% overhead. All systems also achieve similar throughput in the CPU-unbalanced setup because the application has a low compute intensity. When there is memory imbalance (memory-unbalanced and both-unbalanced), it is crucial to optimize data locality to achieve good performance. Hermit's transparent paging prevents programmer control over memory placement and results in poor locality: Hermit achieves 9–11% of the ideal throughput in unbalanced setups (4–8× worse than Quicksand), and merely 4% in the memory-disaggregated setup. By contrast, Nu allows programmers to control placement to optimize locality and achieves 40–84% of the ideal throughput, similar to Quicksand.

These results demonstrate that Quicksand successfully uses stranded resources, and matches or outperforms state-of-the-art disaggregation and granular computing frameworks.

	Number of shards	Avg. shard size (MiB)	Avg. mem. usage (GiB)
Quicksand	1,086–19,034	1.7	17.25
Static-small-table	1,053	14.0	14.75
Static-large-table	19,928	1.4	27.5

Figure 14: In the social network application, Quicksand dynamically splits and merges memory procets of the hash table, ensuring granularity. This allows Quicksand to mitigate memory pressure (gray region) with rapid proclet migration, resulting in stable low tail latency. The Nu-based *static-small-table* baseline statically provisions a small hash table, resulting in larger shards that are slower to migrate, thereby experiencing disruptions. The *static-large-table* baseline, by contrast, statically overprovisions a large hash table, achieving low latency but using 37% more memory than Quicksand.

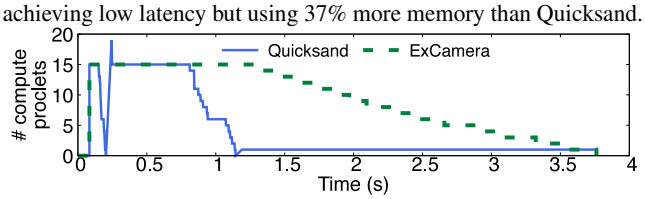

Figure 15: In the video encoding application, Quicksand adapts to the changing parallelism of the application by reducing the number of compute proclets, saving 60% CPU compared to ExCamera.

7.2 Adapting to Changing Resource Availability

We now study how well Quicksand reacts to changes in the availability of scarce resources.

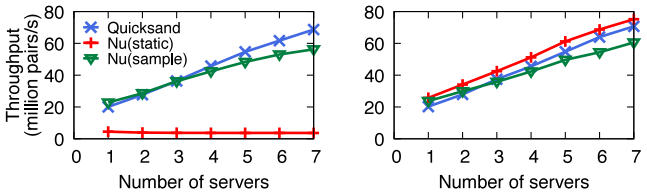
7.2.1 Reacting to Changing GPU Availability

In this experiment, we vary the number of GPUs available for the training stage of the ML pipeline between five and ten every 200ms, mimicking the burstiness reported by Park et al. [44]. We measure the amount of CPU cores allocated by Quicksand for the pre-processing stage. We compare Quicksand to two baselines that statically provision CPUs, implemented using Nu: *static-high-GPU* provisions CPUs for the peak number of available GPUs (ten), while *static-low-GPU* provisions for the minimum number (five). A good result for Quicksand would demonstrate it saturating available GPUs, comparable to *static-high-GPU*, without wasting CPUs.

Figure 13 shows that Quicksand rapidly scales compute proclets by splitting or merging them to match changing GPU availability. As a result, Quicksand achieves GPU saturation, while *static-low-GPU* achieves only 75% average GPU utilization. Quicksand consumes an average of 105 cores, but *static-high-GPU* consumes 140 cores. This shows that Quicksand effectively adapts to rapid changes in GPU availability.

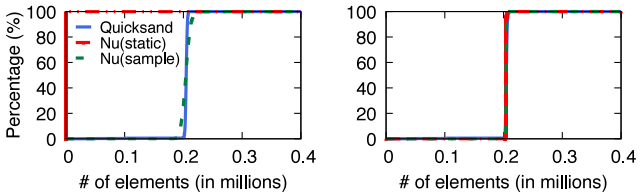
7.2.2 Reacting to Memory Pressure

We now investigate if Quicksand can quickly react to memory pressure to avoid performance disruption by splitting, merging, and migrating resource proclets across machines.



(a) Normal distribution. **(b)** Uniform distribution.

Figure 16: Sorting normally-distributed data, Quicksand achieves higher throughput than the *static* baseline because it avoid stragglers through dynamic splitting. For both normally and uniformly distributed data, Quicksand achieves higher throughput than the *sample* baseline because it avoids the extra sampling phase.



(a) Normal distribution. **(b)** Uniform distribution.

Figure 17: The CDF of shard sizes in the sort benchmark. Quicksand balances shard sizes well by dynamically splitting resource proclets. The *sample* baseline also balances shard sizes but requires an extra phase. The *static* baseline experiences serious load imbalance with a normal distribution of input due to its static partitioning.

We run the latency-critical social network application on all available machines with constant load (1.5 MOPS), and launch a memory antagonist that keeps allocating new pages at one machine, creating memory pressure. The memory usage in the social network application mainly comes from its sharded hash table, so the experiment focuses on this data structure. We compare Quicksand to two baseline systems that statically provision the number of shards, implemented using Nu: *static-small-table* provisions for a small hash table with a few shards; while *static-large-table* baseline overprovisions for a large hash table with many shards. A good result for Quicksand would show it achieving constant, low latency despite memory pressure and consuming less memory than the *static-large-table* baseline.

Figure 14 shows the results. Between 0–30 seconds, there is no memory pressure, so all setups achieve low and stable 99$^{\text{th}}$ percentile latency (≈0.3 ms). The memory antagonist starts at t=30 seconds and all setups react by migrating shards during the gray region. Both Quicksand and *static-large-table* experience only a small latency increase as they can quickly migrate their small (<2 MiB) shards. However, Quicksand uses 37% less average memory than *static-large-table*, as it rightsizes the number of shards through dynamic splitting and merging. *Static-small-table*, by contrast, ends up with a few large shards (≈14 MiB) that are slow to migrate, and therefore experiences latency spikes. After resolving memory pressure through migration, the latency returns to normal. These results show that Quicksand effectively mitigates memory pressure while keeping good tail latency and memory usage.

7.3 Adapting to Changing Resource Demand

We now study if Quicksand adapts to changing resource demand caused by phased program behavior or load imbalance.

7.3.1 Phased Application Behavior

The video encoding application has multiple concurrent stages that encode chunks, followed by a serial stage that stitches together encoded chunks. We run the ExCamera[6,16] encoding scheme[2] and compare our performance to the baseline. A good result for Quicksand would show its resource usage matching the application's available parallelism.

Figure 15 shows the results. The concurrent encoding stages in the beginning (0–0.8s) have high parallelism, and both ExCamera and Quicksand use 15 CPUs. Quicksand's gap at 0.2s occurs because our prototype performs synchronization between two consecutive parallel stages; when Quicksand scales back up, it briefly overshoots the right level of parallelism and scales back down to 15 compute proclets. After 0.8s, the parallelism gradually decreases as encoding tasks complete. In Quicksand, compute proclets write their outputs to a sharded vector built from memory proclets; once they finish encoding, they terminate. Quicksand starts the serial stitching stage with a single core at 1.2s, which combines data from the sharded vector. By contrast, ExCamera's serverless implementation couples compute and state; the encoding lambdas must remain alive until the stitching lamdba consumes their output, leading to many allocated but idle CPUs between 1.2–3.7s. Even though Quicksand and ExCamera complete the job at the same time, Quicksand saves 60% CPU resources, represented by the area between the two lines.

This result demonstrates that Quicksand can quickly adapt to phased application behavior to improve resource utilization without impacting performance.

7.3.2 Load Imbalance

We study Quicksand's ability to adapt to load imbalance, which causes poor utilization and stragglers [10]. We use the sorting application with an input that follows either a skewed normal distribution or a uniform distribution without skew. We compare Quicksand with two baselines implemented using Nu. The *sample* baseline handles the skewed input by running an initial phase that samples 0.5% of the input to learn its distribution and choose appropriate pivots to partition the data across machines. The *static* baseline ignores skew and partitions by uniformly spaced pivots. Quicksand avoids the need for sampling, as its auto-sharding dynamically splits memory proclets when they become too large. We measure the sorting throughput and shard size distribution as we scale the number of machines. A good result for Quicksand would show that it adapts to skew and achieves balanced partitions without the cost of an additional sampling phase.

Figure 16a shows the sorting throughput for the normal

[2] In ExCamera's notation, this means encoding chunks of 6 frames in parallel, and then combining them in strings of 16 chunks [16].

Apps	Compute proclet			Memory proclet		
	CPU (cores)	Mem (MB)	Ratio (core/MB)	CPU (cores)	Mem (MB)	Ratio (core/MB)
ML training	1.0	0.7	1.43	0.0038	31	0.00012
Social network	0.58	5.4	0.11	0.00044	1.3	0.00034
Sorting	0.34	1.3	0.26	0.022	32	0.00068
Video encoding	0.75	4.1	0.18	0.0016	12	0.00013

Figure 18: The CPU and memory usage for compute and memory proclets, averaged over time and across all proclets within each category, along with their CPU-to-memory ratios. Hybrid proclets, used only in the sorting application, have an average use of 0.28 cores and 32 MB memory, resulting in a CPU/memory ratio of 0.0087.

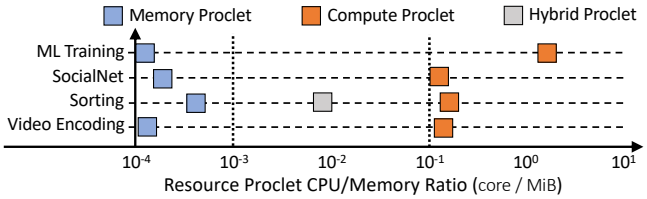


Figure 19: Different types of resource proclets vary significantly in CPU/memory ratio (*x*-axis, in log-scale). Compute proclets range from 0.1 to 10 in ratio, hybrid proclets range from 0.001 to 0.1, and memory proclets range from 0.0001 to 0.001.

distribution. *Static* performs and scales poorly due to stragglers caused by load imbalance, while *sample* and Quicksand perform and scale well. Figure 17a explains the load imbalance of *static*: a few partitions have most of the data, while others have little data. *Sample* and Quicksand have balanced partitions of 200K elements and thus balance load well across machines. Quicksand performs better than *sample* as it avoids the need for an extra sampling phase, saving 1.4 seconds.

Figures 16b and 17b show the results for a uniform distribution. Here, *static* is optimal because it partitions the input well without sampling work. Quicksand is slightly slower because splitting resource proclets incurs overhead. *Sample* is the slowest due to the extra sampling phase.

These results show that Quicksand efficiently adapts to load imbalance by splitting resource proclets dynamically.

7.4 Drill-Down Experiments

7.4.1 The Effectiveness of Resource Proclets

We now investigate the effectiveness of resource proclets in separating the usage of different types of resources. Figure 18 presents the resource consumption for each application's resource proclets. For each type of resource proclet, it shows the CPU and memory usage (averaged over time and across all proclets within that category) along with the CPU/memory ratio (*i.e.,* average CPU usage to average memory usage).

Different types of resource proclets exhibit drastically different CPU/memory ratios, as shown in Figure 19. Compute proclets primarily utilize CPU resources with small memory usage, exhibiting CPU/memory ratios between 0.1 and 10;

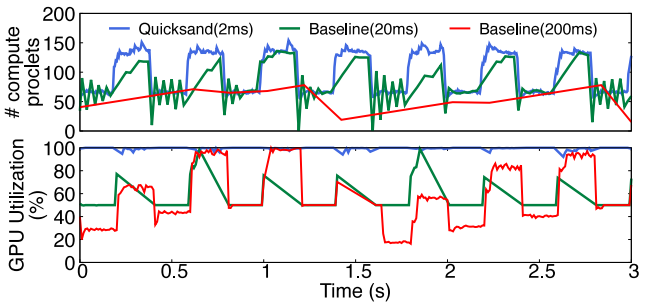

Figure 20: Quicksand's rapid scaling (2 ms) is crucial for saturating GPUs in the ML training pipeline. Slowing down reaction time to 20 ms or 200 ms causes GPU utilization to drop as it takes too long to provision enough CPUs to keep the GPUs busy.

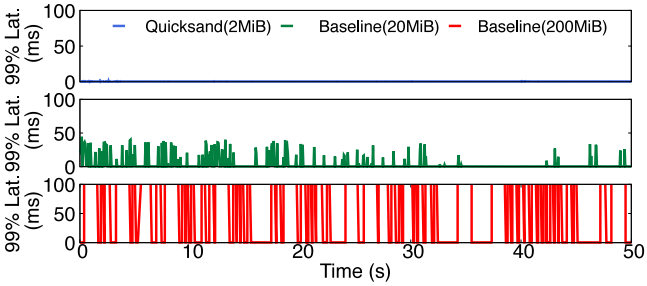

Figure 21: Fine granularity of memory proclets in Quicksand (2 MiB) is crucial for low tail latency in the social network application. Larger memory proclets (20 MiB or 200 MiB) causes intermittent latency disruption due to the impact of splitting larger proclets.

this indicates a significant bias towards CPU in its resource usage. With compute proclets, Quicksand is able to unstrand 1 CPU core in exchange for consuming 2 MiB of memory.

Memory proclets, by constrast, predominately utilize memory resources with low CPU consumption, exhibiting CPU/memory ratio ranging from 0.0001 to 0.001—four to five orders of magnitude lower than compute proclets; this indicates a significant bias towards memory in its resource usage. With memory proclets, Quicksand is able to unstrand 1 GiB memory with an average CPU consumption of 0.3 cores.

Hybrid proclets fall between memory proclets and compute proclets, with CPU/memory ratio ranging from 0.001 to 0.1.

This shows that compute proclets and memory proclets effectively separate the use of CPU and memory resources.

7.4.2 Benefit of Rapid Scaling

We now investigate the importance of Quicksand's rapid scaling to react to changes in resource availability. We use the ML pipeline and the same setup as in §7.2.1, but slow down Quicksand's reaction time from 2 ms to 20 ms or 200 ms to measure the impact of fast scaling on utilization.

Figure 20 shows the result. Unlike the original Quicksand, baselines with slower reaction time fail to saturate GPUs as they scale the number of compute proclets too slowly to match the changing GPU availability. This shows Quicksand's rapid scaling is crucial for harnessing changing resources.

7.4.3 Benefit of Fine Granularity

Finally, we examine the necessity to keep resource proclets fine-grained. We run the social network application on all available machines with constant load (1.5 MOPS). For latency-critical applications, by default Quicksand splits memory proclets above a 2 MiB threshold. Larger proclets impact tail latency in two ways: first, splitting them takes longer, causing a longer stall; second, larger proclets imply fewer proclets, thus stalling a proclet impacts a larger proportion of requests. To quantify the impact, we compare the original Quicksand to modified versions that use 20 MiB and 200 MiB as the split threshold.

Figure 21 shows the result: original Quicksand has a stable 99^{th} percentile latency, but coarser-grained proclets suffer latency disruptions during splitting. These results show that Quicksand's fine granularity is crucial for tail latency.

8 Discussion

8.1 Applicability and Limitations of Quicksand

Quicksand is ideal for cloud applications that benefit from flexible resource allocation and fine-grained scaling. However, some traditional single-machine applications, like high-performance computing simulations that depend on low-latency memory access, may be difficult to adapt without performance loss. Similarly, applications optimized for specific hardware, such as those requiring direct access to accelerators or GPUs, may face challenges. Legacy systems with monolithic architectures may also need significant refactoring to fully utilize Quicksand.

8.2 Relation between Quicksand and Disaggregation

Unlike recent hardware-based resource disaggregation systems [5, 26, 34, 51, 55, 59], which rely on specialized interconnects like CXL [11] or GenZ [18], Quicksand enables practical resource disaggregation on commodity hardware through its software-based approach. By decomposing applications into independent, granular resource proclets, Quicksand disaggregates compute and memory, unlike pure memory disaggregation systems [2, 22, 45]. Quicksand's abstractions simultaneously give library developers more control over data locality than transparent memory disaggregation. While hardware-based solutions may ultimately offer lower latency, Quicksand represents a practical intermediate step that delivers many disaggregation benefits on today's commercial datacenter hardware.

9 Related Work

Data Analytics Frameworks. Distributed frameworks like Spark [58], MapReduce [12], and Dryad [27] offer high-level APIs (e.g., DataFrames) to automate task decomposition for data analytics, but they are ill-suited for other domains like sharded services. While providing some resource management, they operate at coarser granularities and timescales, coupling resources and lacking the flexibility to respond dynamically to resource fluctuations. As a result, they cannot leverage stranded resources as effectively as Quicksand, which uses fine-grained proclets and millisecond-scale adaptability.

Autoscaling Frameworks. Slicer [1] and Shard Manager [33] help developers add sharding to applications, and add or remove shards in response to load. However, they target long-running, large-scale systems with big shards and minute-scale reaction times. Instead, Quicksand targets millisecond-scale reaction times to unstrand short-lived resources.

Resource Decoupling. Resource decoupling, as demonstrated by Monotasks [42, 43], involves breaking down jobs into single-resource tasks, akin to resource proclets. However, Monotasks primarily aim to facilitate performance analysis of Spark jobs, which leads to distinct design choices and implications: Monotasks cannot combine stranded resources across machine and operates at a coarser time granularity.

VM Consolidation. VM consolidation is a classic method for enhancing resource utilization by packing VMs onto physical machines [24, 30, 54]. However, it is inefficient due to resource overprovisioning and fragmentation [49]. StopGap [41] introduces VM splitting and fusion to improve consolidation, but it is restricted to stateless services (relying on reconfiguring the load-balancer to support splitting and fusion), and second-scale reaction times (as VMs are heavyweight).

Resource Harvesting. Resource harvesting aims to improve resource utilization by using idle resources that may be available only intermittently, using evictable VMs [3, 7, 20] and subsequent improvements [4, 47, 52, 56, 60]. This idea targets secondary applications that execute opportunistically but need not run if the resources are unavailable or disappear. Quicksand targets primary applications and uses more fine-grained execution abstractions.

10 Conclusion

We presented Quicksand, a new system to unstrand datacenter resources. Quicksand introduces resource proclets, which decouple the consumption of resources of different types, automatically regulate resource granularity, and support fast migration. Quicksand offers familar high-level abstractions to programmers while hiding the complexity of resource decomposition into resource proclets in extensible libraries.

Our results show that Quicksand successfully unstrands resources other systems cannot utilize, while also promptly responding to changes in resource availability and demand. Quicksand is available as open-source software [48].

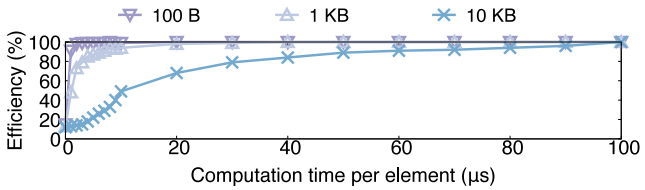

Figure 22: Quicksand's efficiency (y-axis) when compute proclets operate on memory proclets at different servers, as a function of compute intensity, normalized to the performance of local computation in a single machine with the same total resources. Quicksand's efficiency increases with compute intensity, requiring 3 μs of computation per 100B element to reach 99% efficiency.

A Appendix

A.1 Impact of Application Compute Intensity

We study the efficiency of Quicksand when its resource proclets separate computation from data across servers, *i.e.,* when a compute proclet operates on remote memory proclet. While prefetching can mitigate some remote access overhead, it introduces its own costs and becomes less effective as compute intensity decreases. Intuitively, the more CPU cycles spent per memory proclet access, the better Quicksand should amortize the overheads of remote access. We thus conduct a sensitivity analysis of performance under different compute intensities.

Our microbenchmark uses 26 compute proclets that iterate through remote data in separate sharded vectors and compute on it. The total memory is ≈15 GiB. We run this microbenchmark on two imbalanced servers (20 cores with 1 GiB memory, and 6 cores with 15 GiB memory). We quantify efficiency with respect to a baseline that computes on local memory with the same total resources (26 cores, 16 GiB memory). We consider vector elements of size 100 B, 1 KB, and 10 KB; and vary the amount of computation per element from 0 μs to 100 μs. A good result would show Quicksand achieving near-ideal efficiency at a broad range of compute intensities.

Figure 22 shows the results. When the element size is 100 B, Quicksand requires 3 μs of computation per element to reach 99% efficiency. For larger elements, higher compute intensity is required to amortize the communication cost: it requires 30 μs and 100 μs for 1 KB and 10 KB elements respectively to reach 99% efficiency.

These results suggest that Quicksand can decouple compute and memory efficiently at moderate compute intensities (microseconds of computation per remote access).

A.2 Resource Proclet API

Type	API	Description
Compute Proclet	`CompProc<Fn> MakeCompProc(Fn)`	Makes a compute proclet that runs `Fn`.
	`CompProc<RangedFn> MakeCompProc(Range, Fn)`	Makes a compute proclet that runs `Fn` over a `Range` of data.
	`CompProc<RangedFn> Split()`	Splits the current compute proclet.
	`void Merge(CompProc<RangedFn>&)`	Merges a compute proclet.
Memory Proclet	`MemProc<Shard> MakeMemProc<Shard>(Args)`	Makes a memory proclet that hosts a `Shard` object
	`Shard::Val Read(Fn)`	Reads data via running `Fn`.
	`void Write(Fn, Shard::Val)`	Writes data via running `Fn`.
	`void Seal()`	Makes the memory proclet read-only; enables prefetching.
	`void Unseal()`	Makes the read-only memory proclet writeable; disables prefetching.
	`Iterable<Shard> Iterator()`	Returns iterator that iterates over shard contents in an impl-defined order.
	`HybridProc<Shard> Hybridize()`	Promotes the memory proclet into a hybrid proclet.
	`MemProc<Shard> Split()`	Splits the current memory proclet.
	`void Merge(MemProc<Shard>&)`	Merges a memory proclet.
Hybrid Proclet	`std::invoke_result_t<Fn> Offload(Fn)`	Ships the computation `Fn` to the hybrid proclet.
	`MemProc<Shard> Dehybridize()`	Demotes the hybrid proclet back into a memory proclet.
	`HybridProc<Shard> Split()`	Splits the current hybrid proclet.
	`void Merge(HybridProc<Shard>&)`	Merges a hybrid proclet.

Figure 23: Quicksand's compute proclet API enables the execution of functions (optionally over a specified data range), while the memory proclet API enables reads, writes, and iterations. When sealed, memory proclets permit safe prefetching. A memory proclet can be promoted into a hybrid proclet, allowing for computation offloading. Compute proclets with ranges, memory proclets, and hybrid proclets support splitting and merging.

Beehive: A Scalable Disaggregated Memory Runtime Exploiting Asynchrony of Multithreaded Programs

Abstract

The Microsecond (µs)-scale I/O fabrics raise a tension between the programming productivity and performance, especially in disaggregated memory systems. The multithreaded synchronous programming model is popular in developing memory-disaggregated applications due to its intuitive program logic. However, our key insight is that although thread switching can effectively mitigate µs-scale latency, it leads to poor data locality and non-trivial scheduling overhead, leaving significant opportunities to improve the performance further. This paper proposes a memory-disaggregated framework, *Beehive*, which improves the remote access throughput by exploiting the asynchrony within each thread. To improve the programming usability, Beehive allows the programmers to develop applications in the conventional multithreaded synchronous model and automatically transforms the code into *pararoutine* (a newly proposed computation and scheduling unit) based asynchronous code via the Rust compiler. Beehive outperforms the state-of-the-art memory-disaggregated frameworks, *i.e.*, Fastswap, Hermit, and AIFM, by 4.26×, 3.05×, and 1.58× on average.

1 Introduction

Memory disaggregation allows applications to utilize the available memory of other servers and acquire orders of magnitude higher memory resources to avoid performance degradation due to insufficient memory, such as swapping data to disk. However, accessing remote memory exhibits microsecond (µs)-scale access latency, which incurs non-trivial performance penalties over accessing local memory [15, 60, 88, 108, 109]. Hence, a new challenge arises in the memory disaggregated data center—how to mitigate the µs-scale latency of remote access.

State of the art. The conventional wisdom of mitigating data accessing overhead is to avoid CPU idle time through the multithreaded synchronous programming model [15, 56, 92, 105]. Taking the memory disaggregated platform, AIFM [92], as an example: when accessing remote data, the thread will be suspended after issuing a request and then yield the core to another ready thread immediately, as shown in Figure 1(a). To further improve CPU efficiency, a series of kernel-bypass techniques have been proposed to alleviate the thread context switching overhead, such as Shenango [82], AIFM [92], and ZygOS [87]. The user-level thread (referred to as *uthread*) context switching consumes only around 200 cycles for context saving and restoration [82], 10× faster than kernel thread (*i.e.*, POSIX thread, referred to as *kthread*), which helps quickly fill the idle CPU by another ready task during the µs-scale remote access.

However, we observed some overlooked performance penalties for applications with an increasing number of uthreads. Intuitively, the µs-scale remote access latency, *e.g.*, reaching up to 6 µs [88, 92], easily outweighs the uthread switching overhead. Hence, launching a large number of uthreads to saturate the CPU resources and achieve high remote memory access concurrency is necessary and profitable. However, a series of consequences caused by thread switching leads to serious performance loss.

Taking Multi-Grid PDE [65] as an example (§ 3). When running on the state-of-the-art remote memory data plane, AIFM [92], the application's performance is still throttled by two main reasons—first, frequent uthread switching worsens data locality, leading to much higher CPU cycles spent on local memory access due to significantly enlarged LLC misses. Second, the scheduling overhead takes up to 23% of the CPU time, which becomes worse as the number of uthread increases or as the local memory size shrinks.

In other words, hiding remote access latency via threading can stealthily consume non-trivial CPU resources due to poorer data locality and heavier scheduling, which shifts the bottleneck from remote memory access to local memory and uthread managing. Although tuning the number of uthreads can alleviate the aforementioned inefficiency, the sweet spot of each application can be different (§ 5.4), which usually incurs unpredictable tuning and profiling overhead.

Major insights. The main question is, *can the application generate enough concurrent remote memory accesses to mitigate the µs-scale latency and also provide good data locality to avoid excessive cache misses?*

On the one hand, improving multithreaded program's data locality has been extensively studied for decades [36, 58,

* Corresponding authors: Chenxi Wang and Huimin Cui.

72, 94]. A series of locality-aware memory allocators have been proposed and integrated into the existing systems. For example, they segregate the objects of different threads via the thread local allocation buffer (TLAB) to avoid false sharing [19, 40, 59] and aggregate the adjacent allocated objects for a better cache/page locality [58]. Therefore, letting a core execute a thread without preemption can largely maintain good data locality due to substantial accessing data in the TLAB.

On the other hand, we find a mass of opportunities to parallelize the code of big data applications. The code of a thread can be split into a series of tiny code blocks (*e.g.*, coroutines [5, 8]) without data dependency, which enables asynchronous execution within a thread —when encountering remote data access, the subsequent coroutines can continue execution without blocking on waiting for the completion of previous remote access, as shown in Figure 1(b). Compared to thread switching, the routine-based asynchronous execution has much smaller working set size (WSS) and context switching overhead, which makes it a good fit for achieving high concurrency.

Beehive. Based on the aforementioned observation, we propose Beehive, an asynchronous framework designed for memory-disaggregated servers. Instead of relying on thread (uthread or kthread) switching to hide the µs-scale latency, Beehive lets each application thread **run to completion** [16] to maintain well-organized data locality and exploit high CPU efficiency and remote access concurrency via coroutine-based **asynchronous execution model** [9, 30, 84, 86]. To eliminate the well-known programming obstacles of asynchronous programming [15], such as *stack ripping* [9] and *callback hell* [56], Beehive allows developers to write programs in the conventional synchronous model with provided APIs and automatically transform the programs to the asynchronous model via the Rust compiler (§ 4).

Beehive's design targets two main challenges:

First, *how to transform synchronous code to asynchronous model automatically?* For code transformation, the compiler needs to split the code into a series of coroutines and then schedule the generated routines based on the program dependency analysis. However, pointer aliasing remains the major obstacle for data dependency analysis. To tackle this challenge, Beehive is implemented in Rust to benefit from its *ownership* types that provide *uniqueness* and *immutability* constraints during programming, which helps manage the pointer aliasing issues [41, 76] (§ 4.3).

Second, *how can we efficiently mitigate µs-scale remote memory access latency via coroutines?* A large number of concurrent remote accesses is necessary. Hence, first, Beehive implements a lightweight execution and scheduling unit, *pararoutine*, based on the Rust coroutine [8] to support high concurrency. The switching (yielding the core and scheduling another task to run) of a pararoutine is 2.3× faster than Shenango uthreads due to the stackless design and a cache-locality-optimized allocator that needs only five instructions to allocate a routine frame. Second, pararoutines employ cooperative scheduling for batch processing applications to contain the scheduling overhead while providing preemption for the latency-critical applications to keep the low tail latency (§ 4.4). Note that Beehive also supports thread switching when it cannot generate enough pararoutines to fill idle CPUs.

In summary, Beehive outperforms state-of-the-art solutions, *e.g.*, AIFM [92] and Hermit [88], through better data locality, more lightweight switching, and similar concurrency.

Results. We have evaluated Beehive with eight workloads that cover a wide spectrum of memory access patterns. Experimental results demonstrate that Beehive outperforms the state-of-the-art kernel paging-based frameworks, Fastswap [11], Hermit [88], and a runtime-based framework, AIFM [92], by, on average, 4.26×, 3.05× and 1.58×, correspondingly. In addition, Beehive also reduces the tail latency by, on average, 502× and 13.2×, compared to Hermit and AIFM. Beehive is available at https://github.com/ICTPLSys/Beehive.

2 Background

This section presents existing disaggregated memory systems and discusses the remote memory programming models.

2.1 Runtime-based Disaggregated Memory

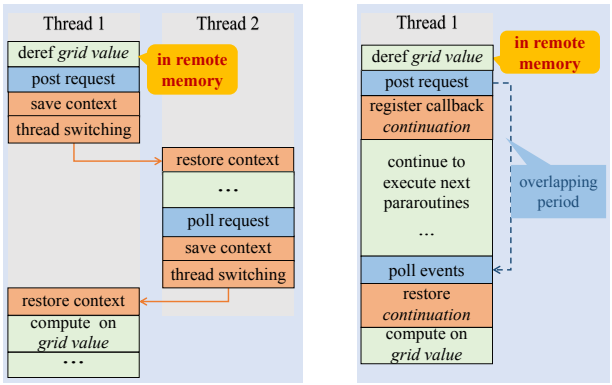
Disaggregated memory systems are generally categorized into three types: runtime-based [21, 24, 47, 66, 92, 106, 107], kernel paging-based [43, 88, 95, 108, 112], and hardware-based [22, 42, 45, 60, 61]. Although the paging-based solutions are transparent, they usually incur severe I/O amplification issues and lengthy remote access latency due to managing memory via the kernel paging [13, 21, 92]. On the other hand, considering that there is no commodity hardware-based solution at this moment, we implement Beehive according to the design of AIFM [92], a runtime-based framework that is built on the Shenango uthreads [82]. There are two major reasons: First, the data is managed in fine-grained object granularity, *e.g.*, *remoteable pointer* [92], to alleviate the I/O amplification and also utilize the program semantics to improve the prefetching effectiveness. Second, kernel-bypassing techniques [70, 87] help alleviate the thread switching overhead to achieve much higher remote access concurrency.

2.2 Programming Model

Compared to hardware mechanisms, *e.g.*, out-of-order execution and non-blocking caches [64], software solutions are more suitable for hiding the µs-scale latency due to their ability to generate high remote memory access concurrency and flexible data access granularity. Remote data management can be programmed in two different ways: *synchronous model* [15, 48, 56, 92, 105] and *asynchronous model* [9, 30, 84, 86].

Synchronous Programming. When developing a synchronous program, developers think linearly about the program's control flow —the thread will block on the I/O call site until the remote access completes, and there is no need to worry about accessing incomplete data. The remote access concurrency can be achieved via threading, which schedules another ready thread to preempt the CPU to alleviate the I/O stall (Figure 1(a)), shifting the programming burden to the thread library [105]. Most existing runtime-based solutions use the synchronous model for programming productivity and robustness [15, 24, 92].

Asynchronous programming. On the contrary, the control flow of asynchronous programs is much more flexible. As shown in Figure 1(b), after issuing the remote data access, the thread can skip the related code that may access the data being fetched and continue executing the subsequent code, hiding the remote access latency. Compared to synchronous programs, asynchronous programs can achieve similar concurrency with lower context switching overhead and better data locality due to sticking to the thread's local data. However, the developers need to be aware of the program data dependency and manually register the skipped code as a *continuation* that needs to be processed after the pending remote access is finished, as in the FaRM [34] (a transaction-based asynchronous programming model for distributed shared memory), which is prone to error and has become one of the main challenges of adopting asynchronous programming [9, 56].



(a) Synchronous execution (b) Asynchronous execution

Figure 1: The (a) synchronous and (b) asynchronous execution flow of traversing grid points in Multi-Grid PDE [65].

2.3 Program Dependency Analytics

Accurate and thorough program dependency analytics is the foundation of transforming the synchronous application into the asynchronous model. Pointer aliasing remains the main obstacle to program dependency analysis [31, 38, 46, 98]. However, *ownership* types are effective in eliminating the alias issues in large-scale programs [25, 26, 69, 80] and have been widely adopted by system languages, such as Rust [69], which gives us an opportunity to build the Beehive compiler for automatic code transformation.

Pointer aliasing means that a memory location is accessible by multiple symbolic names, such as pointers and references. The alias may escape the compiler's static analysis. As a result, the data can be modified through some of the aliases without the compiler being aware of the aliasing. Hence, the compiler needs to conservatively treat the potential alias when converting the code into concurrent routines to avoid violating execution orders, such as read-after-write (RAW). As a result, plenty of asynchronous code transformation opportunities (*i.e.*, concurrency) are wasted in large-scale programs that have complicated pointer usage and data dependency.

Ownership. When programming with the Rust *ownership* types, the references have the *uniqueness* and *immutability* properties, which help control aliasing [69, 80]. Uniqueness ensures that an object can only have one active mutable reference at a time. Another reference can *borrow* the mutable reference from the owner for a period of time (within a scope), during which time the owner cannot modify the data. As a result, the compiler can statically capture the transition of data's unique mutable reference and locate all the data dependencies, *i.e.*, true dependency (read-after-write, RAW), anti-dependency (write-after-read, WAR), and output dependency (write-after-write, WAW) [80], that can be used for concurrent routine generation. Note that multiple immutable references (read-only) can be created from the owner for reading, which is safe for the concurrent routine generation. Refer to § 4.3 for more details.

3 Motivation

This section demonstrates the performance bottleneck in today's remote memory systems, which shifts from remote memory access to local memory access and thread management, and the potential benefits of exploiting the asynchrony within a uthread.

We use Multi-Grid PDE (referred to as MGP, § 5.1), a memory-intensive scientific partial differential equation solver from NAS Parallel Benchmarks (NPB) [65], as the example to demonstrate the performance breakdown. MGP performs V-cycle multi-grid method to compute a 3D scalar Poisson equation, which exhibits good spatial locality due to its iterative stencil computation on fine-grained and coarse-grained grids. We evaluate MGP on two kinds of far-memory data planes, the paging-based Hermit [88] and the runtime-based AIFM [92]. We execute the original MGP on Hermit and re-implement the MGP on AIFM by using its uthread and Shenango runtime [82]. When running on Hermit, MGP is configured to one kthread per core, while the number of application uthreads is tuned to optimal, *i.e.*, 64 uthread per core, when running on AIFM (§ 5.4). Note that we configured the same number of uthreads for its prefetching and evacuation uthread pool as AIFM does [92]. We allocate 8 cores and 34 GB memory in total, among which 13% memory is

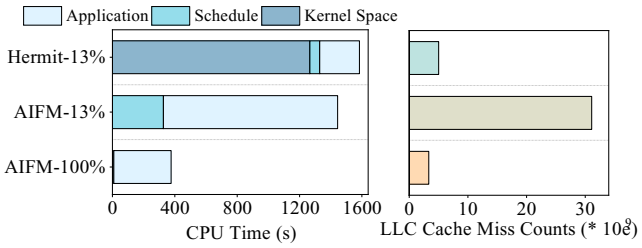


Figure 2: Performance breakdown of MGP when running on Hermit and AIFM. Although AIFM can reduce remote access overhead, it incurs non-trivial thread scheduling overhead and results in degraded application performance due to excessive LLC misses.

local and the rest is remote. The local and remote servers are connected via a pair of 100 Gbps Mellanox ConnectX-5 InfiniBand adapters.

As shown in Figure 2, Hermit and AIFM achieve similar performance, *i.e.*, AIFM slightly outperforms Hermit by 10%, while they are throttled by different reasons—(1) when running on Hermit, application throughput is throttled by the kernel paging that is used for remote access due to the page table management [12, 13], swap entry allocation [108], and other kernel space overhead [112]. Note that Hermit is the SOTA far-memory data plane and has already improved the paging efficiency for disaggregated memory; (2) AIFM is designed to address the kernel space overhead and I/O amplification [21] (which is negligible in MGP due to the good spatial locality). AIFM reduced 64% of CPU cycles spent on remote access (on-demand fetching, prefetching, and evacuation) by avoiding trapping into the kernel and efficient thread switching. However, except for the runtime bookkeeping overhead [24], we observed non-trivial thread scheduling overhead and significantly degraded application throughput due to LLC misses, which becomes the new bottleneck.

Thread switching leads to poor data locality. MGP organizes the data as two arrays, one for the fine-grained grid and another for the coarse-grained grid. The two grids are sliced into chunks and evenly assigned to different uthreads for load-balancing and high parallelism. Each uthread iterates and process the slices alternating between the fine and coarse grids. As shown in Figure 2, AIFM leads to 6.5× more LLC misses than running on Hermit due to frequent uthread switching. There are two root causes of why the multithreaded synchronous model has poor data locality.

On the one hand, the application data needs to be partitioned across application uthreads to reduce data racing, resulting in a separate data hotspot for each application uthread. At the same time, AIFM relies on frequent uthread switching to fill the CPU idle time during the µs-scale synchronous remote accesses, which urges for a large number of uthreads and high switching frequency, resulting in a large working set size (WSS). For example, MGP requires 64 application uthreads to achieve optimal performance (§ 5.4), causing the application uthread switching up to 4×10^8 times during the execution.

On the other hand, the runtime-based solution, *i.e.*, AIFM, is designed to manage data at fine granularity to exploit application semantics and reduce the I/O amplification [92], which further increases the demand for uthread-level concurrency. For example, AIFM maintains two separate uthread pools for object prefetching and evacuation, 17 for prefetching, and 40 for evacuation under the configuration of 8 cores [92], further increasing the number of uthread switchings.

Thread scheduling overhead. Another major performance penalty of the AIFM-based MGP comes from the thread scheduling overhead, which consumes 23% of total CPU cycles in this case. Although, the uthread context switching consumes only around 200 cycles [82], the cost of scheduling is non-trivial. During each uthread switching, the uthread needs to be paused and inserted into a waiting queue for the next step of scheduling, the cost of which can be 10× higher than the context switching. The uthread switching frequency in AIFM is high, reaching up to 2.2 million times per second. Hence, it is beneficial to continue reduce the thread context switching and scheduling overhead.

On the other hand, the large number of concurrent uthreads lead to heavy synchronization overhead, both within the uthread group and across different uthread groups. As aforementioned, MGP utilizes up to 121 uthreads under 8 cores (64 for application, 17 for prefetching and 40 for evacuation). Taking the synchronization between the application and the evacuation uthread groups as an example, the evacuator is used to concurrently compact the live objects for defragmentation. To avoid data race, a fence (*dereference scope*, § 4.4) is used to synchronize the application uthreads and the evacuation uthreads—the evacuation uthreads needs to be held until all the executing application uthreads exit their dereference scopes at least once [24, 92]. Hence, more live uthreads can potentially lead to more synchronization overhead.

Conclusions. Mitigating µs-scale latency through frequent uthread switching is the root cause of the poor data locality and scheduling overhead, not the number of uthreads. Hence, exploiting asynchrony within a thread provides opportunities to maintain a better data locality while achieving even similar (even higher) remote access concurrency.

4 Design and Implementation

4.1 Overview

Beehive is an asynchronous framework built for applications running on the memory-disaggregated platform. Beehive is developed based on the Rust language to benefit from the *Ownership* type system and contains three layers, programming interfaces (§ 4.2), a Rust compiler (§ 4.3) and the associated runtime (§ 4.4), as demonstrated in Figure 3.

For the asynchronous execution, programmers only need to develop the application in a conventional multithreaded syn-

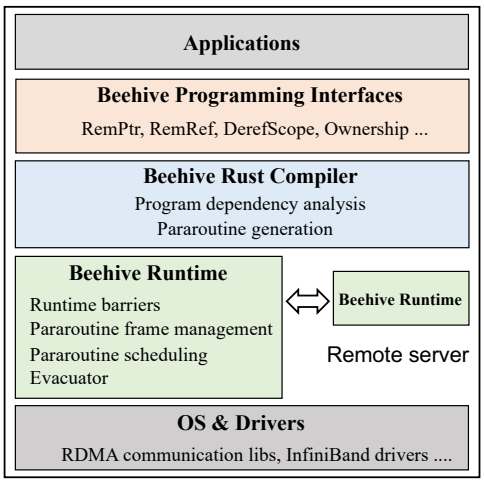

Figure 3: Design overview of the Beehive.

```
// remoteable pointer
struct RemPtr<T> { metadata: u64 /* see Figure 4 */ }
impl<T> RemPtr<T> {
    fn deref(&self) -> RemRef<T>;
    fn deref_mut(&mut self) -> RemRefMut<T>;
    // allocate remoteable object,
    // the position can be local, remote or offloaded
    fn allocate(&mut self, value: T, position: Pos);
    /* ... */
}
// remoteable references
struct RemRef<'a, T>; // immutable

struct RemRefMut<'a, T>; // mutable
impl<T> DerefMut for RemRefMut<'_, T>;
```

Listing 1: Remote data management interfaces

chronous model via the Beehive interfaces, and the provided Rust compiler transforms the code of a thread into a series of *pararoutines* (§ 4.4.1) that can execute concurrently. Beehive compiler adds runtime barriers to support data location checks and movement between the local and remote memory. When encountering remote access, the compiler wraps the rest of the pararoutine code snippet as a *continuation* and inserted into a waiting queue after issuing the remote access request. The thread will continue to execute the subsequent code (or pararoutines) continuously to process the thread's local data.

4.2 Programming interfaces

Listing 1 demonstrates the Beehive APIs for manipulating the remote data. There are two types of interfaces: (1) the *remoteable pointer* (`RemPtr`) that is derived from the Rust `Box<T>` type is used for allocating objects in the remoteable space (Figure 7); and (2) the *remoteable references* (`RemRef` and `RemRefMut`) that is derived from the Rust *reference* type is used for (mutable and immutable) borrowing and accessing the remote objects.

Remoteable pointer. When allocating data via the remoteable pointer (`RemPtr`), the data can be explicitly allocated in the remote memory, local memory or offloading spaces (§ 4.4.2) by setting the parameter `position`. For each `RemPtr`, there are 64 bits of metadata recording the address and control information. As shown in Figure 4, the low 48 bits are used for address and the high 16 bits are used to record control information, including a `present` (P) bit for local and remote status, a `moving` (M) bit to indicate if the object is being moved by the evacuator, an `accessed` (A) bit and a `dirty` (D) bit for hotness tracking, eight bits to record the number of references (`ref_count` (RC)). There are also several `reserved` bits that can be used by the developers to customize their own hotness tracking mechanisms, such as the CLOCK replacement algorithm [101, 111] and the LRU-like algorithm [17].

```
present   : 63
moving    : 62
accessed  : 61
dirty     : 60
ref_count : 59-52
reserved  : 51-48
addr      : 47-0
```

(a) Local object

```
present   : 63 // = 0
moving    : 62 // = 0
offloaded : 61
reserved  : 60
size      : 59-48
r_addr    : 47-0
```

(b) Remote object

Figure 4: The metadata layout of the remoteable pointer (`RemPtr`) for objects (a) in the local memory or (b) in the remote memory.

Remoteable pointer dereferencing. Beehive adds runtime barriers, *i.e.*, `deref` and `deref_mut`, to the `RemPtr` to dynamically check the the control bits of the remoteable pointer during execution for object management (referred to as *dereferencing*). For example, the object will be retrieved into the local memory if the `present` bit is unset, or the dereferencing will be hold if the `moving` bit is set. The barrier is optimized to minimize the execution overhead. For the hot path (object is already in the local memory), only five instructions are needed for the location check, which is comparable to AIFM [92]. For the slow path (object is in the remote memory), we use atomic instructions to modify the pointer, avoiding the cost of locking, and the overhead is trivial when compared to the µs-scale latency for retrieving the data from the remote memory.

Remoteable reference. A `T`-typed object in the remoteable space is uniquely owned by a `RemPtr<T>`. To avoid the runtime barrier overhead of accessing data via the `RemPtr`, Beehive lets programmers borrow the data from the `RemPtr` to a zero-runtime-overhead remoteable reference, `RemRef<T>` (or `RemRefMut<T>` for mutable access), as shown in Listing 2, for subsequent accesses. During the borrowing, the dereferencing methods, *e.g.*, `deref` for immutable borrow and `deref_mut` for mutable borrow, will be invoked to inspect the control bits of the remoteable pointer and retrieve the data to local if necessary. After the one-time dereferencing (aligned with borrowing), the data will reside in the local memory and can be accessed through the zero-runtime-overhead `RemRef` (or `RemRefMut`) as that of raw pointers.

```
elements: [RemPtr<T>; N];

impl<T, const N: usize> RemArray<T, N> {
    fn for_each<F>(&self, f: F) where F: Fn(&T) {
        for e in self.elements.iter() {
            // immutable borrow
            let r: RemRef<T> = e.deref();
            f(*r); // zero-runtime-overhead access
            // end of the immutable borrow
        }
    }
    fn initialize(&mut self, val: T) {
        for e in self.elements.iter_mut() {
            e.allocate();
            // uniquely mutable borrow
            let mut r: RemRefMut<T> = e.deref_mut();
            // let r2 = e.deref(); Compiler Error
            *r = val;
            // end of the mutable borrow
        }
    }
}
```

Listing 2: Example code of an implementation of RemArray. The programming should follow the constraints of Rust *ownership*.

```
pararoutine! {
    let remref_1 = remptr_1.deref_mut();
    *remref_1 += 1;
};
pararoutine! {
    let remref_2 = remptr_2.deref_mut();
    *remref_2 += 1;
};
```

(a) User code with pararoutine interfaces

```
let closure_1 = #[pararoutine] || -> bool {
    // inlined deref_mut()
    if !present(remptr_1) {
        post_request(remptr_1);
        yield remptr_1;
    }
    let remref_1 = RemRef(remptr_1);
    *remref_1 += 1;
};
scheduler.run_async(closure_1);
let closure_2 = /* ... */;
scheduler.run_async(closure_2);
```

(b) Compiler generated pararoutine closures

Listing 3: Code sample of pararoutine generation. The code snippet of pararoutine is created as a closure [7],*e.g.*, `closure_1`, and passed to the scheduler.

Pararoutine scope. We let developers explicitly define the pararoutine scope and rely on the compiler to finish the generation of the pararoutine, *e.g.*, frame allocation and free variable capturing (Listing 3). Automatic parallelization (relying on the compiler to analyze and automatically split the code into concurrent pararoutines) remains a very challenging problem [28, 100, 110] beyond the scope of this paper. Hence, we leave the automatic parallelization as future work and let developers manually split the code. Note that each remoteable pointer dereferencing and the following accesses must be wrapped by a pararoutine, otherwise a compilation error occurs.

Ownership and program dependency analysis. Beehive forces programmers to follow Rust's *ownership* constraints when developing applications, providing the compiler with a clear picture for program dependency analysis (§ 4.3). Each object in Beehive should have only one active mutable reference or multiple immutable references at any time. To modify an object, the type system ensures that the object is borrowed as mutable by one and only one remoteable reference, *i.e.*, `RemRefMut`, from the remoteable pointer, *i.e.*, `RemPtr`, as shown in Listing 2 (Line 16). Another mutable borrow can only occur if the previous `RemRefMut` goes out of its scope (the end of its lifetime), or explicitly releases the mutable borrow. As a result, the compiler can precisely track the flow of mutable borrowing statically, which is essential for addressing the pointer aliasing during program dependency analysis [26, 98] and data races [6], which form the basis of pararoutine generation and scheduling.

4.3 Beehive Rust Compiler

Beehive introduces a new unit of computation and scheduling, *pararoutine* (§ 4.4.1), which is derived from Rust's experimental coroutine feature [8], an unstable language construct currently in development. The pararoutine is defined by programmers and generated by the Beehive compiler. Beehive first statically orchestrates the pararoutines to improve the concurrency according to the program dependency graph (PDG) through compiler code motion. Then, Beehive dynamically schedule the pararoutines to avoid tail latency issues during execution (§ 4.4). The pararoutine generation can be split into three basic steps: program dependency analysis, layering and optimizations, pararoutine generation and static scheduling, as shown in Figure 5.

Program dependency analysis. Beehive should guarantee that there is no data or control dependency across the concurrently executing pararoutines. Beehive compiler uses the program dependency graph (PDG) for data and dependency analysis, which is a program representation which makes the data and control dependencies explicit for each expression, and is widely employed in program analysis [37, 81, 90]. In a PDG, each vertex, *e.g.*, u and v, corresponds to a statement, a predicate expression or a pararoutine, and an edge, $u \rightarrow v$, indicates vertex v is dependent on vertex u. A dependency edge can represent either a data dependency or a control dependency (*e.g.*, decided by the conditional and branching statements) [10]. Dependencies between statements will prevent them from executing asynchronously. The PDG analysis relies on type safety to ensure code properties like immutability, which is ensured in the safe Rust and the APIs provided by Beehive. See Appendix 4.5 for more details.

Before constructing the PDG, Beehive applied classic loop transformations such as the unrolling, fission, and fusion [37, 85] to preprocess the code to increase potential concurrency. Additionally, Beehive provides an `async_loop` API for developers for better pararoutine static scheduling. Given that loop optimization is well-studied and not our focus, we

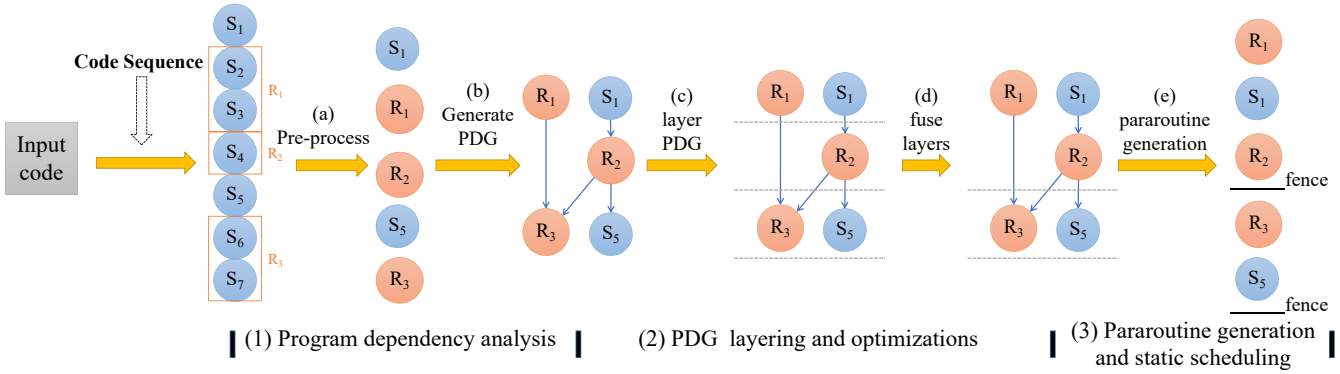

Figure 5: Automatic asynchronous code transformation. S is for statements and R is for pararoutines.

omit further details. Then, Beehive merges the statements belonging to the same pararoutine (defined by developers, as shown in Listing 3(a)) into one vertex, as shown in Figure 5 (a). Finally, Beehive creates the PDG on the optimized code sequences.

The PDG is constructed by following (Ferrante et al [37]), with pointer aliasing managed by ownership in Beehive. In particular, given two PDG vertices u, v with u preceding v in the program order, (1) a data dependency $u \rightarrow v$ exists when u, v access the same data object and at least one of them is write, and (2) a control dependency $u \rightarrow v$ exists if u determines whether or not v executes. Finally, we get a pararoutine-based PDG, as shown in Figure 5 (b).

Layering and optimizations. To enable efficient concurrent execution, the Beehive compiler groups pararoutines into *layers*. The pararoutines can execute asynchronously within each layer, while they cannot go out of the layer and must be synchronized by the fence primitives inserted between layers. Layers are initially generated by Algorithm 1. Each vertex represents a pararoutine or a statement outside the pararoutine. The compiler groups the dependency-free vertices, which have no immediate predecessors, into the same layer. Then, it removes the visited vertices from the PDG and continues the procedure until all the vertices are partitioned into different layers. Beehive applies optimizations to remove unnecessary fences by merging unnecessary layers. For example, a layer will be merged into its immediate predecessor if there is no dependency across pararoutines. This layer fusion pass is shown in Algorithm 2.

Pararoutine generation and static scheduling. The Beehive compiler statically schedules the pararoutines based on the layered PDG, as shown in Figure 5 (e). The pararoutines within a layer can execute asynchronously. Hence, Beehive can reschedule and output the pararoutines in any topology order. However, the statements and pararoutines should be scheduled by following the dependency, *e.g.*, the vertex $S1$ and vertex $R2$ must be scheduled in sequence. In addition, the compiler tends to let the pararoutine execute

Algorithm 1 Layering the PDG

```
1:  Input: G = {V, E} - PDG of pararoutines
2:  procedure PDG-LAYERING
3:      while V ≠ ∅ do
4:          Create a new layer l
5:          for all v ∈ V do
6:              ▷ Find vertices without immediate predecessors. ◁
7:              if HasNoDependency(v) then
8:                  ▷ v can be either pararoutine or statement. ◁
9:                  add v into l
10:         Remove vertices in l from V
11:         output l
```

Algorithm 2 Layer fusion

```
1:  Input: G = {V, E, L} - Layered PDG
2:  procedure LAYER-FUSION
3:      V_R ← {v ∈ V | v is a pararoutine}
4:      l ← pop the front layer from L
5:      while L is not empty do
6:          l' ← pop the front layer from L
7:          if ∃v_r ∈ l ∩ V_R, ∃v ∈ l', v depends on v_r then
8:              output l
9:              l ← l'
10:         else
11:             l ← l ∪ l'                    ▷ fuse the two layers
12:     output l
```

before the dependency-free statements, *e.g.*, $R3$ and $S5$, to prepare enough instructions to fill the idle CPU during remote access triggered by the pararoutine. After the vertex sequence is scheduled, Beehive compiler inserts the fence primitives between each layer to synchronize the pararoutines.

Each pararoutine is closed by making free variables that are used but not defined in this pararoutine captured and accessible in this pararoutine [73]. The generated pararoutine is as shown in Listing 3.

4.4 Beehive Runtime

The Beehive Runtime is responsible for task scheduling and memory management.

4.4.1 Pararoutine

Beehive introduces a stackless compute abstract, *pararoutine*, which is derived from the Rust experimental coroutine [8]. A pararoutine contains a series of compute instructions and at least one remoteable pointer dereferencing (and subsequent access through remoteable references). The pararoutine supports lightweight cooperatively scheduling at the dereferencing point and can be preempted at any point with heavier overhead.

Cooperative scheduling. The efficient cooperative scheduling of pararoutinelets the Beehive programs achieve higher remote memory concurrency while consuming less CPU resources. Pararoutine's cooperative scheduling outperforms the Shenango uthread switching by up to 2.3×, mainly due to two reasons: the reduced context and the lock-less waiting queue.

First, Pararoutines significantly reduce context switching overhead. Pararoutine switching only incurs one extra continuation invocation, which is as lightweight as a function invocation and leads to one store instruction to register continuation, as few as four instruction to restore context (*e.g.*, `mov, pop`), one `ret` and one indirect jump instruction. Compared to pararoutine switching, the uthread switching incurs several times more register and memory operations, including uthread state maintenance, lock operations, and register saving and restoration. For example, the Shenango uthread switching involves 30 assembly instructions, including 21 memory operations and 1 lock operation [83].

Second, exploiting concurrency within the uthread helps reduce the scheduling overhead. During the switching, only three instructions are needed to push the pararoutine into a lock-less per-thread waiting queue or pop a ready pararoutine for execution. On the contrary, the uthread needs to consider more complicated scheduling conditions, such as task stealing and shedding, which involves a series of uthread state check and locks [83]. Note that Beehive also supports task stealing at the uthread level, which works well to achieve high throughput and low latency (§ 5).

Beehive also supports thread switching when there is insufficient concurrent pararoutines within a thread. Specifically, when the program reaches a pararoutine fence, the thread will execute the scheduling code and poll the pending continuations, which may result in thread switching if it cannot acquire any ready task to process for 1 µs (an empirical threshold). Although thread switching may impair locality, we prioritize improving CPU efficiency.

Preemptive scheduling. Cooperative scheduling is good at achieving high CPU efficiency but usually fails to maintain µs-scale tail latency [70]. This is especially true because pararoutines are defined statically by developers without the benefit of runtime information. Some pararoutines can be large and lead to long tail latency issues due to the head-of-line blocking. For example, the suspended pararoutines (continuations) can not be rescheduled to run in time due to waiting for the completion of a large pararoutine, resulting in violations of the service level objective (SLO). Hence, Beehive provides µs-scale preemption to the pararoutine to improve the predictability of latency critical applications.

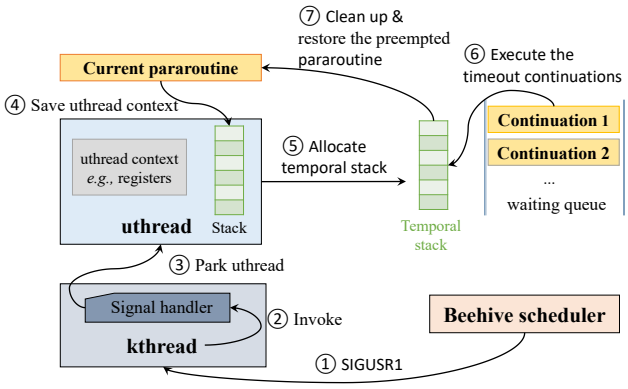

Figure 6: Preempt the large pararoutine to avoid tail latency issues

The pararoutine preemption is implemented on the SIGUSR1 signal, and the procedure is shown in Figure 6. When the scheduler detects that a suspended continuation exceeds the threshold of waiting time, it sends a SIGUSR1 signal to the kthread that the uthread runs on and invokes the signal handler. As a result, the uthread that executes the pararoutine (that leads to the blocking) will be interrupted and parked. The uthread context will be saved on the stack frame. Next, the signal handler will allocate a temporal stack and pop the stranded continuations from the waiting queue to run. Finally, the scheduler will resume the suspended pararoutine on the original stack frame. The preemption consumes 1.2 µs, which is comparable to the uthread preemption [82].

4.4.2 Memory management

Beehive's heap is divided into three spaces, as shown in Figure 7: the *native space* that resides in the local memory and is used for local-only data; the *remoteable space* that spans the local and remote memory, and the data can be swapped in and out on demand; and the *offloading space* that is used for supporting the offloaded computations.

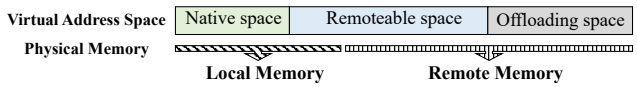

Figure 7: Memory layout of the Beehive application

Object allocation. If the programmers allocate data via the native (original) Rust data types, such as the smart pointer (`Box<T>`), the data will be put into the *native space*, which

is pinned in the local memory, and managed by the original Rust allocator.

Programmers need to explicitly use the remoteable pointer to allocate objects into the remoteable space. The objects are initially allocated in local memory and will be evicted by the *evacuator* to the remote memory when becoming cold. However, programmers can explicitly adjust the allocation site to the remote memory (for cold data) or offloading space by tuning the parameter, `position` (Listing 1). Beehive utilizes the log-structured allocator [24, 92, 93] to manage the remoteable space. Each thread maintains a thread local allocation buffer (TLAB) to reduce the lock contention. The TLAB is divided into a series of *segments*, which is set as 8MB in default by following the original design [93].

Beehive reserves a dedicated address space as the offloading space. The offloaded data is also managed by the remoteable pointer, *i.e.*, `RemPtr`, with the `offloaded` bit set. Programmers can offload computations on the offloaded data and retrieve the results via the RPC call.

Evacuator. Beehive adds a concurrent evacuator to the log-structured allocator for defragmentation and cold data eviction. When memory availability drops below the threshold (20% by default), the evacuator initiates concurrent scanning of cached local memory objects and evicts cold data to remote memory using the CLOCK replacement algorithm. This lightweight approach achieves comparable effectiveness to LRU-like alternatives [24, 111]. There are four reversed bits in remoteable pointers (Figure 4(a)) that enable optional implementation of the LRU-style algorithm.

Beehive adopts AIFM's design, *i.e.*, *dereference scope*, to synchronize the application threads with the concurrent evacuation threads to avoid data races. However, instead of using the dereference scope as a coarse-grained fence, *i.e.*, the evacuator is blocked until the application threads exit their dereference scope at least once, Beehive uses the dereference scope in a per-object way similar to Atlas [24]. An object enters the dereference scope when being dereferenced, *e.g.*, `deref` or `deref_mut`, and exits the scope when the remoteable reference dies (going out the scope of the `RemRef` or `RemRefMut`). The benefits are twofold. First, fine-grained synchronization opportunistically facilitates the evacuator in reclaiming more space. Achieving higher remote access concurrency means that more objects will be pinned in the local memory (within the deference scope), and timely memory reclamation helps alleviate the out-of-memory error due to the live-lock. Second, a frequently launched evacuator helps improve the data locality.

4.5 Limitations and Generality

Beehive relies on the Rust borrow checker for PDG analysis. Consequently, for programs with unsafe Rust code, the PDG analysis is less accurate, resulting in restricted pararoutines scheduling (§ 4.4). For example, the Rust compiler cannot properly handle the interior mutable types such as `Cell` and `RefCell`, which are implemented with `UnsafeCell`. As a result, Beehive will give up the PDG analysis and automatic asynchronization for these affected pararoutines. For libraries with source code, safety violations can be identified by checking for unsafe code blocks [33]. In this case, Beehive can skip applying automatic asynchronization to the affected code snippets to ensure correctness. On the other hand, the code transformation should be disabled if unsafe binary libraries are used due to a lack of effective ways to detect the usage of unsafe code. In this situation, developers can still manually schedule the pararoutines through the provided Beehive APIs, *e.g.*, `async` and `await`, as conventional asynchronous programming frameworks do [27, 34, 35].

In addition, the design of Beehive is not limited to Rust borrow checker. For example, Beehive can adopt deterministic parallelization [18] and reference immutability [41, 76, 80] to perform PDG analysis and automatically transform the code into asynchronous mode in other languages. We chose to implement Beehive on Rust because it is popular and widely adopted by the system community. System developers are more familiar with Rust's programming syntax. On the other hand, Beehive is designed to mitigate the µs-scale hardware latency while preserving applications' data locality. Hence, Beehive's techniques can be potentially applied to emerging storage devices exhibiting similar I/O latencies. We leave these as future work.

5 Evaluation

5.1 Setup and Methodology

We wrote about 8,000 lines of Rust and C++ code to implement Beehive. We ran experiments with one compute server and one memory server connected by the 100 Gbps Mellanox ConnectX-5 InfiniBand adapters. Each server is equipped with 2 Intel Xeon Gold 6342 CPUs, 256 GB of memory. We use one memory server for the evaluation by default, while evaluating the scalability by using up to 24 servers in § 5.4.

Baselines. Beehive is built on Rust following the design of AIFM. Hence, we implement all the evaluated applications on AIFM with all the mentioned optimizations [92], *e.g.*, non-temporal hints and prefetching techniques, enabled for performance and latency comparison. In addition, we run original applications on two state-of-the-art kernel paging-based platform, Hermit [88] and Fastswap [11], as another baseline to evaluate the runtime overhead potentially introduced by Beehive. Both Fastswap and Hermit employ a paging-based data path. Hermit consistently outperforms Fastswap due to its higher remote access throughput by exploiting asynchrony during swap-out.

The Rust versions of applications exhibit very similar performance when compared to the C++ versions, as shown in Figure 8, under the 100% memory configuration. Hence, the performance benefits of Beehive mainly come from the good data locality and the lightweight scheduling. We imple-

mented asynchronous optimization by modifying less than 5% of the core codebase per application in the Rust versions. AIFM utilizes a kernel-bypass TCP/IP networking stack implemented by Shenango for uthreads, while Beehive, Hermit, and Fastswap employ RDMA. The TCP stack overhead in AIFM is less than 2% [92], meaning that differences in the network stacks should not impact the conclusions drawn from the evaluation.

Workloads. As shown in Table 1, we evaluated seven applications under eight workloads, including Llama2 [55, 102], an open-source large language model, Multi-Grid PDE [65], a scientific partial differential equation solver, Social Network [39], a web service framework , and a synthetic workload, Key-Value Store, that is implemented in microservice, as well as Ligra [97], a graph processing framework, LiveGraph [114], a graph database, and DataFrame [74], a real-world data analysis program.

From the perspective of memory access patterns, these benchmarks can be divided into three categories: regular, random and mixed.

First, Llama2 (LMA) and Multi-Grid PDE (MGP) are both memory-intensive with good spatial locality when processing their data in arrays and vectors. The main difference between these two applications is that LMA exhibits regular access patterns, *i.e.*, sequential patterns, when performing matrix multiplication. However, MGP exhibits mixed access patterns due to its iterative stencil computation on two grids. Llama2 is a collection of pretrained and fine-tuned large language models (LMA) optimized for dialog use cases. In the evaluation, we use the float32 model with 7 billion parameters and deploy it on the CPU side. Performing inference in CPU has been widely adopted by a series of studies [44, 62]. As mentioned in § 3, MGP uses the V-cycle multi-grid method to compute a 3D scalar Poisson equation on grids.

Second, Social Network (SN) [39] and Key-Value Store (KVS) both exhibit random memory access patterns with poor spatial data locality. SN is a web service that stores the user relationship [91], *i.e.*, a dynamic sparse graph, into multiple hash tables and allows users to retrieve, update and delete the user data, which exhibits skewed access patterns. The KVS stores its data in a huge hash map and allows clients to manipulate the data by keys under uniformed distribution [4].

Third, Livegraph (LG) [114], Ligra (L) [97] and DataFrame (DF) [74] are data analytic frameworks exhibiting mixed memory access patterns. LG is a transactional graph database for real-time graph analytics. LG achieves high throughput by ensuring that adjacency list scans, a key operation in graph workloads, are purely sequential while exhibiting complicated patterns when accessing the vertices and edges. Ligra is designed for a single multicore machine and large shared memory, which is an order of magnitude faster on a per-core basis for graph traversal than distributed graph systems. The vertices and edges are stored in separate arrays. Each thread needs to access the vertices array and the edge array back and forth, exhibiting mixed access patterns. DF is a data analytics framework in Pandas [79]. The DF organizes data as a table-structured in-memory data structure and does a series of operations, such as *slicing*, *copy* and *aggregate*, which exhibit different access patterns.

Application	Dataset
Llama2 (**LMA**) [102]	Llama-7B [55, 102]
Multi-Grid PDE(**MGP**) [65]	NAS-benchmark [65]
Social Network (**SN**) [39]	Facebook network-A-anon [91]
Key-Value Store (**KVS**)	Synthetic, 50% Get, 50% Insert [4]
Livegraph Betweenness Centrality (**LG-BC**) [114]	Arabic-2005 23M Vertices, 640M Edges [91]
Ligra Connected Component (**L-CC**) [97]	Synthetic 134M Vertices, 1B Edges [14]
DataFrame Taxi (**DF-T**) [74]	NYC Taxi [2]
DataFrame Flight (**DF-F**) [74]	Airline on-time Performance [3]

Table 1: Applications and inputs for the evaluation.

Setup. Every application is running with five different local memory configurations: 13%, 25%, 50%, 75% and 100%, each of which represents a ratio of the whole memory usage of the application that can fit in local memory. The first four configurations are used to evaluate applications' performance when using different size of remote memory. The 100% (referred to as *all local*) is used to demonstrate the runtime overhead of AIFM and Beehive, introduced by barriers, profiling and other bookkeeping overhead [92]. All applications have the same number of application and evacuation threads. The number of application threads are tuned to optimal for each application (§ 5.4).

5.2 Throughput

We first measured the throughput of the applications with varying local memory ratios. Beehive outperforms Fastswap, Hermit and AIFM, respectively, by 4.26×, 3.05×, and 1.58×, over the eight workloads from 13% to 75% local memory. Beehive demonstrates particularly strong performance for workloads with well-partitioned data across threads and parallelizable, independent work within threads, such as MGP and DF. These types of applications benefit significantly from Beehive's ability to maintain data locality while exploiting asynchronous execution within threads.

Llama2 (LMA) and Multi-Grid PDE (MGP). As mentioned in § 5.1, both LMA and MGP are memory-intensive applications with good spatial locality. LMA mainly performs matrix multiplication exhibiting sequential access patterns (while MGP exhibits mixed patterns due to its iterative stencil computation). The data prefetching of Fastswap, Hermit, AIFM and Beehive all work very well for LMA, resulting in little on-demand remote accesses. In addition, LMA almost has no temporal locality. Hence, LMA is not sensitive to local memory ratios under these four platforms, as shown in Figure 8(a). The performance is mainly limited by the RDMA bandwidth.

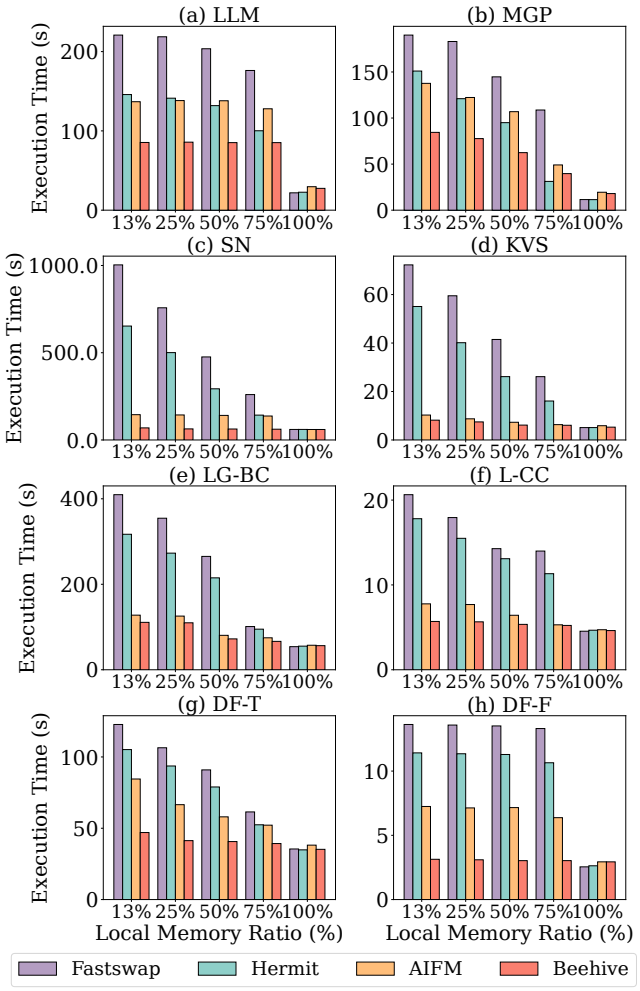

Figure 8: Throughput comparison between Fastswap, Hermit, AIFM and Beehive with varying local memory ratios.

Due to the good spatial locality of both LMA and MGP, most of fetched data will be accessed before being swapped out, which significantly alleviates the data amplification issues for the paging-based solutions, *e.g.*, Fastswap and Hermit [21, 22]. Hence, compared to Hermit, the performance improvement of runtime-based solutions, *i.e.*, AIFM and Beehive, are marginal. AIFM and Beehive outperform Fastswap by 1.56× and 2.41×, and Hermit by 0.93× and 1.47× on average, due to eliminating the overhead of trapping into kernel space and rich program semantics for prefetching during the remote memory access. At the same time, as the local memory ratio increases, *e.g.*, reaching up to 75%, AIFM and Beehive even start underperforming Hermit, *e.g.*, by 36% and 21% for MGP, due to runtime overhead, such as the barrier and profiling overhead. During the process, MGP continuously updates the data, leading to a large amount of dirty data being swapped out to remote. Compared to Fastswap, the asynchronous reclamation of Hermit [88] achieve by up to 1.94× higher throughput.

However, we still observed non-trivial performance improvement by utilizing the async execution model. Beehive outperforms AIFM by 1.58× and 1.54× on average, correspondingly under four remote memory configurations for LMA and MGP. This is because LMA and MGP partition the data, *e.g.*, matrices and arrays, into a bunch of tiles and assign them to different threads, leading to poor data locality during thread switching. The LLC misses sharply increase as the local memory shrinks, which enlarges the thread switching frequency due to escalating remote accesses. Taking MGP as an example, on average, AIFM introduces 3.5×, 5.3×, 5.5× and 7.3× more LLC misses than Beehive under 75%, 50%, 25% and 13% local memory ratios, correspondingly.

Social Network (SN) and Key-Value Store (KVS). SN exhibits random memory access with highly skewed distribution, while KVS exhibits uniformed memory access pattern. As a result, under the four remote memory configuration, both Beehive and AIFM significantly outperform Fastswap by 8.27× and 5.14×, and Hermit by 5.4× and 1.7× for SN and KVS on average, respectively. Beehive and AIFM fetch data in fine-grained object granularity, significantly reducing the data amplification seen in Fastswap and Hermit.

Unlike in LMA and MGP, the data of KVS is shared by application uthreads. Each uthread scan the data randomly so that the uthread does not have its own hotspot. Hence, even the uthread switching number reaches up to 2.3M/s under 13% local memory, Beehive's LLC misses is only slightly 2.6% less than AIFM. However, Beehive's scheduling overhead is 6.9× smaller than AIFM, leading to 1.28× higher throughput. As discussed in § 4.4, although Beehive has the same number of application uthreads, the number of active uthreads is much less than in AIFM. In addition, the pararoutine switching is 2.3× faster than uthreads. Due to the skewed workload of SN, the number of remote access is significantly reduced. However, under the four remote memory configurations, Beehive still outperforms AIFM by 2.21× on average.

Livegraph BC (LG-BC) and Ligra CC (L-CC). Due to the mixed access patterns, both Livegraph and Ligra have I/O amplification issues. Hence, compared to Fastswap and Hermit, Beehive improves the performance by 3.03× and 2.44×for LG-BC, and 3.04× and 2.62× for L-CC, correspondingly. AIFM improves the performance by 2.67×, 2.15× and 2.46×, 2.12× for L-BC and L-CC, correspondingly.

Compared to AIFM, Beehive's performance improvement is modest, by 1.13× and 1.23× for LG-BC and L-CC, respectively, on average. The performance benefits of Beehiveare limited mainly due to two reasons: first, the complicated graph results in intricate PDG, which limits the number of generated pararoutines in each layer (*e.g.*, 3.8 pararoutines per layer on average for the L-CC); second, the LG-BC is very memory-intensive: the average RDMA bandwidth reaches up

to 8.7GB/s under the 13% local memory. Both Beehive and AIFM are quickly limited by the limited network bandwidth.

DataFrame Taxi (DF-T) and Flight (DF-F). We perform two sets of operations on two different datasets. For the DF-T, a series of *Filter*, *Range extraction*, *GroupBy* operations are performed on the NYC Taxi dataset [2], while *Aggregate* and *Copy* are performed on the Flight data set [3]. Offloading is disabled in Beehive and AIFM to evaluate the efficiency of remote memory access. Compared to Fastswap and Hermit, the performance improvements of AIFM is less significant for the DF-T (1.46× and 1.25× on average) than DF-F (1.94× and 1.6× on average). This is mainly because DF-F contains more fine-grained data access.

For DF-T and DF-F, Beehive outperforms AIFM by 1.54× and 2.27× on average, under the four remote memory configurations. The performance improvements mainly come from the reduced LLC misses. As aforementioned, DataFrame organizes data as a table-structured in-memory data structure that contains millions of columns and rows. The columns are sliced into chunks and evenly assigned to different uthreads for load-balancing and high parallelism. For AIFM, frequent uthread switching leads to frequent changes of thread local data, resulting in 2.8× and 8.8× higher LLC misses than Beehive, for DF-T and DF-F, respectively.

5.3 Latency

We then evaluated the latency of the applications with a fixed configuration of 16 cores and 13% local memory ratio. We choose Social Network (SN) and Key-Value Store (KVS) to measure the tail latency of different platforms under varied offered load.

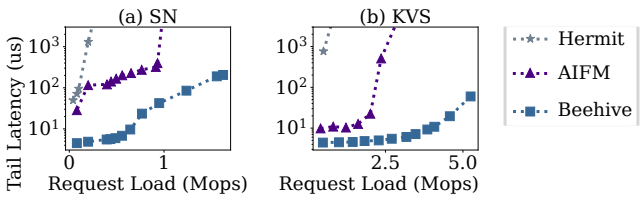

Figure 9: 90th latency as a function of offered load

Social Network(SN). Both SN and KVS exhibit random access patterns, leading to non-trivial I/O amplification issues for Hermit. Hence, the 90th tail latency of Hermit rapidly grows under the request rate of 0.1 Mops and 0.5 Mops for SN and KVS, respectively. Compared to AIFM, Beehive improves the compute capacity of cores by reducing the LLC misses (by 40%) and scheduling overhead (by 80%), significantly reducing the queuing latency of SN. As a result, Beehive's tail latency stays low until 0.64 Mops, and then the tail latency rapidly grows.

Key-Val Store (KVS). KVS is similar to SN as they both access key-value pairs from hash tables. The difference is that the request key in KVS follows a uniform distribution, as opposed to highly skewed accessing in SN. For the 90th latency, Beehive outperforms AIFM and Hermit by 5.5× and 2,869× under the load of 2Mops. Beehive achieves superior efficiency in two aspects—(1) improved CPU efficiency due to reduced WSS and (2) the effective preemptive scheduling.

5.4 Performance Drill Down

Sensitivity to the number of threads. As demonstrated in Figure 10, at first, the performance of four kinds of applications running on AIFM all increases with the number of uthreads due to improving CPU efficiency by switching to other ready tasks after issuing the requests, effectively hiding the µs-scale far memory access latency. However, as the number of uthreads increases, applications' throughput decreases to varying degrees due to LLC misses and scheduling overhead, exhibiting different optimal numbers of uthreads for AIFM.

On the contrary, Beehive is not sensitive to the number of uthreads. The performance differences are within 4% for the evaluated applications. This is due to Beehive's cooperative scheduling approach, where each uthread only yields after completing its task, effectively maintaining only one active uthread per core. L-CC-Beehive exhibits the most significant performance degradation. This is because the Beehive compiler cannot generate enough pararoutines for each layer, eventually resulting in uthread switching (§ 5.2).

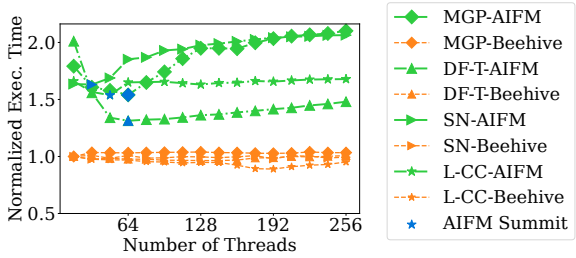

Figure 10: 16 cores are used, with 13% local memory ratio. The execution time is normalized to Beehive with 16 application uthreads.

LLC miss and scheduling overhead. In this section, we evaluate the LLC miss and scheduling overhead between Hermit and Beehive for four kinds of applications, as shown in Figure 11. Compared to AIFM, Beehive reduced LLC misses by 57% and scheduling overhead by 82%, on average.

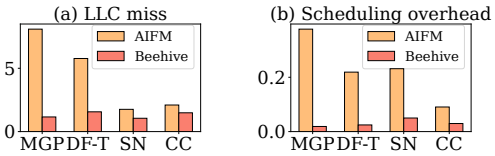

Figure 11: LLC miss (normalized to Hermit) and scheduling overhead to the CPU time, under 13% local memory ratio.

Scalability of the memory servers. Developing memory-disaggregated applications based on µs-scale I/O fabrics, *e.g.*,

InfiniBand [1], has two main benefits—first, it can utilize the conventional hardware; second, it can build a memory pool larger than rack-scale. Hence, we evaluate the scalability of Beehive by requiring memory resources from up to 24 memory servers (connected to one switch). As shown in Figure 12, performance degradation is limited to 2.5% for all the applications. However, we observed significant performance variation for the SN. The root cause is that SN exhibits random memory access patterns with a large memory footprint, resulting in frequent and unpredictable queue pair (QP) switching between different servers. According to previous research [34, 103], excessive QP switching can potentially lead to performance fluctuation.

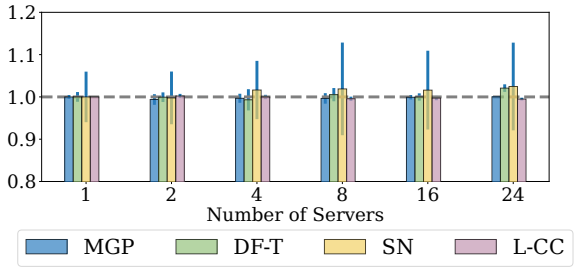

Figure 12: Impact of the number of memory servers on performance, with error bars, normalized to using one memory server

6 Related Work

Emerging hardware. Hardware-based schemes, such as the Pond [60] and Kona [21], are expected to provide direct load/store access to remote memory in cache line granularity, sub-microsecond-level data accessing latency, and hardware-support cache coherency across servers. However, these schemes need specialized hardware that is not commercially available at this moment. In addition, they still need software support to mitigate the µs-scale latency due to inefficient concurrency of remote accesses [15, 57]. For example, the number of miss status holding registers (MSHRs, used by CPUs to track the on-the-fly memory requests) is so limited that it cannot provide enough memory parallelism to hide nanosecond-scale local memory (DRAM) access [57, 104].

Kernel paging. Kernel-based schemes are popular because they are transparent to existing applications. The remote memory works as the second-tier memory layer and is managed by the kernel paging system —the cold pages will be swapped out to remote memory when there is not enough local memory space, and the swapped-out pages will be fetched back when being accessed by the application. However, the kernel-based schemes are notorious for non-trivial page fault overhead and I/O amplification [22, 24, 29, 89, 92] that not only degrades the throughput but also leads to performance variation and latency issues [88, 108].

Prefetching. Prefetching is effective to hide the data access latency. The prefetching techniques have been studied extensively, and a series of software-based [68, 71, 92, 108] and hardware-based [50, 51, 61, 96, 113] prefetchers are proposed. Beehive can also benefit from these works and adopts similar semantics-guided prefetching techniques as AIFM [92].

Disaggregated memory frameworks. A series of frameworks [20, 23, 34, 35, 53, 54, 67, 75, 77, 78, 99, 103, 106, 107] have been proposed for distributed memory models, such as distributed shared memory (DSM) [63] and disaggregated memory [95]. Although some of these works adopt asynchronous programming models, they mainly focus on providing high-performance asynchronous remote access primitives [34, 35, 78, 103] or reducing the synchronization overhead while maintaining the data coherency across distributed servers [20, 67, 106]. The developers are still expected to handle the asynchronous remote access manually.

For example, Storm [78] proposes *one-two-sided* operations, which use one-sided reads for simple data retrieval and two-sided RPCs for complicated memory operations, such as doing pointer chasing in a tree structure. In addition, FaRM [34] provides an event-driven programming model and still asks developers to define and register the *continuations* explicitly, which Beehive generates them automatically. For DSM frameworks, GAM [20] adds an extra level of cache atop the distributed memory to reduce costly remote memory access by exploiting applications' data locality, while dRust [67] reduces RDMA communications further during the cache coherency maintenance by leveraging the ownership semantics. In addition, RackOut [77] re-organizes the data in rack-scale granularity to improve the load balance of pooled memory. These works are orthogonal to Beehive, which mainly focuses on improving the data locality and reducing the scheduling overhead for applications exhibiting excessive thread switching. Their techniques can be potentially integrated into Beehive to enhance the network performance. We leave this to future work.

7 Conclusion

We present Beehive, a runtime framework developed for memory-disaggregated platforms. Beehive achieves superior remote access concurrency by exploiting the asynchrony within each thread while keeping the programming usability as the multithreaded synchronous programming framework.

A Appendix of Beehive Programming

A.1 Case Study for Programming Effort

To demonstrate Beehive's programming efficiency, we have refactored and minimized a representative code snippet from the Social Network (SN, Table 1) application to construct a minimal working example. Through careful abstraction of non-essential implementation details, we have distilled the core functionality while preserving the essential characteristics of the original code snippet. Next, we will use the function `post_reply`, which is used for posting a reply from user A, *i.e.*, `sender`, to user B, *i.e.*, `receiver`, as an example to demonstrate the programming effort of Beehive when compared to that of AIFM.

Let us start from implementing the function in AIFM, as shown in Listing 4. When the `sender` replies to the `receiver`, the `post_reply` function accesses their profiles stored in remote objects to generate a textual message "`sender name` replies to `receiver name`". A dereference scope is created in Line 2 to synchronize the application threads with the evacuator in the specific scope, *i.e.*, from Line 2 to Line 14, to prevent potential data races (Section 4.4.2). The evacuator will be blocked when the remote objects, such as the object referenced by `sender` in Line 7, are being dereferenced and accessed. Lines 5-6 retrieve `sender_ptr`, the remoteable pointer referencing the `sender`'s profile data. This pointer is then dereferenced to fetch the corresponding data from the remote in Line 7. The value of the filed `name` of `sender` is copied in Line 8 after the remote access is complete. Lines 9-12 perform analogous operations to obtain `receiver`'s name. Finally, the message is composed of data retrieved from the remoteable objects.

```
1  std::string post_reply(const Request& req) {
2      DerefScope scope;
3      std::string sender_name;
4      std::string receiver_name;
5      RemUniquePtr<User>& sender_ptr =
6          get_user(req.sender_id);
7      const User* sender = sender_ptr.deref(scope);
8      sender_name = sender->name;
9      RemUniquePtr<User>& receiver_ptr =
10         get_user(req.receiver_id);
11     const User* receiver = receiver_ptr.deref(scope);
12     receiver_name = receiver->name;
13     return sender_name + " replies " + receiver_name;
14 }
```

Listing 4: Programming with the AIFM.

The code in Listing 5 is basically the same as those written with AIFM, except for some annotations. To enable asynchronous execution in Beehive, developers simply annotate the two remote access operations with `pararoutine!` (Line 4, Line 9), and the compiler will generate the pararoutines as discussed in § 4.3. In contrast, manual implementation using Rust coroutines require significant additional code, including yield condition checks, waiting for coroutines to complete execution, and even manually scheduling and resuming the suspended coroutines on remote access completion. Thus manual approach substantially may increase the development effort, resulting in potential concurrent bugs and performance issues [9, 15, 56, 105].

```
1  fn post_reply(req: &Request) -> String {
2      let mut sender_name = String::new();
3      let mut receiver_name = String::new();
4      pararoutine! {
5          let sender_ptr = get_user(req.sender_id);
6          let sender = sender_ptr.deref();
7          sender_name = sender.name as String;
8      }
9      pararoutine! {
10         let sender_ptr = get_user(req.receiver_id);
11         let receiver = sender_ptr.deref();
12         receiver_name = receiver.name as String;
13     }
14     format!("{} replies {}", sender_name,
15         receiver_name)
15 }
```

Listing 5: Programming with the Beehive.

A.2 Performance Impact of Beehive Asynchronization

Figure 13 demonstrates the performance differences with (*Beehive-async*) and without (*Beehive-sync*) compiler code transformation, which is responsible for generating and enabling the synchronous execution of pararoutines. For the code written in Beehive while disabling the code transformation, the annotated pararoutines will be ignored, and the code will execute in the conventional multithreaded synchronous model—switching to another user-level thread when encountering remote accesses (§ 4.4). As a result, the performance of MGP, DF-T, SN, and L-CC on average drops by 72.6%, 70.9%, 81.1% and 32.8%, correspondingly, when compared to enabling the code transformation, *i.e.*, Beehive-async. However, Beehive-sync still outperforms AIFM by 1.09× on average due to the optimized evacuator and the adoption of atomic instructions (§ 4.4).

A.3 Preemptive Scheduling

Improvement from coroutine. Pararoutines are fundamentally based on stackless coroutines but are automatically scheduled by the compiler and runtime system. This automation eliminates the need for explicit `await` statements, streamlining the programming process. The data structure of pararoutines is designed with additional fields that support runtime scheduling and resumption (e.g., the pointer of the accessing remoteable object), enhancing operational efficiency. A significant improvement over traditional coroutines is the support for preemptive scheduling.

In addition, a cache-locality-aware allocator is implemented for pararoutine frame allocation to alleviate the context switching overhead further, drawing inspiration from the slab [19] and the TCMalloc [40] allocators. Each allocation is lock-free, requiring less than 10 instructions, with all frames

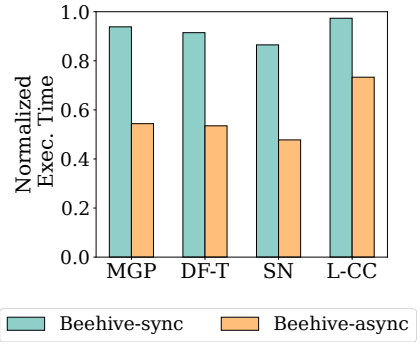

Figure 13: Performance comparison with (*i.e.*, Beehive-async) and without (*i.e.*, Beehive-sync) asynchronous remote access by enabling and disabling the Rust compiler code transformation. The execution time is normalized to AIFM. All experiments are executed under 13% local memory ratio.

allocated from a thread-private memory block that fits in the L1 cache to minimize cache misses.

Preemption. The Beehive preemption is designed to alleviate the HoL (head-of-line) blocking within latency-critical applications exhibiting wide service time distribution [32, 52] . For example, SN contains different kinds of requests whose service time, *i.e.*, execution time without queuing latency, ranges from 0.7µs to 76µs, a tend fold difference, as shown in Figure 14. As a result, the heavy-tailed request, *i.e.*, `Compose post`, can easily block hundreds of short requests and enlarge their execution time by more than 200×, hurting the overall responsiveness. This is because, when compared to short requests, heavy-tailed requests usually contain much larger and more pararoutines, which can occupy excessive CPU resources under the cooperative scheduling. In this section, we set an execution threshold, *i.e.*, 14µs (20 times the average execution time), for the short requests to demonstrate how preemptive scheduling help improve the SLOs of SN. Note that the service time of KVS requests, *i.e.*, `Get` and `Insert`, that are used in this paper are both short requests, as shown in Figure 14. Hence, we only evaluate the SN in this section.

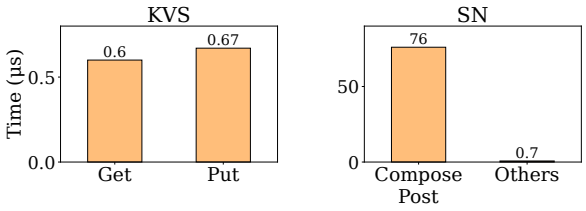

Figure 14: The service time of requests used in SN and KVS.

We tested the effects of preemptive scheduling and cooperative scheduling on request latency under a local memory ratio of 13% and a load of 0.8 Mops to avoid lacking computing capability. As illustrated in Figure 15, preemptive scheduling significantly reduces the occurrence of short request 99th latencies exceeding 20µs. The tail latency is 85% smaller than that of cooperative scheduling on average. At the same time, the 99th latency of the heavy-tailed request is slightly enlarged by 30% on average when compared to that of cooperative scheduling. Note that we add a preemption mechanism to the stackless pararoutine without fine-tuning its scheduling policy, which is not the main contribution of this work. The previous µs-scale scheduling policies, such as the Concord [49], Perséphone [32] and Shinjuku [52] are orthogonal to Beehive. We will improve the scheduling efficiency according to previous research in future work.

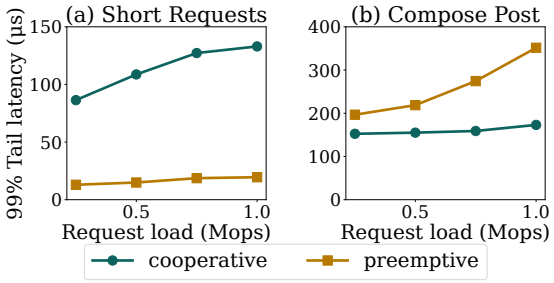

Figure 15: The 99th tail latency of SN requests under 13% local memory.

Making Serverless Pay-For-Use a Reality with Leopard

Tingjia Cao Andrea C. Arpaci-Dusseau Remzi H. Arpaci-Dusseau Tyler Caraza-Harter
University of Wisconsin–Madison

Abstract

Serverless computing has gained traction due to its event-driven architecture and "pay for use" (PFU) billing model. However, our analysis reveals that current billing practices do not align with true resource consumption. This paper challenges the prevailing SLIM (static, linear, interactive-only model) assumptions that underpin existing billing models, demonstrating that current billing does not realize PFU for realistic workloads. We introduce the *Nearly Pay-for-Use (NPFU)* billing model, which accommodates varying CPU and memory demands, spot cores, and preemptible memory. We also introduce *Leopard*, an NPFU-based serverless platform that integrates billing awareness into several major subsystems: CPU scheduler, OOM killer, admission controller, and cluster scheduler. Experimental results indicate that Leopard benefits both providers and users, increasing throughput by more than 2x and enabling cost reductions.

1 Introduction

Serverless computing, also known as Function-as-a-Service, is increasingly popular in cloud computing environments [43, 51, 64]. This paradigm enables users to build event-driven applications through a collection of short-lived functions [6, 15, 18, 22, 39, 62]. It lets users define the events that trigger these functions; the platform provisions resources for function execution when said events occur [55, 64, 66]. Serverless computing is economically appealing as it has "pay-as-you-go" billing: developers are only charged when their function invocations are active [5, 13, 28]. Therefore, most cloud providers have a serverless offering, including AWS [13], Azure [5], and Google Cloud [28], and a majority of organizations running cloud workloads utilize serverless in some capacity [54, 63].

However, our examination of the details of serverless billing models (*i.e.*, how much a user is charged for an invocation, based on function configuration and resource usage), reveals more nuance to what providers mean when they advertise a "pay-per-use model" (Azure [5]) or claim that you only pay "for what you use" (GCP [28] and AWS [13]). To providers, these terms apparently mean something akin to "fine-grained billing" with respect to wall-clock time. An ideal pay-for-use platform for customers, in contrast, would charge based on actual resource consumption.

Characterizing these platforms as pay-for-use is justifiable if one makes four strong assumptions about function resource usage. The assumptions are: (1) resource usage is constant across time; (2) resource usage is similar across invocations; (3) CPU/memory usage is proportional; (4) all invocations are interactive. When these hold for a workload, most popular serverless platforms charge in proportion to resource usage; otherwise, invocations are charged for unused resources. We define a billing model, called SLIM (static, linear, interactive-only model) that captures these common billing practices.

Our first contribution is a detailed empirical evaluation of a suite of serverless functions that we have assembled (§2). The suite consists of a wide range of functions from different domains (developer, machine learning, and database workloads) and runs on varied input payloads. Our analysis shows that serverless workloads do not match SLIM assumptions. CPU and memory usage often fluctuate during a single invocation (it is not constant); resource consumption depends on input size, which varies across invocations; memory usage is rarely proportional to CPU usage; and most functions have non-interactive use cases. Put simply, "pay-for-use" models often charge for both used and unused resources.

Our second contribution is a new billing model, *Nearly Pay-for-Use (NPFU)* (§3), that can approximate pay-for-use efficiently. NPFU enables users to better express actual resource demands and eliminate SLIM assumptions. Specifically, NPFU separates memory and CPU demands and adds spot cores and preemptible memory for less urgent (non-interactive) work. Note that this approach does not depend on provider subsidization to reduce customer cost; NPFU is more flexible than current serverless approaches and can generate a win-win scenario for *both* providers and users. Users (nearly) pay for what they use and can better reach their objectives while providers can allocate their resources more effectively.

Our third contribution is an exploration of how billing models affect system design. We introduce *Leopard* (§4), a serverless system based on OpenLambda [34] that supports NPFU. Leopard builds billing awareness into several major subsystems. At the kernel level, we add support to the isolation API (cgroups), CPU scheduler (CFS), and preemption mechanism (OOM killer). These improvements enable efficient co-location of interactive and batch functions, which use reservation and spot billing, respectively. The new admission control logic leverages this support to aggressively run more functions concurrently, without sacrificing QoS. Finally, the load balancer creates more opportunities to resell unused resource reservations as spot cores and preemptible memory. Leopard demonstrates that billing must be considered as part of the system design process, rather than a late-stage addition.

Finally, we demonstrate the benefits of NPFU through rigorous experimentation (§5). We first illustrate a new methodology for comparing billing models. We show that Leopard's billing awareness improves worker throughput by 2.3x (on average). This efficiency may be delivered to customers in the form of price reductions (while keeping provider revenue per machine constant): 34% for interactive functions and 59% for batch functions for the average invocation.

2 Pay-for-Use Serverless Billing Models

When customers pay cloud providers for services, the *billing model* describes the cost of those services. Most services are highly configurable with various knobs (*e.g.*, the number of threads to use, or amount of memory), and those knobs may impact cost. Thus, a billing model consists of those knobs as well as a *billing function* that computes the cost based on those knobs and the actual usage of the service.

There are two families of billing models: pay-for-use (PFU), designed to charge based on actual resource consumption, and provisioned. Increasingly, modern services offer dual billing options: AWS EC2 allows customers to pay for instances on-demand (PFU), or commit to long-term reservations (provisioned); GCP BigQuery offers on-demand pricing (PFU) and capacity pricing (provisioned); AWS Lambda offers its original model, which charges for memory time used by invocations (PFU), as well as a newer provisioned concurrency option. Our focus is on PFU billing models for FaaS.

Pay-for-use vocabulary is frequently used to market popular serverless platforms, yet this term is subject to interpretation. We formalize a strict interpretation of PFU that we call strict PFU (SPFU) (§2.1). Real serverless billing models are usually an approximation of SPFU where the quality depends on the workload. We define another billing model in the PFU family called SLIM: a static, linear, interactive-only model (§2.2). SLIM resembles many billing models in use today, but it poorly approximates SPFU for realistic workloads (§2.3).

2.1 Idealized Billing: SPFU

We formalize a strict pay-for-use model (SPFU). In SPFU, the cost for each function invocation is computed as a constant factor multiplied by the used resources (*e.g.*, CPU time and bytes of memory) measured at arbitrarily fine granularity. The values for those constants are determined by *pricing*, a concept related to, but distinct from, *billing*. If the usage of each resource was plotted over time, the cost would be proportional to the area under each curve, where each resource is billed independently. For simplicity, we focus on CPU and memory as the billable resources, but the model is extensible to others (*e.g.*, network throughput, disk utilization). Given that a "CPU minute now" can be argued to be more valuable than "a CPU minute whenever it becomes available", SPFU may charge more for functions marked interactive (*i.e.*, urgent).

SPFU avoids billing for anything that is not a computing resource, such as function invocations, wall-clock time, or resource limits. Not charging for invocations implies that SPFU cannot have minimum charges per invocation. CPU time is a billed resource, but wall-clock time is not; a function that blocks mid-invocation can only be billed for memory during this idle time. A service offering SPFU can allow customers to configure resource limits, but these limits must be excluded from the billing function; customers might find resource caps useful to bound costs, but SPFU does not allow providers to charge more if resource caps exceed actual consumption.

SPFU billing has advantages for customers: not paying for unused resources can reduce costs, and decoupling billing from resource limits simplifies configuration. However, implementing SPFU presents challenges for providers; in particular, SPFU complicates admission control, as customers have less incentive to specify accurate resource limits. Lacking accurate limits, providers may concurrently execute too many functions, forcing functions to be terminated if a memory spike occurs; alternatively, providers may concurrently execute too few functions, leading to low utilization. A billing model that is bad for providers is usually bad for customers: providers are likely to compensate for inefficiencies with higher pricing.

2.2 Practical Billing: SLIM

We now define SLIM billing (static, linear, interactive-only model), another billing model in the pay-for-use family. SLIM is a generic billing model resembling real billing models used by popular platforms and can be viewed as an approximation of SPFU. With SLIM, users can specify a memory limit for each function, where the limit applies to all its invocations; a CPU size is calculated that is proportional to this memory limit (*i.e.*, the memory and CPU caps cannot be adjusted independently). The memory and CPU sizes are guaranteed to be available during execution. The cost of an invocation is proportional to the execution time multiplied by the memory limit, regardless of how much memory is actually used.

SLIM may still be considered a pay-for-use billing model given a weak definition of "use", *i.e.*, execution time of a function multiplied by an upper bound on resource consumption. SLIM's main advantage is that it may be better for admission control than SPFU, as customers have a strong incentive to set resource limits as low as possible. We suspect SLIM is common because it lends itself to FaaS implementations with greater profit potential than SPFU.

2.3 Does SLIM Approximate SPFU?

We now consider to what extent SLIM approximates SPFU. *For realistic workloads, are "pay-for-use" serverless platforms strictly pay-for-use?* For some workloads, SLIM and SPFU may indeed produce similar billing outcomes. We enumerate four workload characteristics that must apply for SLIM and SPFU to produce similar bills (§2.3.1), collect a suite of realistic serverless functions (§2.3.2), and evaluate whether the SLIM assumptions hold for our workload (§2.3.3).

2.3.1 Workload Assumptions

Given the following four assumptions about the workload, we can expect SLIM to approximate SPFU:

Assumption SI (Static Internal): Resource usage is constant throughout the invocation of a function. SLIM invocation cost is proportional to a resource cap for an entire invocation. If usage is close to the cap, the cap properly approximates usage; however, if resource limits are selected to provision for short bursts of peak usage, tenants will pay for unused resources.

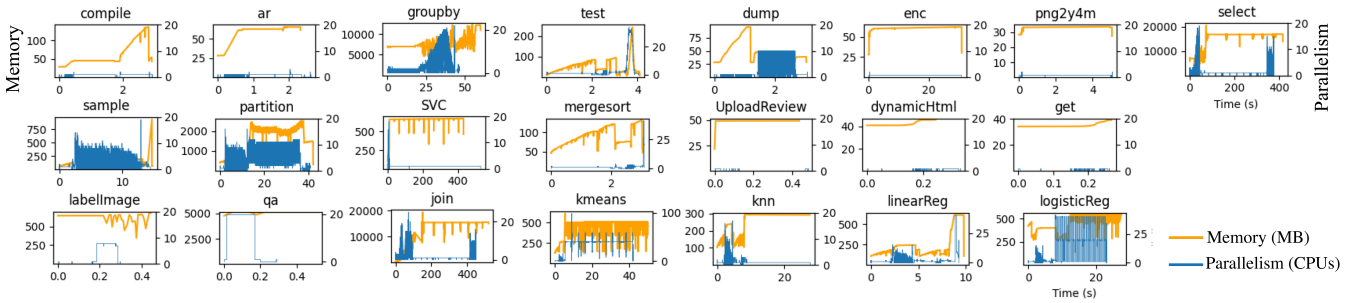

Figure 1: The diversity of parallelism behavior and memory usage over time within an invocation with medium payload.

Assumption SE (Static External): Resource usage is similar across invocations. SLIM uses same-size instances for all invocations of a given function. Resource limits are presumably chosen to be sufficient for the largest expected invocations so that those invocations will not fail. If many invocations have computational needs significantly lower than the large invocations, they will incur excess charges for unused resources.

Assumption L (Linearity): CPU and memory usage are linearly proportional. SLIM services offer instances with fixed compute-to-memory ratios (*e.g.*, 1 vCPUs to 1,769 MB of memory in AWS Lambda). As a result, CPU-dominant functions pay for unused memory resources (and vice versa). In contrast, functions that are relatively balanced across CPU and memory pay approximately for what they use.

Assumption I (Interactive): The QoS for all invocations are interactive. When invocations are triggered, SLIM-based platforms immediately provision resources. Although some triggers enable batching (*e.g.*, event hubs in Azure), when a batch arrives, the platform still immediately provisions instances for the batch. To support interactivity, providers maintain idle instances [51], although they could save memory by shutting down non-interactive instances. Under SLIM, all functions pay for low latency, even when it is not needed.

2.3.2 A Serverless Function Suite

Based on realistic workloads from a range of serverless research papers [21,23,27,39,42,47,48,70,72], we collected 22 serverless functions in 7 domains, representing applications in scientific, multimedia, engineering, and database usage scenarios, as listed in Table 1. For each function, we provide small, medium, and large input sizes. When possible, we try to anchor the sizes to actual inputs to make the workload more realistic (*e.g.*, the large input of the Compile function compiles the largest C file in the Linux kernel).

The function suite enables an analysis of SLIM assumptions across a variety of resource usage patterns. The average CPU and memory usage for each invocation varies significantly, from 0.04 CPU to 35 CPUs and from 28 MB memory to 28 GB memory, respectively. Additionally, the functions stress possible QoS: those that must complete urgently ("interactive") or those that prioritize cost and throughput ("batch"). Both types are desirable for the elasticity and pay-for-use characteristics of serverless computing [40–42, 62, 70, 73].

Table 1: A serverless function suite.

2.3.3 Workload Analysis

We now revisit those assumptions and evaluate how well they hold for realistic workloads.

Assumption SI: To evaluate whether resource usage is constant throughout a single invocation, we measure the parallelism of each function and resident memory size over time; for parallelism we trace the number of runnable tasks throughout an invocation by recording when tasks join a CPU's runqueue within Linux. As shown in Figure 1 for medium-sized functions, CPU and memory consumption varies dramatically during the execution of a single invocation.

Assumption SE: Figure 2 plots the memory and parallelism under different payloads for three representative functions. We observe that resource usage can be quite different across invocations: larger input usually corresponds to greater resource consumption. On average, CPU usage for large sizes is 1.5x higher than medium and 3x higher than small sizes, while memory usage is 8x and 16x greater, respectively.

Assumption L: Figure 3 plots the memory-to-CPU ratio for average and max usage for all functions; the line shows the memory-to-CPU ratio of AWS Lambda and extrapolated past the max support size (Google Cloud Functions and Azure Functions use similar ratios). We observe a departure from the fixed AWS Lambda ratio for most functions; 91% could use more CPU than memory relative to the AWS Lambda ratio, suggesting that CPU may be more scarce than memory.

Platform	Knobs	Instance Size r: memory to cpu ratio	Concurrent Invocations per instance	Bill per Execution T: Execution time CP: CPU unit price *MP*: memory unit price	Resource Limitation
AWS Lambda	Memory (M)	Memory: M, CPU: M*r	1	M * T * MP + M * r * T * CP	10GB Mem, 6vcpu
GCP	Memory (M)	Memory: M, CPU: M*r	1	M * T * MP + M * r * T * CP	32GB Mem, 8vcpu
Azure (premium)	Memory (M), Target	Memory: M, CPU: M*r	< target	M * T * MP + M * r * T * CP	14GB Mem, 4vcpu
Azure (consumption)	Target	Memory: 1.5GB, CPU: 1vcpu	< target	AvgMemory * T * MP	1.5GB Mem, 1vcpu
CloudFlare	Memory (M)	Memory: 128MB CPU: No dedicate CPU	1	AvgCPU * T * MP	128MB Mem, 10ms cputime

Table 2: The resource allocation policy and billing model of mainstream commercial serverless platforms.

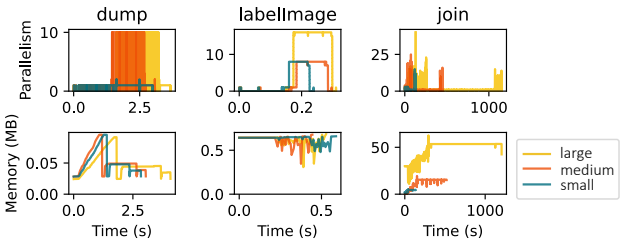

Figure 2: The resource demands with different payloads.

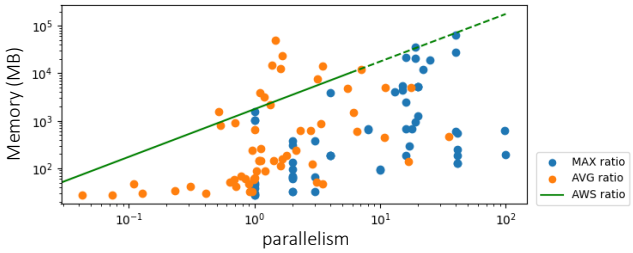

Figure 3: The ratio of cpu/memory demands.

Assumption I: In Table 1 the "possible QoS" column indicates whether a function must be urgently completed upon invocation, *i.e.*, is it latency critical (interactive) or not (batch). For example, model training is typically done offline; video analytics are used in both real-time stream processing systems and as background jobs. Thus, not all functions require interactivity all of the time.

Conclusion: Our analysis shows that serverless workloads challenge all four SLIM assumptions. CPU and memory usage fluctuate during a single invocation (assumption SI); resource consumption depends on input size, which varies across invocations (SE); memory usage is rarely proportional to CPU usage (L), and most functions have some non-interactive use cases (assumption I). Therefore, SLIM is a poor approximation of SPFU.

2.4 Serverless Billing in Practice

We now summarize the billing models in practice, as shown in Table 2. AWS Lambda, GCP, and Azure Functions (Premium Plan) closely resemble SLIM, the weakest interpretation of PFU billing. While Azure Functions (Consumption Plan) and Cloudflare align with SPFU, they enforce small, untunable resource limits (*e.g.*, Azure allocates 1.5 GB of memory and 1 vCPU and Cloudflare Workers are limited to 128 MB of memory and 10 ms of CPU time); these limits prevent customers from over-provisioning resources, but restrict the platforms' generality, prohibiting functions with larger resource requirements. Existing billing models either resemble SLIM, or SPFU with restrictive resource limit options.

3 NPFU: Nearly Pay-for-Use Billing

SPFU billing offers the most natural interpretation of "pay-for-use", but is rarely used in practice because providers must provision for resources that are unused (and unbilled). Instead, most providers adopt a billing model that resembles SLIM. We propose an alternative billing model that more closely approximates SPFU while exceeding SLIM's support for efficient and profitable FaaS implementations. We call this new model NPFU, Nearly Pay-for-Use. NPFU has two goals:

Profitable: The billing model should lend itself to efficient FaaS implementations. The drawback of SPFU is that it generally requires implementations to provision resources that may go unbilled. An ideal billing model will support greater utilization, leading to greater profits for providers (and perhaps lower costs for consumers).

Closely Approximates SPFU: SPFU offers the strongest interpretation of "pay-for-use" terminology, while SLIM only approximates SPFU for unrealistic workload assumptions. A good PFU billing model should better approximate SPFU for a wide range of workloads. Therefore, it requires adding proper knobs that enable users to describe resource requirements more accurately for workloads that breaks SLIM assumptions.

We introduce NPFU, defining the knobs for billing (§3.1) and the billing function that calculates cost per invocation (§3.2); we then compare NPFU to other billing models (§3.3).

3.1 NPFU Knobs

NPFU provides four knobs for customers to describe their resource demands: *cpu-cap*, *spot-cores*, *mem-cap*, and *preemptible-mem*. These options allow users to independently specify their CPU and memory demands instead of using the strict memory-to-CPU ratio of SLIM.

CPU: Cap and Spot. NPFU requires serverless users to specify *cpu-cap*, which is the maximum number of CPUs it can use; this bounds their cost. Given that many serverless functions are not interactive, NPFU introduces *spot-cores*: a subset of *cpu-cap* that a function does not need immediately, but could use if available. NPFU guarantees that *cpu-cap* minus *spot-cores* is available; this number of *reserved-cores* number is crucial for ensuring the function meets its QoS. Spot cores improve CPU usage: if instances underutilize their reserved cores, other instances can use them as spot cores.

Figure 4 shows an example of a server with 4 physical CPUs, where at t_0, the server hosts function invocations F1 and F2. F1 sets *cpu-cap* to 4 and *spot-cores* to 1 (*reserved-cores* is 3); F2 sets its *cpu-cap* as 3 and *spot-cores* as 2

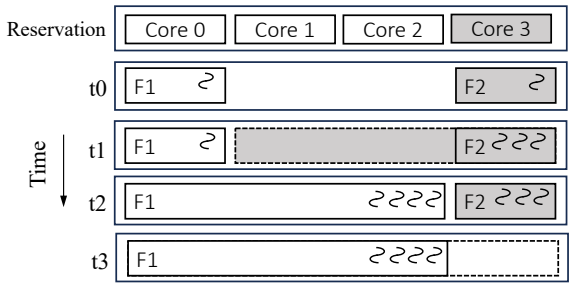

Figure 4: NPFU stresses allocated but unused cputime.

(*reserved-cores* is 1). The system ensures that each invocation can expand to its full set of reserved cores. At t_1, F2 forks two children; since there are idle CPUs from F1's reserved cores, F2 expands to use 3 CPUs. However, at t_2 when F1 forks 3 children and needs more cores, F2 immediately shrink to its reserved allocation. By t_3, F2 terminates, at which point F1, which has pending tasks, expands to all cores.

Decoupling *cpu-cap* and *spot-cores* helps batch functions describe low CPU urgency. It also benefits some interactive functions: although these functions have strict deadlines, their *reserved-cores* do not need to match maximum parallelism if deadlines can be met with fewer cores. Adding *spot-cores* creates opportunities to further reduce latency and costs.

Memory: Cap and Preemptible. Like the CPU knob, NPFU requires users to specify *mem-cap*, which is its maximum amount of memory; however, NPFU does not expose knobs for spot memory because reclaiming memory that has been borrowed by other functions can impose unacceptable overhead for interactive functions. Instead, NPFU allows users to simply specify if instances can be preempted (*preemptible-mem* as true). Preemptible instances can use the allocated-but-idle memory of non-preemptible instances; if memory usage exceeds physical memory, the preemptible instances are killed, allowing non-preemptible instances to access the reserved memory with minimal overhead. NPFU ensures that the total mem-cap of non-preemptible invocations does not exceed the available memory.

3.2 NPFU Billing Function

NPFU provides a flexible billing model that generates a win-win scenario for providers and users. NPFU leverages a used/lent model that enables users to buy/sell CPU and memory capacity from/to each other.

To calculate CPU cost, we define three kinds of cputime: *reserved-cputime*, the total reserved cputime (*execution_time* $\times$*reserved-cores*); *lent-cputime*, the idle reserved cputime used by other functions; *borrowed-cputime*, the used cputime of spot CPUs. The CPU cost, where C_r is the unit price for *reserved-cores*, and C_s for *spot-cores*, with $C_r > C_s$, is:

$$\begin{aligned} & C_r \times \textit{reserved-cputime} \\ + & \ C_s \times \textit{borrowed-cputime} \\ - & \ C_s \times \textit{lent-cputime} \end{aligned} \tag{1}$$

To calculate memory cost, non-preemptible memory acts as the lender, while preemptible instances are borrowers. For non-preemptible instances, the memory cost is:

$$\begin{aligned} & M_r \times \textit{mem-cap} \times \textit{execution_time} \\ - & \ M_p \times \textit{avg-lentMem} \times \textit{execution_time} \end{aligned} \tag{2}$$

$M_r > M_p$ since reserved memory is more valuable than preemptible memory. The cost for preemptible instances is:

$$M_p \times \textit{avg-memory} \times \textit{execution_time} \tag{3}$$

If a preemptible instance is preempted mid-invocation, the customer is not charged, and its invocation is simply requeued.

3.3 Comparison with existing PFU family

NPFU can reproduce many of the advantages of SLIM. Specifically, NPFU offers both bounded performance and bounded cost by allowing users to specify minimal resources (with *reserved-cores* and non-preemptible *mem-cap*); and maximal resource boundaries (using *cpu-cap* and *preemptible* option). Although the cost can be less predictable when functions lend or borrow CPU, it ensures a clear upper bound: for functions with *reserved-cores*, the upper bound occurs when there are no available *spot-cores* and no CPU time is lent to other invocations; for functions without *reserved-cores*, the cost is determined by the used CPU time. Furthermore, the used/lent billing function ensures that providers can maintain the same revenue as SLIM.

In terms of simplicity, NPFU introduces three more knobs than SLIM, which is acceptable as simplicity is not merely a knob count; a single knob that must be tuned with high precision is arguably more complex to tune than a handful of less sensitive knobs. SLIM offers a single "size" knob that controls CPU and memory for all function invocations, making four unrealistic assumptions and requiring precise tuning to estimate the worst-case scenario: overestimating results in an overpayment, while underestimating causes the largest invocations to fail. NPFU can be configured to behave identically to SLIM by setting *cpu-cap* to be linear with *mem-cap*, *spot-cores* to 0, and *preemptible* to false; customers who prioritize simplicity could use these default values.

NPFU takes significant steps toward approximating SPFU. NPFU addresses SLIM's workload assumptions: it enables functions to sell their "allocated but unused" CPU time and memory (removing Assumption-SI and SE); decouples CPU and memory (resolving Assumption-L); and enables users to specify their urgency on requested resource by setting reserved (or spot) CPUs and non-preemptible (or preemptible) memory (removing Assumption I). NPFU allows batch function to set *reserved-cores* to zero and use preemptible memory, aligning their billing with SPFU; for interactive functions, NPFU offers a discount on wasted resources, making it more cost-effective than SLIM.

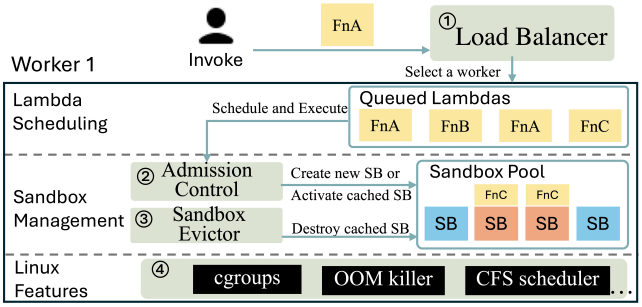

Figure 5: Overview of popular serverless platforms.

4 Billing-Aware Serverless

FaaS platforms are a composition of many subsystems, including load balancers, admission controllers, and kernel-level schedulers and resource controllers; efficiently supporting new billing models, such as NPFU, requires support from each of these subsystems. We give background for each subsystem (§4.1), describe the limitations of each for billing (§4.2), and propose Leapord (§4.3), a new FaaS platform with billing support built into every layer of the stack.

4.1 Background: Serverless Subsystems

Figure 5 illustrates the key components in a serverless platform. ① *Load Balancer:* dispatches incoming invocations to workers using a load-balancing strategy. ② *Admission Control:* selects the next request for execution and creates, or activates, a sandbox when sufficient resources are available. ③ *Sandbox Evictor:* removes cached sandboxes when too many are in memory ④ *Resource Isolation:* manages CPU and memory allocations across sandboxes. We now describe the typical implementations for each.

Load Balancing: In mainstream serverless platforms, after reaching the global controller, invocations are immediately dispatched to workers, eliminating memory usage for arguments and enabling scalability [4,34,45]. To avoid cold starts, the load balancer aims to minimize the number of workers handling invocations from the same function. For example, OpenWhisk [4] uses consistent hashing by mapping invocations to "home" workers; if a home worker is overloaded, the function is forwarded along the ring until a non-overloaded worker is found. Systems [9] built on Kubernetes [1] use greedy load balancing, sending requests to the first worker until it reaches capacity. Hermod [45] uses a greedy algorithm under low load and a least-loaded algorithm during high load.

Admission Control: The selected worker determines when to execute the incoming invocations, deciding how many invocations can run concurrently while ensuring that reserved resources are maintained for each invocation. For example, in OpenLambda [34], the provider manages the number of active sandboxes to ensure that total CPU/memory allocation across all active sandboxes does not exceed the physical resources available on each worker. Platforms typically use a priority queue; to improve average slowdown, many use Shortest Job First [16], estimating runtime based on historical data [45].

Sandbox Evictor: When a function completes, its sandbox is kept alive for future use. Cached sandboxes reduce latency but consume memory, so deciding when to evict cached sandboxes is critical. For instance, OpenLambda evicts the LRU sandbox when memory usage exceeds a threshold. Some approaches retain idle sandboxes for a specified duration [5,13,64]. FaasCache [26] evicts sandboxes only when memory is insufficient, evicting sandboxes with lower usage frequency, longer runtime, and larger memory footprints.

Resource Isolation: Resource isolation is crucial for maintaining performance in multi-tenant environments. To isolate requested CPU and memory resources, most serverless platforms use containers [4,9,34] and microVMs [13], such as Docker [3], Kubernetes pods [10], OpenLambda's SOCK [59], and AWS Lambda's Firecracker [11]. These solutions all rely on Linux cgroups. For memory management, cgroups provide the memory.max option, which enforces a memory limit for all tasks in the group; if a task exceeds this limit, the Out-of-Memory (OOM) killer is triggered and terminates one or more tasks based on metrics like memory consumption and age. Linux cgroups offer two mechanisms to manage the CPU: *CPU pinning* restricts tasks to specific CPUs, supporting both minimum and maximum CPU limits; *weighted sharing* relies on Linux's Completely Fair Scheduler (CFS) to allocate CPU time based on proportional shares. CFS divides available CPU cycles among threads in proportion to their weights. In multicore systems, each physical CPU has its own runqueue; load balancing periodically adjusts task distribution, moving tasks from burdened CPUs to lightly-loaded CPUs. With these mechanisms, containers can implement their own resource models. For instance, Kubernetes's "request" interface uses CPU sharing to reserve at least the requested amount of CPUs for a specific container [2]. The correctness and efficiency of its reservation depend on the implementation of cgroup.

4.2 Subsystem Support for NPFU: Challenges

Given that these subsystems were built without considering billing, each has limitations that make a correct and efficient implementation of NPFU difficult.

Challenge 1: cgroup API does not support efficient CPU reservations. NPFU uses *reserved-cores* to maintain performance and *spot-cores* to allow CPU sharing. The CPU scheduler should support two requirements. First, cgroups must be assured immediate access to their *reserved-cores* when needed (correctness); second, cgroups should be allowed to use idle *reserved-cores* of other co-located cgroups (efficiency).

The cgroup API and underlying CFS scheduler support both CPU pinning (via CPU sets) and weighted sharing (via CPU shares), but neither meets our requirements. To demonstrate the issue, we perform an experiment: two functions run concurrently, each of which has "paid" to reserve 16 of the machine's 32 cores. Function F1 runs 32 tasks continuously, and is willing to pay for additional spot cores. F2 starts with one task, fans out to 16 tasks, and does not use spot cores.

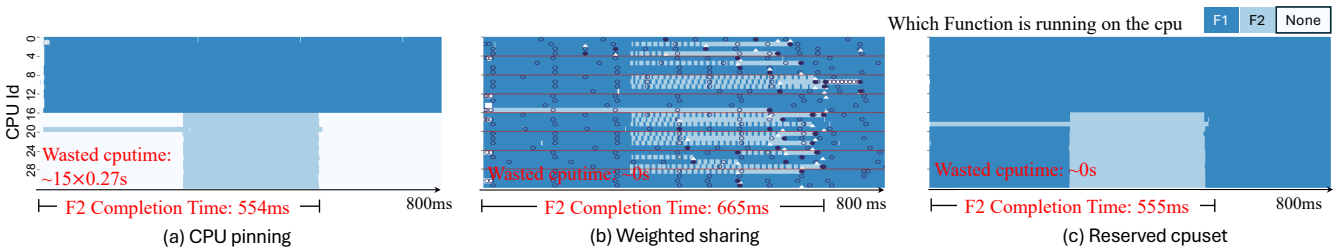

Figure 6: Colocation of Function 1 (32 processes) and Function 2 (1 process forks 15 processes at 270ms).

First, we evaluate CPU pinning via CPU sets in Figure 6(a). Reservations are implemented by applying a CPU set to all functions: the CPU set for F1 is cores 0-15, and for F2, it is cores 16-31. The figure shows that each function has sole use of its reserved cores, but the strictness of CPU sets wastes ∼4 seconds of CPU time on cores 16-31 that F1 would have been willing to purchase (at a reduced rate). Thus, CPU pinning only support inefficient reservations.

We evaluate weighted sharing with cpu.share in Figure 6(b); cpu.share the task to run on any core. We give both functions an equal share and expect each to be allocated approximately its reservation of 16 cores. The results show that no CPU is wasted because F1 uses whatever is available, but F2 is denied full access to its reserved CPUs and runs 20% slower. We conclude that cpu.share cannot correctly provide reservations.

CFS load balancing is resource-intensive, involving computational costs and cache misses, so CFS uses many heuristics to reduce overhead. For example, when CFS finds no imbalance, it doubles the interval before its next load balancing attempt and keeps the interval until the next successful migration. These heuristics undermine CFS's ability to promptly split CPU time among cgroups according to their cpu.shares. Figure 6(b) illustrates when CFS load balancing occurs: empty circles represent load balancing without migration, black circles represent migration, and white triangles show the source CPU of the migration. The figure shows that the interval between load balancing is around 100 ms. The infrequent rebalancing of cpu.shares is not sufficient for serverless workloads, where billing occurs at 1 ms granularity.

An alternative approach is to adjust the CPU set or the share weight of serverless functions over time dynamically, pushing their actual CPU usage closer to their proportional shares. However, it introduces overhead (*e.g.* adding a core to a VM takes approximately 0.1 milliseconds [14]), impacting millisecond-scale serverless invocations. The high overhead also limits the frequency of adjustments [32, 35, 46].

Challenge 2: sandbox evictor does not support preemptible memory. NPFU introduces a preemptible memory knob to allow efficient memory usage, and, to utilize idle reserved memory, NPFU allows preemptible sandboxes to be admitted even when all of memory is allocated. However, if memory is exhausted, the Linux OOM handler takes over before the sandbox evictor can react. The Linux OOM killer lacks access to sandbox-specific properties and may kill non-preemptible instances, violating the guarantees of NPFU. It also prevents the implementation of more sophisticated eviction strategies; for example, FaasCache [26] needs statistics for each sandbox such as execution recency, invocation frequency, and termination costs. Thus, NPFU requires improvements to the sandbox evictor and Linux OOM handler.

Challenge 3: NPFU complicates load balancing and admission control. By decoupling CPU and memory, NPFU introduces complexity for load balancing, leading to a multidimensional bin-packing problem and increasing the likelihood of stranded resources. This issue is worsened by locality-aware load balancing, which may assign memory- or CPU-heavy functions to the same "home" worker. Additionally, current loaded balancers rely on simple metrics like the number of invocations; consequently, interactive tasks may experience degraded performance even when another worker has sufficient unreserved resources but appears loaded due to batch tasks. Similarly, admission control that does not distinguish between spot CPUs and reserved CPUs will not know when it is safe to admit a given function invocation.

4.3 Leopard: Billing-Aware FaaS

As existing subsystems cannot handle novel billing models, we introduce a new billing-aware FaaS platform, Leopard, based on OpenLambda. Leopard implements spot CPUs and other NPFU features with several new subsystems. It introduces a new resource isolation mechanism for task groups, including CPU scheduler support for reservations (§4.3.1) and a billing-aware out-of-memory (OOM) killer (§4.3.2). It also presents a serverless-specific admission control policy at the worker level that accounts for spot CPUs (§4.3.3). Additionally, it introduces a serverless-specific cluster-level load balancer that considers both alignment and locality (§4.3.4).

4.3.1 Efficient CPU Reservations

Linux cgroups and CFS cannot support CPU reservations, so Leopard provides a new cgroup interface, *cpu.resv_cpuset*. Tasks in this new type of cgroup are guaranteed reserved CPUs on demand, but other cgroups may use the reserved CPUs if the reserver does not need them. To borrow a legal term, a cgroup reserving some cores has the *right of first refusal* for using them. Unlike the prior CPU-set interface, cpu.resv_cpuset does not prevent a cgroup from running on CPUs outside of the set; non-reserved CPUs may be used if computational needs exceed the reservation and there is a willingness to pay for additional spare compute.

Leopard modifies the CFS scheduler to support the new cgroup reservation API. The new CFS mode has two goals:

(1) Do not rely on fairness to achieve isolation. The previous approach of weighted sharing in cgroups relies on fairness, which current CFS implementations do not enforce effectively due to the high overhead of monitoring other cores for load-imbalance. In contrast, a new approach that ensures isolation for reserved cores is simpler and less resource-demanding, as it can be achieved locally without inter-core checks.

(2) Allow tasks to use flexible policies on different cores. CPU pinning allowed different policies for different cores (*e.g.*, a sandbox was permitted or forbidden on each core), but this policy was too blunt. We propose an enhanced model, where the scheduler differentiates more refined policies. Specifically, on reserved cores, a task can have the highest priority allowing immediate preemption; conversely, on other cores, the same task can have a lower priority, following spot tasks rules. This approach ensures that the new scheduler achieves both reservations and flexible sharing.

Based on these goals, Leopard adds reservation support in CFS as follows. When CPUs are added to *cpu.resv_cpuset*, the core marks the tasks as *reserving tasks*; other tasks are treated as *spot tasks*. When a core scheduler picks a task, it always picks a reserving task if any are runnable; otherwise, it pulls a runnable reserving task from the busiest runqueue in its cgroup; if that fails, the scheduler picks a spot task on the core's runqueue or makes an *idle-balance* CFS call to find a spot task elsewhere. When a reserving task wakes up (*e.g.*, after an I/O completion) and a spot task is running, the reserving task preempts the core immediately.

To maintain fairness within a cgroup, Leopard keeps the CFS design for managing tasks inside cgroups, but divides the load metric of a runqueue to track classes of tasks. When one CPU triggers load balancing, if the current task is a reserving task, the scheduler only balances the reserving cgroup load; if the current task is a spot task, the scheduler balances the load of all spot groups.

Figure 6(c) shows that Leopard's new reservation API behaves as desired: there are no wasted cores, and each task receives its reserved allocations. Specifically, F1 expands to more cores when they are available, and F2's performance is not harmed because it has top priority on cores 0-15.

In addition, to compute CPU billing in Equation 1, Leopard tracks reserved CPUtime, spot CPUtime, and lent CPUtime of the invocations by modifying the cgroup CPU Accounting (*cpuacct*) subsystem, which reports the used CPUtime of a cgroup. Linux updates the used CPUtime of a cgroup incrementally by calling *cgroup_account_cputime(Task p, int delta_exec)* when a task's state changes.

We add three interfaces in *cpuacct*: *resv_usage*, *spot_usage*, and *lent_usage*. Each time *cgroup_account_cputime* is called for a task p, (1) if the current CPU is p's reserved CPUs, add *delta_exec* to *resv_usage* of *p's* cgroup; (2) otherwise, add *delta_exec* to the *spot_usage* of p's cgroup, and to the *lent_usage* of current CPU's reserving cgroup. The overhead is negligible, as it involves simple arithmetic operations within *cgroup_account_cputime* when the task state changes. Once the invocation finishes, the CPU billing can be computed by reading these metrics from the cpuacct interface, with less than 1 ms per invocation.

4.3.2 Sandbox Evictor

NPFU allows preemptible sandboxes to be admitted even when all memory is allocated to non-preemptible sandboxes, so memory exhaustion may occur under heavy load. However, Linux's original OOM handler sometimes takes over sandbox eviction before the userspace sandbox evictor can react. To support NPFU, Leopard contains a mechanism that gives control to the sandbox evictor during OOM events.

Leopard enables customizable OOM victim selection for different cgroups, allowing evictors to use rich user-space information. Specifically, Leopard contains two new Linux cgroup APIs for handling out-of-memory scenarios: *memory.oom.listener* specifies a user-space process to perform victim selection; *memory.oom.victim* sends the selected victim's PID to the kernel. For example, in user-space, Leopard can estimate the revenue lost for preempting different sandboxes (since preempted sandboxes are not charged) and preempt the sandbox that loses the least revenue; this information is unknown in the kernel. Specifically, when receiving an OOM signal, the evictor first selects cached sandboxes (*i.e.*, the same policy as FaasCache [26]), but if none are available, chooses the active preemptible sandbox with the shortest runtime and using the fewest resources, in order to lose the least revenue.

With this mechanism, Leopard can easily support sophisticated preemption policies. The communication overhead of victim selection in userspace is minimal ($\sim$0.4 ms), and is mitigated by proactive eviction and admission control of preemptible sandboxes. In summary, these enhancements allow Leopard's evictor to make informed decisions during OOM events caused by including preemptible sandboxes.

4.3.3 Admission Control

Leopard uses the following criteria to determine whether to admit an invocation into a sandbox: interactive invocations with *resv-cores* or non-preemptible memory are admitted if sufficient unreserved resources are available; batch invocations with preemptible memory and no *resv-cores* are admitted if currently idle memory and CPU resources are sufficient.

To determine whether or not preemption is likely, Leopard collects historical CPU and memory usage from past invocations and monitors the total of these averages for current active invocations. If the sum of historical memory usage exceeds the total memory, there is a high likelihood of preemption. In such cases, to avoid the risk of OOM events and unnecessary preemptions, Leopard does not admit the next batch function. Overcommitting CPU is less harmful, as it does not trigger preemption; therefore, Leopard admits new batch functions as long as the total historical CPU usage remains less than twice the total CPU resources.

When reserved resources are released, Leopard admits queued interactive invocations using the Shortest Job First. When the utilization of a worker falls below a threshold, Leopard admits the batch request with the shortest runtime that does not request reserved capacity. Thus, Leopard ensures high utilization for each worker while ensuring that reserved resources for active sandboxes are available when needed.

4.3.4 Load Balancer

Leopard provides a new load balancer for invocations. At low load, function placement does not significantly impact performance, so Leopard prioritizes alignment (to strand fewer resources) and locality (to improve warm-up). For alignment, we follow Grandl *et al.* [29] and define the alignment score of a task relative to a worker, *score-align*, as the dot product between the vector of task's reserved resources and the worker's available resources; a higher score indicates a better fit. To preserve locality, Leopard calculates a *score-locality* for each worker based on its priority scheduling with the traditional hashing sequence [4]. At low load, Leopard places tasks based on a combined score for each worker as $\textit{score-align} + \alpha\ \textit{score-locality}$.

At high load, the queueing delay is the most critical factor. Leopard balances the load while accounting for the QoS requirements of each function. Specifically, for interactive invocations, Leopard chooses the worker with the lowest *reserved-load*, which is the amount of reserved resources needed to complete all queued interactive jobs; $\textit{resv-load} = \sum_r r.avgRT \times (r.resv\text{-}cores + mem\text{-}cap \times !preemptible\text{-}mem)$, where r is the queued request in this worker. In contrast, for batch invocations, Leopard chooses the worker with the lowest *usage-load*, which is the actual resources used to complete all queued jobs; $\textit{usage-load} = \sum_r r.avgRT \times (r.avg\text{-}CPU + r.avg\text{-}Mem)$, where *avg-CPU* and *avg-Mem* are the historical CPU and memory utilization for the function. Thus, the load balancer ranks workers differently for interactive versus batch tasks.

4.3.5 Limitations

Further improvements on Leopard are worth considering. First, resv_cpuset does not consider placement: whether the reserved CPUs should reside on the same NUMA node and hyperthreads from the same core. Second, resv_cpuset cannot support the reservation of a fraction of a core, which may be desirable for some applications [25, 37]. Finally, conflict between alignment and locality goals can make the combined load balancer score ineffective [52]; deployment in a disaggregated cluster could be a potential solution [30].

5 Evaluation

We describe a new methodology for evaluating billing (§5.1). Then, we explore four questions: *How does Leopard with NPFU perform relative to other models* (§5.2)? *Can Leopard adapt to workload changes* (§5.3)? *Does Leopard scale effectively* (§5.4)? *How does building a serverless platform from billing-aware components improve efficiency* (§5.5)?

5.1 Methodology for Billing Model Evaluation

We discuss the limitations of existing methods when applied to billing and present a billing-oriented benchmark.

5.1.1 Existing Workloads

The Microsoft Azure dataset [64] provides the most complete details on invocations in a major serverless platform, including 52,000 functions invoked 8.8 billion times over 14 days. The dataset is divided into three major components: *Invocations*, the number of function invocations per minute; *Execution Time*, average and percentile execution-times per function; *Memory Usage*, average and percentile memory usage per application. However, the Azure dataset does not contain CPU usage data or details on resource fluctuations over time. Thus, researchers often use synthetic workloads and make some assumptions about unknown information [26, 45, 65] (*e.g.*, Hermod [45] and Orcbench [31] simulate spin loops for each execution, which assumes that the CPU utilization for each invocation is 100%).

Existing serverless benchmarks measure aspects of performance and cost [20, 31, 68, 71], but rarely focus on billing, and their function suites exhibit simplistic resource usage patterns. For example, SeBS [20] contains functions with a maximum CPU usage of one. Moreover, prior work [20, 71] considering customer cost does so only for SLIM-like billing.

5.1.2 BilliBench

We introduce a new billing-oriented benchmark, BilliBench (BB). We describe BB's essential components and how it can be used to evaluate billing models.

BB Functions: We utilize the function suites collected earlier (§2.3.3) as BB Functions. Unlike previous serverless benchmarks, our function suite exhibits varied resource usage behaviors (as shown in Figures 1, 2, and 3).

BB Trace: To realistically compare different billing models, invocation traces must contain detailed resource usage fluctuations. Our key insight is that, given summarized coarse-grained trace data from major cloud providers (such as Azure), we can supplement incomplete information with detailed fine-grained data from real-world serverless functions (*e.g.*, BB functions). By combining these two sources of information, we can generate realistic traces of function invocations.

The BB Trace includes three components: functions, invocations, and resource-usage phases. A function contains a list of invocations, and each invocation contains a list of resource-usage phases; each phase specifies a duration and the resource utilization in that interval (*i.e.*, active thread number and memory size). Each function in the Azure dataset, F_{Azure}, is represented as a function in the BB Trace; for each F_{Azure}, we randomly select a function F_{BB} from the BB function suite (shown in Table 1) to provide detailed data on resource usage.

We then translate the Azure dataset into a list of function invocations, following previous work [26, 45, 64]. After that, BB represents each invocation as a sequence of resource-usage phases: for each phase, we randomly choose the number

of active threads below F_{BB}'s maximum parallelism, ensuring the invocation's average parallelism across all phases matches that of F_{BB}; next, we randomly sample the memory size from the distribution of F_{Azure} in the Azure dataset; finally, we randomly select the runtime of the entire invocation from F_{Azure}'s runtime percentile in the Azure dataset. The number of resource-usage phases is based on F_{BB}, and the duration of each phase is the total runtime divided equally among the phases. The QoS of each invocation is based on whether the corresponding F_{BB} is interactive or batch.

Given the constructed dataset, we synthesize a function F_S with Python code for the function F_{Azure} that imitates its specific resource usage phases during invocation.

The above default BB Trace leverages CPU usage behavior and QoS of BB functions. To mitigate bias from the limited function suite, BB allows users to configure the trace parameters. Users can generate a trace with a configured average CPU utilization across all functions; BB randomly selects the active thread number for each phase to maintain the overall average. Users can also configure batch task proportions. These configurable synthetic traces offer a method for evaluating billing models across diverse workloads. In our experiments, we evaluated NPFU with the default BB Trace (§5.2) and BB Traces with varying average CPU utilization (ranging from 10% to 90%) and batch task proportions (ranging from 10% to 60%) (§5.3). Each combination of these two parameters generates a unique trace.

Knob Tuning: To compare billing models with different configuration options, we configure the functions in the BB Trace with four base limits to imitate real users. We set *cpu-cap* to the function's maximum parallelism and *mem-cap* to its maximum memory usage; *preemptible-memory* is set to false for interactive functions and true for batch functions; for interactive functions (*e.g.*, ML inference and database clients), *spot-cores* is set to zero, while for other interactive functions, *spot-cores* is set to *large_parallelism* minus *medium_parallelism* for performance variability.

BB can run with simple and complex models. Models that enforce strict memory-to-CPU ratios can round-up either *mem-cap* or *cpu-cap*. Platforms that do not differentiate between interactive and batch jobs can ignore *spot-cores* and *preemptible-memory*, assuming that all cores are reserved.

BB Metrics: We compare billing models using five metrics across providers and customers. For performance issues, we measure resource utilization and throughput for providers and job completion time for customers. Customer cost (per invocation) and provider revenue (per machine) are two other interrelated metrics. We explicitly separate billing from pricing, since pricing merely shifts value between producers and consumers (*e.g.*, reducing prices by 10% lowers revenue by 10%), while better billing models can create additional value. To compare billing models, we fix provider revenue per machine per time unit by adjusting the pricing constants (*e.g.*, M and C in Table 3); keeping provider revenue constant lets us compare models using a single metric: user cost. When models allow tenants to tune both memory and CPU, we fix the C/M ratio at 9.6 to match Google Cloud Functions [8].

Baselines	Tunable Knobs				Billing Function	
	cpu cap	spot core	mem cap	preemptible	CPU Bill (per time unit)	Memory Bill (per time unit)
SLIM			✓		mem-cap / $r \times C$	mem-cap$\times M$
SIM	✓		✓		cpu-cap$\times C$	mem-cap$\times M$
SPFU	✓		✓		avg-cpu$\times C$	avg-mem$\times M$
NPFU	✓	✓	✓	✓	resv-cores$\times C_r$ +avg-spot-cpu$\times C_s$ −avg-lent-cpu$\times C_s$	mem-cap$\times M_r \times \neg P$ +avg-mem$\times M_p \times P$ −avg-lent-mem$\times M_p$

Table 3: The tunnable knobs and billing functions of baselines. Billing functions contain the price constants that providers can adjust: C for per cpu-second, M for per GB-second. NPFU includes two CPU prices for reserved CPU (C_r) and spot CPU (C_s) (Similarly for M_r and M_p) and resv-cores = cpu-cap − spot-cores. r indicates the fixed memory-to-CPU ratio in SLIM. P indicates whether the user set preemptible-memory or not.

Billing Models: We have implemented the following mainstream billing models in Leopard, as summarized in Table 3. *SLIM:* AWS Lambda, GCP, and Azure's premium plan use SLIM-like billing models, where users specify a memory limit for each function, and CPU is proportionally allocated; these limits serve as both minimal and maximal thresholds. *SIM:* SLIM without Assumption L provides independent knobs for memory and CPU limits. *SPFU*[1]: Strict PFU has no knobs, since cost is a function of usage and not knob settings; however, a platform using SPFU may still expose resource limit settings (*e.g.*, Azure's consumption plan and Cloudflare use mostly fixed resource limits), and so we optimistically assume customers set these limits as restrictively as possible, despite having little billing incentive to do so. *NPFU:* NPFU contains four knobs (*cpu-cap*, *spot-cores*, *mem-cap*, and *preemptible-mem*) and supports paying more or less when resources are borrowed or lent, respectively. NPFU aims to closely approximate SPFU while remaining profitable in practice.

5.1.3 Experiment Setup

We conduct experiments on machines with two Intel Xeon Silvers, each with 10 physical cores. We disable hyperthreading to eliminate hardware-level interference, allowing us to focus on CPU isolation mechanisms in the kernel. We use Ubuntu 22.04 with the latest Linux kernel v6.7-rc2 using cgroups V1.

We build support for each of the above billing models in Leopard. We use BB Traces based on a random sample of 1,000 functions in the BB dataset. The client initiates a task to send the invocation at the designated timestamp and wait for the response. We use one load-balancing node to route invocations to one of eight worker nodes. For each worker node, we assigned 16 CPUs and 8 GB of DRAM to serve invocations and 1 CPU to handle worker logic, including admission control and communication with the controller.

[1] In §2, we claim that SPFU is an idealized billing model, but it's not very profitable in practice as it usually provisions resources that may go unbilled.

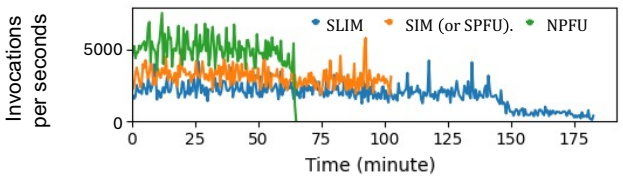

Figure 7: The throughput vary based on different billing knobs.

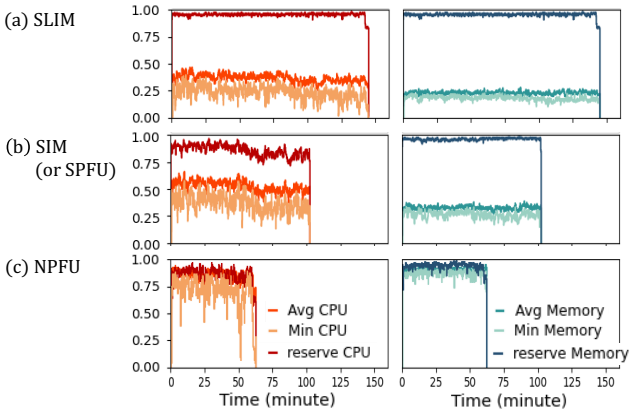

Figure 8: The utilization vary based on different billing knobs.

5.2 Evaluation of NPFU

We show that NPFU benefits both providers and users: providers obtain greater efficiency while users pay lower costs and still meet their QoS needs.

5.2.1 Provider Side

Figure 7 shows the benefits of NPFU for providers: the throughput for SLIM, SIM, and NPFU billing models in the first hour of invocations from the BB Trace. We observe that decoupling the linear memory-CPU relationship (*i.e.*, going from SLIM to SIM) leads to a 1.3x increase in throughput. Switching from SIM to NPFU provides an additional 1.6x improvement because Leopard NPFU can admit invocations when all resources are reserved but happen to be idle.

Figure 8 shows the average and minimum resource utilization in the cluster, explaining the higher throughput of NPFU. With SLIM, over 50% of CPU and 75% of memory are wasted, while SIM improves resource utilization by decoupling CPU and memory, and NPFU further increases memory utilization to 90% and CPU utilization to 80%, thanks to spot cores and preemptible memory. We observe that all billing models maintain high reservation rates: SLIM achieves near-100% CPU and memory reservation, while SIM and NPFU have lower CPU reservations due to CPU-memory decoupling. In summary, Leopard's load balancer and admission control ensure full resource rental under high load. These benefits come from the more expressive knobs of NPFU, allowing users to specify which portions of allocated resources can be borrowed without compromising their objectives. In contrast, SLIM lacks such knobs, as it makes four assumptions about resource allocation, preventing resource schedulers from sharing unused resources across invocations and leading to low utilization.

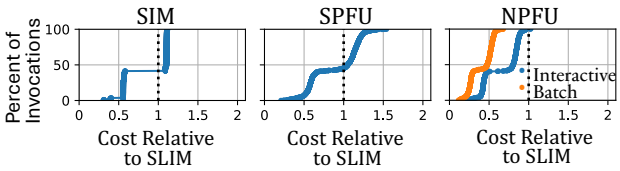

Figure 9: User cost relative to SLIM with different billing models.

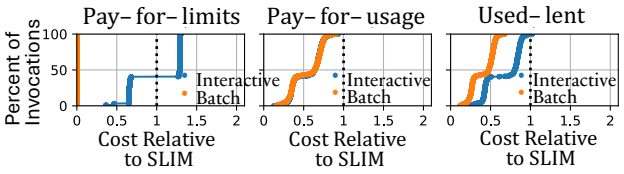

Figure 10: User cost of NPFU with different billing functions.

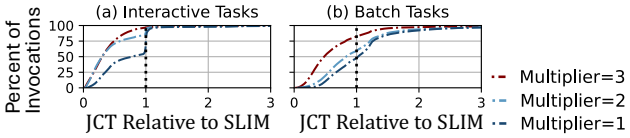

Figure 11: CDF of Job Completion Time (JCT) of invocations when running with NPFU (relative to that when running with SLIM).

5.2.2 User Side

For users, we examine both cost and performance.

User cost: To perform a fair comparison for each billing model, we adjust the unit prices of CPU and memory to ensure that the provider revenue remains the same as the SLIM. Figure 9 shows the CDF of invocation cost relative to the cost of running with SLIM. With SIM, approximately 50% of invocations save money since they no longer over-allocate CPU to meet the memory requirements of the linear model; however, other functions become slightly more expensive. For SPFU, maintaining provider revenue necessitates increasing SPFU's C and M price parameters by 1.6x; as a result, some functions cost more than 50% because SPFU distributes the cost of resource wastage across all users. Most importantly, NPFU reduces the cost of nearly every invocation, often significantly: about 40% of functions cut costs by at least half. Batch tasks save more than interactive tasks, as they pay lower rates for spare resources that interactive instances reserved. In total, the costs for NPFU clients are 66% (for interactive functions) and 41% (for batch functions) of those under SLIM.

In Figure 10, we examine the benefits of used-lent billing by comparing NPFU with pay-for-limits (like SLIM) and pay-for-usage (like SPFU). Pay-for-limits lets batch tasks run at no cost, as they did not require any reserved resources, making interactive tasks more expensive. Pay-for-usage charges interactive and batch jobs similarly and lacks incentives for users to relax their QoS requirements; it also does not charge for limits, giving users no incentive to set realistic restrictions.

Job Completion Time: We now examine whether interactive functions meet their QoS. To simulate different load levels, we repeat each invocation a *multiplier* number of times. Figure 11(a) compares job completion time (JCT), including queuing and execution time, with NPFU versus SLIM. Under

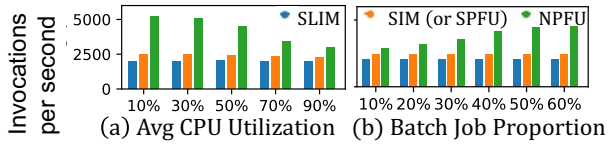

Figure 12: The throughput as the workload characteristics change.

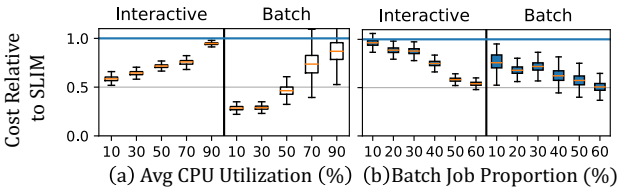

Figure 13: The cost of NPFU as the workload characteristics change.

high system load, when most invocations experience queuing, NPFU significantly reduces JCT for nearly all interactive functions. As the load decreases, the JCT for NPFU and SLIM becomes similar. A comparison with SIM (or SPFU) produced similar results. Batch tasks do not have strict latency requirements. As shown in Figure 11(b), batch tasks may take up to three times longer with NPFU compared to SLIM; however, some batch tasks can achieve shorter JCT as NPFU allows them to run when resources are not fully available.

5.3 Robustness to Different Workloads

We now analyze billing models for a range of BB Traces; we adjust CPU utilization and the proportion of batch tasks.

CPU Distributions: In a BB Trace, each invocation derives its parallelism from BB functions. In Figure 12(a), we vary the CPU utilization for each function following a normalized distribution with a given average. As CPU utilization increases for each invocation, NPFU delivers reduced throughput for the provider and smaller savings for customers, as Leopard admits extra batch tasks only when CPU utilization is below a threshold. Other billing models have unchanged throughput, as they admit tasks based on reserved resources, not usage. Still, the throughput of NPFU always remains higher than that of the other models. Figure 13(a) shows the user cost with varying CPU utilization; when CPU utilization exceeds 70%, a small number of batch invocations become slightly more expensive for customers with NPFU.

Batch Task Proportions: Previously, we assigned functions as interactive or batch based on BB functions. In Figure 12(b) we analyze how Leopard's performance changes with different batch task proportions. NPFU achieves higher throughput for the provider as the batch task proportion increases; for other models, the throughput stays constant. Figure 13(b) shows that NPFU offers greater financial benefits for users when there are more batch tasks; with more batch tasks, they can better use idle but reserved resources and boost throughput. Compared to SLIM, NPFU may not reduce the costs for a small portion of interactive tasks, as idle resources remain underutilized without sufficient batch tasks.

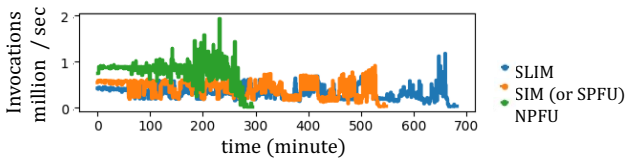

Figure 14: The provider throughput running large-scale BB Trace on different billing knobs.

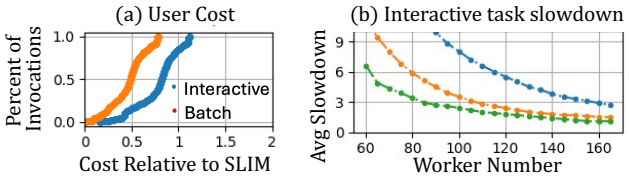

Figure 15: The NPFU's (a) user cost (b) JCT of interactive jobs running large-scale BB Trace.

In conclusion, NPFU outperforms SLIM for every point we explored in the space of CPU utilization and batch-job proportion. The benefits are greatest when interactive jobs have low CPU utilization relative to resource caps and there are many batch jobs to take advantage of those leftover resources.

5.4 Large-Cluster Simulations

To study a larger cluster, we build a simulator to evaluate different billing models on a cluster of 160 workers and use the entire first hour of the complete BB Trace (instead of only a random sample of 1,000 functions). Figure 14 shows that the simulated results on a 160 workers obtain the same benefits as a real 8-worker cluster (Figure 7).

Figure 15(a) shows that improvements in user cost with NPFU relative to SLIM are similar to that shown for small-scale experiments (Figure 9); however, about 5% of interactive functions are now up to 15% more expensive than with SLIM. Given that NPFU differentiates between interactive and batch functions, it is natural that some revenue collection shifts from batch to interactive. Figure 15(b) shows that the QoS of interactive functions is still satisfied under NPFU as the number of workers changes, with consistently lower slowdown than in other billing models.

5.5 Evaluation of Leopard Components

CPU Reservations: We evaluate whether the cgroup interface cpu.resv_cpuset and modifications to CFS of Leopard efficiently support CPU reservations. We examine three settings: (1) SLIM with CPU pinning: each sandbox is assigned a fixed CPU set and exclusively uses its allocated CPUs. (2) NPFU with weighted sharing: all CPUs are shared among active sandboxes, where interactive sandboxes with reserved CPUs have a weight of $1024 \times resv_cpu$ and non-interactive sandboxes have a weight of 1. (3) NPFU with reserved CPU set: sandboxes with reserved CPUs are assigned to a reserved CPU set; sandboxes can access their reserved CPUs when needed but still lend idled CPUs.

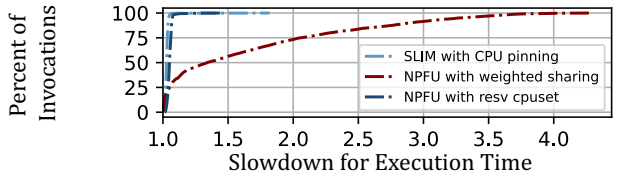

Figure 16: The CDF for the invocation execution time slowdown relative to running without contention, excluding queuing delay.

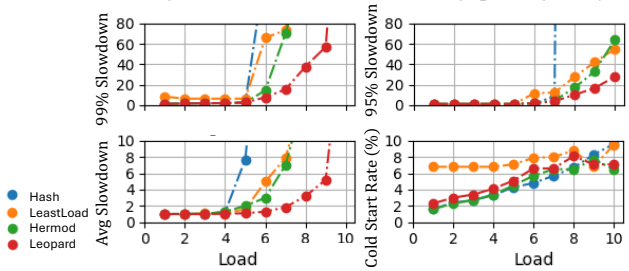

Figure 17: The slowdown and cold start rate when implementing different load balancers on Leopard.

Figure 16 shows the CDF of execution time slowdowns for interactive invocations in the BB Trace. Execution time excludes queue delay, so the slowdown is primarily due to CPU contention among co-located invocations. We observe that CPU pinning cannot support spot-cores; fair-share scheduling cannot correctly provide performance isolation for interactive jobs; and Leopard's reserved cpuset enables the spot-core while maintaining performance isolation for interactive jobs.

Load Balancer: With NPFU, we implement the following load balancers on Leopard: (i) Consistent Hashing scheduler from OpenWhisk [4], (ii) Least-Loaded Scheduler as in Kogias *et al.* [49], and (iii) Hermod [45] scheduler, which uses a greedy approach under low load and the least-loaded scheduler during high load. In Figure 17, we present the slowdown in job completion time (including queue delay) for all interactive functions in Leopard (with NPFU enabled) under different load balancers. A few key observations: First, under low load, the 99% slowdown of Least-Loaded balancer is higher compared to other load balancers since it does not account for locality (the cold start rate is depicted in Figure 17). Second, the performance of the Consistent Hashing deteriorates significantly as the load increases, as it is load-unaware. Finally, Leopard performs as well as, or better than, these common serverless schedulers across all load conditions.

6 Related Work

Improving Serverless Utilization: Existing research has explored ways to increase the resource utilization of serverless platforms. Owl [67], Golgi [50], and Jiagu [53] stress overcommitment of function instances. However, these approaches still use SLIM billing models. Overcommitment breaks the promise made by the SLIM. They rely on predicting user performance to avoid breaking the QoS of user requests, which is difficult for real workloads [17]. Other works [58,75] search for a near-optimal configuration for functions under SLIM or SIM. However, our evaluation shows that even if users choose precise resource limits, the cluster still suffers from low resource utilization. This problem arises because actual usage fluctuates both within individual invocations and across different invocations. We introduce a new perspective by formalizing existing billing models and proposing a novel model aimed at improving utilization.

Resource Harvesting: Cloud services (*e.g.*, EC2 [12]) offer on-demand and spot instances, while Harvest VMs [14] improve cost-efficiency by adjusting VM cores over its lifetime. Harvest VMs adjust CPU affinity with interprocessor interrupts, introducing high overhead (~0.1 milliseconds). These approaches are cost-effective, but VM size changes are infrequent compared to serverless workloads; supporting QoS-aware sandboxes on serverless platforms presents additional challenges. As shown in Figure 1, CPU demand fluctuates frequently, and adjusting CPU affinity with every change would incur unacceptable overhead. BigQuery [7] offers capacity and on-demand pricing, but the resources are static in a sandbox in both pricing models. Running interactive tasks alongside batch tasks with efficient resource schedulers [19,61] has been explored in multi-tenant datacenters. However, serverless platforms do not effectively support co-location, as their billing models assume that all functions are interactive.

CPU Reservation: The user-space schedulers [24,38,44,57,60] support CPU reservation by adjusting CPU affinity over time, using a centralized CPU for allocation and ensuring sub-microsecond tail latency. However, they are not well-suited for serverless environments. Their simple load balancing methods inside a task group (*e.g.*, work stealing) are difficult to maintain fairness within a group. Additionally, some require users to modify their code for process creation.

Serverless Trace Analysis: Many studies have offered comprehensive overviews of the serverless computing [33,43,51,56,69]. For example, Microsoft researchers [64] characterize serverless workloads in their production platform, revealing a clear gap between maximum and average memory usage, indicating dynamic memory usage. Similarly, FirePlace [17] shows the fluctuating CPU and memory usage of 200K micro VMs on AWS Lambda.

7 Conclusion

We introduced the NPFU billing model and built Leopard to support NPFU with kernel-level and cluster-level changes. NPFU improves throughput by more than 2x, and reduces customer costs while maintaining provider profitability. Our work demonstrates that billing models should be considered not as an afterthought, but as a central part of system design.

Abstract

Parallel applications are typically implemented using multi-threading (with shared memory, e.g., OpenMP) or multi-processing (with message passing, e.g., MPI). While it seems attractive to deploy such applications in cloud virtual machines (VMs), existing cloud schedulers fail to manage such applications efficiently: they cannot scale multi-threaded applications dynamically when more CPU cores in a VM become available, and they cause fragmentation over time due to the static allocation of multi-process applications to VMs.

We describe GRANNY, a new distributed runtime that enables the fine-granular management of multi-threaded/process applications in cloud environments. GRANNY supports the vertical scaling of multi-threaded applications within a VM and the horizontal migration of multi-process applications between VMs. GRANNY achieves both through a single WebAssembly-based execution abstraction: *Granules* can execute application code with thread or process semantics and allow for efficient snapshotting. GRANNY scales up applications by adding more Granules, and de-fragments applications by migrating Granules between VMs. In both cases, it launches new Granules from snapshots efficiently. We evaluate GRANNY with dynamic scheduling policies and show that, compared to current schedulers, it reduces the makespan for OpenMP workloads by up to 60% and the fragmentation for MPI workloads by up to 25%.

1 Introduction

Compute-intensive parallel applications are common in many domains including machine learning [23], weather forecasting [44], hydrodynamics [35], genomics [5], simulation, and modeling [43]. These applications exploit massive parallelism and are built using multi-threaded or multi-process programming models, such as OpenMP [36] and MPI [33] that utilize the CPU cores within a node and across nodes.

To satisfy their resource needs, such applications are increasingly deployed on cloud-hosted clusters with a high total virtual CPU (vCPU) core count made up of virtual machines (VMs). These cloud clusters are managed by cloud resource schedulers, e.g., Slurm [48] or Azure/AWS/Google Batch [2, 16, 27], which monitor a queue of submitted applications and allocate them to VMs and vCPUs.

Existing cloud resource schedulers, however, cannot change an application's resource allocation after it has started executing. This lack of *elasticity* prevents multi-threaded applications from leveraging new cloud resources as they become available, e.g., when other applications have released vCPUs. This reduces utilization: our experiments show that, when deploying multi-threaded (OpenMP) applications, Azure Batch and Slurm consistently leave 60% and 40% of vCPUs idle, respectively, even when there are pending applications to be scheduled (§6.3). No matter how effective a resource manager's bin-packing approach is, it cannot completely avoid idle resources.

For multi-process applications, high utilization can be achieved by allocating resources at a fine granularity (e.g., allocating vCPUs to applications as soon as they become available), but this leads to *resource fragmentation*. If multi-process applications become fragmented across many VMs, it increases their network communication, thus reducing overall application performance.

Cloud resource schedulers handle this tension between utilisation and compute/data locality differently: when executing distributed multi-process applications, the Azure Batch [27] scheduler allocates resources at a VM granularity. This achieves good locality at the cost of resource utilization, because idle vCPUs in VMs cannot be used to execute other applications; in contrast, Slurm [48], another popular scheduler, allocates resources at vCPU granularity. It exhibits high utilization, but incurs fragmentation.

While high utilization is desirable for cloud providers, low fragmentation improves application performance. We observe that an ideal cloud resource scheduler for parallel applications must navigate this trade-off by *elastically scaling* and *migrating* applications at a fine granularity (i.e., individual vCPUs) at runtime. Existing runtimes for multi-threaded and multi-process applications in cloud environments, however, do not support such fine-granular management.

We describe **GRANNY**, a distributed runtime for executing unmodified multi-threaded/multi-processing (OpenMP/MPI) applications in cloud environments, which supports *vertical scaling* of multi-threaded application and *horizontal migration* of distributed multi-process applications. GRANNY achieves both with the help of a new execution abstraction called *Granules*. It makes the following contributions:

(1) Granules for thread/process execution. GRANNY executes each application as a set of Granules (§3.2). Each Granule contains application code with a single execution thread, capable of executing with thread (i.e., for multi-threaded applications) or process (i.e., for multi-process applications) semantics. A Granule executes a sandboxed WebAssembly [17] module, so that all Granules on a VM execute safely within a single host process. This allows Granules to implement an efficient snapshotting operation, share memory directly by mapping pages, and exchange messages with low overhead.

A Granule's execution state can be captured completely as part of a *snapshot* (§3.3). A Granule's snapshot contains its WebAssembly linear memory, with its static data sections, stack and heap, as well as other execution state, such as stack pointers, function tables, messaging queues, and file descriptors. Since their execution state is self-contained, Granules, unlike processes or containers [60], can be snapshotted and migrated robustly and with low performance impact.

(2) Granule elasticity and migration. GRANNY leverages Granules to perform management actions: it can (a) spawn a new Granule with thread semantics to scale a multi-threaded application (§4.2); or (b) change the distribution of a multi-process application by migrating the snapshot of a Granule with process semantics to a different VM (§4.3).

When performing the above management actions, GRANNY must not break the consistency of a multi-threaded/process application. GRANNY therefore only controls Granules when their execution reaches well-defined *control points* (§4.1), such as certain system calls or OpenMP/MPI calls. At these control points, a Granule is guaranteed to have a consistent state with respect to its shared data and messages, and it is safe to spawn new Granules, or snapshot and migrate them.

(3) Granule-aware scheduling policies. Using Granule's support for vertical scaling and horizontal migration, GRANNY implements dynamic scheduling policies for fine-granular management of compute-intensive applications in the cloud (§5). The policies enable (i) multi-process (MPI) applications to migrate processes between VMs to reduce inter-VM communication and thus improve application performance (§5.1); (ii) multi-threaded (OpenMP) applications to launch extra threads, increasing their parallelism when further vCPUs become available at runtime on a VM (§5.2); and (iii) checkpoint applications on spot VMs [7] before they are evicted and migrate them to replacement VMs (§5.3).

In our experiments on a 32-VM cluster, we execute a workload of existing OpenMP/MPI applications based on a 100 job trace. We compare GRANNY's execution to that with Azure Batch [27] and Slurm [48]. Azure Batch and Slurm use the OpenMPI [39] and LLVM OpenMP (`libomp`) [26] runtimes to execute MPI and OpenMP jobs, respectively.

We show that, by defragmenting multi-process applications using horizontal migration, GRANNY reduces end-to-end execution time (makespan) by 20% and fragmentation by 25% (§6.2). By elastically scaling multi-threaded applications to use idle CPU cores, GRANNY reduces makespan by 60% and the tail job completion time by 50% (§6.3). Finally, when using spot VMs, GRANNY reduces makespan by 50% (§6.4).

2 Compute-Intensive Workloads in Cloud

Next, we discuss compute-intensive parallel applications (§2.1), their runtime support (§2.2), describe associated schedulers (§2.3), and explain why existing schedulers fail to manage these applications efficiently in cloud settings (§2.4).

2.1 Compute-intensive applications

Compute-intensive applications include large-scale data analytics [61], video processing [4], and deep learning training [52], and also typical high performance computing (HPC) workloads, such as fluid dynamics [35], molecular simulation [47], and weather forecasting [44]. These applications require plentiful hardware resources, because they parallelize computation by distributing it across many CPU cores, both within nodes and across nodes.

To handle large problem sizes without increasing execution time or exhausting memory, compute-intensive applications make use of vertical *scale-up* and horizontal *scale-out* patterns. These are typically implemented using multi-threading (with shared memory among threads) and/or multi-processing (with distributed message passing between processes located on different nodes), as offered by programming models such as OpenMP [36] and MPI [33]. In this work, we focus on OpenMP and MPI, as representative examples of APIs and runtimes for parallel applications. They also benefit from long-standing popularity and widespread adoption.

2.2 Runtimes for multi-threading/processing

Multi-threaded/process applications typically require *runtime* support. Multi-threaded runtimes such as LLVM's OpenMP runtime (`libomp`) [26] manage threads, coordinate access to shared memory, and provide synchronization primitives; multi-processing runtimes such as OpenMPI [39] provide APIs for inter-node message passing, message synchronization, and data partitioning.

Internally, these runtimes use OS primitives to implement their APIs. In Linux, most OpenMP implementations use POSIX threads and standard synchronization primitives, such as mutexes and locks. MPI implementations use the OS kernel's TCP/IP stack to send and receive messages between processes reliably. Runtimes typically do not restrict other OS system calls e.g., for file system access. In this case, however,

it becomes the responsibility of the developer to access the underlying resources in a race-free manner, as the runtime's coordination and synchronization guarantees do not apply.

Depending on whether an application uses multi-threading or multi-processing, application state is handled differently. For multi-threaded applications, application state resides in the process' address space, but may be divided in different thread's stacks and local storage (TLS). The state associated with synchronization primitives, e.g., mutexes and locks, resides in the OS kernel. For multi-process application, the state is partitioned across all processes. In addition, the state of the network stack is spread across all VMs involved in the distributed computation.

2.3 Resource scheduling for applications

Compute-intensive applications are deployed on large shared clusters (either on-premise or in the cloud) with high CPU core and node counts. Users submit applications as jobs to a work queue managed by a resource *scheduler*. The scheduler allocates applications to compute resources (i.e., CPU cores) according to an application's demand for parallelism. Multi-threaded/process applications specify their resource needs at deployment time, e.g., using `mpirun`'s `np` flag [40], or the `OMP_NUM_THREADS` environment variable [37].

Cloud providers use a range of resource schedulers to execute compute-intensive parallel applications, such as AWS Batch [2], Azure Batch [27], and Google Batch [16]. These schedulers control a pool of cloud VMs that can be scaled up or down on-demand. They schedule jobs once sufficient VMs are available, and idle vCPU cores in VMs cannot be allocated to other pending jobs.

In addition, some cloud providers also support general-purpose schedulers such as Slurm [48], KubeBatch [21], or Volcano [53], which are often used for on-premise clusters. These schedulers support more fine-grained policies in which they allocate applications to individual vCPU cores.

2.4 Challenges in cloud scheduling

While cloud providers strive for high utilization, cloud users want to combine high parallelism with locality, as this reduces avoidable inter-VM communication. Cloud schedulers thus try to optimize both for resource utilization and compute/data locality [20, 49], but they struggle to achieve this goal: the allocation of a multi-threaded application to a VM determines its parallelism based on the number of available vCPUs. If the scheduler cannot perfectly bin-pack multi-threaded applications to VMs, vCPUs remain idle, decreasing utilization.

Similarly, a scheduler must allocate the processes of a distributed multi-process application to sufficiently many VMs that offer the required total number of vCPUs. This potentially reduces locality, as it may spread the allocation across multiple VMs, depending on their vCPU availability.

Ideally, the scheduler should be able to *change* this initial allocation of a parallel application at the granularity of individual vCPUs. In particular, it should (a) add more threads to a multi-threaded application when vCPUs become available, increasing utilization; and (b) move processes to VMs that already contains other processes of the same application, reducing fragmentation and improving locality.

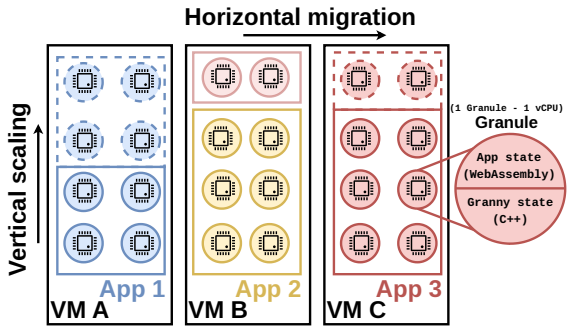

Figure 1: GRANNY executes applications as sets of Granules (GRANNY supports elasticity by vertically scaling multi-threaded applications, adding more Granules, or horizontally migrating Granules of multi-process applications to consolidate them across VMs.)

Such fine granular resource management, however, is not possible due to the limitations of today's runtimes for multi-threaded/process applications: elastically scaling threads requires runtime support, otherwise it may violate consistency with concurrent memory accesses by threads. For example, threads may have shared variables pending synchronization; similarly, migrating processes between VMs requires support for *process-level checkpointing*, e.g., CRIU [11], which incurs significant overheads [18, 60]. Without runtime support, it also cannot ensure consistent checkpoints across all distributed processes when messages are in-flight. Applying existing migration techniques [54] thus would require changes to applications, runtimes, and OS kernels.

3 GRANNY Design

We describe the design of GRANNY, a distributed runtime for multi-threaded/processing applications (§3.1). At its core lies the abstraction of a *Granule* (§3.2), which is the building block for the execution of both thread- and process-based applications. The state of Granules can be captured efficiently using *snapshots* (§3.3), thus enabling elasticity and migration.

3.1 Overview

GRANNY executes multi-threaded and multi-process applications as a set of Granules (shown as circles in Fig. 1). A Granule represents a single thread of execution and has its own mappings for code and data: a multi-threaded application (OpenMP) is therefore a set of Granules with shared-memory code and data mappings; a multi-process application (MPI) is a set of Granules with non-shared data mappings.

Each Granule runs in a single WebAssembly [17] module with its application code and executes on a vCPU in a VM. The GRANNY runtime decouples Granule state from OS ker-

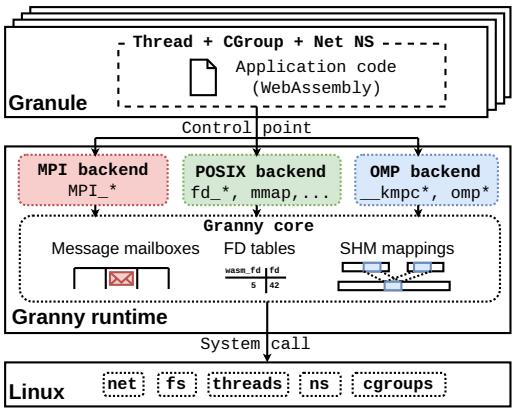

Figure 2: GRANNY architecture (Application code, cross-compiled to WebAssembly, can make calls, via control points, to different backends. The GRANNY core maintains relevant runtime system state and defers to OS system calls when necessary.)

nel state, which makes the snapshotting of Granules simpler and faster than traditional process checkpoints [11]. It also allows GRANNY to execute multiple Granules within the same process (shown as different colors in Fig. 1), because WebAssembly modules are isolated from each other and the runtime. Each VM runs a single instance of the GRANNY runtime, and there is also one cluster-wide GRANNY scheduler.

GRANNY uses the Granule abstraction (§3.2) and snapshots (§3.3) to implement management actions (§4): it can spawn Granules with thread semantics to vertically scale multi-threaded applications (§4.2), and it can horizontally migrate the snapshot of a Granule with process semantics (§4.3). The GRANNY scheduler uses these management actions to implement dynamic scheduling policies (§5): as shown in Fig. 1, it can speed up App 1 with the newly released vCPUs of VM A, improving utilization, or consolidate App 3 to VM C, improving locality.

3.2 Granule abstraction

Fig. 2 shows the GRANNY architecture. A Granule executes as an OS thread inside the VM in which it is spawned. Application code is deployed in an isolated WebAssembly module that only has external access to pre-defined OpenMP, MPI, and POSIX operations implemented by the GRANNY runtime (the various backends in Fig. 2). The GRANNY backends are built on top of a shared GRANNY runtime core that keeps the per-Granule state and decouples backends from the OS.

Applications must be cross-compiled to WebAssembly [17], a memory-safe and platform-independent binary instruction format that supports a wide range of programming languages. The use of WebAssembly allows Granules to execute side-by-side within one virtual address space, together with the GRANNY runtime, while enforcing memory safety [19] and reducing interaction with the privileged OS kernel. In addition to the file system and network operations necessary for multi-process applications, GRANNY only relies on the OS kernel to schedule threads and guarantee resource (CPU and network) fairness.

WebAssembly code cannot, in general, interact with its host environment. In GRANNY, application code can use *control points* to interact with the runtime (§4.1). A control point is triggered by a call to one of the supported APIs, POSIX, MPI, and OpenMP, implemented in the backends. Control points come at no cost for developers and at little cost for the runtime: they are injected by leaving the corresponding API symbol (e.g., `MPI_Barrier`) as undefined during cross-compilation and marked as a function import [13]. The symbol is resolved at runtime and triggers a WebAssembly context switch executed in tenths of cycles, similar to a function call [34].
The GRANNY runtime makes, whenever necessary, system calls to the underlying OS, e.g., to send cross-VM messages or write to a file descriptor. It records these interactions to ensure that Granule state can be encapsulated in a snapshot.

3.3 Granule implementation

Control points. Our GRANNY prototype has three backends:

The **MPI** backend implements the standard `MPI_*` APIs (e.g., `MPI_Reduce` [33]) and provides reliable Granule-to-Granule messaging. It uses in-memory message mailboxes for message reception, and the host network stack for cross-VM messaging. The GRANNY runtime maintains consistent Granule addressing tables across Granule migrations.

The **OpenMP** (OMP) backend implements the interface exposed by LLVM's OpenMP runtime (`libomp`) after OpenMP pragmas have been expanded (e.g., `__kmpc_fork_call` [26]). For correct and safe OpenMP execution, the GRANNY runtime must carefully manage the shared and private memory regions of different Granules (see §3.3).

The **POSIX** backend implements WebAssembly's standard system interface (WASI) [55]. The use of WASI simplifies the cross-compilation of large codebases, because it enables the static linking of applications with WASI-aware libraries, such as `wasi-libc` [57]. The backend only implements the symbols needed by compute-intensive applications, which are mostly filesystem APIs. To maintain a consistent Granule state and facilitate snapshots and migration, the GRANNY runtime maps the file descriptors used internally in WebAssembly code, to the OS file descriptors used in practice.

Memory layout. Due to WebAssembly's linear memory model [17], Granules have a simple memory layout, shown in Fig. 3, which facilitates spawning and snapshotting. A Granule occupies a contiguous region of virtual memory with the code, data, a stack, and a heap. Spatial isolation comes from a combination of WebAssembly's memory safety and guard pages, and is it enforced by the WebAssembly runtime [10].

The main difference between a Granule executing with process semantics and with thread semantics is their memory layout (red and blue Granules in Fig. 3, respectively): Granules

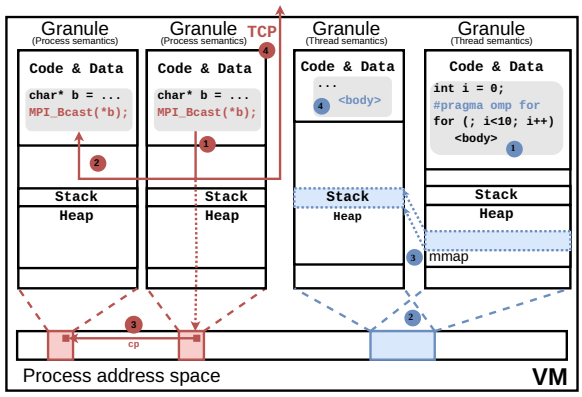

Figure 3: Granules memory layout in a single GRANNY instance (Granules execute side-by-side in an address space, and rely on WebAssembly's sandboxing for spatial isolation. Granules executing with processes semantics execute in different sandboxes, whereas Granules executing with thread semantics share the same sandbox.)

with processes semantics have separate linear memories, with the same application mapped into them. To send messages, the sender Granule indicates the buffer to be sent (Fig. 3, ❶), and the MPI backend in the GRANNY runtime decides if it is a local or a remote message. For a local message, the runtime can directly enqueue the message metadata (❷) and copy the buffer contents into the reception buffer (❸). For a remote message, the runtime will send the whole payload over TCP to the appropriate GRANNY runtime instance (❹).

Granules with thread semantics share a linear memory and have separate stacks. When a Granule creates new threads, such as with OpenMP `#pragma omp for` (Fig. 3, ❶), the GRANNY runtime spawns a new Granule mapped to the same linear memory (❷). To give each thread a separate execution context, but maintain WebAssembly's memory sandboxing, GRANNY allocates an area in the parent's heap for the child's stack (❸), and sets the child's code entrypoint to the corresponding OpenMP task (❹). Additional care goes into maintaining shared variable visibility, as well as their consistency.

Snapshots. Granules thus have a simple memory layout, which means that their execution state can be captured combining the span of the linear memory, together with the Granule state in the GRANNY runtime (Fig. 2). The combined linear memory and runtime state is what we call a Granule *snapshot*. Having a concise snapshot representation for Granules is essential for migration. Since all state is contained in a snapshot, GRANNY does not require host kernel modifications to obtain a Granule's full execution state. This is in contrast to general process checkpointing [11], which must also extract process state from the host kernel.

4 Granule Management

GRANNY performs management actions, vertical scaling (§4.2), and horizontal migration (§4.3) by interrupting application execution at well-defined *control points* (§4.1). This ensures GRANNY always operates with a consistent application state. The following sections describe these operations in more detail.

4.1 Interrupting Granules at control points

GRANNY takes control over Granule execution at control points, i.e., at every call to one of the supported runtime backend APIs (see Fig. 2). GRANNY defines two types of control points, *regular* and *barrier* control points, that enable the runtime core to perform different operations. At regular control points, such as calls to the POSIX API, the application state is not guaranteed to be consistent, but this still allows GRANNY to send point-to-point messages or operate on shared memory. In contrast, barrier control points guarantee that the application state is consistent, i.e., no messages are in-flight and no modifications to shared variables are pending to be synchronized. Therefore, GRANNY can only perform management operations at barrier control points.

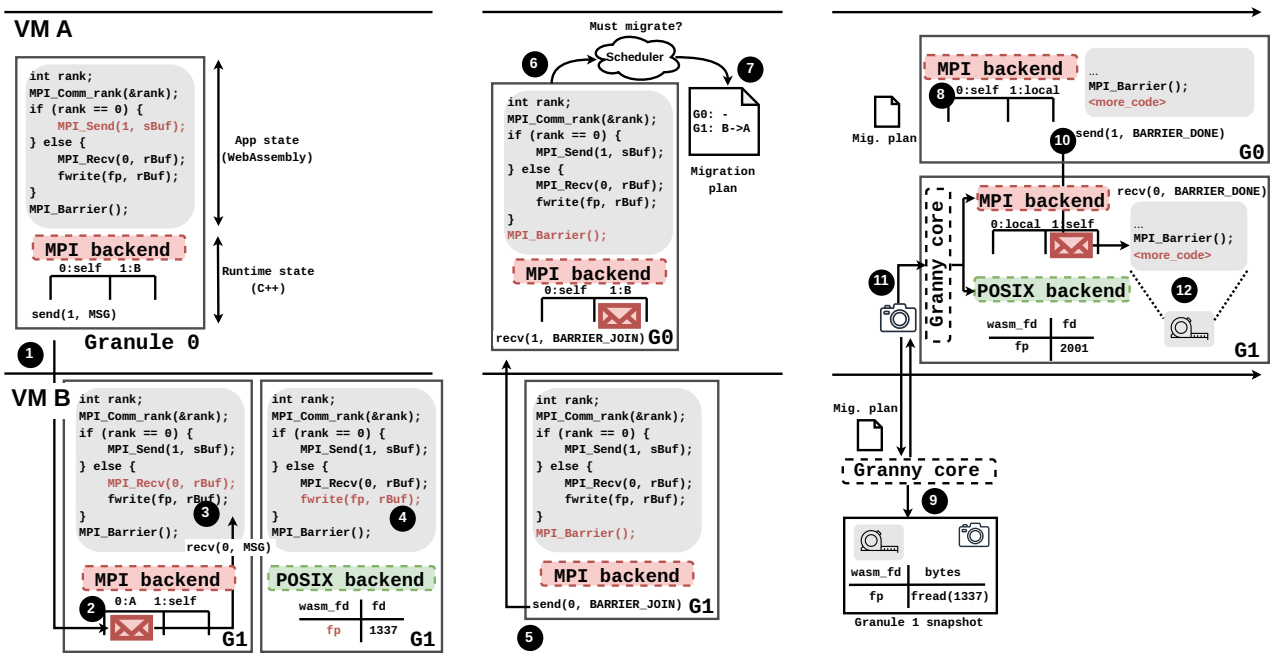
Differentiating between regular and barrier control points requires semantic knowledge of the shared memory/message passing API, as well as control over its implementation. For example, GRANNY's MPI backend implementation of `MPI_Barrier` has a reduce phase in which all Granules send messages to the Granule with the lowest MPI rank, and a broadcast phase in which all Granules are notified that the barrier has completed. After the reduce phase, the Granule with the lowest MPI rank can rely on the fact that there are no outstanding messages and has thus reached a consistent state. A similar explanation, with shared memory synchronization instead of messages, applies to GRANNY's OpenMP backend implementation of `#pragma omp barrier`.

As a consequence, vertical scaling and horizontal migration in GRANNY is a co-operative process. When a Granule triggers a barrier control point, the runtime interacts with the scheduler and adds, removes, or migrates Granules as indicated. In practice, barrier control points are frequent enough, so that their co-operative nature does not hinder the benefits in resource management, as we can see later in §6.

4.2 Vertical scaling

Implementing vertical scaling in GRANNY is straightforward if we take into account the memory layout presented in Fig. 3. To create a child Granule from a parent Granule, the runtime allocates the child's stack in the parent's heap, and instantiates a new Granule on top of the same WebAssembly linear memory, changing only the stack pointer. The child's entrypoint is indicated as an index in the WebAssembly module's function table. We also add guard pages around each child's stack to mitigate potential stack overflows (typical of various threading implementations in WebAssembly [58]).

Since vertical scaling happens during barrier control points in OpenMP, the runtime can easily distribute the work across any Granules by simply setting the appropriate per-thread and



(a) Normal execution (b) Barrier control point (c) Migration

Figure 4: Horizontal migration overview (When Granules reach a barrier control point, such as `MPI_Barrier`, the application's main Granule queries the resource scheduler. If triggered, the runtime performs a horizontal migration by taking a snapshot of the migrated Granule and transferring it to the destination VM. Runtime state, such as open file descriptors, is also snapshotted and reconstructed at the destination.)

global variables in the OpenMP specification. We design a scheduling policy using vertical scaling in §5.2.

4.3 Horizontal migration

Fig. 4 illustrates horizontal migration. The MPI backend gives each Granule a unique integer identifier, akin to the MPI rank, and implements messaging as a three-step process: it captures the send operation as a call to a backend operation such as `MPI_Send` (❶); it copies the message into the receiving Granule's mailbox within the target GRANNY runtime core (❷); and it delivers the message to the application by capturing (❸), and potentially blocking, calls to a receive operation (which the MPI backend matches to the corresponding mailbox, according to the MPI specification). Note that Granules may also call other API backends, such as file writes via the POSIX backend (❹). As previously introduced, the POSIX backend serves the request and keeps track of the mapping between WebAssembly file descriptors and OS ones.

When Granules reach a barrier control point (such as `MPI_Barrier` in Fig. 4b), the runtime can perform horizontal migrations safely. For example, in the case of `MPI_Barrier`, all Granules send a `BARRIER_JOIN` message (❺) to the zero-th MPI rank (Granule 0 in VM A in the example), and wait for a `BARRIER_DONE` message before continuing. When the runtime for Granule 0 has received all messages, it queries the scheduler for any horizontal migrations (❻). The resource scheduler then applies the scheduling policy and returns a migration plan (❼). After all migrations have been performed (if any), the runtime broadcasts a `BARRIER_DONE` message so all blocked Granules resume execution. In our example, Granule 1 must be migrated from VM B to VM A.

To perform the migration, shown in Fig. 4c, the runtime in VM A distributes the migration plan to the other runtimes involved in the execution (in this case the runtime in VM B), and all proceed to individually prepare for the migration. For VM A, this means the runtime must create a new, empty Granule 1, setup its mailbox mappings, and update the entry for Granule 1 on the mailbox of Granule 0 (❽). For the runtime in VM B, this means creating a snapshot of Granule 1, including any runtime state, and terminating the old Granule 1 (❾).

Once the migration has been prepared, the runtime in VM A can resume execution of Granule 0, which broadcasts the `BARRIER_DONE` message to the *updated* mailboxes (❿). The runtime in VM A can also restore Granule 1 from the received snapshot, re-construct the file descriptor tables, and resume execution where it left off, i.e., blocked waiting for a `BARRIER_DONE` (⓫). Since the restored Granule 1 uses the updated mailboxes, it has the message and resumes execution (⓬). We design two scheduling policies using horizontal migration in §5.1 and §5.3.

5 Granular Management Policies

We implement three scheduling policies, described in the following sections, to improve the utilization and performance

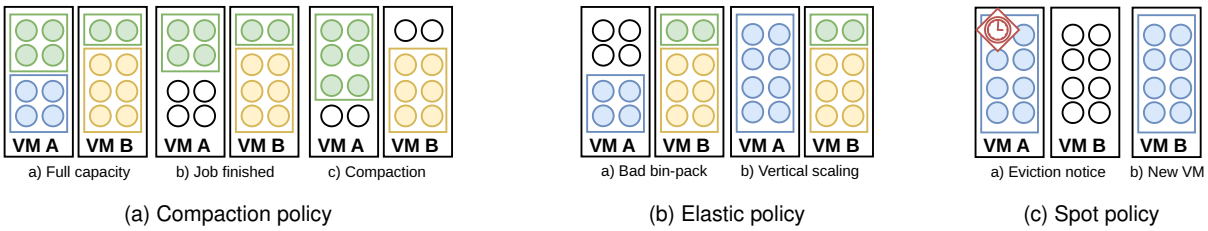


Figure 5: Dynamic scheduling policies implemented for their use with GRANNY (Different colors indicate different jobs.)

of cloud-based multi-process and multi-thread execution. The policies use GRANNY's support for vertical scaling and horizontal migration, and treat scheduled the applications as black boxes, i.e., without knowledge of future applications, their distribution of sizes, or their expected duration.

5.1 Improving locality with compaction policy

When scheduling MPI applications, existing cloud schedulers face a utilization/locality trade-off: they can either assign available vCPUs to an MPI application to achieve high utilization, or assign an entire VM to an MPI application to achieve high locality at the expense of having unused vCPUs in those VMs. The former reduces queue wait times for applications, but it may increase execution time, because applications may have to communicate across different VMs; the latter optimizes execution time at the cost of increasing queuing time due to the wait for an available VM of the required size.

Instead, we adopt a *compaction* policy (see Fig. 5a) that uses GRANNY to combine the benefits of both approaches. The scheduler first eagerly deploys MPI applications on any available vCPUs, which results in the highly fragmented green application in our example. When vCPUs are later released (e.g., the blue application terminates), the scheduler performs horizontal migration of Granules to increase the locality of executing applications. This results in less cross-VM communication, which speeds up the green application.

We define our fragmentation metric as the total number of Granule-to-Granule connections that cross a VM boundary in an application. When the application reaches a barrier control point, the scheduler checks if it can reduce its cross-VM links by performing any set of horizontal migrations. We show experimentally in §6.2 that, using this policy, GRANNY maintains high cluster utilization while keeping fragmentation low, thus improving performance.

5.2 Improving utilization with elastic policy

Even with a compaction policy, some cluster resources remain idle due to the nature of bin-packing scheduling. VMs may have some spare capacity that is insufficient to deploy the next application in the queue. This is particularly true with OpenMP applications that cannot be distributed across VMs.

In response, we introduce an *elastic* policy (see Fig. 5b). When there is spare capacity in a VM (Fig. 5b-a) and an OpenMP application reaches a barrier control point, the scheduler triggers a vertical scale-up to utilize these idle resources (Fig. 5b-b). This improves cluster utilization and application performance by exploiting extra parallelism. Our policy is careful to not mistake fork-join patterns of co-located OpenMP application with truly available resources by keeping track of the `OMP_NUM_THREADS` environment variable.

In §6.3, we show that the elastic policy reduces end-to-end execution time while decreasing idle vCPUs.

5.3 Ephemeral VMs with spot policy

Compute-intensive applications may be deployed on a pool of spot VMs [7] to benefit from lower costs. This introduces the challenge of handling partial failures, because spot VMs are withdrawn by the cloud provider after a short grace period.

Fig. 5c shows our *spot* policy. We follow a two-part horizontal migration approach: (1) when the cloud provider notifies the scheduler of an upcoming spot VM eviction (Fig. 5c-a), the scheduler stops scheduling Granules to that VM; (2) when a Granule running on the to-be-evicted VM reaches a barrier control point (e.g., `MPI_Barrier` or `#pragma omp barrier`), the resource manger tries to re-schedule it on the remaining VMs (Fig. 5c-b). If there are insufficient resources, snapshots are taken of all Granules in the application, and they are terminated. Interrupted applications are then added to the beginning of the scheduler's queue.

We show experimentally in §6.4 that, using a spot policy, GRANNY reduces end-to-end execution time when deploying compute-intensive applications on spot VMs.

6 Evaluation

Our evaluation explores the benefits of using GRANNY to run MPI and OpenMP applications. We show how, using GRANNY's dynamic scheduling polices (§5), we can: (i) improve performance and locality of MPI applications while maintaining a target utilization (§6.2); (ii) improve performance and utilization of OpenMP applications by allocating extra CPU cores (§6.3); and (iii) ensure efficient fault-tolerant execution with ephemeral spot VMs (§6.4).

In our microbenchmarks (§6.5), we analyze the baseline overheads of: (i) executing MPI applications with GRANNY instead of OpenMPI (§6.5.1); (ii) executing OpenMP applications with GRANNY instead of LLVM's `libomp` (§6.5.2); (iii) the horizontal migration of Granules (§6.5.3); and (iv) the vertical scale-up of Granules (§6.5.4).

Figure 6: Improving locality with compaction policy (We compare with Azure Batch and Slurm's default policies.)

6.1 Experimental setup

Implementation. GRANNY is implemented in 24,000 lines of C++20 code (compiled with clang-17) on top of the Faasm runtime [51]. GRANNY extends Faasm by implementing the MPI/OpenMP backends, a centralized scheduler, and migration/scale-up, but it re-uses the underlying sandbox abstraction (using WAMR [10] as the WebAssembly runtime). GRANNY is available as open-source.[1] We compile all deployed applications and their library dependencies, such as *libc*, to WebAssembly [17] using clang-18 [45], as part of GRANNY's CPP toolchain.

As baselines, we compare against two cloud resource schedulers, batch and slurm, that mirror the behaviour of Azure Batch [27] and Slurm [48], respectively. Unless otherwise stated, batch and slurm execute MPI applications with OpenMPI v4.1 [39] and OpenMP ones with `libomp` v4.5 [25].

Testbed. We deploy GRANNY and any baselines on a Kubernetes cluster [22] on Azure [28]. The cluster consists of *Standard_D8_v5* VMs [29] with 8 vCPU cores and 32 GB of memory. We deploy the resource scheduler in a separate VM in the same cluster.

Workloads. We evaluate GRANNY with unmodified applications that use OpenMP [36] for multi-threaded shared memory computation, and MPI [33] for multi-process message passing. Applications require no changes to source code, just re-compilation with the GRANNY toolchain.

6.2 Improving locality with compaction policy

This experiment explores the benefits of using a *compaction* policy (§5.1) to navigate the utilization/locality trade-off: it horizontally migrates Granules executing with process semantics. We execute a trace of MPI applications as jobs, and each application executes the LAMMPS [43] molecule dynamics simulator, running the Lennard-Jones (LJ) benchmark with a varying number of MPI processes. Applications are executed in order and may wait in a queue until sufficient resources become available in the cluster. To measure only the benefits of the policy and not differences in the MPI implementation, we configure our two baselines, batch and slurm, to use GRANNY's MPI backend.

Fig. 6 shows various performance metrics, as we increase the number of VMs and the number of applications in the trace. Fig. 6a shows that the compaction policy improves end-to-end execution time (makespan) by up to 20%. Using compaction, GRANNY always improves makespan across all baselines and cluster sizes.

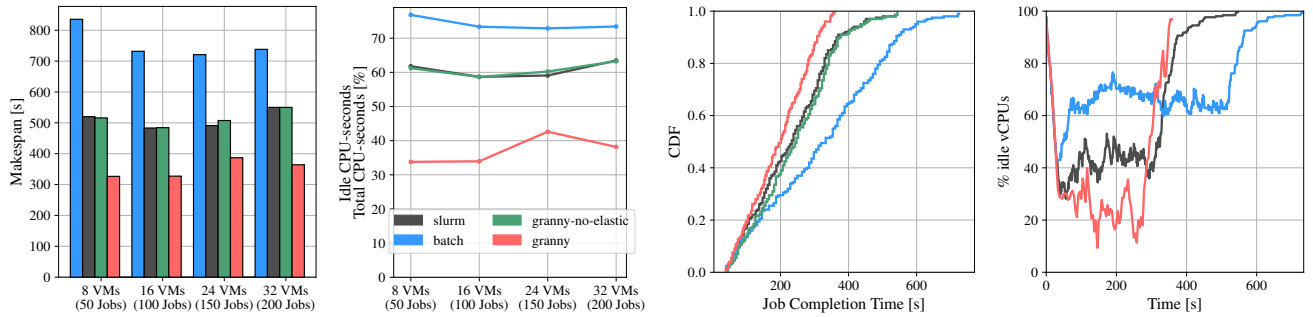
To show the compaction policy in action, Fig. 6c and Fig. 6d plot the time-series of idle vCPUs (as a proxy for cluster utilization) and cross-VM network links (as a proxy for locality) for the (32 VMs, 100 jobs) execution. We see that, differently to Slurm, GRANNY deliberately leaves a percentage of vCPUs idle corresponding to a target utilization (5% in this experiment). GRANNY can use these spare vCPUs to defragment applications at runtime by performing horizontal migrations, achieving consistently 25% less fragmentation than Slurm. In fact, GRANNY, with only 5% idle vCPUs, is closer in terms of fragmentation to Azure Batch, which behaves optimally with respect to this metric but leaves 30% of vCPUs unused.

Fig. 6b shows that this reduction in fragmentation at high cluster utilization has a direct impact on job completion time (JCT). For the (32 VMs, 100 jobs) execution, GRANNY improves median and tail JCT by up to 20%. We conclude that the compaction policy enables GRANNY to exploit the utilization/locality trade-off more effectively compared to Azure Batch and Slurm.

6.3 Improving utilization with elastic policy

This experiment explores the benefits of using an *elastic* policy (§5.2) to vertically scale OpenMP applications by adding Granules with thread semantics (§5.2). We execute a trace of OpenMP applications as jobs, and each application executes a large-scale version of the `p2p` ParRes OpenMP kernel [41], which performs a compute-intensive pipelined parallel algorithm on a large matrix, and requires a different number of

[1] https://github.com/faasm/faasm/



(a) Makespan (b) Aggregate idle vCPUs (c) JCT (32 VMs, 200 Jobs) (d) Idle vCPUs (32 VMs, 200 Jobs)

Figure 7: Improving utilization with elastic policy (We compare to Azure Batch and Slurm with `libomp` as OpenMP runtime, and Slurm with GRANNY's OpenMP backend, granny-no-elastic.)

OpenMP threads. In this experiment, the baselines (batch and slurm) execute applications using `libomp` [25]. We include an additional baseline, granny-no-elastic, which corresponds to slurm using GRANNY' OpenMP backend.

Fig. 7a shows that GRANNY improves makespan by up to 60% compared to the native baselines and GRANNY without the elastic policy (granny-no-elastic). This confirms that the performance improvements come from the policy. Indeed, we can assert that GRANNY reduces the idle CPU cores in the cluster by up to 30% (Fig. 7b), and it uses these extra cores to improve median and tail JCT by up to 50% (Fig. 7c).

This large performance gap can be understood when considering how many compute resources are left idle by the native baselines. Fig. 7d shows a time series of the percentage of idle vCPUs when running 200 jobs on a 32-VM cluster. Azure Batch and Slurm, even when the job queue is not empty, consistently leave 60% and 40% of vCPUs idle. This is due to multiple reasons: (i) OpenMP applications have fixed parallelism; (ii) it is not possible to distribute them across VMs; and (iii) in the case of Azure Batch, it is not possible to run different applications on the same VM concurrently. By vertically scaling-up, GRANNY maintains the fraction of idle vCPUs at around 20% while there are still pending jobs.

GRANNY's improvements in terms of JCT are partly due to the fact that our OpenMP workload always benefits from increasing its parallelism (§6.5.4). In a real deployment, an elastic policy should be accompanied by runtime profiling to determine when a workload exhausts its parallelism.

6.4 Ephemeral VMs with spot policy

This experiment explores the performance benefits of using a *spot* policy (§5.3) to execute compute-intensive applications on a cluster with ephemeral spot VMs. The submitted applications and the native baselines are the same as in §6.2. In this experiment, the native baselines execute applications using the OpenMPI [39] runtime. To emulate the behaviour of spot VMs while making our findings reproducible, we withdraw VMs at a pre-defined rate with a 1-min grace period.

The eviction rate for this experiment is 25% of the VMs, selected at random, each minute. We choose this eviction rate after measuring the eviction rate for `Standard_D8_v5` spot VMs using Azure's Resource Graph Analyzer [8] (25% per hour) and scaling it to our MPI applications' length (minutes, instead of hours, to make the experiments reproducible).

Fig. 8a shows the reduction in makespan when comparing each baseline to itself without evictions. We see that, across cluster and batch sizes, all native baselines experience a minimum of a 50% slowdown, and a maximum of a 2× slowdown. This is because batch and slurm are unaware of evictions and must restart jobs each time they fail due to an evicted VM. Instead, GRANNY uses the spot policy and, as a consequence, its slowdown is at most 25%, consistent with the eviction rate.

The native slowdowns of 50%–100% can potentially thwart the cost benefits of using spot VMs. Indeed, Fig. 8b shows the normalized cost of each execution for the range of discounts based on Azure's spot VM price list [6]: 30%, 60%, and 90%. We calculate the cost by assuming a unit price per VM-hour and applying the corresponding discount. We also overlay the cost of not using spot VMs.

We observe that, for the native baselines, the effectiveness of spot VMs in terms of cost savings depends on the discount rate at which they are offered. Counterintuitively, for many discount ranges, it is not cost-effective to run applications using OpenMPI on spot VMs, because the re-execution costs outweigh the price discount. In contrast, with GRANNY, it is always cost-effective to use spot VMs, because the eviction slowdown is lower than the smallest cost discount.

Discussion. Our experiments are conducted on a 32-VM cluster with job traces that contain one type of application and do not capture inter-arrival times. Given the co-operative and on-demand nature of vertical scale-up and horizontal migration, however, we expect our results to generalize to larger cluster sizes. We also believe that GRANNY can improve performance and utilization for other workloads, but this may require the design of further scheduling policies.

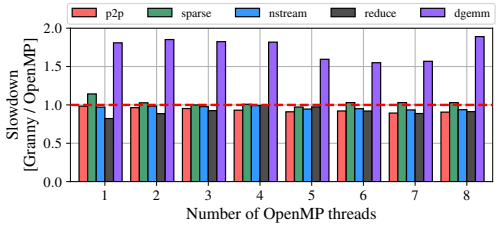

Figure 10: OpenMP backend performance

6.5 Microbenchmarks

In this section, we isolate different components of GRANNY and evaluate overheads. We evaluate GRANNY's MPI backend (§6.5.1), OpenMP backend (§6.5.2), as well as horizontal migration (§6.5.3) and vertical scale-up (§6.5.4).

6.5.1 MPI backend

This experiment investigates the overhead of GRANNY's MPI backend implementation compared to OpenMPI [39]. We run the same MPI application as in §6.2. To stress GRANNY's communication layer, we update the benchmark and increase the synchronisation steps, resulting in three orders of magnitude more cross-VM messages. We refer to the unmodified LJ benchmark as compute, and the modified one as network. We also execute a subset of the ParRes kernels [41] to evaluate specific parts of GRANNY's MPI implementation.

Fig. 9a shows the slowdown in execution time of GRANNY compared to OpenMPI when executing the two LAMMPS simulations with different levels of parallelism on two VMs. We observe that the overhead introduced by GRANNY is within 10% and often negligible. GRANNY occasionally introduces minor performance gains due to the benefits of intra-process co-location of Granules.

Fig. 9b shows the slowdown when executing the ParRes kernels with different levels of parallelism. For this workload, the performance of GRANNY and OpenMPI varies more than for LAMMPS, because these kernels execute MPI operations in a tight-loop. As a consequence, the performance benefit of intra-process co-location of Granules becomes more significant, leading to a performance benefit for GRANNY. In these cases, GRANNY can replace the sending of messages (reduce) with reducing shared memory variables.

6.5.2 OpenMP backend

Next, we investigate the overhead of GRANNY's OpenMP backend compared to LLVM's `libomp`. We execute the ParRes kernels [41] in their OpenMP implementation. We execute each kernel with a varying number of threads and take the average execution time over 5 runs.

Fig. 10 shows the slowdown in execution time of GRANNY compared to `libomp` for a variety of kernels. We observe that, for most kernels, GRANNY's performance matches the native baseline. This is because GRANNY's OpenMP backend adds minimal book-keeping at runtime and relies on the OS' synchronization primitives. For the `dgemm` kernel, GRANNY introduces an 80% slowdown. This kernel performs a dense matrix multiplication, and the overheads come from WebAssembly's less efficient floating-point operations [51]. We expect future WebAssembly releases and compilers to improve floating-point performance.

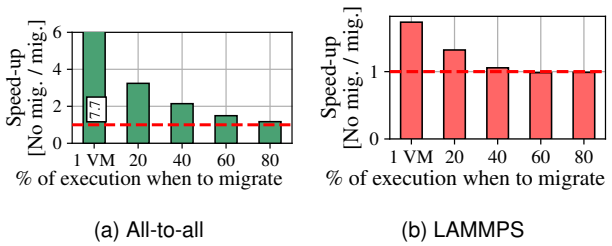

Figure 11: Speedup when migrating Granules (We deploy 8 Granules with process semantics across two VMs, and migrate 4 at runtime. We report the speedup over no migration.)

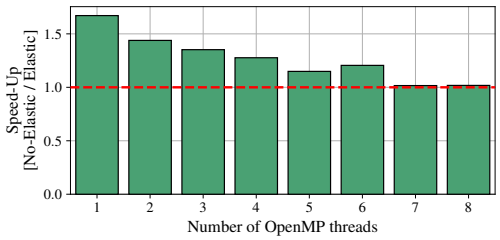

Figure 12: Speedup when elastically scaling to more vCPUs (We deploy a varying number of Granules with thread semantics, and elastically scale up to all CPU cores after 50% of execution.)

6.5.3 Granule migration

This experiment explores GRANNY's performance overhead when doing a horizontal migration of Granules at runtime, and the benefits of improved co-location. As workloads, we use the compute-bound LAMMPS simulation, and a network-bound *all-to-all* kernel, which performs synchronisation over a vector in a loop. For each experiment, we artificially fragment the 8 Granules with process semantics across two VMs. We then trigger a horizontal migration of half of them to the other VM at 20%, 40%, 60%, or 80% of execution time.

Fig. 11a shows the speedup when migrating a network-bound application compared to no migration. For such an application, fragmentation has a high cost: the speedup for running in one VM (1 VM) is 7.7×. By migrating after 20%, 40%, 60%, and 80%, of execution, GRANNY achieves speedups of 3.5×, 2.2×, 1.5×, and 1.1×, respectively. For network-bound applications, the overheads of horizontal migration are thus outweighed by the benefits of co-location.

Fig. 11b shows the speedup when migrating a compute-bound application. Here, fragmentation is less of an issue: the speedup for running in one VM is 1.7×. By migrating after 20% and 40% of execution, we achieve speedups of 1.3× and 1.1×, respectively. We observe no benefit when migrating later during execution. There exists a trade-off between the frequency and cost of migration, however, GRANNY's horizontal migration mechanism introduces a negligible overhead, thus enabling cloud providers to optimize for locality.

Migration time is dominated by the time to transfer the snapshot from one VM to another. For a 4 MB snapshot, corresponding to the *all-to-all* kernel, Granule migration is on the order of 30 ms. From this, only 3 ms correspond to creating the snapshot, which is almost an order of magnitude faster than a highly-optimized version of CRIU [60].

6.5.4 Elastic scale-up

Finally, we investigate GRANNY's performance overhead when doing vertical scaling of a multi-threaded application, and the potential benefits of increased parallelism. As a workload, we deploy the same OpenMP application as in §6.3. We initially use a varying number of Granules, and scale up to all available CPU cores (8) after 50% of execution.

Fig. 12 shows that, by scaling-up to use more CPU cores, GRANNY achieves a speedup of up to 60% when scaling from 1 to 6 threads. With more than 7 initial threads, we do not observe a benefit, because we have exhausted the application's parallelism. We conclude that elastically scaling-up does not slow down execution, because elastic scaling naturally fits with OpenMP's fork-join semantics.

7 Discussion

We now discuss some of GRANNY's design decisions and how its insights could be transferred to other cloud systems.

WebAssembly. Despite offering an efficient sandboxed environment where Granules execute, WebAssembly is still an evolving technology. The performance of some WebAssembly operations, particularly floating point operations, still remains below natively compiled code [14] and sandboxes that exceed 4 GB incur a higher sandboxing overhead [56]. We expect these issues to be addressed as compiler support for WebAssembly matures.

Programming models. GRANNY supports OpenMP and MPI and is therefore capable of running a large set of compute-intensive applications. GRANNY's design, however, is not tied to any programming model, and other programming models could be supported after identification of barrier control points for elastic scaling and migration.

A limitation of GRANNY is that it offers a CPU execution model only and cannot support GPU-based computation. This is due to its reliance on WebAssembly as an execution format. We plan on exploring GPU-based Granules with APIs such `wasi-nn` [59] in future work.

Resource schedulers and policies. GRANNY can integrate with other schedulers. For this, a resource scheduler needs to expose an endpoint to receive notifications from running applications and implement dynamic scheduling policies.

8 Related Work

Compute-intensive cloud applications. All major cloud providers offer solutions to support compute-intensive applications in the cloud [5, 30, 31]. To execute such applications, providers deploy batch scheduling solutions [2, 27] inspired

by HPC batch schedulers. Much previous work focuses on making scheduling decisions more effective [24].

Complementary to this, our work demonstrates that vertical scaling of multi-threaded applications and horizontal migration of multi-process ones is a fundamental missing piece for granular management of compute-intensive applications in cloud environments. GRANNY enables a number of scheduling policies that can be implemented to jointly optimize resource utilization and compute and data locality.

Checkpointing and migration. Nu [46] is a distributed computing platform that supports resource *fungibility* through migration. It uses multi-threaded *Proclets*, which can only communicate with each other by sending messages. This means that Nu's execution model is not transparent to existing multi-threaded applications, but rather requires a complete application re-write to partition shared application state and use its C++ messaging API. In contrast, GRANNY transparently executes and migrates existing multi-threaded and multi-process applications with no extra source code modifications required (with only recompilation to WebAssembly).

CloudScale [50] automates fine-grained elastic resource scaling in a shared cluster. It uses migration to handle scheduling or scaling issues. GRANNY is complementary to CloudScale in that it focuses on fine granular (thread/process) resource management.

There are various approaches to migrate parts of running applications transparently without violating integrity. MigrOS [42] checkpoints the state of RDMA-enabled applications executing in containers, but requires expensive modifications to the underlying network protocol. Other work [54] has performed live migration of MPI applications with process-level migration, which incurs high bandwidth consumption and necessitates OS kernel modifications. General-purpose process (e.g., CRIU [11] or DMTCP [15]) or VM migration techniques have been shown [18] to be poorly suited for efficient shared memory and message passing applications.

In contrast, GRANNY executes entirely in user-space and exploits lightweight sandboxing and traps using WebAssembly. Through its semantic knowledge of shared memory and message passing APIs, GRANNY achieves the same migration support but at a lower performance cost, independently of the employed VMs or host OS kernel.

Shared memory and message passing runtimes. Hoplite [62] uses collective communication primitives for building fault-tolerant task-based distributed applications. Ray [32] unifies task-parallel and actor-based computation using a single interface. It offers transparent state and message passing, irrespective of distribution, together with transparent scaling.

GRANNY could be extended to support these programming models. Our initial prototype implementation of GRANNY focuses on two existing programming models, namely MPI and OpenMP, which constitute opposite ends of the spectrum when writing parallel applications.

GRANNY's threading implementation is similar to that of `wasi-threads` [58]: both rely on WebAssembly's atomic intrinsics and have similar memory layouts, but GRANNY delegates control of shared memory synchronization (e.g., mutexes and locks) to the host runtime, whereas `wasi-threads` handles it in WebAssembly.

Elastic scaling. Elasticity for cloud-based execution has been traditionally implemented at the programming model level. MapReduce [12], actor-based models such as Akka [1] or Orleans [9], or serverless system such as AWS Lambda [3] or Faasm [51] implement elasticity at the worker/actor/function levels. In this work, we enable elasticity at the finer granularity of threads in multi-threaded applications. OpenMP has some elasticity support via `omp_set_dynamic`, but such support is only used to scale *down* in case of contention [38].

9 Conclusions

Existing resource schedulers fail to jointly optimize resource utilization and application performance, because application resource allocation cannot be modified after an application begin execution. To address this issue, we presented GRANNY, a new distributed runtime for unmodified multi-threaded (OpenMP) and multi-processing (MPI) applications. Through its Granule abstraction, GRANNY is able to spawn and migrate Granules at run-time. With this mechanism, we implement dynamic scheduling policies that improve both resource utilization and application performance when compared to existing cloud resource schedulers.

On Temporal Verification of Stateful P4 Programs

Delong Zhang* Chong Ye* Fei He†
School of Software, BNRist, Tsinghua University, Beijing 100084, China
Key Laboratory for Information System Security, MoE, China

Abstract

Stateful P4 programs offload network states from the control plane to the data plane, enabling unprecedented network programmability. However, existing P4 verifiers overapproximate the stateful nature of P4 programs and are inherently inadequate for verifying network functions that require stateful decision-making.

To overcome this limitation, this paper introduces an innovative approach to verify P4 programs while accounting for their stateful feature. We propose a specification language named P4LTL, tailored for describing temporal properties of stateful P4 programs at the packet processing level. Additionally, we introduce a novel concept called the *Büchi transaction*, representing the product of the P4 program and the P4LTL specification. The P4 program verification problem can be reduced to determining the existence of any fair and feasible trace within the Büchi transaction. To the best of our knowledge, our approach represents the first endeavor in temporal verification of stateful P4 programs at the packet processing level. We implemented a prototype tool called p4tv. Evaluation results demonstrate p4tv's effectiveness and efficiency in temporal verification of stateful P4 programs.

1 Introduction

Software Defined Networking (SDN) [22] is an innovative network architecture that offers unprecedented network flexibility and programmability by decoupling the control plane and data plane. In traditional SDN architecture, the data plane's sole responsibility is forwarding packets [30]. Unfortunately, this configuration often results in frequent communication between the control and data planes, leading to significant network delay and overhead [55].

Recently, a more intelligent data plane has emerged, capable of maintaining network states locally to determine forwarding behaviors [9, 32, 38, 43, 45, 46, 49]. This novel architecture is known as the *stateful data plane* [55]. By updating the states of the data plane locally and adjusting forwarding behaviors based on these local states, the architecture reduces the excessive controller interaction. As a result, it offers faster response time and enhances network flexibility. In this paper, we focus on P4 [10], a widely adopted data plane language that supports the stateful data plane.

Formal methods play a pivotal role in ensuring the correctness of P4 programs. In recent years, numerous P4 program verifiers have been developed, including ASSERT-P4 [24], Aquila [50], bf4 [21], p4v [40], P4-NOD [41], and Vera [47]. However, these existing P4 program verifiers have primarily focused on per-packet processing. They treat the register states of P4 programs as fully nondeterministic at the beginning of each packet processing, simplifying the checks for continuous packet processing events into a single check. Consequently, they overlook the preservation of network states, treating each packet processing in isolation. As a result, these P4 program verifiers are inherently inadequate for verifying network functions that require stateful decision-making [31]. For example, a simple functionality like "if link failure is detected, then packets arriving *afterward* will all be forwarded to the backup port" [38, 45, 49] is not currently expressible and verifiable by existing verifiers.

Verifying P4 programs while accounting for their stateful nature presents significant challenges. The first challenge relates to environment modeling. It is important to note that P4 programs are deployed within switches, which continuously receive packets from the network and invoke the P4 programs to process these packets. The processing of packets by the P4 program can be influenced by the network states, and the behaviors of the P4 program for different packets can be interrelated. Therefore, when verifying the correctness of a P4 program, it is inadequate to consider its behaviors solely in the context of processing a single packet (as in the existing approach [24, 40, 47, 50]); instead, we should consider its behaviors in processing a series of packets. To address this challenge, we propose the use of an environment model (in Section 3) and verify the behaviors of P4 programs within the

*Both authors contribute equally to this work.
†Fei He is the corresponding author.

context of this environment model.

The second challenge pertains to the specification language used to describe the behaviors of a P4 program as it processes a series of packets. Unlike current P4 verifiers [21, 24, 40], which primarily focus on verifying properties for individual packet processing, our task now requires specifying properties that span multiple packet processings. This is considerably more challenging as it demands consideration of multiple executions of the P4 program. Existing data plane specification languages tend to either be too high-level, focusing on events of the entire network but not the executions of the P4 programs (e.g., NetKAT [3], SNAP [4], and NICE [11]), or too low-level, focusing solely on events within individual packet processing (e.g., NetCTL [47]). Although some simple safety properties (i.e., ensuring that something bad never happens [35]) can be reformulated into assertions for a single packet processing, the specification language for individual packet processing generally lacks the capacity to depict complex properties, especially those related to liveness (i.e., ensuring that something good eventually happens [35]). To tackle this challenge, we extend Linear Temporal Logic (LTL) [44] and introduce a specification language called P4LTL (in Section 4) that facilitates specifying temporal properties of P4 programs at the packet processing level.

Throughout the paper, we use the term *temporal verification of stateful P4 programs* to refer to the verification of temporal properties that span multiple packet processings. The third challenge lies in the development of algorithms for conducting such verification. It is important to note that the granularity of time steps plays a crucial role in temporal verification. In our specific context, we need to consider two distinct time steps: the time step that occurs after the execution of a P4 program statement, referred to as the *small time step*, and the time step that occurs after processing a packet, referred to as the *big time step*. Notably, a big time step comprises multiple small time steps. We introduce a novel concept known as a *Büchi transaction*, representing the product of the P4 program and the P4LTL specification. This concept is carefully defined to harmonize these two distinct time steps. We prove that the P4 program satisfies the P4LTL specification if and only if the Büchi transaction does not exhibit any fair and feasible trace. Building upon this observation, we develop an efficient verification algorithm (in Section 5) for temporal verification of stateful P4 programs.

With the above techniques, we develop p4tv, a temporal verifier tailored for stateful P4 programs. The framework of p4tv is illustrated in Figure 1. Given a P4 program and a P4 specification as inputs, it either returns "Verified" if the program meets the specified property or provides a counterexample that exposes a defect in the program.

We manually collected 9 benchmarks of stateful P4 programs from open-source communities and formulated 19 temporal verification tasks to evaluate p4tv. Experiment results demonstrate both effectiveness and efficiency of p4tv in verifying the temporal properties of stateful P4 programs. Furthermore, we conducted experiments to evaluate p4tv's efficiency in assertion verification and to assess its scalability concerning program complexity and specification complexity.

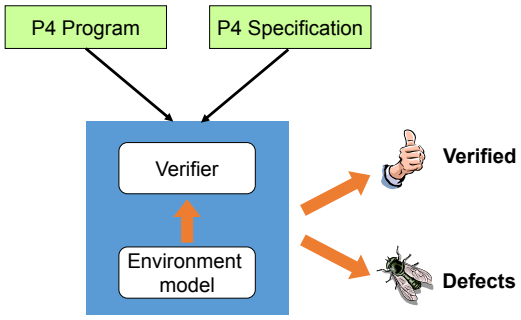

Figure 1: The workflow of p4tv .

Our contributions can be summarized as follows:

- We present, to the best of our knowledge, the first approach for temporal verification of stateful P4 programs.
- We design P4LTL, a specification language for describing temporal properties of stateful P4 programs at the level of packet processing.
- We propose a novel concept called the Büchi transaction, representing the product of a P4 program and a P4 specification. This concept allows us to reduce the P4 program verification problem to determining the existence of any fair and feasible trace within the Büchi transaction.
- We implement a prototype tool called p4tv and show its effectiveness on publicly-accessible benchmarks.

2 Motivations

In this section, we present the processors-based network immune scheme (P4NIS) mechanism [38] to provide motivation for our approach. P4NIS is designed to safeguard the network from packet eavesdropping within the programmable data plane. A snippet of P4NIS code (slightly modified for clarity) is depicted in Figure 2, where *count* serves as a register variable and *check_passed* validates whether all forwarding conditions are met. This validation includes a packet validity check (i.e., the ingress port and header validity check) and a range check on *count* (i.e., $0 \leq count \leq 2$). Upon the arrival of a packet that passes *check_passed*, the switch circularly distributes the packet traffic and executes various eavesdropping defense mechanisms.

One essential safety property for P4NIS states: *"The forwarding ports for valid incoming packets should always remain within the valid range (1 to 3 inclusively)."*

Nevertheless, existing P4 verifiers assess P4 programs on a single-packet basis, abstracting registers as fully nondeterministic. Consequently, these verifiers will report that the property

```
1  count.read(temp,(bit<32>)0);
2  if(check_passed()){
3      // send packages circularly
4      temp = temp + 1;
5      standard_metadata.egress_spec = temp;
6      if (temp == 3) temp = 0;
7      count.write((bit<32>)0,(bit<32>) temp);
8      // other operations
9      ...
10 }
```

Figure 2: The snippet of P4NIS code.

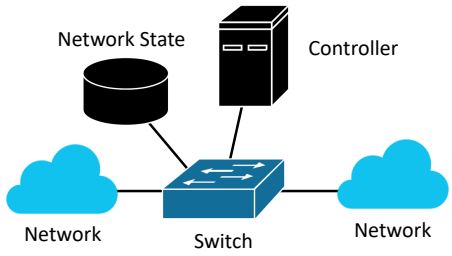

Figure 3: The environment model of p4tv.

does not hold for P4NIS. This is evidenced by a counterexample where the register *count* is initially set to a value of 4, bypassing the condition check (at line 2) and resulting in an implicit drop.

However, to reason about the precise behaviors of stateful P4 programs, it is necessary to analyze them across multiple packets. Considering the P4NIS example, if the register *count* is initialized with 0 during network setup, as per the code from lines 4 to 7, the value of *count* cannot exceed the valid range regardless of the number of packets processed by this P4 program, thereby proving the property. This underscores the importance of assessing P4 programs in the context of multiple packets.

One could suggest revising the property to: *"If the value of count is valid at the start of processing, the forwarding ports will remain valid."* While this simplifies verification into a single-packet check, identifying the specific precondition (i.e., the value of *count* falls within the valid range) requires substantial expertise and manual effort.

Furthermore, there exist properties that can hardly be simplified into a single-packet check. For instance, consider the liveness property for P4NIS that ensures the consistent activation of all defense mechanisms: *"When valid packets arrive infinitely often, they should be forwarded to every valid port infinitely often."* Expressing liveness concept like "infinitely often" in the context of a single-packet check is challenging.

These challenges motivate us to model the P4 execution process in a stateful manner (Section 3), introduce specification language P4LTL for stateful P4 programs (Section 4), and propose its corresponding automated verification algorithm (Section 5). Leveraging these techniques, p4tv is able to effectively and automatically verify complex temporal properties.

3 Environment Model

A P4 program specifies the behavior of a switch upon receiving a packet. To ensure the correctness of P4 programs, it is necessary to specify their environment model. As illustrated in Figure 3, the programmed switch receives packets from the network and processes them based on rules provided by the controller and local network states. In Section 3.1, we present our modeling mechanism for network environment and register states in comparison with existing P4 verifiers. In Section 3.2, we introduce our control plane interface which models the controller part.

3.1 The Basic Model

The modeling mechanism employed in current P4 verifiers can be seen as follows:

```
1  procedure main(){
2      nondet_register_variables();
3      call P4Program();
4  }
```

The model only considers the processing of a single packet and assumes that register variables are fully nondeterministic. However, this level of abstraction overlooks the stateful nature of packet processing, where register values in fact persist and are preserved for subsequent processing.

The real-world switch may receive arbitrarily many packets from the network environment. As a result, the P4 program needs to be executed arbitrarily many times. To model the stateful nature of packet processing, we regard a P4 program as an infinite while loop, similar to the idea presented in the probabilistic P4 test tool [31]. Since we consider the correctness of the P4 program, the network environment should not be constrained and the input packets should be nondeterministic. Therefore, we add an initialization block at the entry of the while-loop, in which we assign each packet field a nondeterministic value. The metadata fields in P4 programs are initialized in accordance with the P4-16 specification [16]. Considering that the control plane may change constantly, the table applications are modeled with a nondeterministic action choice, similar to the technique used in p4v [40] and bf4 [21]. This approach ensures that the control plane remains unconstrained. Notably, we declare the registers outside the loop to keep their value after each iteration (i.e., each packet processing). Our modeling mechanism is as follows:

```
1  procedure main(){
2      declare_registers();
3      while(true){
4        packet_initialization();
5        call P4Program();
6      }
7  }
```

$$
\begin{array}{lcl}
\text{P4LTL}\,\varphi & \rightarrow & \psi \mid \neg\varphi \mid \varphi \wedge \varphi \mid \varphi \vee \varphi \mid \varphi \rightarrow \varphi \\
& & \mid \circ\varphi \mid \Diamond\varphi \mid \Box\varphi \mid \varphi\, \mathcal{U}\, \varphi \mid \varphi\, \mathcal{W}\, \varphi \\
\text{Pred}\,\psi & \rightarrow & t\,\text{comp}\,t \mid \text{fwd}(t) \mid \text{valid}(h) \mid \text{hit}(t) \mid \text{drop} \\
& & \mid \text{apply}(t,a) \mid \neg\psi \mid \psi \wedge \psi \mid \psi \vee \psi \mid \psi \rightarrow \psi \\
\text{Term}\,t & \rightarrow & d \mid h \mid m \mid v \mid r[t] \mid \text{old}(t) \mid \text{key}(t,k) \\
& & \mid \text{para}(t,a,p) \mid t\ \text{op}\ t
\end{array}
$$

Figure 4: Syntax of P4LTL.

It is important to note that our modeling mechanism differs from previous P4 verification studies. Existing P4 verifiers only consider a single packet processing, assuming register states are fully nondeterministic at the start of each packet processing. While this technique simplifies the verification process, it hinders the ability to track changes of register states throughout packet processings. On the other hand, we consider the execution sequences in a continuous and correlated manner, reflecting their actual occurrence. This approach models the stateful nature of packet processing, which is crucial for stateful P4 program analysis and verification.

3.2 Control Plane Interface

Some P4 functionalities cannot be properly verified without additional information regarding the control plane. Therefore, we present *control plane interface* (CPI). which facilitates users specifying the control plane assumption.

For instance, consider a scenario where a rule exists in the table *rt* that triggers the action fwd with the parameter *pt* set to 1 when the key $m.d$ equals 2. In this case, the corresponding rule can be expressed in CPI as follows:

$$
\Box(\text{hit}(rt) \wedge \text{key}(rt, m.d) == 2 \rightarrow \\
\text{apply}(rt, fwd) \wedge \text{para}(fwd, pt) == 1).
$$

CPI provides a novel feature that assists developers by allowing not only concrete table entries but also symbolic ones. For instance, developers can modify the equality condition above to inequality, creating a symbolic CPI. This symbolic CPI encompasses the set of rules triggering fwd when the key $m.d$ is not equal to 2. This allows developers to verify P4LTL under control plane snapshot (i.e., table rules) sets instead of a single control plane snapshot. A blank CPI simply indicates that every table rule is possible.

4 Specification Language

To specify temporal properties spanning states of packet processing in stateful P4 programs, we introduce P4LTL, a language that extends the well-established formalism of Linear Temporal Logic (LTL) [44].

Among various temporal logics such as CTL, LTL, and CTL* [51], all capable of expressing temporal properties, we choose LTL as the foundational logic of P4LTL for the following reasons: (1) its linear time framework aligns more naturally with our problem domain, and (2) its rich expressiveness allows for specifying intricate properties along the packet processing traces.

4.1 P4LTL

The syntax of P4LTL is shown in Figure 4. In this section, we describe the P4LTL design in a bottom-up fashion.

Terms. Terms of P4LTL mainly consist of integer numbers d, packet headers h, metadata m, header field h, free variables v and register r. They represent the corresponding values *at the end of* packet processing. Furthermore, $key(t,k)$ denotes the value of key k when applying table t, while $para(t,a,p)$ represents the value of parameter p for action a when invoked by table t. Additionally, P4LTL provides a special construct $old(t)$ to refer to the value *at the start of* the ingress pipeline (i.e., at the end of the parsing pipeline). For instance, we can use $old(r[i])$ and $old(h)$ to refer to the register value of r at index i and the header value at the start of core packet processing. [1] Moreover, P4LTL allows the use of arithmetic operations between two terms with the arithmetic operator op that is supported by P4. Notably, P4LTL supports the use of free variables v, whose values are non-deterministic and can be further constrained by predicates.

Predicates. P4LTL provides several predicates for users to describe packet forwarding behaviors. To be specific, the semantics of predicates are defined as follows:

1. Predicate $t\ comp\ t$ is true if the corresponding terms meet the situation in the packet forwarding process, where *comp* denotes the comparison operators in P4.
2. Predicate $valid(h)$ is true if the corresponding header h is valid after the parsing progress.
3. Predicate *drop* is true if the packet is dropped at the end of packet processing.
4. Predicate $fwd(t)$ is true if the packet is forwarded to port t at the end of packet processing.
5. Predicate $hit(t)$ is true if the table t is hit during the packet processing.
6. Predicate $apply(t,a)$ is true if the action a is invoked by table t during the packet processing.

Note that $fwd(t)$ can be rewritten as a special case of the predicate $t\,\text{comp}\,t$. In P4 programs, the forwarding port can be

[1] For the sake of completeness, we consider the values of $old(key(t,k))$ and $old(para(t,a,p))$ to be arbitrary.

represented as *standard_metadata.egress_spec*, so the predicate *standard_metadata.egress_spec* $== t$ is equivalent to $fwd(t)$. We present it as a syntactic sugar for convenience.

Time step for stateful P4 programs. The LTL component is the key part of P4LTL. As the semantics of LTL hinge on the idea of *execution trace*, it is necessary to define what its *time step* is at the outset. An execution trace constitutes a sequence of valuations, which map P4LTL terms to their values at the end of every packet processing. A time step is performed every time the P4 program finishes processing a packet. It is important to note that the semantics of P4LTL are different from LTL in standard program verification [17, 18, 20] or NetCTL [47]. P4LTL concentrates on temporal properties across multiple packet processing, whereas other approaches primarily center around temporal properties across statements or pipelines in a single packet processing.

P4LTL. Based on the illustrations of P4LTL time steps, we define the semantics of P4LTL operators.

- Operator *next* $\circ$ is satisfied when the condition holds at the end of the next packet processing.
- Operator *eventually* $\Diamond$ is satisfied when the condition holds at the end of some packet processing eventually.
- Operator *always* $\Box$ is satisfied when the condition holds at the end of every packet processing.
- Operator *until* $\mathcal{U}$ is satisfied if the left-hand condition stays true until the right-hand condition becomes true, and the right-hand condition eventually holds true.

We further introduce syntactic sugar *weak-until* $\mathcal{W}$ in the following manner: $\varphi_1 \mathcal{W} \varphi_2$ is equivalent to $(\varphi_1 \mathcal{U} \varphi_2) \vee \Box \varphi_1$. A trace τ satisfies a P4LTL specification φ is written as $\tau \models \varphi$. For a P4 program $\mathcal{P}$ and a P4LTL specification φ, $\mathcal{P} \models \varphi$ if and only if all $\mathcal{P}$'s feasible execution traces $\tau \models \varphi$.

CPI. To specify the control plane assumption, developers can leverage terms $key(t,k)$, $para(t,a,p)$ and predicates $hit(t)$, $apply(t,a)$, as exemplified in Section 3.2. As per the semantics of P4LTL, alterations in the control plane amidst a packet sequence do not affect the validity of the verified P4LTL property, as long as the control plane still complies with the symbolic CPI. We integrate the control plane assumption ψ_C along with the property φ_{old} to form the new P4LTL formula $\varphi_{new} = \psi_C \rightarrow \varphi_{old}$ and proceed with the verification.

Example. Consider the liveness property, "Specific packets arriving infinitely often should be forwarded to every valid port infinitely often," introduced previously in Section 2. We can express the property with P4LTL as follows. The environment assumption $\varphi_E = \Box\Diamond(\text{valid}(hdr.label))$ states that we only consider the situation when specific packets come infinitely often. The temporal property $\varphi_P = \Box(\neg \text{valid}(hdr.label) \rightarrow \text{drop}) \wedge \Box\Diamond \text{fwd}(1) \wedge \Box\Diamond \text{fwd}(2) \wedge \Box\Diamond \text{fwd}(3)$ specifies that the specific packets should be forwarded infinitely often to valid ports, while other packets are dropped. In the end, the P4LTL formula $\varphi = \varphi_E \rightarrow \varphi_P$ depicts the desired property.

5 Verification

In this section, we present our approach for temporal verification of the stateful P4 programs. A fundamental challenge arises from the fact that the semantics of P4 programs and the semantics of the P4LTL specification attribute different meanings to the concept of a time step. Consequently, there arises a necessity to align these two distinct time steps within our verification algorithm. To address the issue, we propose a novel concept Büchi transaction, extending the classical program LTL verification approach [20].

5.1 Büchi Transaction

Our approach is rooted in the verification paradigm proposed in [20], which relies on its definition of the Büchi program product.

The concept Büchi program product extends from the concept of *Büchi automaton*, designed to accept infinite words. A Büchi automaton is a tuple $\mathcal{A} = (\Sigma, Q, q_0, \delta, \mathcal{F})$, which consists of a finite alphabet Σ, a finite state sets Q with an initial state $q_0 \in Q$, a transition relation $\delta : Q \times \Sigma \rightarrow Q$ and a set of final states $\mathcal{F} \subseteq Q$. Büchi automaton $\mathcal{A}$ accepts a word $w \in \Sigma^\omega$ if its corresponding run on $\mathcal{A}$ contains any final states infinitely often. The word accepted by Büchi automaton can also be called a *fair* trace. In addition, each LTL formula can be transformed into an equivalent Büchi automaton following the well-established algorithm [25].

Definition. (Büchi program product) A program is a tuple $\mathcal{P} = (\mathcal{S}, \mathcal{L}, \ell_0, \delta_p)$ consisting of a statement set $\mathcal{S}$, a program location set $\mathcal{L}$ with program entry ℓ_0 and a transition relation $\delta_p : \mathcal{L} \times \mathcal{S} \rightarrow \mathcal{L}$. Given a specification Büchi automaton $\mathcal{A}_\varphi = (\Sigma, Q, q_0, \delta, \mathcal{F})$, the Büchi program product $\mathcal{P} \times \mathcal{A}_\varphi$ is a Büchi automaton $\mathcal{B} = \left(\widehat{\Sigma}, \widehat{Q}, \widehat{q_0}, \widehat{\delta}, \widehat{\mathcal{F}}\right)$ where:

- $\widehat{\Sigma} = \{s; \text{assume } (\phi) \mid s \in \mathcal{S} \wedge \phi \in \Sigma\}$
- $\widehat{Q} = \{(l,q) \mid l \in \mathcal{L} \wedge q \in Q\}$ and $\widehat{q_0} = (\ell_0, q_0)$
- $\widehat{\delta} = \{((l,q), s; \text{assume}(\phi), (l',q')) \mid (l,s,l') \in \delta_p \wedge (q,\phi,q') \in \delta\}$
- $\widehat{\mathcal{F}} = \{(\ell,q) \mid l \in \mathcal{L} \wedge q \in \mathcal{F}\}$

The definition of Büchi program product is actually the product of two automatons, the program $\mathcal{P}$ and the specification $\mathcal{A}_\varphi$. The product is also a Büchi automaton, which enables acceptance of infinite traces. Informally, one can view the Büchi program product of $\mathcal{P}$ and the specification negation $\mathcal{A}_{\neg\varphi}$ as the Büchi automaton that witnesses the violation, i.e., accepts counterexamples. It has been proven that every

fair and feasible trace of this Büchi program product is a counterexample demonstrating that $\mathcal{P}$ violates the specification φ in [20], where a corresponding checking algorithm is also proposed. A trace is *feasible* if the corresponding sequence of statements is executable. The notion executable means that the *assume* conditions along the execution are all satisfiable.

Yet by definition, Büchi program product only concerns traces at the *small time step* (i.e., at the level of statements), which can not be directly applied to verify P4LTL that concerns the *big time step* (i.e., at the level of packet processing). For brevity, we denote the execution of the P4 program in our execution model as a *transaction*. In P4LTL verification, we can not allow the LTL automaton to transition every time the control flow automaton transitions. The LTL automaton should only take its step to transition whenever the *transaction* of the control flow automaton finishes, in correspondence with the semantics of P4LTL. Thus, we extend Büchi automaton to *Büchi transaction*, aiming to check LTL properties at the packet processing level. Its formal definition is as follows:

Definition (Büchi Transaction) Consider a program $\mathcal{P} = (\mathcal{S}, \mathcal{L}, \ell_0, \delta_p)$. We call it $\mathrm{TE}(s)$/ $\mathrm{TR}(s)$ when $s \in \mathcal{S}$ is an entering/return statement to/from the transaction. Given a specification automaton $\mathcal{A}_\varphi = (\Sigma, Q, q_0, \delta, \mathcal{F})$, the Büchi transaction $\mathcal{P} \otimes \mathcal{A}_\varphi$ is a Büchi automaton $\mathcal{B} = \left(\widehat{\Sigma}, \widehat{Q}, \widehat{q_0}, \widehat{\delta}, \widehat{\mathcal{F}}\right)$ where:

- $\widehat{\Sigma} = \{s; \text{assume } (\phi) \mid s \in \mathcal{S} \wedge \phi \in \Sigma\}$
- $\widehat{Q} = \{(l,q) \mid l \in \mathcal{L} \wedge q \in Q\}$ and $\widehat{q_0} = (\ell_0, q_0)$
- $\widehat{\delta} = \{((l,q), s; \text{assume}\,(\phi), (l',q')) \mid$
  $(\mathrm{TR}(s) \wedge (l,s,l') \in \delta_p \wedge (q,\phi,q') \in \delta) \vee$
  $(\neg \mathrm{TR}(s) \wedge (l,s,l') \in \delta_p \wedge q = q' \wedge \phi = true)\}$
- $\widehat{\mathcal{F}} = \{(\ell,q) \mid q \in \mathcal{F} \wedge (\mathrm{TE}(\ell) \vee \mathrm{TR}(\ell))\}$, where
  - $\mathrm{TE}(\ell) : \exists \ell' \in \mathcal{L}, s \in \mathcal{S}.\ (\ell, s, \ell') \in \delta_p \wedge \mathrm{TE}(s)$,
  - $\mathrm{TR}(\ell) : \exists \ell' \in \mathcal{L}, s \in \mathcal{S}.\ (\ell', s, \ell) \in \delta_p \wedge \mathrm{TR}(s)$.

The Büchi program product and Büchi transaction are both products of a control flow automaton and a specification automaton. The key distinction lies in the asynchronous nature of defining the Büchi transaction product. One can conceptualize the products of two Büchi automatons as their concurrent executions. In the Büchi program product, this manifests as a synchronized execution, where each step taken by the control flow automaton corresponds to a step by the specification automaton, and vice versa.

In the context of Büchi transaction, the behavior is distinct. As per the transition definition $\widehat{\delta}$, the LTL automaton advances only when a *transaction step* occurs. A "transaction step" is based on the predicate $\mathrm{TR}(s)$, which indicates whether the statement s is a "transaction return" statement. The LTL automaton can only progress when $\mathrm{TR}(s)$ is satisfied, whereas the control flow automaton can advance without additional constraints. It is worth noting that while Büchi transaction resembles Büchi program product, they diverge in the definition of transition and final state. To be specific, since P4LTL is defined at the big time step, only a "transaction return" triggers the progression in the LTL automaton, and only states corresponding to a "transaction entering/return" are labeled as final states $\widehat{\mathcal{F}}$. This extension is of importance, for it enables verification at the transaction level semantics (i.e., P4LTL semantics) and substantially reduces the number of transitions and accepted traces that are semantically irrelevant to P4LTL.

Theorem 5.1. *The P4 program $\mathcal{P}$ satisfies the P4LTL specification φ if and only if the Büchi transaction $\mathcal{B} = \mathcal{P} \otimes \mathcal{A}_{\neg\varphi}$ does not have any fair and feasible trace.*

The proof of the theorem resembles the proof for Büchi program product discussed in [20]. Therefore, we refer the interested readers to the appendix for further details.

Example. To better illustrate the distinction between Büchi transaction and Büchi program product, consider the pseudocode and property shown in Figure 5. The snippet aims to decrease the packet field *hdr.cnt* by one and set the register *status* to zero if *hdr.cnt* is less than zero, or one otherwise at every packet processing. For brevity, we denote *hdr.cnt* as x and *status* as y. In the Büchi program product, each step in the control flow automaton corresponds to a step in the LTL automaton, as depicted in Figure 6. In contrast, for the Büchi transaction, edges $(l_0,q_0) \rightsquigarrow (l_1,q_1)$ and $(l_1,q_0) \rightsquigarrow (l_2,q_1)$ are removed, and assumptions not from $(l_2,*)$ to $(l_0,*)$ all become true. This is because only edges from l_2 to l_0 correspond to a step in the LTL automaton. The formula $\Diamond(x > 0) \rightarrow \Diamond(y = 0)$ does not hold under the definition of Büchi program product, as evidenced by a counterexample where x is consistently assigned a value of 1 at the loop front. That is, $x > 0$ eventually holds, but $y = 0$ never becomes true. However, the formula is satisfied under the notion of Büchi transaction, since only edges from l_2 to l_0 will trigger progression of the LTL automaton. As a result, the Büchi transaction has no fair and feasible trace, indicating the validity of the property. Intuitively, $x > 0$ is always accompanied by $y == 0$ at the end of every *transaction*, but not necessarily for every *statement*. Furthermore, the greater concision of Büchi transaction compared to the Büchi program product in Figure 6 and Figure 7 visually demonstrates that Büchi transaction reduces the number of accepted traces that are semantically irrelevant to P4LTL.

5.2 Verification Algorithm

Based on Theorem 5.1, the temporal verification of stateful P4 programs is reduced to checking whether the Büchi transaction has any fair and feasible trace. Note that the Büchi transaction is a special case of Büchi automaton. Therefore, we can leverage the existing verification algorithm for the Büchi automaton proposed in [20].

Algorithm 1 illustrates our verification framework. It takes a program $\mathcal{P}$ and a LTL formula φ as inputs, and outputs

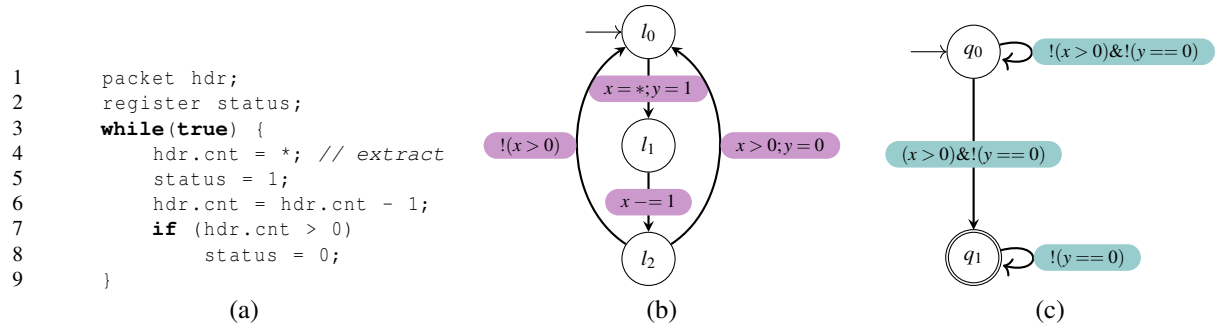

Figure 5: The program is presented in (a) as code and in (b) as control flow automaton. For brevity, we denote *hdr.cnt* as x and *status* as y. The Büchi automata representing the negation of $\Diamond(x > 0) \rightarrow \Diamond(y = 0)$ is presented in (c).

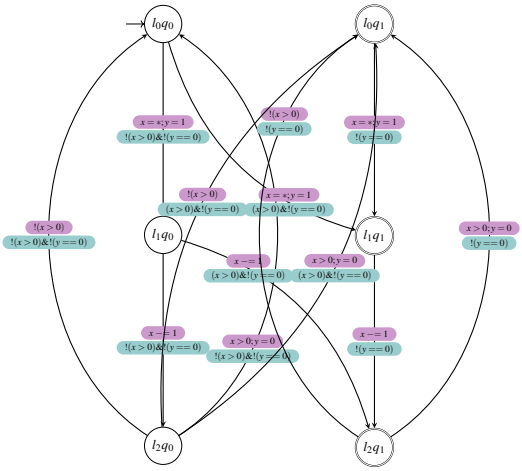

Figure 6: Büchi program product for Figure 5.

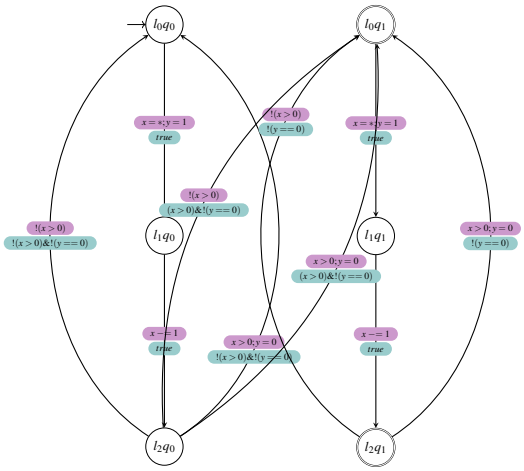

Figure 7: Büchi transaction for Figure 5.

Algorithm 1 The verification framework

Input: Program $\mathcal{P}$ and LTL property φ
Output: *Yes* if $\mathcal{P} \models \varphi$, and counterexample π otherwise

1: $\mathcal{A}_{\neg\varphi} \leftarrow$ LTL2Buchi$(\neg\varphi)$
2: $\mathcal{B} \leftarrow \mathcal{P} \otimes \mathcal{A}_{\neg\varphi}$
3: **while** $\mathcal{L}(\mathcal{B}) \neq \emptyset$ **do**
4: Let $\pi \in \mathcal{L}(\mathcal{B})$
5: **if** π is feasible **then**
6: **return** π
7: $\mathcal{B} \leftarrow$ refine$(\mathcal{B}, \pi)$
8: **return** *Yes*

the verification result. In the first place, the negation of the LTL formula $\neg\varphi$ is transformed into its corresponding Büchi automaton $\mathcal{A}_{\neg\varphi}$ (line 1). Next, the Büchi transaction is constructed to represent the counterexamples that witness the violation (line 2). The while loop (lines 4-7) aims to identify any fair and feasible trace that belongs to $\mathcal{B}$. First, it extracts a fair trace π that belongs to $\mathcal{B}$ (line 4). If π is feasible, then a counterexample is found according to Theorem 5.1. Otherwise, $\mathcal{B}$ is reduced to not accept π and other spurious traces that can be generalized from it (line 7). Finally, if there exists no fair trace for $\mathcal{B}$, the framework concludes that the property φ has been verified (line 8).

6 Implementation

The implementation of p4tv comprises approximately 10,000 lines of code in C++ and Java. As a common approach adopted by P4 verifiers [24, 40, 41, 47], we first translate P4 to an intermediate representation called Boogie [7] and proceed with the downstream verification. Next, we instrument the program with ghost variables to keep track of the terms and predicates introduced in P4LTL, similar to the approach used in p4v [40]. Our verification approach is implemented as an extension to Ultimate Automizer model checker [20]. Given a P4LTL specification, our implementation constructs the corresponding Büchi transaction introduced in Section 5 and checks for the existence of a fair and feasible trace. If the trace is discovered, the corresponding counterexample will be reported to the developer. Otherwise, p4tv will confirm that the P4LTL property is satisfied by the given P4 program.

Limitation. Currently, we note several limitations with

Name	Benchmark Description
Bfs [45]	The fast failover mechanism in a Bfs fashion to reroute packets without control plane interference.
Blink [28]	Detect characteristic failure based on information aggregated with registers and trigger rerouting.
CoDel [36]	An active queue implementation for RFC 8289.
Dfs [45]	A Dfs variation of the Bfs benchmark.
Ndn [46]	A named data networking paradigm where data are retrieved based on names rather than addresses.
P4NIS [38]	Several mechanisms for eavesdropping protection.
P4sp [37]	A sensor failure recovery system.
P4xos-acceptor [19]	P4 implementation of the acceptor in Paxos protocol.
P4xos-learner [19]	P4 implementation of the learner in Paxos protocol.

Table 1: P4 benchmark descriptions.

p4tv. Firstly, while it fully supports V1Model, it offers only limited support for TNA and PSA. Nonetheless, as demonstrated in Section 3.1, we assert that our modeling techniques remain applicable to these architectures, requiring only a more intricate design in the `P4program` process. We plan to support them in the future. Additionally, although the utilization of Büchi transactions can decrease the number of accepted traces, p4tv may still encounter the state explosion problem, which is an intrinsic challenge for model checking. Lastly, p4tv only permits developers to specify properties at the packet processing boundaries. Specifically, developers cannot directly specify or verify properties within packet processing. As per the P4LTL semantics, if a property violation occurs within packet processing but remains unobservable at the boundary, p4tv does not regard such violations as an issue.

7 Evaluation

Dataset. As p4tv pioneers temporal verification for stateful P4 programs, we introduce a dedicated dataset tailored for this purpose. This dataset comprises nine non-trivial stateful P4 programs sourced from both the open-source community and academic papers (further details provided in Table 1). For each program, we carefully analyze its design proposal and manually formulate temporal properties that we anticipate to be satisfied. Furthermore, besides several bugs that have been found in our evaluation, we intentionally inject additional artificial bugs into the control plane or code implementation to further test p4tv's bug-finding capabilities. In total, we formulate 19 stateful verification tasks.

P4 verifiers. We compare p4tv with bf4 [21], p4v [40], Vera [47], and Aquila [50], representing the state-of-the-art P4 verifiers in recent years.

All experiments were conducted on a machine with an Intel(R) Core(TM) i5-12400 2.50 GHz CPU and 32GB RAM.

7.1 Verifying Stateful Temporal Properties

Table 2 presents the evaluation results of our tool, including the specification size and detailed description of verified properties. The CPI column indicates whether the corresponding verification task requires additional control plane information. The number with an asterisk superscript denotes an artificial bug injection. Symbol ✓ represents the successful verification, and ✗ denotes a counterexample revealing a discrepancy between program behavior and the property.

Effectiveness. All of the compared verifiers (i.e., bf4 [21], p4v [40], Vera [47] and Aquila [50]) currently do not support the temporal verification of stateful P4 programs at the packet processing level. These verifiers assume the register values to be non-deterministic at the start of each packet processing, overlooking its stateful nature. This limitation restricts their ability to specify and verify temporal properties related to register state changes and history traces.

Of all the 19 stateful verification tasks, p4tv successfully verifies 14, while reporting counterexamples for the remaining. In the 9th verification task, we discover that insufficient consideration for register initialization in the P4 implementation leads to property failure. According to the P4-16 specification [16], the initial register value is non-deterministic without manual specification, potentially causing constant packet dropping. Concerning the 13th verification task, the improper implementation of the heartbeat check for the primary port results in property violation. Moreover, p4tv effectively reveals bugs through corresponding counterexamples for manual bug injections in both CPI (task 8) and codes (tasks 15 and 18). In task 8, swapping the matching action for data packet and interest packet in CPI causes a resource interest packet to reset, rather than set, the "can be forwarded" status for the corresponding data packet. P4tv identifies the violation and reports a packet processing sequence where the switch receives an interest packet followed by a data packet but fails to forward the latter. For tasks 15 and 18, p4tv helps pinpoint the injected bugs by revealing counterexamples where the port state and round registers are incorrectly updated.

Efficiency. The verification time of p4tv ranges from 10 seconds to 21 minutes, with median and average time costs of 51 seconds and 181 seconds, respectively. Memory usage ranges from 201MB to 6.1GB, with violation detection tasks tending to require more memory. Some verification tasks, such as task 8, require relatively longer verification time, attributed to numerous refinement iterations. Generally, the inherent complexity of verification tasks primarily determines the solving time. Moreover, while larger programs and specifications often lead to more complex verification tasks, it is not always the case, e.g., tasks 5 and 16.

7.2 Verifying Assertions

This experiment compares p4tv with prior tools for assertion verification. An assertion ψ is a Boolean predicate associated with a specific P4 program point, that should always evaluate to true at that point during code execution [27]. Each assertion corresponds to a particular case of P4LTL property described

Benchmark	No.	Property Description	CPI	Prog Size	Spec Size	p4tv
Bfs	1	Reroute packets are sent to parent ports only after the whole route process is complete.		355	34	✓ (51s, 1.6GB)
Blink	2	The packets are retransmitted only after the failure signal is detected over multiple flows.		745	44	✓ (154s, 1.8GB)
CoDel	3	If in normal state, the switch will not drop packets until the queuing delay exceeds the threshold.		285	40	✓ (51s, 497.9MB)
	4	If in drop state, packets will be dropped until the queuing delay resumes.			33	✓ (18s, 286.3MB)
Dfs	5	Packets are sent to parent ports only after the whole route process is complete.		306	34	✓ (47s, 201.3MB)
Ndn	6	Forwarding data packets occurs only if the switch has received corresponding interest packets before.	✓	470	50	✓ (895s, 1.4GB)
	7	After forwarding data packets, the arrival of an immediate data packet entails drop.	✓		34	✓ (274s, 1.8GB)
	8*	Bug inject: swapping matching action for data packet and interest packet in CPI. Check property 6.	✓		50	✗ (1260s, 6.1GB)
P4NIS	9	If user packets arrive infinitely often, then they will be forwarded to certain ports infinitely often.		303	82	✗ (185s, 2.7GB)
	10	Egress ports for packets from the same source are not fixed.			40	✓ (39s, 1.8GB)
P4sp	11	When timeout is detected, the switch will forward packets from the redundant port until the primary port recovers.		222	64	✓ (14s, 623.8MB)
	12	If a packet from the primary port is forwarded, packets below the threshold will be dropped next time.			38	✓ (22s, 836.0MB)
	13	Early packets from the secondary port are forwarded only if the time threshold has been exceeded before.			38	✗ (64s, 1.7GB)
	14	If a packet from the primary port arrives, the forwarding decision will depend on the corresponding timestamp until the arrival of the next primary port packet.			39	✓ (10s, 513.1MB)
	15*	Bug inject: The state update action is interchanged between primary pory and secondary port. Check property 12.		231	38	✗ (85s, 1.9GB)
Paxos-acceptor	16	After a p4xos packet is forwarded, the p4xos packets of earlier rounds will not be forwarded by the switch.	✓	355	66	✓ (45s, 857.9MB)
	17	The acceptor switch only votes for the value it stores until a new election packet arrives.			31	✓ (28s, 719.1MB)
	18*	Bug inject: Wrongly updating the value round instead of the current valid round for round register. Check property 17.			31	✗ (176s, 2.8GB)
Paxos-learner	19	The learner switch will not forward votes until the vote has reached majority agreements.		322	43	✓ (21s, 396.5MB)

Table 2: Results of stateful temporal verification.

by $\square\psi$, indicating that "the predicate ψ should hold at the end of every packet processing." We can use p4tv to verify assertion by instrumenting a shadow variable to track the assertion's value at that point and initializing it with *true* at the beginning of each packet processing stage.

Given Vera's limited support for user-defined assertions and Aquila's not publicly accessible, we contrast p4tv with bf4 and p4v, the current state-of-the-art P4 verifiers. We utilize the publicly available code for bf4 and employ the approximate implementation for p4v in [21], as p4v is not open-sourced. Furthermore, it's important to note that while assertions are supported by prior tools, they operate under a model that assumes all register values to be nondeterministic and only considers a single packet processing. In the subsequent discussion, an assertion is deemed *stateful* (or *stateless*) based on whether it is related to registers or not.

Table 3 presents the results of the assertion verification. The symbol ✓ indicates successful validation of the property, ✗ signifies a genuine counterexample, and Δ denotes that the tool returns a spurious counterexample, which would not occur under the given configuration. SimpleNat is a simple stateless NAT P4 implementation. For conciseness, the results of all six invalid header access checks are combined into one line since their verification tasks are nearly identical as well as their verification time. The results of valid header access checks are similar.

As depicted in Table 3, p4tv is able to verify stateless assertions as the priors do. It's worth noting that while its performance seems relatively degraded, this is attributable to the fact that p4tv evaluates assertions within the multiple-packet model, introducing additional complexity to the verification process. Regarding stateful assertions, p4tv effectively con-

Benchmark	Assertion	Stateful?	p4tv	bf4	p4v
SimpleNat-bug1_6	Whether the header is valid before accessing.	No	✗ (2m)	✗ (3s)	✗ (4s)
SimpleNat-safe1_11			✓ (10s)	✓ (3s)	✓ (4s)
P4NIS-safe1	The egress port should be equal to the register value if tunnel is applied.	Yes	✓ (2m36s)	✓ (3s)	✓ (2s)
P4NIS-safe2	Labeled packets cannot be implicitly dropped.	Yes	✓ (59s)	Δ(3s)	Δ(3s)
P4xos-acceptor-safe	Stored consensus round must be always less than the current valid round.	Yes	✓ (28m21s)	Δ(4s)	Δ(3s)
P4xos-learner-unsafe	The value of vote counter register is always zero.	Yes	✗ (6m54s)	Δ(2s)	Δ(3s)
P4xos-acceptor-unsafe	Stored consensus round must be always equal to the current valid round.	Yes	✗ (3m40s)	Δ(3s)	Δ(2s)

Table 3: Results of assertion verification.

firms safe assertions and reports genuine counterexamples for unsafe ones. Conversely, bf4 and p4v, assuming registers to be entirely non-deterministic, exhibit incompleteness in verifying assertions under specific register configurations. For instance, under the zeroing register configuration, the assertion $vround[hdr.inst] \leq round[hdr.inst]$ for P4xos-acceptor-safe remains valid throughout subsequent processing, but may easily fail under the non-deterministic configuration. Furthermore, for benchmarks like P4xos-learner-unsafe, although bf4 and p4v successfully invalidate the assertion, they reported counterexamples that would never occur under the given configuration. In conclusion, the overapproximation of the priors results in imprecision in verifying stateful properties.

7.3 Scalability Evaluation

In this section, we explore the scalability of p4tv in two dimensions: program complexity and specification complexity.

To assess the scalability of p4tv concerning program complexity, we introduce a parameter named PORT_NUM for P4NIS to parameterize the range of valid ports. We verify the following valid P4LTL property: if the register *count* is set within PORT_NUM, it will remain within this range for all subsequent processing. Since P4 is a loop-free language, increasing PORT_NUM by 1 entails adding an additional if block to the program that updates the *count* register and sets the metadata, without expanding the size of the P4LTL property. The verification results are presented in Figure 8.

To examine the scalability of p4tv concerning specification complexity, we conduct experiments on P4xos-acceptor. An essential property of the acceptor is that the round recording the consensus value must always be less than or equal to the current valid round, as expressed by the P4LTL property:

$$\wedge_{i=0}^{\mathrm{CNT}} vround[i] \leq round[i] \rightarrow \Box(vround[i] \leq round[i]).$$

This ensures that outdated messages are disregarded, which is crucial for achieving consensus. We verify P4xos-acceptor with the property as the parameter CNT increases. The verification results are illustrated in Figure 9.

As indicated in Figure 8 and Figure 9, with the other dimension fixed, the verification time of p4tv exhibits rapid growth as the complexity factors PORT_NUM and CNT become relatively large. Moreover, the validity of the property also impacts the verification time. For instance, manually substituting $\leq$ with $>$ in every clause of the P4xos-acceptor specification, the time required to return a counterexample remains nearly identical for CNT $= 8$ and CNT $= 16$ (in about 90s), since constructing a counterexample trace is straightforward. Ultimately, the root cause of verification time is the intrinsic complexity of the verification task.

8 Case Studies

P4tv can verify a wide range of temporal properties within stateful P4 programs. In this section, we present our verifying experiences with p4tv through some case studies.

P4NIS [38]. Processors-based network immune scheme (P4NIS) aims to protect the network against packet eavesdropping within the programmable data plane. The snippet of P4NIS is presented previously in Section 2. An important liveness property associated with the defense mechanism can be expressed as follows:

If specific packets keep arriving and being forwarded, they should be forwarded to ports 1, 2 and 3 infinitely often.

We can use P4LTL to concisely express the temporal property. Firstly, it is necessary to define the term "specific packets" within the context of P4NIS. These packets are identified as those with an IPv4 destination address other than the domain name server (123.123.123.123) and received from port 0. Moreover, the environment assumption in P4LTL can be leveraged to describe the "If" part of the property. Specifically, the environment assumption can be formulated as $\varphi_E = \Box\Diamond\phi_{sp}$, where

$$\phi_{sp} = standard_metadata.ingress_port == 0 \\ \wedge \mathrm{old}(hdr.ipv4.dstAddr) \neq 123.123.123.123,$$

denoting the "specific" condition in the context of P4NIS mechanism. Moreover, we utilize ϕ_{sp} to specify the subsequent portion of the property, which states that "they should be forwarded to ports 1, 2 and 3 infinitely often" as follows:

$$\varphi_P = \bigwedge_{i=1}^{3} \Box\Diamond(\phi_{sp} \rightarrow \mathrm{fwd}(i))$$

In summary, we can use the formula $\varphi = \varphi_E \rightarrow \varphi_P$ to formalize the temporal property of such stateful functionalities. However, the property φ does not hold. Upon inputting φ

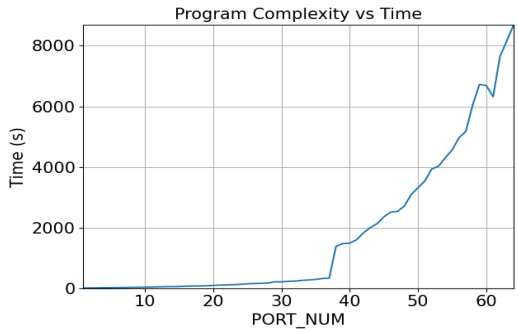

Figure 8: Verification time curve as PORT_NUM grows.

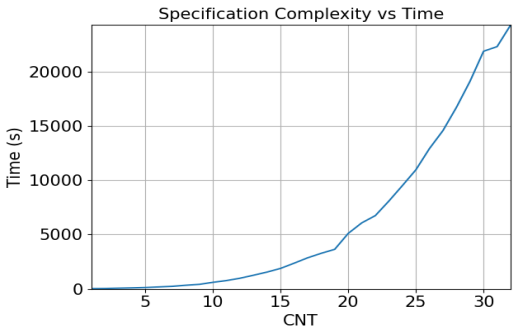

Figure 9: Verification time curve as CNT grows.

and the P4NIS code, p4tv will report a counterexample indicating that the value of the port record register `count[0]` is improperly configured. The oversight of register configuration leads to the potential of a packet skipping all the conditional branches and being implicitly dropped (i.e., the forwarding port *egress_spec* is not set). The intrinsic issue is that the P4 language specification [16] assumes that the default value of the register `count[0]` is undefined. Consequently, a switch deployed with the P4NIS mechanism may drop all the receiving packets when `count[0]` is configured with a value outside the range $[0,2]$, e.g., configured with 4.

To fix the potential vulnerability, we can adopt two strategies regarding different aspects. Suppose we are not certain about whether the underlying hardware performs the default zero configuration. In that case, we can amend the code with an additional branch condition, resetting `count[0]` when it is improperly configured.

```
1       count.read(temp,(bit<32>)0);
2       // set count back to normal value
3       if(temp > 2){
4           count.write((bit<32>)0, (bit<32>)1);
5           standard_metadata.egress_spec = 1;
6       }
```

If we have a certain confidence in the hardware configuration, the property part φ_P becomes

$$\square(count[0] \geq 0 \wedge count[0] \leq 2 \rightarrow \bigwedge_{i=1}^{3} \square\Diamond(\phi_{sp} \rightarrow \text{fwd}(i))),$$

which states that when `count` is appropriately configured, packets will be forwarded to ports 1,2 and 3 in a circular way. Either application of the strategies will enable p4tv to verify the correctness of the specification, proving that the temporal property is satisfied by P4NIS.

NDN [46]. Named-Data Networking (NDN) implements a content-centric networking paradigm that aims to provide an efficient and scalable way to manage distributed storage, as opposed to the typical destination-centric approach.

NDN employs two packet types, interest and data, to implement its content-centric paradigm. Interest packets represent requests, while data packets represent responses. If the request name in an interest packet is not matched in the Forwarding Information Base (FIB) table, the switch will drop the packet. Conversely, if the request name is present in the FIB, the switch will store the incoming port information in the Pending Interest Table (PIT) and forward the packet based on the port information stored in the FIB.

If a data packet experiences a miss in the Pending Interest Table (PIT), the switch will drop it. This occurs because the corresponding pending request is not logged. Conversely, if the data packet matches an entry in the PIT, the switch will forward the packet through the port where the request packet originates from and remove the entry. Both the Forwarding Information Base (FIB) and Pending Interest Table (PIT) are using registers as keys.

Based on the NDN implementation, its property φ_{ndn} can be formulated in P4LTL as

$$\square(\phi_{data} \wedge \neg\text{drop} \rightarrow \circ((\phi_{data} \rightarrow \text{drop})\mathcal{W}(\phi_{int} \wedge \neg\text{drop}))),$$

where $meta.nameHash == a \wedge meta.packetType == DATA$ is represented by ϕ_{data}, and ϕ_{int} denotes $meta.nameHash == a \wedge meta.packetType == INT$.

The specification φ_{ndn} states that, for any given name hash a, the switch will always drop the data packet until it forwards the corresponding request packet. Note that a serves as a free variable, indicating that the specification is expected to hold for any name hash. Additionally, we use $\phi_{data} \rightarrow$ drop to specify that we only expect the specification to hold after a data packet has been forwarded, since the corresponding PIT entry is cleared afterwards.

Upon inputting the specification and the NDN code, p4tv returns a counterexample. The reason for this outcome is that the table entries control a part of the key forwarding logic. The property does not hold if we assume that the table entries are arbitrary. To address the problem, we employ CPI to complement the forwarding logic, stating that if the requesting data is not recorded in PIT or FIB, the tables `routeData_table` and `updatePit_table` should apply the action drop, and otherwise the table `updatePit_table` should update the PIT table accordingly, as shown below:

$$\begin{aligned}&\square(\text{apply}(ut) \wedge \text{key}(ut, meta.FIB) == 0 \rightarrow \text{apply}(ut, drop)\\ &\wedge \text{apply}(ut) \wedge \text{key}(ut, meta.FIB) \neq 0 \rightarrow \text{apply}(ut, update)\\ &\wedge \text{apply}(rt) \wedge \text{key}(rt, meta.PIT) == 0 \rightarrow \text{apply}(rt, drop))\end{aligned}$$

After inputting the CPI along with the NDN implementation, p4tv verifies the correctness of the property.

9 Related Work

SDN verification. The verification for SDN can be classified into control plane and data plane verification.

Traditionally, studies analyzing the control plane have focused on topological properties such as reachability and isolation. Arc [26] facilitates rapid control plane verification without the data plane generation. Batfish [23] introduces a general approach to detect errors in network configurations by deriving the data plane effectively. CrystalNet [39] offers a proactive means of validating network operations using emulation techniques. Minesweeper [8] converts network configurations into logical formulas and checks for satisfiability to identify any network state that violates the specified query. These studies primarily analyze network configurations and strive to address queries related to network-wide properties.

Data plane verification tools address similar queries by requiring a snapshot of the network's data plane. Numerous techniques have been proposed to verify the data plane from various perspectives. Anteater [42] employs graph theory algorithms to verify network-wide properties, representing the network as a graph. HSA [33] develops an optimized formalism to statically check network configurations with specifications and identify network failures. Veriflow [34] aims to enable real-time validation of network-wide invariants, while Symnet [48] validates network-wide queries by injecting symbolic packets and tracking their behavior through the network. Our tool, p4tv, falls within the category of data plane verification tools and is specifically designed for verifying processing-level temporal properties of stateful P4 programs.

P4 verification tools. Aquila [50], bf4 [21] and p4v [40] encode P4 programs with SMT formulas and verify the properties using constraint solving. ASSERT-P4 [24] and Vera [47] use symbolic execution to verify P4 programs. However, these P4 verifiers overlook the stateful nature of packet processing. They assume register states are nondeterministic before each packet processing, which fundamentally hinders them from verifying the behaviors of stateful P4 programs. Moreover, Aquila, ASSERT-P4, bf4, and bf4 use Hoare logic and Vera proposes NetCTL that is a subset of temporal logic language CTL [13]. Both Hoare logic and NetCTL focus on properties of an individual packet processing and do not consider historical information. On the contrary, p4tv considers the preservation of register states in its execution model, and provides P4LTL to support processing-level temporal specification.

Stateful network verification tools. Several studies have previously addressed the verification of stateful networks, but they have focused on different aspects compared to p4tv. For instance, [54] concentrates on the behaviors of match-action tables in SDN, while [5] verifies congestion control protocols by transforming network models into SMT formulas. Previous works such as [1, 2, 52] utilize abstract interpretation to verify stateful networks, with a focus on network-level properties such as isolation. These works fall under the category of control plane verification. In contrast, p4tv targets data plane verification with its focus on P4. Aragog [53] aims to verify distributed network functions, but is limited to verifying network invariants and run-time checks. P4wn [31] is a symbolic execution tool for stateful P4 programs that reports the probability of each program path. In our work, we adopt a similar approach as P4wn, treating stateful P4 programs as infinite loops. However, we enhance this approach by incorporating additional register initializations to adapt it to our specific verification scenario. Notably, our research question differs from P4wn as our primary objective is *formal verification* rather than *statistical testing* for P4 programs.

Temporal verification. There have been a number of approaches to verifying the temporal properties of state-based systems [6, 12, 14, 15, 17, 18, 20, 29]. Several approaches [14, 15, 17, 18, 20] employ counterexample-guided abstraction refinement to verify temporal properties. They refine the abstract model iteratively utilizing spurious counterexamples encountered until no counterexample exists or a real counterexample is discovered. In our verification approach, we adopt the framework proposed by [20]. However, it is important to note that our approach differs in several aspects. Firstly, we aim at different semantics for temporal properties. Instead of verifying properties at the small time step, we focus on checking them at the big time step, which limits the direct application of the common approach to P4LTL. Moreover, for verification purposes, we construct Büchi transaction rather than Büchi program product. This imposes additional constraints on the transitions and final states, resulting in a reduced number of transitions and accepted traces and making the verification more practical.

10 Conclusions

Current P4 verifiers simplify P4 verification by overapproximating register states, which leads to challenges in specifying and verifying complex stateful P4 programs. We present p4tv, the first automated tool for temporal verification of stateful P4 programs at the packet processing level. We introduce a specification language called P4LTL to describe stateful functionalities and formulated Büchi transaction to make the verification more tractable. The evaluation of verification tasks demonstrates p4tv's effectiveness in verifying temporal properties of stateful P4 programs. P4tv is available at https://thufv.github.io/research/p4tv.

Appendix

A Theorem Proof

Theorem A.1. *The P4 program $\mathcal{P}$ satisfies the P4LTL specification ϕ if and only if the Büchi transaction $\mathcal{B} = \mathcal{P} \otimes \mathcal{A}_{\neg\varphi}$ does not have any fair and feasible trace.*

Proof. To begin with, we introduce the general idea of the theorem at the high level. The Büchi transaction $\mathcal{B} = \mathcal{P} \otimes \mathcal{A}_{\neg\varphi}$ corresponds to the automaton that represents the set of every *counterexample*. In other words, every fair and feasible trace of $\mathcal{B}$ corresponds to a counterexample indicating that $\mathcal{P} \not\models \varphi$. Next, we present the sketch of the theorem proof.

For every trace $\pi = (s_0, \text{assume } a_0)\ (s_1, \text{assume } a_1)\ \cdots$ that is fair and feasible to $\mathcal{B}$, we can extract the statement part $\pi_{\mathcal{P}} = s_0\ s_1 \cdots$ and the LTL part $\pi_{\mathcal{A}} = a_0\ a_1 \cdots$. For the LTL part, we can reduce $\pi_{\mathcal{A}}$ to $\pi'_{\mathcal{A}}$ by deleting the *true* characters imposed by Büchi transaction, and use the definition of Büchi transaction to show that π is fair and feasible to $\mathcal{B}$ if and only if $\pi_{\mathcal{P}}$ is fair and feasible to $\mathcal{P}$, $\pi'_{\mathcal{A}}$ belongs to $\mathcal{A}_{\neg\varphi}$ and $\pi_{\mathcal{P}} \models \pi'_{\mathcal{A}}$.

Moreover, we prove that P4 program $\mathcal{P}$ satisfies the P4LTL specification ϕ if the Büchi transaction $\mathcal{B} = \mathcal{P} \otimes \mathcal{A}_{\neg\varphi}$ does not have any fair and feasible trace. We prove it by contradiction. If it were false, then $\mathcal{P} \models \varphi$ and there exists an fair and feasible trace of $\mathcal{B}$. Therefore, we know that there also exists $\pi_{\mathcal{P}}$ and $\pi_{\mathcal{A}}$ such that $\pi_{\mathcal{P}}$ is fair and feasible to $\mathcal{P}$, $\pi'_{\mathcal{A}}$ belongs to $\mathcal{A}_{\neg\varphi}$ and $\pi_{\mathcal{P}} \models \pi'_{\mathcal{A}}$. According to the semantics of P4LTL, $\pi_{\mathcal{P}}$ can serve as a witness to the violation of φ since the execution conform to the formula $\neg\varphi$, and therefore leads to a contradiction.

Furthermore, we prove that P4 program $\mathcal{P}$ satisfies the P4LTL specification ϕ only if the Büchi transaction $\mathcal{B} = \mathcal{P} \otimes \mathcal{A}_{\neg\varphi}$ does not have any fair and feasible trace. Assume that $\mathcal{B}$ does not have any fair and feasible trace while $\mathcal{P}$ does not satisfy the P4LTL specification ϕ. According to the semantics of P4LTL, there must exists a fair and feasible trace $\pi_{\mathcal{P}} = s_0\ s_1 \cdots \in \mathcal{P}$ such that $\pi_{\mathcal{P}} \models \neg\varphi$. Moreover, there also exists a corresponding $\pi'_{\mathcal{A}} = a_0\ a_1 \cdots \in \mathcal{A}_{\neg\varphi}$ that witnesses the violation. We then reduce $\pi_{\mathcal{P}}$ to $\pi'_{\mathcal{P}} = s'_0\ s'_1 \cdots$ by deleting statements that do not satisfy $\text{TE}(s) \vee \text{TR}(s)$, and aligns

$\pi'_{\mathcal{P}}$ with $\pi'_{\mathcal{A}}$ to form $\pi' = (s'_0, \text{assume } a'_0)\ (s_1, \text{assume } a'_1)\ \cdots$. Next, we construct $\pi = (s_0, \text{assume } a_0)\ (s_1, \text{assume } a_1)\ \cdots$ by recovering $(s, \text{assume } true)$ for every deleted statement s from $\pi_{\mathcal{P}}$. The trace π is fair and feasible to $\mathcal{B}$ based on the definition of Büchi transaction, and therefore contradicts the assumption. □

NDD: A Decision Diagram for Network Verification

Zechun Li*, Peng Zhang*, Yichi Zhang*, Hongkun Yang†
*Xi'an Jiaotong University, †Google

Abstract

State-of-the-art network verifiers extensively use Binary Decision Diagram (BDD) as the underlying data structure to represent the network state and equivalence classes. Despite its wide usage, we find BDD is not ideal for network verification: verifiers need to handle the low-level computation of equivalence classes, and still face scalability issues when the network state has a lot of bits.

To this end, this paper introduces *Network Decision Diagram (NDD)*, a new decision diagram customized for network verification. In a nutshell, NDD wraps BDD with another layers of decision diagram, such that each NDD node represents a *field* of the network, and each edge is labeled with a BDD encoding the values of that field. We designed and implemented a library for NDD, which features a native support for equivalence classes, and higher efficiency in memory and computation. Using the NDD library, we re-implemented five BDD-based verifiers with minor modifications to their original codes, and observed a 100× reduction in memory cost and 100× speedup. This indicates that NDD provides a drop-in replacement of BDD for network verifiers.

1 Introduction

Network verification is becoming an important toolchain for network operators to ensure the correctness of their networks [9, 10, 13, 14, 16, 19, 24–28, 30, 32–34, 37, 39, 41, 47, 48, 50–58], and some of them have been deployed by large service providers to detect misconfigurations [32, 37, 48, 54].

Many network verifiers use *Binary Decision Diagram (BDD)* [11, 20], to compactly represent network state like packet headers, routes, failures, etc. Despite its extensive usage, we find that BDD is not ideal for network verification tasks, in the following three aspects.

Memory inefficiency. We observe BDD-based network verifiers create a lot number of redundant nodes, which share the same sub-structure on some fields, but cannot be reduced since their differences on other fields. This redundancy is magnified when verifiers [13, 57] compute equivalence classes (i.e., atomic predicates, or simply atoms [1]), which leads to an "explosion of atoms" and overflows the memory.

Computation inefficiency. We observe that BDD-based network verifiers are slowed down by logical operations, e.g., $a \wedge b$. The reason is BDD operations proceed in a recursive way, with each recursion looking at a single bit of a and b. Even worse, if the BDDs encode different variables, more recursions are needed to "align" their variables. Considering networks often match on multiple fields (e.g., 5-tuple, 104 bits), the recursions can be deep and therefore very slow.

Lack of support for network verification. We observed that BDD libraries offer little support for common tasks of network verification, e.g., computation of atoms [51], incremental update of atoms [13, 57], and handling of packet transformers [53]. As a result, network verifiers need to design their own algorithms, which can be quite complex, for these common tasks, and still encounter scalability problems due to the aforementioned explosion of atoms.

We attribute the above problems to the fact that BDD is agnostic of *fields*, an important semantics in networks, where a device processes routes and packets by matching one or multiple fields. Moreover, the matching shows a characteristic of "field locality": *each rule matches few but different fields of the network.* This makes the fields mostly orthogonal, such that the number of nodes can be a cross-product of that for each field, and therefore quite large.

Based on the above observation, our basic idea is: *instead of viewing the entire network state as a whole, we partition it into a set of* ***fields***, so that logical operations are restricted to BDDs of the same field, and redundant nodes of the same fields can be reduced, fully independent of other fields.

After decoupling fields, a question arise: how to represent network state with the per-field BDDs? A naive way of using conjunctions of per-field BDDs is not compact, and can lead to an explosive number of conjunctions. Our approach to the

[1] For brevity, the following of this paper will use the term "atoms" to refer equivalence classes or atomic predicates [51].

representation problem is to wrap the per-field BDDs with another layer of decision diagram, termed *Network Decision Diagram (NDD)*. In an NDD, each NDD node u encodes a field f of multiple bits, and each edge of u is labeled with a BDD of field f. We show such a representation is *compact*, and prove it is actually *canonical*. In addition, since NDDs can look at many bits each time, logical operations of NDDs require much less recursions.

Finally, instead of computing single set of atoms for all fields, we compute a set of atoms for each field f, and transform the labels of each NDD edge from BDDs into a set of atoms. We term the resultant NDD as *atomized NDD*. Then, logical operations (e.g., $\wedge$, $\vee$) on NDDs can be replaced with simpler set operations (e.g., $\cap$, $\cup$), similar to [51].

The atomized NDD offers a lot of benefits. First, since the atoms are over a single field, we avoid the cross-product effect and can dramatically reduce the total number of atoms in the network. Moreover, all atom-related operations can be *fully transparent* to network verifiers, such that verifiers are agnostic of atoms, and do not need to realize their own atom-related algorithms.

Based on the above ideas, we realize an NDD library [2]. It features a native support for the computation and incremental update of atoms, and provides an efficient way for handling packet transformers. We use the NDD library to re-implement 5 BDD-based network verifiers, i.e., AP Verifier [52], APT [53], APKeep [57], SRE [58], and Batfish [19], with minor modifications to their original codes. After replacing the BDD library with the NDD library, these verifiers show a 2 orders-of-magnitude reduction in both memory and time.

Contributions. In sum, this paper makes three contributions:

- We introduce Network Decision Diagram (NDD), a new decision diagram customized for network verification.
- We implement an NDD library, and use it for 5 different network verifiers with small modified LOCs.
- We use real and synthetic datasets to show that by using NDD, the 5 verifiers achieve a 2 orders-of-magnitude reduction in both memory and time.

Limitations. NDD builds on the assumption of field locality, which generally holds on our datasets. However, if rules in a network match most of the fields, NDD may not perform better than BDD (§6.6).

2 Motivation

2.1 Preliminary to BDD

Binary Decision Diagram (BDD) is a rooted, directed acyclic graph (DAG) with two terminal nodes (`true` and `false`), and multiple non-terminal (variable) nodes (refer to Figure 1 as an example). Each non-terminal node u represents a test of a boolean variable $var(u)$, and has two outgoing edges, i.e., a high edge and low edge (shown as solid and dashed line, respectively). These two edges point to two *successor* nodes $high(u)$ and $low(u)$, i.e., a high successor and a low successor, respectively. The semantics is that: if x is tested to be *true* (*false*), then the high (low) edge will be followed and the next test will be $high(u)$ ($low(u)$). Each path from the root node to the terminal node `true` corresponds to one truth assignment of a boolean formula. For the BDD in Figure 1, there are only two paths from the root node to the terminal node `true`, encoding two truth assignments of $x_1 = false, x_2 = true$, and $x_1 = true, x_2 = true, x_3 = true$, respectively. Therefore, this BDD represents a boolean formula $(\neg x_1 \wedge x_2) \vee (x_1 \wedge x_2 \wedge x_3)$.

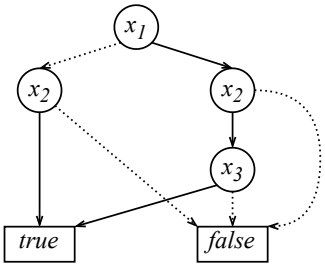

Figure 1: An example of BDD encoding the boolean formula $(\neg x_1 \wedge x_2) \vee (x_1 \wedge x_2 \wedge x_3)$.

Reduced Ordered BDD. A BDD is said to be an *Ordered* (OBDD) if the boolean variables follow a fixed variable order (say $x_1 < x_2 < \ldots, < x_n$ where $x_i < x_j$ means variable x_i appears before variable x_j) on all paths through the graph. An OBDD is said to be a *Reduced* (ROBDD) if it satisfies the following two conditions:

(C1) Uniqueness: no two distinct nodes represent the same variable and have the same successors;

(C2) No redundant node: no non-terminal node has identical high and low successor.

An important property of ROBDD is *canonicity*, i.e., for any boolean formula, if the variable ordering is specified, there is a unique ROBDD representing it [11]. As a result, ROBDD can significantly reduce the node redundancy [20] for a compact representation of boolean formulas, and is very efficient for logical operations. Without specified otherwise, the BDDs in this paper are ROBDDs.

BDD library. To use BDD, applications like network verifiers leverage off-the-shelf BDD libraries [7, 8]. A BDD library needs to realize logical operations, e.g., `and`, `or`, `not`, and other useful functions like `exist`, `restrict`, `oneSat`, `satCount`, etc. Most of them are realized in a recursive way.

To achieve high efficiency of memory and time, modern BDD libraries rely on some efficient algorithms and data structures. The *node table (unique table)* is a hash table holding all BDD nodes, each of which is a distinct tuple $(var, low, high)$. When the node table is full, a BDD library will free unused nodes with *garbage collection (gc)*. A common way to realize

BDD

```
1. foreach 1≤i≤32: vars(i) ← bdd.createVar();
2. foreach d ∈ devices: Preds.add(calPortPred(d, vars));
3. foreach pred ∈ Preds:
4.   foreach a ∈ Atoms:
5.     set.add(bdd.and(a, pred));
6.     set.add(bdd.and(a, bdd.not(pred)));
7.   Atoms ← set;
8. foreach d ∈ devices, p ∈ d.ports:
9.   foreach a ∈ Atoms:
10.    if (bdd.and(p.pred,a) = a):
11.      p.atoms.add(a);
12. traverseRec(Atoms, src);

13. Function traverseRec(pktSet, d)
14.   if (!pktSet.isEmpty()):
15.     foreach p ∈ d.ports:
16.       forwarded ← pktSet.intersect(p.atoms);
17.       traverseRec(forwarded, p.nextHop);
```

NDD

```
1. var ← ndd.createVar(32);
2. foreach d ∈ devices: Preds.add(calPortPred(d, var));
3. ndd.atomize(Preds);
4. traverseRec(ndd.true, src);

5. Function traverseRec(pktSet, d)
6.   if (pktSet != false):
7.     foreach p ∈ d.ports:
8.       forwarded ← ndd.and(pktSet, p.pred);
9.       traverseRec(forwarded, p.nextHop);
```

Figure 2: Pseudo code to verify networks based on BDD and NDD, respectively.

gc is to maintain a reference count for each node, and when the reference count of a node reaches zero, the node is marked as dead, and will be freed when gc is called. Most BDD libraries use *operation cache* to speed up logical operations: before each operation, the library firstly checks whether the result exists in the operation cache, and returns the result if there is a match; otherwise, the operation is performed and the result is put into the cache.

2.2 The use of BDD in network verification

In the recent decade, BDD has been extensively used for network verification. For example, many data plane verifiers [13, 51, 57] use BDDs to efficiently represent packet equivalent classes, and some control plane verifiers like SRE [57] use BDD to represent failure equivalence classes. Interested readers can refer to Appendix §G for an incomplete list of network verifiers based on BDDs.

The top of Figure 2 shows a code snippet to implement data plane verification based on BDD [51]. Note that we oversimplify the codes to reflect the core logic. First, the verifier creates a BDD variable for each bit of the field. Then, it computes port predicates for each device (Lines 1-2), computes atoms of all port predicates(Lines 3-7), and compute the set of atoms for each port (Lines 8-11). Finally, it computes reachability by recursively traversing the network with a packet set initialized to all atoms, and at each node filters some of atoms based on the forwarding rules (Lines 12-17).

Despite its extensive usage in network verification, we find BDD, however, is not ideal for achieving high efficiency for either memory or computation. To show this, we use a toy example with four nodes, as shown in Figure 3. For simplicity of illustration, we assume there are four fields, i.e., `dstIP`, `dstPort`, `srcIP`, and `srcPort`, where `srcIP` has only four bits and other fields each has only two bits.

Memory inefficiency. First, we observe that there are a lot of redundant BDD nodes that cannot be reduced. Figure 4(a) shows three BDDs encoding three sets of packets that are reachable from A to port 1 of D, following three different paths (i.e., $A \to B \to D$, $A \to C \to D$, and $A \to D$). These three BDDs have a common sub-structure consisting of 14 nodes which encode variables x_1 to x_6 of `srcIP` and `srcPort` (inside the red dashed box). That is, two copies of the sub-structure ($14 \times 2 = 28$ nodes) are redundant. However, we cannot eliminate these 28 nodes. The reason is that their nodes encoding x_6 point to different successor nodes encoding x_7 (the first bit of `dstIP`), and therefore satisfy the uniqueness condition of ROBDD and cannot be represented with a single node. We term such a redundancy as *partial redundancy* as it only exhibits on a subset of variables. The number of 28 redundant nodes may not seem a big issue in this toy example, while for real networks, this number can be as large as $O(10^8)$, leading to a huge memory cost (§6.5).

In addition, the effect of partial redundancy is magnified by the computation of atoms. When computing atoms, a verifier needs to perform many logical conjunctions on BDDs, thereby creating even more redundant nodes for each field. On our virtualized datacenter network datasets, which have multiple layers of packet headers, the number of redundant nodes can overflow the BDD node table, a phenomenon which we term as *explosion of atoms*. Interested readers can refer to Appendix D for an example.

Computation inefficiency. In addition to the high memory cost due to redundant nodes, we observe BDD-based network verifiers are also unnecessarily slow due to the frequent but inefficient logical operations. Specifically, to compute atoms or check reachability, network verifiers need to perform many logical operations ($\wedge$, $\vee$, $\neg$). Inside a BDD library, these operations are realized recursively: a conjunction $a \wedge b$, where a and b encode the same variable, boils down to two recursive calls of $low(a) \wedge low(b)$ and $high(a) \wedge high(b)$. Since each recursion only proceeds one bit, the recursions can go very deep when there are many bits (e.g., 104 bits for 5-tuples).

Worse still, if a and b encode different variables, with an ordering say $var(a) < var(b)$, many recursions may be needed to "align" variables, i.e., recursively find a descendant node of a, say a', such that $var(a') = var(b)$. For example, in Figure 4(a), to compute `and` of BDDs labeled by $A \to B \to D$ and b_3, we first need to recursively find the node of b_1, which encodes the same variable x_7 as b_3, rather than directly jumping to the field `dstIP`. This amounts to 17 recursions in total.

One may wonder whether we can mitigate these limitations with a better variable ordering. Putting aside finding an optimal variable ordering is a co-NP-complete problem [20], we observe that the redundancy is there no matter what the ordering of BDD variable is: when we re-order the variables, the redundancy is just shifting from one place to another (see Appendix A.9 for some numerical results.)

Lack of support for network verification. As a general-purpose data structure, BDD offers little support for some important tasks of network verification, including: (1) the computation of atoms, (2) the incremental update of atoms, and (3) the handling of packet transfomers.

First, many verifiers compute atoms over the network state for a faster verification. For example, BDD-based data plane verifiers like AP Verifier [52] partition the header space into a small set of atoms, such that packets in the same atomic predicate have the same forwarding behavior. When computing reachable packet sets from source to destination, the verifiers can use set operations ($\cup$, $\cap$) on sets of atoms, instead of the more expensive logical operations ($\vee$, $\wedge$) on BDDs. However, using BDD, these verifiers need to implement their own algorithms to compute atoms, which is nontrival and leads to explosion of atoms.

Secondly, to avoid from-scratch re-computation of atoms after each network update, network verifiers [13, 30, 57] need to design efficient algorithms to incrementally update the atoms. For example, APKeep [57], a state-of-the-art data plane verifier, designs efficient algorithms to achieve a realtime update of atoms; Katra [13] extends APKeep to multi-layer networks by computing *partial equivalence classes*, which can significantly improve the scalability of data plane verification for multi-layer networks. However, both APKeep and Katra need to implement their own algorithms for updating the set of atoms, which tend to be more complicated than the from-scratch computation of atoms, as in AP Verifier [51].

Finally, packet transformers such as NAT, IP-in-IP [40], VXLAN [38], etc., are common in networks. The existence of packet transformers makes the computation of atoms more complicated. Verifiers like APT [53] and APKeep [57] use customized algorithms to compute the atoms, such that the input and output of any transformer can be represented by a set of atoms. Such algorithms are also complex and may end up with many atoms.

3 Introducing NDD

3.1 Observations

We observe the inefficiency of BDDs in network verification is mainly due to the fact that BDD, as a general-purpose data structure, lacks the notion of "field", an important semantics in networks. For example, network devices forward or filter packets by matching one or multiple packet fields. Without such a notion, network verifiers based on BDDs model the network state as a whole, and the number of BDD nodes can grow exponentially with the number of fields, due to the following "field locality" phenomenon.

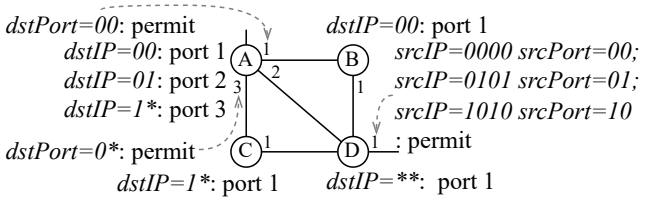

Figure 3: A toy example network used throughout this paper.

Field locality refers to the fact that even though there can be many fields in the network, each rule only matches on one or few of these fields, and different rules may match different fields. For example, forwarding rules in the underlay of a network virtualized with VXLAN only match on the `dstIP` of the outer header, while forwarding rules in the overlay only match the `dstIP` of the inner header. As another example, most ACL rules match a single or rather few fields, e.g., only 25 of 392 ACLs in the Purdue campus network match more than one field [46]. Finally, each route policy filters routes only based on one or two of all attributes, e.g., prefix, communities, AS path.

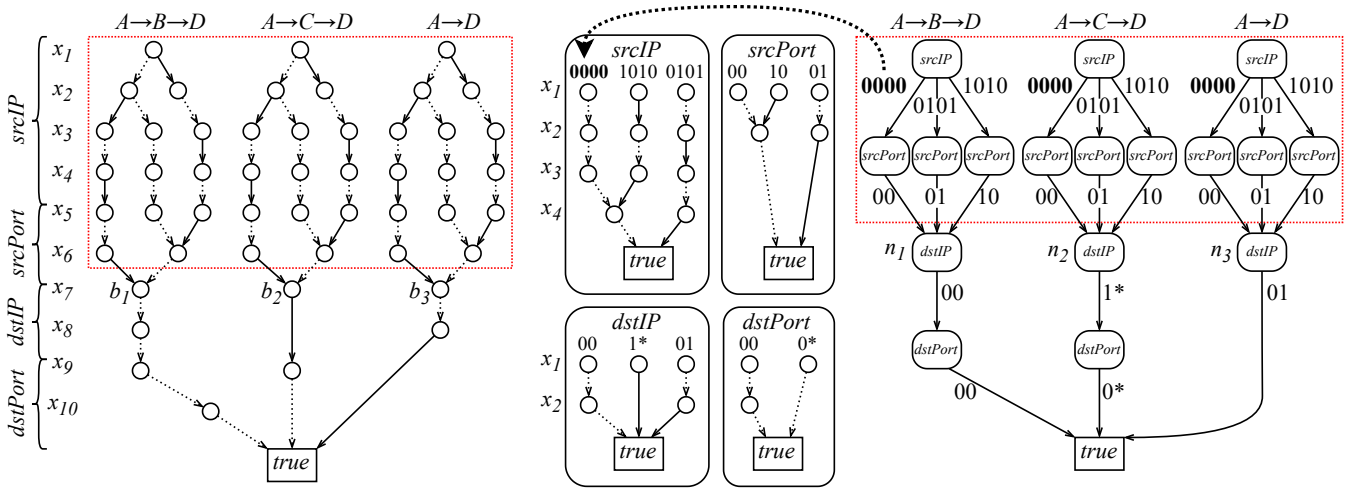
Due to field locality, the different fields in network state are *orthogonal*, meaning that the values of each field tend to be independent of those of other fields. As shown in Figure 4(a), the nodes for `src IP/Port` fields are orthogonal to those of the `dst IP/Port` fields. As a result, multiple copies of the same sub-structure for `src IP/Port` need to be created, due to the different sub-structures for `dst IP/Port`.

3.2 Idea

Decoupling the fields. Our basic idea is partitioning the whole network state (a bit vector) into a set of *fields*, which can be packet headers (e.g., 5-tuple), route attributes (e.g., community, AS Path), or up/down state for different sets of links, etc. Then, for each field, we create per-field BDD nodes and place them into their own *namespace*, such that logical operations and reduction of redundant nodes are restricted to BDDs in the same namespace. As shown in Figure 4(b), after reducing the redundant nodes for each of the four fields, there are only 11, 5, 5 and 3 BDD nodes, respectively. This amounts to a total number of 24 BDD nodes, instead of 50 ones as previously shown in Figure 4(a).

After the decoupling of fields, we can effectively reduce the number of redundant nodes. The question is how can we represent the network state with these BDDs, each of which only encodes a field? A straightforward way is to use a set of conjunctions or arrays of BDDs, where each BDD in an array encodes a specific field (see Appendix E for details). Such an approach is simple but can lead to an explosion of arrays after logical operations (see Appendix A.10 for details).

Assembling fields. We approach this representation problem



(a) BDDs (b) Per-field BDDs (c) NDDs

Figure 4: Illustrations of BDDs and NDDs. The dashed/solid lines represent `false`/`true`, and all edges to the BDD/NDD terminal node `false` are omitted for simplicity.

by layering another layer of decision diagram on top of the per-field BDDs. We term this layer of decision diagram as *Network Decision Diagram (NDD)*. In an NDD, each NDD node represents a field of multiple bits and has multiple edges; each edge of it is labeled with a BDD encoding those bits.

Such a representation is more compact than using BDD arrays or conjunctions. Returning to the example, Figure 4(c) shows the NDDs representing three sets of packets reachable from A to D. Compared to (a) BDDs, NDD only creates one copy of per-field BDD nodes in (b), as shown inside the red box. This leads to 24 BDD nodes in total, instead of 50 ones as in (a). Note that NDD also needs three copies for the same sub-structure; otherwise, it cannot distinguish the three different packet sets. However, since each NDD variable represents a field, each copy of the sub-structure has only 4 NDD nodes, which is much less than 14 BDD nodes as in (a) (in red rectangles).

Moreover, logical operations on NDDs is much faster than those on BDDs, since it can quickly skip a field in one recursion. For example, in Figure 4(c), to compute `and` of the NDD nodes labeled by $A \rightarrow B \rightarrow D$ and n_3, from the root node of $A \rightarrow B \rightarrow D$, NDD only needs 6 recursion for all paths in total to reach the node n_1, which has the same variable with n_3. This contrasts with BDDs, which need 17 recursions.

Finally, recall that network verifiers compute atoms over the whole network state, leading to an explosion of atoms. In addition, network verifiers need to design and implement their own algorithm, in order to efficiently compute and update the atoms, which are non-trival tasks.

Atomizing fields. Towards this problem, we design efficient algorithm for the computation and update of atoms as an internal process of NDD. Specifically, we compute a separate set of atoms for each field, and then transform the label of each NDD edge from a BDD to a set of atoms for that field. After that, the logical operations (e.g., conjunctions) on BDDs become set operations (e.g., intersections), which tend to be faster. By computing atoms over individual fields, NDDs avoid the problem of explosion of atoms. We term the NDDs where labels of edges are represented with atoms as *atomized NDDs*. Since NDD natively supports atomization, network verifiers become fully agnostic of atoms, and can still use the same logical operators after the NDDs are atomized.

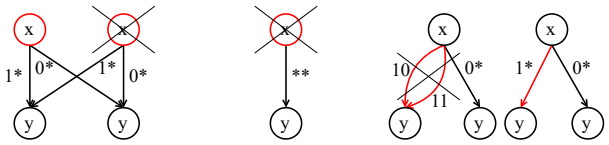
3.3 Network Decision Diagram

Similar to BDD, an Network Decision Diagram (NDD) is also a rooted, directed acyclic graph with two terminal NDD nodes `true` and `false`. The key difference is that there are multiple non-terminal NDD nodes, each of which represents a *field*, rather than a *bit*. Formally, we have the following definition, which is adapted from the definition of BDD in [11].

Definition 1. *A **Network Decision Diagram (NDD)** is a rooted, directed acyclic graph with*

- *two terminal NDD nodes `true` and `false`, with an out-degree of zero.*
- *a set of non-terminal NDD nodes. Each node u is associated with a variable $var(u)$ representing a **field** of one or multiple bits, and has a set of outgoing edges, denoted as $edges(u)$. Each $e \in edges(u)$ points to a successor of u, denoted as $next(e)$, and has a predicate over the variable $var(u)$, denoted as $label(e)$.*
- *$\forall u$, $\forall x, y \in edges(u)$ with $x \neq y$: $label(x) \wedge label(y) = false$, and $\bigvee_{e \in edges(u)} label(e) = true$.*

Note above the third condition generalizes that of BDD, saying that the labels of edges from the same NDD node are exclusive, and the union of these labels covers all values of



(a) Non-unique nodes (b) Redundant nodes (c) Redundant edges

Figure 5: Three types of redundancy in NDD.

the field. For BDD, a label is either 0 or 1, clearly satisfying this condition.

Reduced Ordered NDD. The definition of Reduced Ordered NDD (RONDD) is similar to that of ROBDD (§2.1). The difference is that besides the two conditions *uniqueness* and *no redundant node*, RONDD has a third condition:

(C3) No redundant edges: no two edges from the same NDD node point to the same successor, i.e.,

$$\forall u, \forall x, y \in edge(u) : next(x) = next(y) \Rightarrow x = y \qquad (1)$$

Figure 5 shows examples of the three conditions for RONDD. Note that the number of edges for a non-terminal NDD node u can be up to 2^n in the worst case, where n is the number of bits for $var(u)$. But due to the third condition (C3), the actual number is much smaller than that. For example, 99% of NDD nodes in SRE have no more than 10 edges (see Appendix A.6 for details). Similar to ROBDD, RONDD also has the canonicity property, such that RONDD can compactly represent equivalent network state.

Lemma 1. ***Canonicity of NDD.*** *For any boolean function $F(x_1, x_2, \cdots, x_N)$ over N boolean variables with ordering $x_1 < x_2 < \cdots < x_N$, there is exactly only one RONDD u with k NDD variables and ordering $f_1 < f_2 < \cdots < f_k$, where f_i has n_i bits $x_i^1 < x_i^2 < \cdots < x_i^{n_i}$, and $N = \sum_{i=1}^{k} n_i$, such that u can represent F.*

Proof. The proof can be found in Appendix C. □

3.4 Atomized Network Decision Diagram

Atomized Network Decision Diagram is an NDD where the label of each edge is a set of atoms, instead of a BDD.

Definition 2. *Given a set of NDDs $\mathcal{N}$ defined over a set of variables F, we say $\mathcal{A}(f) = \{a_1^f, \ldots, a_k^f\}$ is the **set of atoms** for variable $f \in F$, with respect to $\mathcal{N}$, if it satisfies the following conditions:*

(1) $a_i^f \neq false, \forall i \in \{1, \ldots, k\}$;

(2) $\vee_{i=1}^{k} a_i^f = true$;

(3) $a_i^f \wedge a_j^f = false$, if $i \neq j$;

(4) $\forall e \in edges(u)$, u is a node of $\mathcal{N}$ with $var(u) = f$: there exists a set $atoms(e) \subset \mathcal{A}(f)$, s.t., $label(e) = \bigvee_{a \in atoms(e)} a$;

(5) k is the minimum number satisfy the above properties.

Definition 3. *Given a set of NDDs $\mathcal{N}$, we say $\mathcal{N}^a$ is the **atomized NDDs** of $\mathcal{N}$, if $\mathcal{N}^a = \mathcal{N}$, except that for each edge e of $\mathcal{N}$, $label(e) \leftarrow atoms(e)$.*

4 Design of the NDD Library

Realizing an efficient NDD library to replace the current BDD libraries for network verifiers is a non-trivial task, given that modern BDD libraries apply various optimizations to reduce memory cost and speed up computation. In this paper, we design an NDD library based on existing BDD libraries like JDD, by (1) extending the standard APIs with new functions, e.g., `atomize`, and `update`; (2) adapting the design of logical operations, garbage collection, and node table of BDDs to work for NDDs, (3) re-using some optimizations of BDD, e.g., operation cache, and (4) applying some new NDD-specific optimizations like removing the `false` NDD node.

4.1 The APIs

Table 1 shows the APIs of our NDD library, which is quite similar to those of BDD libraries: The NDD library provides operations similar to BDD, including `createVar`, `apply`, `not` and `exist`, etc., such that existing verifiers can use the same operators when switching from BDD to NDD. One exception is `createVar`, which takes a parameter of *len* to represent the number of bits for the NDD variable. To enable a native support for the computation and update of atoms, the NDD library also provides two additional functions, `atomize` and `update`, using which a verifier can instruct the NDD library to compute and update the atoms, respectively.

`createVar`. This API lets verifiers to declare a variable in NDD, to represent a field in network. When a verifier calls `createVar` with parameter *len*, the NDD library firstly calls the `createVar` function of BDD libraries to create *len* BDD variables, and then creates an NDD variable based on these *len* BDD variables. Then, the NDD library maintains the mapping between the NDD variable and the set of BDD variables, which helps find the related BDD namespace of an NDD node during NDD operations.

`apply`. This API provides a unified logical operation $op \in \{and, or, diff\}$ on two NDDs. In BDD libraries, `apply` is realized in a recursive way. Taking $c = \texttt{apply}(\texttt{op}, a, b)$ for example, where a and b encode the same BDD variable *var*, the function will recursively compute $l = \texttt{apply}(\texttt{op}, low(a), low(b))$, and $h = \texttt{apply}(\texttt{and}, high(a), high(b))$, and returns a BDD node c with $var(c) = var$, $low(c) = l$ and $high(c) = h$.

Table 1: The APIs of NDD library. The first four are similar to BDD libraries, and the last two are introduced by NDD.

Function	Description
`createVar` (Integer *len*)	create an NDD variable with *len* bits
`apply` (*op*, NDD *a*, NDD *b*)	apply a logical operation *op* on two NDDs *a* and *b*, where $op \in \{and,\ or,\ diff\}$
`not` (NDD *a*)	apply a logical negation on an NDD *a*
`exist` (NDD *a*, Field *field*)	apply existential quantification for field *field* on NDD *a*
`atomize` (Set<NDD> *N*)	compute per-field atoms for a set of NDDs *N*, replace BDDs of edges in *N* with a set of atoms
`update` (NDD δ, NDD *a*)	update the set of atoms when a new NDD δ is added; *a* is an atomized NDD satisfying that $\delta \Rightarrow a$

For NDD, things become more complicated since each NDD node may have multiple successors, each with a predicate. We use the example in Figure 6 to illustrate this. Suppose there are 2 fields x and y each with 3 bits, and we want to compute `apply`$(op, \#5, \#6)$. Without loss of generality, we assume `op=and`. Unlike in BDD, where both BDD nodes have the same number of 2 successors, the first NDD #5 has 3 successors while the second NDD #6 has a singleton successor. Therefore, we need to enumerate all pairs of successors (one from #5 and the other from #6). If the two successors have overlapping test conditions, we can recursively call `apply` on these two successors; otherwise, we continue to another pair. For this example, the test condition of the left successor of #5 does not overlap with that of #6, since `bdd_and`$(0**, 10*) = false$. Therefore, we continue to the middle successor of #5, whose test condition overlaps with that of #6. Then, we compute `apply`$(and, \#3, \#2)$, and the result is the NDD node #2, and the test condition for this node is 100, as shown on the left of Figure 6(c). Similarly for the right successor of #5, we have the result shown on the right of Figure 6(c). As we can see, there are two edges both pointing to the NDD node #2, with different conditions 100 and 101. Then, NDD can merge these two edges into a single one, and compute a disjunction of the two conditions as $10*$, resulting in the NDD node #6. Thus, we have `apply`$(and, \#5, \#6) = \#6$.

Theoretically, if two NDD nodes have m and n successors, respectively, we need to enumerate $m \times n$ pairs of successors, and for each pair, we need to compute a conjunction of two BDDs. However, in practice, this number is small. For example, 99% of NDD nodes have less than 10 successors, when we use NDD-based SRE [58] on an 80-nodes fattree networks (Appendix A.6).

`atomize`. This API takes a set of NDDs as input, and computes atoms for each variable, and transforms each of the NDDs into atomized NDDs, where each edge has a set of atoms $atoms(e)$, satisfying $\vee_{a \in atoms(e)} a = label(e)$. We realize this by firstly dividing all the NDD nodes and their successors into groups, one for each NDD variable. After that, for each group, we compute the atoms over all NDD nodes in the group, in a similar way as [51]. Finally, for each edge $e \in edges(u)$ of some NDD node u, we compute $atoms(e)$ as follows: for each atom a of $var(u)$, if $a \Rightarrow label(e)$, we insert a into the atom set $atoms(e)$. For logical operations on two atomized NDDs, we can use set operations over $atoms(e)$ instead of logical operations over $label(e)$.

`update`. This API takes an NDD δ and an atomized NDD a satisfying $\delta \Rightarrow a$ as input, updates per-field atoms and computes the atom set $atoms(e)$ for each edge e of δ and all (direct or indirect) successors of δ. For the NDD node δ, we can compute the conjunctions of BDDs of edges of δ with each atom of field $var(\delta)$. But this is not necessary as $\delta \Rightarrow a$, where a is an atomized NDD: we just need to compute conjunctions with the atoms on paths from a to terminal `true`, since atoms not in a never intersect with BDDs in δ. After that, we recursively apply the `update` for the successors of δ and a. But instead of enumerating all the edges of a for each $e_\delta \in edges(\delta)$, we just need to consider an edge e if any atom in $atoms(e)$ has a non-false conjunction with $label(e_\delta)$. Finally, we need to replace the atoms being split with new atoms on all related edges of atomized NDDs.

Details on the implementations of the above APIs can be found in Appendix B.

4.2 The Internals

Node table, also termed as unique table, is a core data structure used by a BDD library to hold BDD nodes. Since the BDD node table often dominates the memory cost of a BDD library, and most API calls need to manipulate the node table, the efficiency of node table will be the key to the performance of a BDD library. A node table is essentially a hash table with each BDD node is uniquely identified by a tuple $(var, low, high)$. In order to achieve a higher efficiency, instead of using the built-in data structures like `HashMap` in Java, modern BDD libraries like Buddy (C++), JDD (a Java version of Buddy), etc., choose to implement their own node table with a dynamic array, with customized hash algorithms and collision resolution methods.

Different from BDD, where each node has exactly two successors, an NDD node can have a variant number of successors, and thus need a variant size of memory. Due to the non-uniform NDD node size, it is nontrivial to adapt the array-based implementation of BDD node table to NDD. Fortunately, we find that the number of NDD nodes is much smaller compared to that of BDD nodes, and therefore choose a simpler implementation based on hash map, as shown in Figure 7. Specifically, we represent an edge set of a node with a hash map , where the key is the next node of the edge, and the value is the label of the edge. Then, for each NDD variable, we also maintain a hash map, where the key is an edge set,

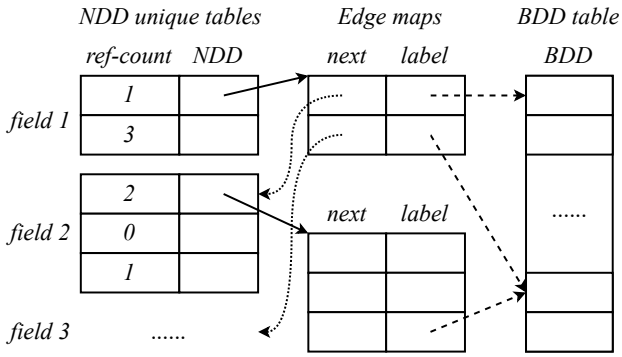

Figure 7: The node table of NDD.

and the value is an NDD node which has such an edge set. This hash map can be seen as a table holding nodes of the same NDD variable. Then, the NDD node table is just a set of these tables, one for each NDD variable. Note that we do not need *var* in the hash key, since each variable has its own sub-table. Also note that the hash function used for the edge set should be associative and commutative; otherwise, two nodes with the same successors and labels, but in a different order may not have the same hash code, and will be treated as different nodes. Our current implementation uses the Java native `HashMap` (JDK 1.8), which satisfies such requirements. Further optimizations may work better but we find the above implementation already achieves a considerable improvement for network verifiers based on BDDs.

As shown in Figure 7, for each NDD node, the library creates a hash map consisting of all its edges. Then, the library stores a tuple of a reference count, and edges of the node, into the NDD node table, which is also a hash map. Note that each field has its own NDD node table, and the BDD nodes for different fields are *logically isolated*: they still share the same BDD node table, but do not interfere with each other.

Redundancy elimination is a function that is necessary for (RO)BDDs to achieve a canonical representation of boolean formulas. Recall that (RO)BDDs use two redundancy eliminations rules *uniqueness* and *no redundant nodes (tests)*. Besides the above two rules, NDDs apply a third rule *no redundant edges*. To apply this rule, the NDD library checks whether two edges of an NDD node point to the same successor; if so, it merges them into a single edge whose condition is the disjunctions of the conditions of the two merged edges. For *uniqueness*, BDD views two nodes as the same if their two edges point to the same successor. NDD, however, requires that not only their edges point to the same set of successors, but also require that for each successor, the test conditions (BDD) are the same. For *no redundant node*, BDD views a node is redundant if both the high and low edges point to the same successor. NDD, however, applies this rule in a slightly different way: since NDD always merges edges pointing to the same successor, an NDD node is viewed as redundant if it has a single edge with condition `true`.

Garbage collection is important for BDD libraries to reduce memory usage. A BDD library maintains a reference count for each node, and marks those nodes with reference count of zero as *dead*. When the size of a node table is reaching a specified threshold, it frees all those dead BDD nodes to make more space for new nodes. Similar to a BDD library, an NDD library also uses reference counts for `gc`. One thing worth mentioning is the dependency of the `gc` processes of the NDD library and the BDD library. Firstly, since an NDD edge uses BDDs to represent the test conditions, when the NDD `gc` frees some NDD nodes and their edges, it should decrease the reference count of BDD nodes used by these edges. Secondly, we should ensure *an NDD `gc` is always be called right before a BDD `gc`*. The reason is as follows. Suppose the BDD `gc` is going to free all dead BDD nodes, some of which are still in use on NDD edges (this can happen when an NDD node is marked as dead but not freed by a `gc`). Those BDD nodes can't be freed without NDD `gc` freeing those edges, and that will affect the performance of BDD library.

Removing the `false` NDD node. In BDD, there are two terminal nodes `true` and `false`, where the `false` node and all edges pointing to it can be removed without affecting the correctness. However, most BDD libraries choose not to do so, since the benefit is marginal. In NDD, however, removing the `false` NDD node can achieve a considerable reduction in memory cost. The reason is that each edge in NDD is associated with a BDD, which represents the test condition of that edge, and by removing edges to `false`, we can save the BDDs on those edges. Moreover, since these BDDs often represent some "default" cases, they tend to be complex and freeing them often brings even larger reduction than other BDDs not on edges to `false`. For atomized NDD, we observe that the edges to the `false` NDD node often hold most of the atoms, and removing the edges allows NDD to maintain much less atoms. On our datasets, 85% edges pointing to `false` take more than 95% atoms of related field, and 30% of the edges each takes more than 2000 atoms (see Appendix A.7 for details). In addition, since the `and` operations do not care about the `false` NDD node (the conjunction of an NDD with it is still `false`), removing edges to the `false` node can reduce the running time by not enumerating these edges.

Operation cache. Similar to BDD libraries, our NDD library also maintains an operation cache, a hash table where the key is the operation, e.g., (`op`, *a*, *b*) and the value is the result of the operation. Our experiment shows an operation cache can significantly speed up NDD operations, thereby making the NDD-based verifiers faster. For example, NDD-based SRE [58] with an operation cache is shown to be over 10× faster than without an operation cache.

4.3 Using NDD

We show how to use the APIs of NDD library to realize the same data plane verification task as using BDD libraries. The bottom of Figure 2 shows the code snippet for data plane

Table 2: Number of modified LOC when replacing BDD with NDD, for different verifiers. Note that the numbers exclude those for trivial string replacement (e.g., "BDD" → "NDD").

Verifiers	AP Verifier	APT	APKeep	SRE	Batfish
Library	JDD	JDD	JDD	JDD	JavaBDD
Add	+25	+84	+66	+205	+8
Delete	-159	-167	-311	-53	-7

verification based on NDD. The logic is mostly the same with that of BDD, with key differences including: (1) NDD creates a single variable with 32 bits, instead of 32 boolean variables (Line 1); (2) NDD uses a single line of `atomize` to automatically compute atoms, after which the predicate of each port becomes an atomized NDD (Line 3); (3) When computing reachability based on atomized NDDs, verifiers use the same `and` operation as the standard (non-atomized) NDD, and therefore fully agnostic of atoms (Line 8). Details about this case, and two more use cases for incremental data plane verification and data plane verification with transformers can be found in Appendix F.

5 Implementation

The NDD Library. We implemented a library of NDD with ∼2K lines of Java code, based on JDD [8], a BDD library used by many verifiers like AP Verifier [51], APT [53], APKeep [57], SRE [58], etc. In addition, we integrated the NDD library as a new factory in JavaBDD, with another ∼100 lines of code, so that verifiers using JavaBDD, e.g., Batfish [4], Campion [47], can switch to use NDD instead.

Network verifiers based on NDD. We use the NDD library to replace the BDD library in 3 data plane verifiers, and 2 control plane verifiers. Table 2 shows the number of modified LOC for each verifier. As we can see, the number of added LOC is small since the NDD exposes similar APIs as BDD, and existing verifiers can directly use them without modifications. On the other hand, the number of deleted LOC is slightly larger. The reason is that NDD natively supports the computation of atoms, and therefore we remove the corresponding codes in those verifiers. An exception is SRE, which uses customized algorithms to traverse BDDs, and we need to adapt those algorithms to NDDs, with more modified LOC. Therefore, we conclude that the NDD library offers a drop-in replacement for BDD-based verifiers, with a small modifications to their original code base. More details can be found in Appendix A.1.

6 Evaluation

We evaluate the performance of NDD in terms of running time and memory cost, and compare to that of using BDD.

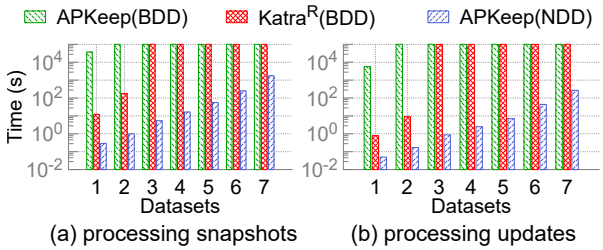

Figure 8: Running time in datacenter networks.

6.1 Setup

Datasets. We use three types of datasets for experiments.

(1) Virtualized datacenter networks (multi-layer networks). We use the virtualized datacenter network datasets (based on VXLAN) to evaluate the performance of NDD on packet transformers. The datasets are synthesized according to production networks [36,55], consisting of 7 different sizes (from 6 to 500 leaf routers), and for each size there are 5 types of updates, e.g., adding a subnet or virtual network. Details can be found in both [36] and Appendix A.2.

(2) WAN and campus networks (single-layer networks). We use three real networks that are extensively used by data plane verifiers [30,33,51,53,57], i.e., the Stanford network [5] of 16 nodes, the Internet2 network [6] of 9 nodes, and the Purdue network [46] of 1646 nodes. The Internet2 has only forwarding rules, while the other two have both forwarding and ACL rules. Details can be found in Appendix A.2.

(3) Fat trees. To evaluate the performance of our NDD libraries for control plane verification, we use different sizes (from 20 to 500 nodes) of fat trees running BGP. The datasets are synthesized and used by SRE [58].

BDD variable ordering. When comparing with data plane verifiers, we use the ordering of `srcIP < dstIP < srcPort < dstPort < protocol` for single-layer networks, and `innerDstIP < srcIP < vni < srcEPG < dstEPG < outerDstIP` for multi-layer networks. When comparing with SRE, we follow the same ordering as SRE, i.e., placing header variables before link variables, and the header variables follow the above ordering as the single-layer networks. For Batfish, we use its default ordering of `dstIP < srcIP < dstPort < srcPort < protocol < flags`.

All experiments run on a server with 2× 12-core Intel Xeon CPUs @ 2.3GHz and 256G RAM (a single core is used).

6.2 Data plane verification: running time

We run the two data plane verifiers, i.e., APKeep and Katra^R, to check all-pair reachability on the multi-layer (virtualized datacenter) networks and the single-layer networks, and compare the running time when using BDD and NDD.

Multi-layer networks (snapshot). Figure 8(a) shows the total time of computing atoms and checking reachability on all snapshots of the virtualized datacenter networks. APKeep(NDD) is the only verifier that runs to complete on

Table 3: Performance in virtualized datacenter networks. Columns 2-4 show memory overhead, columns 5-7 show BDD nodes used for representing atoms, columns 8-10 show the number of atoms and columns 11-13 show the number of new atoms introduced by updates. TO means timeout ($> 24h$).

# Leaf nodes	Memory overhead(GB)			BDD nodes			Atoms			New atoms		
	APKeep (BDD)	Katra^R (BDD)	**APKeep (NDD)**	APKeep (BDD)	Katra^R (BDD)	**APKeep (NDD)**	APKeep (BDD)	Katra^R (BDD)	**APKeep (NDD)**	APKeep (BDD)	Katra^R (BDD)	**APKeep (NDD)**
6	4.36	0.17	**0.01**	1354365	114536	**2195**	28077	5467	**112**	8043	1309	**7**
10	>20	2.88	**0.01**	TO	513069	**3716**	TO	25542	**195**	TO	4062	**10**
20	>32	>115	**0.05**	TO	TO	**8659**	TO	TO	**483**	TO	TO	**14**
50	>80	>115	**0.16**	TO	TO	**19775**	TO	TO	**1173**	TO	TO	**14**

500	>180	>115	**7.19**	TO	TO	**161603**	TO	TO	**11544**	TO	TO	**15**

all snapshots, while the other two BDD-based verifiers either time out (>24h), or run out of memory (>256GB). For snapshots that all verifiers finish, APKeep(NDD) is much faster than the other two: for dataset 1 with 6 leaf nodes, APKeep(NDD) runs $>10\times$ and $10^5\times$ faster than Katra^R(BDD) and APKeep(BDD), respectively.

Multi-layer networks (update). Figure 8(b) shows the average time to incrementally check properties after the 5 types of update. Since incrementally checking the updates relies on finishing the check of snapshots, we set the running time of the two BDD-based verifiers to maximum for snapshots that they can not finish. Still, APKeep(NDD) is orders-of-magnitude faster than two BDD-based verifiers.

Single-layer networks (snapshot). Figure 9 shows the running time for the three single-layer networks. We do not include the results for Katra^R, since it has no performance improvement over APKeep on these single-layer networks. We can see that for Stanford and Internet2, the running times of BDD and NDD are comparable, while for Purdue, using NDD is $3\times$ faster than using BDD. The reason for the limited speedup is that these networks mostly match a single field, i.e., dstIP (even Stanford and Purdue have ACL rules that match 5-tuples, the number of ACL rules is quite small). This makes the benefits of decoupling fields less significant than in multi-layer networks.

Single-layer networks (update). To simulate updates on single-layer networks, we choose the Purdue dataset, which has relatively more ACL rules such that the result are more statistically significant. For each ACL rule r, we initially insert all ACL rules other than r, and then insert r and measure the time to update the network model. As shown in Figure 10, the running time for APKeep(BDD) is highly skewed: most updates cost less than 50ms, while 1% of them cost 300ms to 2000ms. In contrast, when using NDD, the update time is always below 150ms. A possible reason is that NDD creates much less atoms after each update: for 7 out of 2707 updates, APKeep(BDD) creates >3000 new atoms (some of them will be merged later), while APKeep(NDD) just creates at most 24 new atoms after each update (see Appendix A.4 for details).

6.3 Data plane verification: memory cost

Table 3 shows the memory usage of different verifiers, computed as the difference of JVM memory usage before and after verification. As shown in Table 3 columns 2-4, the memory usage of APKeep(NDD) is orders-of-magnitude smaller than its BDD counterpart, and also Katra^R(BDD). Specifically, for the network of 6 leaf nodes, the memory cost of APKeep(NDD) is less than $1/100$ and $1/10$ that of APKeep(BDD) and Katra^R(BDD), respectively. The reason that APKeep(BDD) requires 4.36GB memory here is that the network matches 6 fields, leading to an explosion of atoms (28077 atoms creates over 10^6 BDD nodes). As shown in Columns 5-7, the number of BDD nodes of the two BDD-based verifiers is quite large, quickly blowing up the BDD node table (a maximum of $O(2^{32}/3)$ nodes as in JDD), while the number of BDD nodes for APKeep(NDD) is relatively small. This shows the power of NDD in reducing the number of BDD nodes. As for single layer-networks, using NDD reduces the memory cost of APKeep by half on the Purdue dataset, and has comparable memory cost on the Stanford and Internet2 datasets, compared to using BDD.

A major factor for the memory cost is the number of atoms. We continue to study the the number of atoms using NDD and BDD, respectively. Columns 8-10 reports the number of atoms, where the number for APKeep(NDD) is the sum of atoms for each field. As we can see, the number of atoms for APKeep(NDD) increases almost linearly with network size, and is orders-of-magnitude smaller than those of the other two BDD-based verifiers. Columns 11-13 further shows the number of newly created atoms after each update. We can see that BDD-based verifiers may create thousands of atoms after updates, while APKeep(NDD) always creates a rather small number ($\leq$15) of atoms after each update. The above results show NDD allow verifier scale better to large networks without explosion of atoms.

6.4 Handling packet transformer

To understand how NDD supports packet transformers, we synthesize a set of NAT rules for the Purdue dataset. We

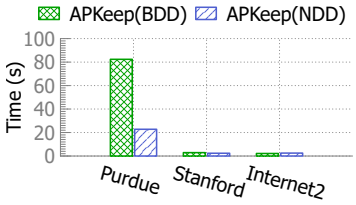

Figure 9: Running time of APKeep on single-layer networks.

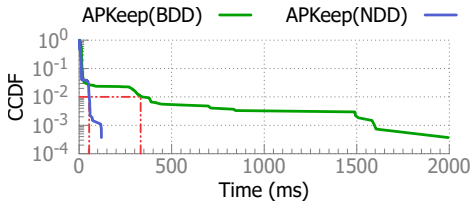

Figure 10: The complement CDF of time for APKeep to update one ACL rule on Purdue dataset.

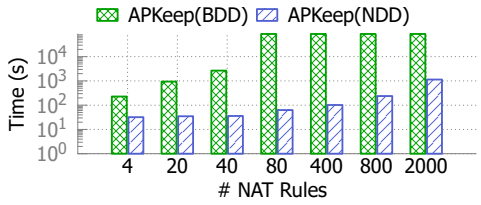

Figure 11: Running time of APKeep on Purdue dataset with NAT rules.

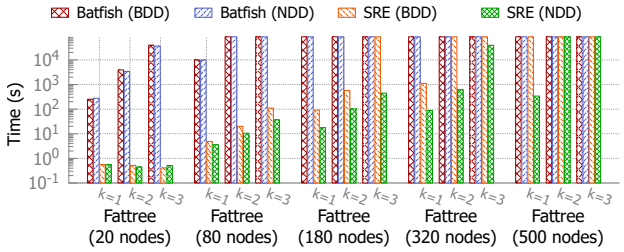

Figure 12: Running time of Batfish and SRE on fattrees.

randomly select k ports not connected to any other, and for each of them add two NAT rules matching srcIP or dstIP , one for each direction. Then, we randomly select another k ports and for each of them add two twice NAT rules (matching srcIP and dstIP simultaneously), one for each direction.

Figure 11 shows the running time of APKeep when using BDD and NDD, respectively. We can see that APKeep(NDD) is 10× faster than APKeep(BDD) even when there are only 4 NAT rules; and 100× faster when 40 NAT rules are inserted. APKeep(BDD) runs out of memory after inserting 80 NAT rules, while APKeep(NDD) runs to complete up to 2000 NAT rules. The reason that NDD can handle packet transformers more efficiently than BDD is NDD computes atoms separately for srcIP and dstIP, leading to much fewer atoms.

6.5 Control plane verification

We run two control plane verifiers, i.e., Batfish and SRE, using both NDD and BDD, to check all-pair reachability on fat tree topologies under $k = 1, 2, 3$ link failures. For Batfish(NDD), we create 4 NDD variables for the 32-bit IP address, each of which has 8 bits. For SRE(NDD), we create 8 NDD variables, each with the same number of bits representing the up/down state of links. An exception is the 500-node fattree, for which we create 16 NDD variables.

As shown in Figure 12, SRE has a better scalability by replacing BDD with NDD: for $k = 1$ failure on the 500-node fattree, SRE(BDD) aborts due to BDD table overflow, while SRE(NDD) can run to complete. We confirm the improved scalability is owing to the reduction of BDD nodes (Appendix A.5). For Batfish, however, the improvement of scalability is limited by using NDD. This is because the datasets only use a single field, i.e., dstIP, and Batfish doesn't have link variables as SRE. While we still find the number of BDD nodes in Batfish is reduced by using NDD (Appendix A.5). The reason is the synthesized IPs in this dataset share the same 16-bit prefix, i.e., 10.0.∗.∗. Using BDD, all packet sets need a copy of BDD nodes for those 16 bits (these nodes can not be shared by the packet sets since they differ in the last 16 bits).

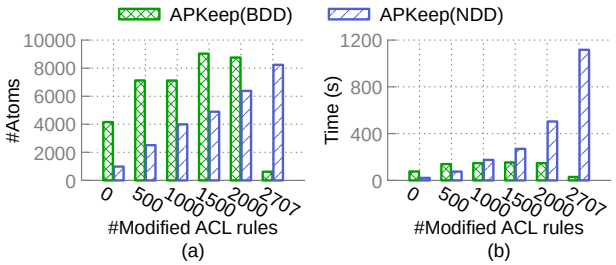

Figure 13: NDD vs. BDD on modified Purdue dataset, with different number of ACL rules matching all the 5 fields.

6.6 The importance of field locality

To study the importance of field locality for the effectiveness of NDD, we modified ACL rules in the Purdue dataset, so that more rules will match all the five fields (against randomly generated values). As shown in Figure 13, both the number of atoms and the running time of APKeep(NDD) grow linearly with the number of modified rules. In contrast, the number and time of APKeep(BDD) significantly decrease when all ACL rules match all fields. The reason is that when all rules match all fields, the phenomenon of field locality disappears, so the number of atoms when using BDD is not so large. This implies that the performance gain of NDD relies on the assumption of field locality, which generally hold in networks, but can theoretically fail (as in this synthesized scenario).

7 Related Work

Besides the classic BDD, researchers have proposed many variants of Decision Diagrams.

Decision diagrams with multiple terminals. Multi Terminal BDD (MTBDD) [12, 22], also termed Algebraic Decision Diagram (ADD), is a variant of BDD but with more than two terminals. MTBDD can model multiple outcomes (rather than true/false) of decisions, and have been used by some network

verifiers [16, 28, 35]. However, since MTBDDs still branch at a single bit, they acknowledge the same limitations of BDD when applied to network verification.

Decision diagrams branching on constraints. Forwarding Decision Diagram (FDD^b) [42, 43] is proposed to compile NetKat programs (a set of `IF-THEN-ELSE` clauses). Each FDD^b node has two edges representing whether a packet satisfies a *specific* constraint, e.g., $dstIP = 10.0.0.1$, or not. When using it for network verification, we may need many levels of nodes for each field, e.g., another level for $dstIP \in 192.168.0.0/16$. Constrained Decision Diagram (CDD) [21] is proposed to represent all solutions to a constraint satisfaction problem (CSP). Different from FDD^b, a CDD node can have multiple edges, each representing a SMT constraint, e.g., $x_1 < x_2 + 4$. In this sense, CDD represents a set of SMT constraints in the form of a decision diagram, but without solving them. To obtain a truth assignment, CDD still needs to try all possible values for variables in the constraints of each node (`cddFindall` algorithm [21]). This can be inefficient when the domain of the variable is large, e.g., if we encode `dstIP` with single variable, CDD needs to try 2^{32} values for each edge labeled by a constraint on the variable of `dstIP`.

Decision diagrams branching on a field. Multi-valued Decision Diagram (MDD) is a diagram that branches on multiple bits each time [44]. However, MDD has an edge for each single value of these bit. This which makes MDD not scalable for network verification, since a field often has many bits (e.g., a 32-bit IPv4 address requires 2^{32} edges). Similarly, Interval Decision Diagram (IDD) [45] and Firewall Decision Diagram (FDD^a) [29] branch based on one or multiple ranges of a field. However, network verifiers often need to reason about arbitrary sets of packets, which lead to a huge number of disjoint ranges, and using IDD or FDD^a is not scalable. NDD differs from the above DDs by using BDDs for a relatively small number of edges for each field.

Other implementations of BDD. Apart from JDD and JavaBDD, there are other excellent implementations of BDD. For example, Sylvan [49] is a BDD implementation which supports parallelism in both operation and algorithm level. Decision Diagram [1] is a native .NET implementation of BDD with better performance than many other BDD libraries. It is used by ZEN [17], a general and compositional framework for network modeling. However, the above implementations still suffer the memory/computation inefficiency when applied to network verification, as discussed in this paper.

Other data structures. Early verifiers like Veriflow [34] and HSA [33] use Trie and ternary bit vectors (TBV), respectively, to represent packet sets. However, such data structures cannot compactly encode arbitrary disjoint ranges. BDD-based verifiers like AP Verifier [52] and APKeep [57] have been shown to be orders of magnitude faster than HSA (based on TBV) and Veriflow (based on Trie). More recently, researchers proposed ddNF [18] and #PEC [31], which uses disjunction normal form to represent packet sets. All these data structures may perform well in some specific settings, but are still unable to supersede BDDs in general scenarios.

In sum, existing data structures are either not compact or inefficient for multiple fields: BDD is compact but the bit-level encoding makes it inefficient for multiple fields; other structures like Trie, CDD, MDD, etc. are more efficient for multiple fields by encoding at field level, but they encode each field with integers, ranges, constraints, etc., are thus not compact. In addition, when applied to network verification, all these data structures require verifiers to implement their own computation of ECs over the whole network state, resulting in a large number of ECs.

Theoretically, NDD can be seen as a special form of symbolic automata [23], where the transitions among nodes are boolean formulas. This paper is not fundamentally contributing to such theory, but provides a new design of design diagram library customized for network verification tasks.

8 Discussion

Extending NDD with multiple terminals. Besides the standard BDD, the Multi-Terminal BDD (MTBDD) [12, 22] has also been used by some network verifiers, e.g., ShapeShifter [16], YU [35], ProbNV [28], etc. For example, YU uses MTBDD to model the different (multiple) traffic volumes on a link, under different failures, so as to verify whether the link will be overloaded under some failures. We tentatively think NDD can be extended to support multiple terminals, such that it can apply to a broader range of network verifiers.

How to partition fields? For network verification, partitioning the packet header into to multiple fields, and encoding each field with an NDD variable achieves good performance. For more general scenarios where fields may not be quite clear (links as in SRE), we leverage some heuristics: (1) variables encoding a complete semantics together should be partitioned into the same field, (2) variables appearing in the same operand of BDD operations should be partitioned into the same field.

9 Conclusion

This paper introduced Network Decision Diagram, a new decision diagram customized for network verification. We designed and implemented a library for NDD, and show it can significantly reduce the memory and time for five BDD-based network verifiers. Our future work includes extending NDD with multiple terminals, making NDD library distributed and parallel, and testing the NDD library with more verifiers.

A More Evaluation Results

A.1 Implementation Details

In the following, we give more details on the implementations of the 5 verifiers with the NDD library.

AP Verifier [51] and APT [53]. AP Verifier is a pioneering work that pre-compute atomic predicates based on BDD, and APT extends AP Verifier to support packet transformers. We used their open-source codes [2], and modified them to use the NDD library. The modifications are to remove their implementations of computing atomic predicates, and re-implement it with the `atomize` API of NDD.

APKeep [57]. APKeep is a data plane verifier that extends AP Verifier to incrementally update atomic predicates, also based on BDD. We used its source codes [3], and modified it to use the NDD library. The modifications are to remove its previous implementation of incremental update of atomic predicates, and re-implement it with the `update` API of NDD.

Katra [13]. Katra is a data plane verifier proposed for multi-layer networks. Katra introduces a novel *partial equivalence classes* to significantly reduce the total number of ECs, and is proven to be more efficient than APKeep when verifying multi-layer networks. We are interested in whether we can achieve the same or even better efficiency as Katra, by simply changing the underlying data structure, without computing partial equivalence classes. Therefore, we re-implemented Katra based on BDD, referred to as Katra^R, and further extended it to support VXLAN overlay networks in Table 5. We confirmed the correctness of Katra^R based on the datasets synthesized according to [13]. However, we did not implement the NDD version of Katra since the core difference of Katra from APKeep is its novel *partial equivalence classes* based on BDD, and replacing BDD with NDD will make Katra no different from APKeep (NDD).

SRE [58]. SRE is a control plane verifier that jointly encodes failure scenarios and packet headers, so as to scale to large networks. We used the authors' implementation and replaced its JDD library with our NDD library. For packet headers, we encode each header field with an NDD variable; for failure scenarios, we divide the set of all links evenly into 8 groups, and encode each link group with an NDD variable.

Batfish [19, 25]. Batfish is an open-source control plane verifier, which uses JavaBDD [7]. We replaced the BDD factory in JavaBDD with our NDD factory, with small modifications of Batfish, including declaring fields and initializing the unique table and operation cache.

A.2 Statistics of datasets

Table 4 and Table 5 show the experimental datasets.

Table 4: Datasets for WAN and campus networks.

Networks	Nodes	Links	Forwarding rules	ACL rules
Purdue	2,159	3,607	3.52×10^6	2707
Stanford	124	182	3.84×10^3	686
Internet2	9	56	1.26×10^5	0

Table 5: Datasets for virtualized datacenter networks.

Networks	Leafs (VPCs)	Subnets (VRFs)	Forwarding rules	MCS rules	Static routes
1	6	36	856	12	12
2	10	100	2,508	20	20
3	20	400	13,428	40	40
4	50	1,000	59,808	100	100
5	100	2,000	144,508	200	200
6	200	4,000	388,908	400	400
7	500	10,000	1,528,538	1,000	1000

A.3 Micro-benchmark results

Table 6: Running time of each stage and the number of atoms for forwarding and ACL rules on Purdue dataset.

Verifiers	IPv4		ACL		Property
	Time(s)	Atoms	Time(s)	Atoms	Check(s)
APKeep(BDD)	13.88	265	22.37	3893	46.11
APKeep(NDD)	14.87	265	7.04	411	0.88

The per-stage running time for Purdue is shown in Table 6. NDD uses more time than BDD when processing forwarding rules (Column 2), due to the overhead of maintaining per-field atoms; while NDD uses roughly $1/3$ the time of BDD when processing ACL rules (Column 4), since the ACL rules match 5-tuples. For checking properties, NDD takes much less time than BDD (Column 6). This is because using BDD will result in much more atoms than using NDD, as shown in column 5: by using NDD, APKeep can reduce the number of atoms by around 89.4%.

A.4 Number of new atoms after each update

Figure 14 shows the complement cumulative distribution of the number of new atoms for each update in Purdue dataset.

A.5 Number of BDD nodes for Control Plane Simulation

Figure 15 shows the number of used BDD nodes for SRE and Batfish on the fattree datasets. The number of BDD nodes of Batfish(BDD) is many times more than that of Batfish(NDD), and the number of BDD nodes of SRE(BDD) is more than that of SRE(NDD) by orders of magnitude, which shows memory inefficiency of BDD.

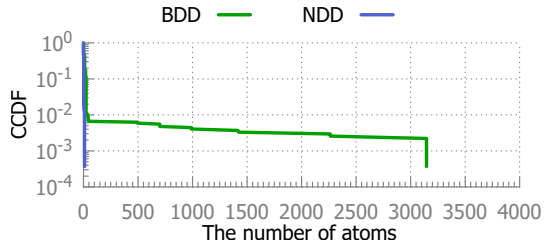

Figure 14: The complement cumulative distribution of the number of new atoms for each update in Purdue dataset.

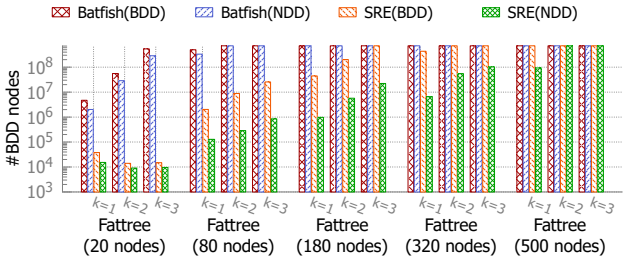

Figure 15: The number of used BDD nodes for control plane simulation on fattree networks.

A.6 Number of edges in NDD

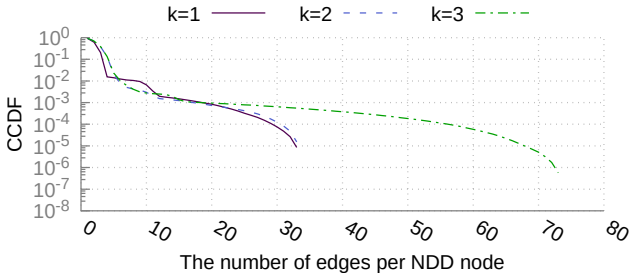

Figure 16: The complement cumulative distribution of the number of edges for each NDD node.

Figure 16 shows the number of edges for each NDD node created by SRE(NDD) on the 80-nodes fattree network. More than 99% of the nodes have no more than 10 edges, and all the nodes have no more than 75 edges, which shows that NDD can efficiently merge redundant edges with a high compression ratio.

A.7 Number of atoms on edges to `false`

Figure 17 (a) shows the number of atoms that are labeled on each edge pointing to the terminal node `false`. We can see that almost 30% of these edges have more than 2000 atoms. Figure 17 (b) shows the percentage of atoms on edges pointing to the `false` node to the total number of atoms of the corresponding field. We can see that for 85% of these edges have more than 95% of atoms of the corresponding field.

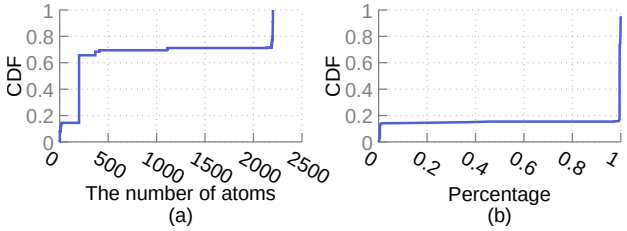

Figure 17: (a) the number and (b) the percentage of atoms on edges pointing to `false`.

Table 7: Time to solve the NQueens problem.

N	6	7	8	9	10	11	12
BDD (s)	0.017	0.023	0.04	0.223	0.615	2.567	19.109
NDD (s)	0.012	0.019	0.038	0.176	0.344	2.257	12.417

A.8 Performance of NDD for general problems

We compare the performance of BDD and NDD in solving the NQueens problem, a widely recognized benchmark for BDD libraries. For BDD, we use the implementation of the JDD library, which is basically an implementation of algorithms in [11]. For NDD, we declare each row as a field (therefore there are N fields), and implement the same algorithm. Table 7 shows that the time of BDD is around 1.5× that of NDD for $N = 12$. This is because the BDD library has an considerable overhead for aligning variables when computing BDD conjunctions, especially for large N. This indicates the phenomenon of "field locality" may not be limited to network verification, and NDD may be used to speedup other applications.

A.9 BDD variable orderings

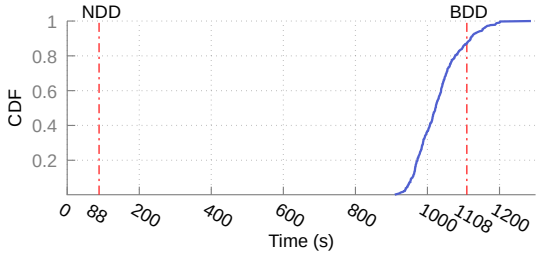

Figure 18: Running time of SRE on fattree (320 nodes, $k = 1$) with random variable orderings. The two dotted lines represent the running time of SRE(BDD) and SRE(NDD) reported in Figure 12, respectively.

As briefly mentioned in §2.2, one may wonder whether we can mitigate limitations of BDD with a better variable ordering. We discuss this for two different types of verifiers.

First, for verifiers that compute atoms, e.g., AP Verifier, APT and APKeep, the performance is highly related to the number of atoms, while little affected by the variable ordering. Therefore, variable ordering makes little differences to their

performance when suffering explosion of atoms.

Second, for verifiers that do not compute atoms, e.g., SRE, variable ordering indeed impact the performance. Here, we use SRE(BDD) as an example to study such impact. We found an ordering with header variables (`dstIP`) before link variables, which was used by SRE, always leads to better performance. Therefore, when we run SRE(BDD), we first declare the variables of `dstIP`, and then declare the link variables with random order. Figure 18 reports the running time, where we can see the time varies from 800s to 1200s with different orderings, but is still much larger than that of SRE(NDD). This confirms that re-ordering the variables does not fundamentally make BDD more efficient for network verification.

A.10 Comparing NDD to BDD arrays

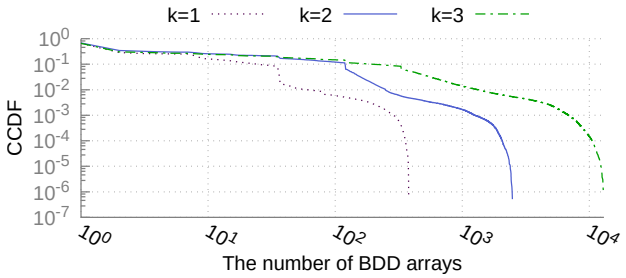

Figure 19: The complement cumulative distribution of the number of BDD arrays to represent a predicate in SRE.

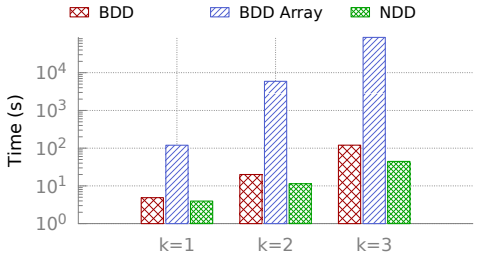

Figure 20: Running time on 80-node fattree of verifiers based on three methods.

We implement SRE based on BDD arrays, which simply assembles per-field BDDs by conjunctions, and compare its performance to that based on NDD and BDD, on a 80-node fattree. Figure 19 shows the number of BDD arrays representing each predicate, which is as large as $10^2, 10^3, 10^4$ for $k = 1, 2, 3$, respectively. Figure 20 further shows the running time. We can see that using BDD arrays is orders-of-magnitude slower than using NDDs, and even slower than directly using BDDs. Especially when $k = 3$, using BDD arrays times out due to too many BDD arrays.

B Algorithms of NDD operations

Algorithm 1 shows the implementation of `apply`(op, a, b), where `op` can be `and`, `or`, `diff`; a and b are two NDDs. For trivial cases such as either a or b is a terminal node, or $a = b$, the algorithm directly returns the result (Lines 1-2). If the variable of a and b is the same (Line 3), the algorithm recursively performs `apply` for each successor of a and each successor of b (Lines 4-5). Note that, the algorithm merges redundant edges in Line 9. If the variable of a has a higher order, the algorithm recursively performs `apply` for b and each successor of a (Lines 10-15). Finally, it looks for an NDD node (or create a new node) from node table representing the result and returns it (Line 16). The algorithm for atomized NDDs is the same with the above, except that BDD operations of *and* and *or* in Line 6, 9 and 15 change to set operations of *intersect* and *union*. Note that, when we enable the optimization of removing the `false` node (§4.2), the implementations of `or` and `diff` need some minor modifications.

Algorithm 1: `apply`$(op,\ a,\ b)$

Input: a logical operator $op \in \{and, or, diff\}$, and two NDDs a and b.
Output: the result of logical operation $a\ op\ b$.

```
1  if a or b is a terminal node, or a = b then
2      return handleTrivialCases(op, a, b);
3  if var(a) = var(b) then
4      foreach e_a ∈ edges(a) do
5          foreach e_b ∈ edges(b) do
6              label ← bdd.and(label(e_a), label(e_b));
7              if label ≠ bdd.false then
8                  next ← apply(op, next(e_a), next(e_b));
9                  edgeMap[next] ←
                     bdd.or(edgeMap[next], label);
10 else
11     if var(a) > var(b) then
12         swap(a, b);
13     foreach e_a ∈ edges(a) do
14         next ← apply(op, next(e_a), b);
15         edgeMap[next] ← bdd.or(edgeMap[next],
             label(e_a));
16 return mk(var(a), edgeMap);
```

Algorithm 2 shows the implementation of `exist`. If the field variable of a has lower priority than $field$, the algorithm directly returns a as the result (Lines 1-2). If the field variable of a is equal to $field$, the algorithm applies existential quantification by merging all successors of a through NDD's function of `or` (Lines 3-7). If the field variable of a has higher priority than $field$, the algorithm invokes a new recursion for each successor of a and merges results (Lines 8-12).

Algorithm 3 shows the implementation of `atomize`. It takes

Algorithm 2: `exist`(a, $field$)

Input: an NDD a and a variable $field$.
Output: an NDD with existential quantification on a for variable $field$.

```
1  if var(a) > field then
2      return a;
3  else if var(a) = field then
4      sum ← ndd.false;
5      foreach e ∈ edges(a) do
6          sum ← apply(or, sum, next(e));
7      return sum;
8  else
9      foreach e ∈ edges(a) do
10         next ← exist(next(e), field);
11         edgeMap[next] ← bdd.or(edgeMap[next],
               label(e));
12     return mk(var(a), edgeMap);
```

Algorithm 3: `atomize`(N)

Input: a set of NDDs N.
Output: a set of atomized NDDs N' that are logically equivalent to N.

```
1  labels ← allLabels(N);
2  foreach field ∈ allFields(N) do
3      atoms[field] ← computeAtoms(labels[field]);
4  N' ← {};
5  foreach n ∈ N do
6      N' ← N' ∪ atomizeNDD(n, atoms);
7  return N';
```

a set of NDDs N to be atomized as input and returns a set of atomized NDDs N', which are logically equivalent to N. The algorithm first collects all labels (BDDs) used by some of the input NDDs, and group these labels by field (Line 1). Then, the algorithm computes atoms for each field (Lines 2-3), in a similar way as AP Verifier does. After that, it transforms the each input NDD into a logically-equivalent atomized NDD (Lines 4-6).

Algorithm 4 shows the implementation of `update`. It takes as input an NDD δ and an atomized NDD a, δ is a predicate to be atomized and a is used to accelerate the function. *split* in Line 2 is a map that maps each old atom to be split to 2 new atoms. The algorithm first recursively traverses δ and a, and detects the atoms to be split (Line 3), then performs the split by replacing each old atom in labels of existing atomized NDDs with 2 new atoms in *split* (Line 4). Since an atom may be split many times by different label BDDs in δ, the function repeatedly performs steps above until *split* is empty after Line 3. If the δ and a have the same variable, for each edge e_δ of δ and each edge e_a of a, the function intersects the BDD on e_δ with only atoms held by e_a to detect atoms to be split (Lines

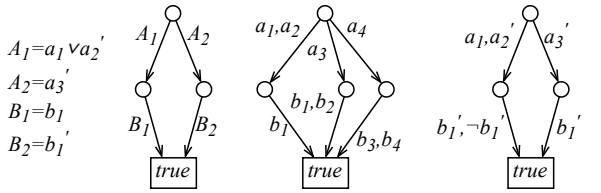
Algorithm 4: `update`(δ, a)

Input: an NDD δ to be atomized; an atomized NDD a satisfying $\delta \Rightarrow a$.

```
1  do
2      split ← {} ;
3      updateRec(δ, a, split);
4      splitAtoms(split);
5  while ¬split.isEmpty();
6  Function updateRec(δ, a, split):
7      if δ = ndd.true then
8          return;
9      else if var(δ) = var(a) then
10         foreach e_δ ∈ edges(δ) do
11             foreach e_a ∈ edges(a) do
12                 hit ← false;
13                 foreach ap ∈ label(e_a) do
14                     t ← bdd.and(ap, label(e_δ));
15                     if t ≠ bdd.false then
16                         hit ← true;
17                         if t ≠ ap then
18                             split[ap] ←
                                   {t, bdd.diff(ap, t)};
19                 if hit then
20                     updateRec(next(e_δ), next(e_a), split);
21     else if var(δ) < var(a) then
22         foreach e ∈ edges(δ) do
23             foreach ap ∈ atoms[var(δ)] do
24                 t ← bdd.and(ap, label(e));
25                 if t ≠ false and t ≠ ap then
26                     split[ap] ← {t, bdd.diff(ap, t)};
27             updateRec(next(e), a, split);
```

9-20). Note that, it only traverses successors of edges whose atoms intersect with the label (Lines 19-20). If the variable of δ has higher priority than that of a, the algorithm intersects the labels with each atom of $var(\delta)$ (Lines 21-27).

Figure 21 shows an example for `update`, where (b) is an NDD δ to be atomized, and (c) is an atomized NDD a. Labels on δ are per-field BDDs and labels on a are per-field atoms. Relations of per-field BDDs and atoms are shown in (a), where $A_1 = a_1 \vee a_2'$ means A_1 contains (is implied by) a_1 and partially intersects (has a non-false conjunction) with a_2. The operation first chooses the left edge of δ and a, computes conjunctions of A_1 with a_1 and a_2, respectively, and splits a_2 into new atoms a_2' and $\neg a_2'$, such that A_1 can be atomized. Then, the operation tries to match the edges labeled by B_1 and b_1 in the second field. After that, the operation tries to match the left edge of δ and the middle and right edges of a, respectively, finds that A_1 doesn't intersect with a_3 or a_4, and skips calculation in the second field. As shown above, A_1



(a) Assumptions (b) NDD δ (c) atomized NDD a (d) atomized NDD δ

Figure 21: An example for `update` operation. A_i and B_i are BDDs; a_i and b_i are atoms. $a_i^{'}$ means it implies a_i, i.e., $a_i^{'} \Rightarrow a_i$.

only needs to intersect with atoms a_{1-4} which appear on the paths from a to terminal `true`, rather than all atoms of the field (e.g., atoms on the edge of a pointing to terminal `false`, which are not shown in the figure), thereby accelerating the operation. The steps are similar for the right edge of δ. Finally, atoms a_2, a_3 and b_1 are split, such that δ can be atomized as shown in (d).

C Proof of canonicity of NDD

Definition 4. ***Boolean formulas.*** *A boolean formula F has $n_1+n_2+\cdots+n_k$ boolean variables, which can be grouped into k fields $f_1, f_2, \ldots, f_k$, where field f_i has n_i consecutive boolean variables $x_{s_i+1}, x_{s_i+2}, \ldots, x_{s_i+n_i}$, where $s_i = n_1+n_2+\cdots+n_{i-1}$.*

Definition 5. ***Truth assignments and restrictions.*** *A truth assignment of a field f_i is denoted as $B_i = [b_{s_i+1}, b_{s_i+2}, \ldots, b_{s_i+n_i}]$, where $b_j \in \{true, false\}$. A restriction of F with respect to a variable x and a boolean constant b, denoted as $F[b/x]$, is defined as the same formula F, except that the variable x is replaced with b. Similarly, we can extend the definition to a field f_i and a truth assignment B_i, as*

$$F[B_i/f_i] = F[b_{s_i+1}/x_{s_i+1}, b_{s_i+2}/x_{s_i+2}, \ldots, b_{s_i+n_i}/x_{s_i+n_i}]$$

Suppose bdd is a BDD defined over f_i, and $\forall B_i \in bdd$, $F[B_i/f_i]$ is the same, then define the restriction of F with respect to field f_i and BDD bdd as $F_{bdd} = F[B_i/f_i], \forall B_i \in bdd$.

Shannon expansion is the theoretical basis of BDD: a BDD node encoding F branches on x, with a *high* edge assigning `true` to x and pointing to the successor encoding $F[1/x]$, and a *low* edge assigning `false` to x and pointing to the successor encoding $F[0/x]$.

Definition 6. ***Single-bit Shannon expansion.*** *First define the if-then-else operator as $x \rightarrow y_0, y_1 = (x \wedge y_0) \vee (\neg x \wedge y_1)$. Then, the Shannon expansion of formula F with respect to a boolean variable x is defined as:*

$$F = x \rightarrow F[1/x], F[0/x].$$

Since each NDD variable (i.e., field) has multiple bits, we extend the above single-bit Shannon expansion to the following multi-bit Shannon expansion.

Definition 7. ***Multi-bit Shannon expansion.*** *Let $\mathcal{BDD}$ be a set of BDDs satisfying $\bigvee_{bdd \in \mathcal{BDD}} bdd = true$, and $\forall bdd_1, bdd_2 \in \mathcal{BDD}$, $bdd_1 \neq bdd_2 \Rightarrow bdd_1 \wedge bdd_2 = false$. Then, the Shannon expansion on formula F with respect to field f_i is:*

$$F = \bigvee_{bdd \in \mathcal{BDD}} (bdd \wedge F_{bdd}) = f \rightarrow F_{bdd_1}, F_{bdd_2}, ..., F_{bdd_n}.$$

Definition 8. ***The formula encoded by an NDD.*** *Suppose u is an NDD node having a set of edges $e_1, e_2, \ldots, e_n$, Then, u encodes a boolean formula F^u defined as:*

$$F^u = var(u) \rightarrow F_{label(e_1)}, F_{label(e_2)}, ..., F_{label(e_n)}. \quad (2)$$

Lemma 2. ***Canonicity of NDD.*** *For any boolean function $F(x_1, x_2, \cdots, x_N)$ over N boolean variables with ordering $x_1 < x_2 < \cdots < x_N$, there is exactly one RONDD u with k NDD variables and ordering $f_1 < f_2 < \cdots < f_k$, where f_i has n_i bits $x_i^1 < x_i^2 < \cdots < x_i^{n_i}$, and $N = \sum_{i=1}^{k} n_i$, such that u can represent F.*

Proof. Clearly the lemma holds for $k = 0$, and for $k \geq 1$, we prove it by induction on k. The proof is adapted from that for BDD canonicity [11].

Assume now that we have proven the lemma for k fields $(f_2, f_3, \cdots, f_{k+1})$. We prove the lemma for $k+1$ fields $(f_1, f_2, \cdots, f_{k+1})$. For a boolean function F with $k+1$ fields, the following two steps proves (1) there exists an NDD node u that can represent F, and (2) if there is another NDD node v, such that $F^v = F$, then we must have $v = u$.

(1) The existence of an NDD for boolean formula F. For f_1 with n_1 bits, there are 2^{n_1} distinct truth assignments, represented as a set $\mathcal{B}$. Each $B \in \mathcal{B}$, the restriction $F[B/f_1]$ has no more than k bits, and thus there exists an NDD node that can represent it (according to our assumption for k). We can partition $\mathcal{B}$ into m classes $C_1, C_2, \ldots, C_m$, satisfying that $\forall B_1, B_2 \in \mathcal{B}, F[B_1/f_1] = F[B_2/f_1] \Leftrightarrow \exists C_i, B_1 \in C_i, B_2 \in C_i$. For each C_i, there exists an NDD node v_{C_i} such that $\forall B \in C_i$, v_{C_i} represents each $F[B/f_1]$, and a BDD bdd_{C_i} that can represent $\bigvee_{B \in C_i} B$. We create an NDD node u with $var(u) = f_1$ and m edges, satisfying that $\forall e_i \in edges(u) \Rightarrow label(e_i) = bdd_{C_i}, next(e_i) = v_{C_i}$. According to Definitions 7 and 8, we have

$$F = f_1 \rightarrow F_{bdd_{C_1}}, F_{bdd_{C_2}}, \ldots, F_{bdd_{C_m}} = F^u$$

, meaning node u represents the formula F.

(2) The uniqueness of NDD for boolean formula F. There are two cases to consider.

(i) u has a single edge e with $label(e) = true$ and $next(e) = v_{C_1}$. This violates RONDD's condition of **no redundant node**. By reducing redundant nodes, u degenerates to v_{C_1}, which is canonic (canonicity of NDD with $\leq k$ fields).

(ii) u has more than one edges. Assume v is an NDD node with $F^v = F$, and we need to show $u = v$. First, we must have $var(v) = f_1$; otherwise if $var(v) \neq f_1$, then the

assignment of f_1 doesn't affect F, and u must be an NDD node with a single edge, which violates the assumption that u is a RONDD. For $\forall e_u \in edges(u)$ and a truth assignment $\forall B_1 \in label(e_u)$, we can find an edge $e_v \in edges(v)$ such that $B_1 \in label(e_v)$, because v must encode any truth assignment in f_1. In addition, we have $next(e_u) = next(e_v)$ because these two nodes encode the same formula $F[B_1/f_1]$ (canonicity of NDD with $\leq k$ fields). For any other truth assignment $\forall B_2 \in label(e_u), B_2 \neq B_1$, we can also find an edge $e_{v'} \in edges(v)$ such that $B_2 \in label(e_{v'})$. We can get that $next(e_v) = next(e_u) = next(e_{v'})$, and if $e_v \neq e_{v'}$, it violates RONDD's condition of **no redundant edges**. Therefore, we get that $e_v = e_{v'}$. That means, for $\forall e_u \in edges(u)$, there must exist $e_v \in edges(v)$, such that $label(e_u) \Rightarrow label(e_v)$. Vice versa, we get $label(e_v) \Rightarrow label(e_u)$ and therefore $label(e_u) = label(e_v)$ and $next(e_u) = next(e_v)$. Therefore, v and u have the same variable and set of edges. According to the **uniqueness** of RONDD, it follows that $v = u$.

□

D An example for explosion of atoms

We use an example in Figure 22 to show why the number of atoms can explode when using BDDs. For simplicity of illustration, we consider only `dst IP/Port` fields, and suppose ACL rules at port 1 of D have not been inserted.

Using BDD, a data plane verifier, i.e., APKeep, works in following steps. First, it splits each node (device) in (a) into *elements* in (b), each of which represents a single action in networks, e.g., forwarding, filter. Then, the verifier encodes match conditions of rules with BDDs, and computes port predicates for each element. The predicates are shown in (c) with labels of $B_1 - B_6$. Packets encoded in a port predicate will be forwarded to the related port or pass the related filter. After that, the verifier computes atoms in (d), each of which represents a set of packets with the same global behaviour. Suppose for now there are only forwarding rules matching `dstIP`. There are only 3 different behaviors, which correspond to $dstIP \in$ 00, 01 and 1*, respectively. Suppose there are also ACL rules matching `dstPort`, and the number of behaviours (atoms) will increase to 3 × 3 = 9, a cross-product of the 3 different behaviors for each of the two fields (B_{1-3} for `dstIP`, B_4, $B_5 - B_4$ and $\neg B_5$ for `dstPort`). As shown in (d), the three sub-structures of BDD nodes for `dstIP` are combined with the three sub-structures of BDD nodes for `dstPort`, resulting in 20 nodes in total. As shown in (e), the verifier replaces each port predicate in (b) with an equivalent set of atoms in (d). Then, as shown in (f), the verifier injects all atoms into A and traverses the network with a set of reachable atoms. At each element, it intersects the set of reachable atoms with atoms of each port of the element by using set operation $\cap$ and $\cup$, and forwards the result to the next element. Finally, atoms of $A_{1-3,5,6,8}$ can pass port 1 of D from A.

Using NDD, in contrast, the data plane verifier also computes port predicates with logical operations of $\wedge$, $\vee$ and $\neg$ as shown in (g), whose edges are labeled by BDDs in (c). Then, it collects all per-field BDDs on the edges, and calculates per-field atoms. As shown in (h), comparing with $3 \times 3 = 9$ atoms for the BDD-based verifier, there are only $3 + 3 = 6$ atoms for the NDD-based verifier, labeled by D_{1-3} and E_{1-3}. After that, as shown in (j), the verifier atomizes each port predicate of NDDs in (g) by atomized NDDs in (i). For example, the BDD label B_5 on the edge of C_5 encoding $dstPort = 0*$, is replaced by atoms E_1 and E_2 encoding $dstPort =$ 00 and 01, respectively. Finally, the verifier traverses the network and computes reachability by the operation $\wedge$ and $\vee$ of atomized NDD and the reachable packets are encoded by F_8.

E An example for BDD arrays

To show the limitation of simply assembling per-field BDDs as arrays, let us take a look at an example in Figure 23 (a), where we use BDD arrays to represent packet sets that are reachable from A to D in the network in Figure 3. Specifically, each array has four BDDs representing four fields, i.e., `src IP/Port` and `dst IP/Port`. Initially, an array of {****, **, **, **} which represents all packets is injected at device A. Then, each device filters the arrays based on its forwarding or ACL rules, and sends the resultant arrays to the next hops. At device D, we end up with 9 arrays which collectively represent all reachable packets from A to D. These 9 arrays correspond to a product of 3×3 paths from the root nodes of the three BDDs in Figure 4 (a) to the BDD terminal node `true` (3 sub-paths for $srcIP/Port$ and 3 sub-paths for $dstIP/Port$). 9 arrays are not a big issue in the example, but what we want to highlight here is the number of arrays can grow quickly due to a cross-product effect. In real scenarios, there can be over $O(10^4)$ arrays even when the network is very small (see Appendix A.10 for details). Figure 23 (b) shows the NDD representing reachable packets from A to D on the right. NDD compactly represents compositions of sub-paths from different fields by a form of decision diagram. Specifically, the 3 sub-paths for $dst\ IP/Port$ are represented once by an NDD node of the $dstIP$ field, and the 3 sub-paths for $src\ IP/Port$ share such NDD node without representing the 3 sub-paths for $dst\ IP/Port$ by 3 times, and therefore occupies much less memory than BDD arrays in practice.

F Use cases of NDD in network verification

F.1 Automatic atomization

We use AP Verifier [51], a data plane verifier, as an example to show how to use the NDD APIs to automatically compute atoms.

Step 1. Computing port predicates. Using NDD, we first use the `createVar` function to declare the header fields (i.e.,

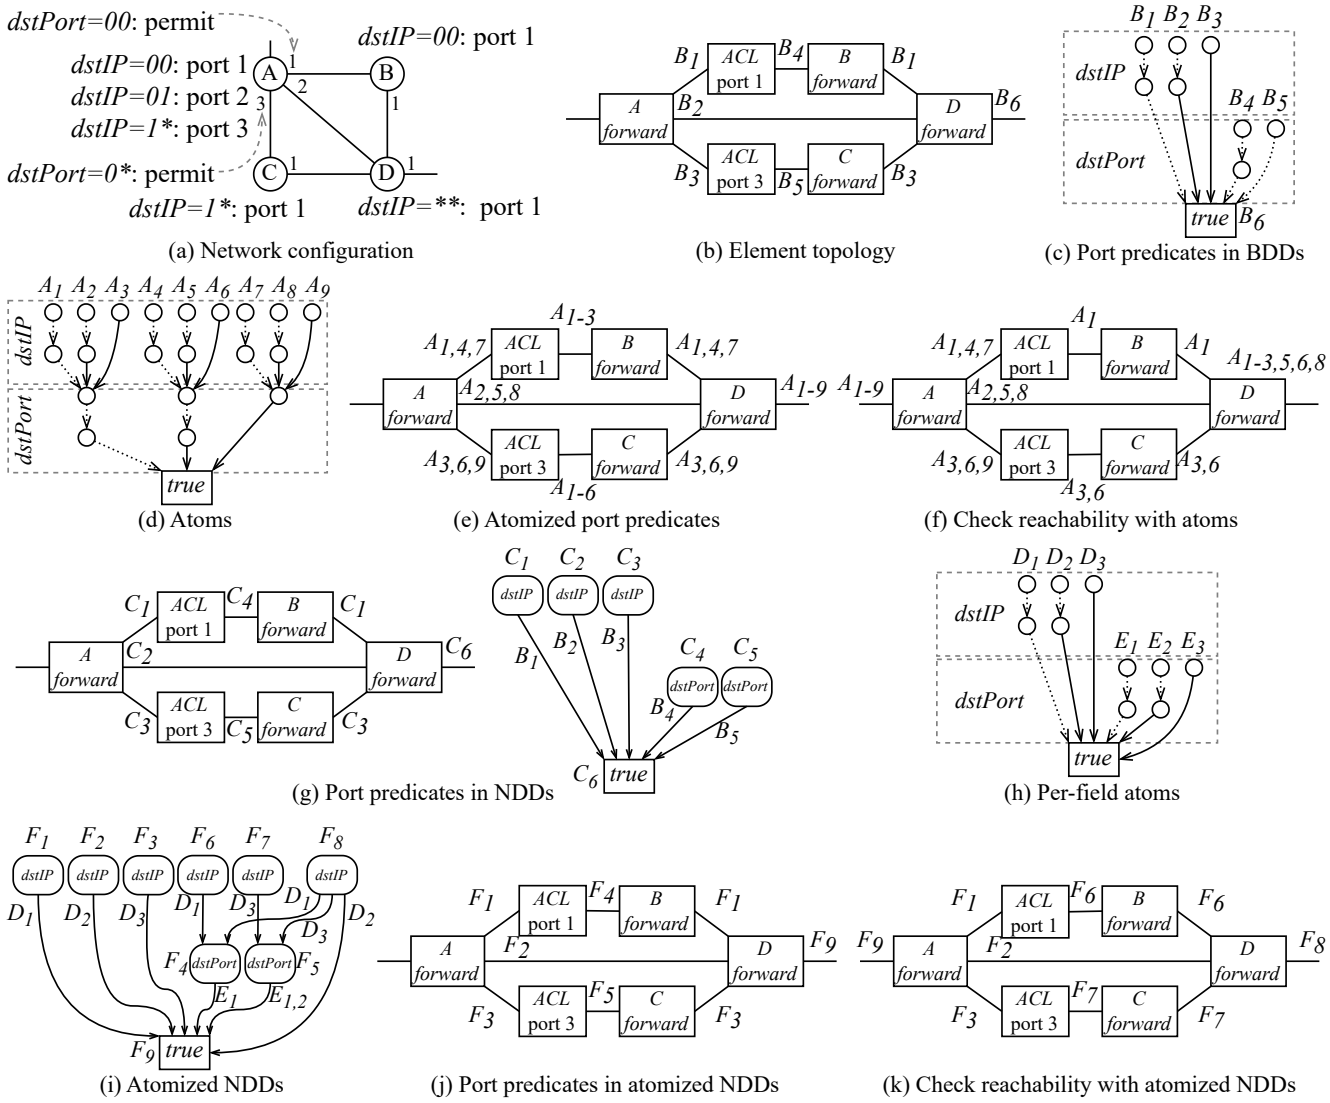


Figure 22: An example for explosion of atoms when using BDDs.

5-tuple). Then, we use the same algorithms as in AP Verifier to compute port predicates, with the only difference that BDD operations are replaced with NDDs operations (`apply`).

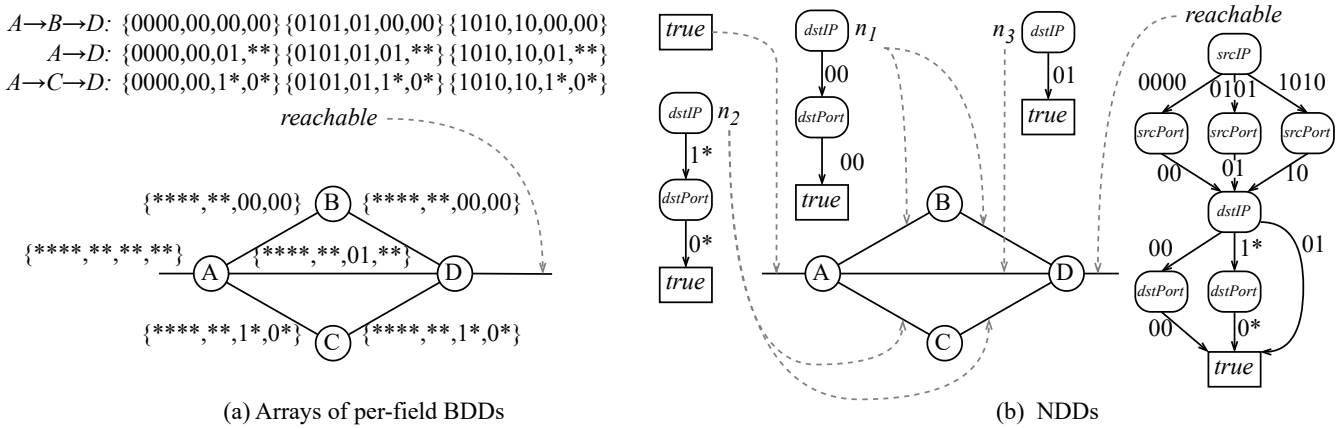
Step 2. Computing atomic predicates. Instead of computing atoms using the port predicates with a custom algorithm (a two-fold loop implemented in AP Verifier), we use the `atomize` function with the port predicates as input. The function will compute atoms for each field, and return the *atomized NDDs*, a new NDD with each BDD on an edge replaced by the equivalent sets of atoms.

Step 3. Checking reachability. We follow the same approach in AP Verifier to check network reachability, which maintains a set of atoms during the traversal, and performs intersections on the set with those of the ports being traversed. The difference is that the traversal uses logical operations on atomized NDD (e.g., `and`, `or`), instead of set operations, as in AP Verifier. In this sense, the process is similar to using BDDs without computing atoms, but can still enjoy a speedup due to computing per-field atoms. Note here the logical operations on atomized NDDs are different from those of standard NDDs: since labels of edges are sets of atoms in atomized NDD, the operations on labels become set operations instead of BDD operations.

F.2 Incremental update of atoms

We use APKeep [57], an incremental data plane verifier, as an example to show how to use the NDD APIs to incrementally update the atoms.

Step 1. Identifying changes. This step takes rule insertions or deletions as input, and calculates changes of forwarding behaviors. A change is represented as a tuple $(from, to, \delta)$, meaning that packets with headers in δ are forwarded to port $from$ before the update and to port to after the update. This



(a) Arrays of per-field BDDs

(b) NDDs

Figure 23: Computing reachable packets from A to D in the example in Figure 3, (a) and (b) use arrays of per-field BDDs and NDDs, respectively. Arrays/NDD on each link represent the reachable packets at that position, each element of an array represents a per-field BDD with an ordering of $\{srcIP, srcPort.dstIP, dstPort\}$.

step is identical to that of APKeep.

Step 2. Updating atoms. This step takes changes from step (1) and updates the set of atoms. For each change in the form of $(from, to, \delta)$, it first gets the atomized port predicate a of port $from$ and invokes `update`(δ, a) to update atoms.

Step 3. Transferring atoms. After step (2), δ can be atomized. This step atomizes δ and transfers it from port $from$ to port to using the `diff` and `or` operations for atomized NDD.

F.3 Handling packet transformers

We show how to use the NDD APIs to efficiently handle packet transformers, which refer to rules that *rewrite*, *encapsulate*, or *decapsulate* packets. A packet transformer can be represented as a tuple $(match, field, action)$, where $match$ is the matching condition, $field$ is the field to be transformed, and $action$ is the value to rewrite/encapsulate.

Step 1. Computing port predicates. For each action of transformers, e.g., encapsulating a new IP header with destination IP 10.0.0.1/32 for packets from source IP 192.0.1.0/24, the verifier creates a logical port on the device of the transformer. Each logical port P_i has two predicates: $P_i.match$, an NDD encoding the match conditions, e.g., `innerSrcIP`= 192.0.1.0/24, and $P_i.action$, an NDD encoding the actions, e.g., `outerDstIP`= 10.0.0.1/32. All these predicates are computed as in AP Verifier [51].

Step 2. Atomizing predicates. In this step, the verifier atomizes the predicates computed by step 1, using the NDD API `atomize`, in the same way as §F.1. The differences is that both the $P_i.match$ and $P_i.action$ are used for computing the atoms.

Step 3. Checking properties. In this step, when the packet set pkt (an atomized NDD) reaches a transformer, the verifier enumerates each logical port of the transformer: for each port P_i, it computes the conjunction of pkt and $P_i.match$, an atomized NDD encoding the match conditions. This is the same as §F.1. If the conjunction is not `false`, and the type of the transformer is `decapsulate` or `rewrite`, the verifier erases the original value of pkt on the field $P_i.field$, e.g., `innerSrcIP`, using the `exist` API of NDD. If the type is `encapsulate` or `rewrite`, the verifier sets a new value of pkt on the field $P_i.field$, e.g., `outerDstIP`, by computing the conjunction of pkt and $P_i.action$. The output is denoted as pkt_i. Finally, the verifier merges the output pkt_i of each logical port P_i into a packet set pkt', and forwards it to the next hop.

G The usage of BDD in network verification

Table 8 shows an incomplete list of network verifiers based on BDDs.

Table 8: Network verifiers based on BDD. ✓means the verifier has already been re-implemented with our NDD library.

	Verifier	BDD library	Symbolic state	Impl.

Smart Casual Verification of the Confidential Consortium Framework

Heidi Howard[*], *Markus A. Kuppe*[*], *Edward Ashton*[*], *Amaury Chamayou*[*], *Natacha Crooks*[*†]
Azure Research, Microsoft[*] *UC Berkeley*[†]

Abstract

The Confidential Consortium Framework (CCF) is an open-source platform for developing trustworthy and reliable cloud applications. CCF powers Microsoft's Azure Confidential Ledger service and as such it is vital to build confidence in the correctness of CCF's design and implementation. This paper reports our experiences applying *smart casual verification* to validate the correctness of CCF's novel distributed protocols, focusing on its unique distributed consensus protocol and its custom client consistency model. We use the term smart casual verification to describe our hybrid approach, which combines the rigor of formal specification and model checking with the pragmatism of automated testing, in our case binding the formal specification in TLA$^+$ to the C++ implementation. While traditional formal methods approaches require substantial buy-in and are often one-off efforts by domain experts, we have integrated our smart casual verification approach into CCF's CI pipeline, allowing contributors to continuously validate CCF as it evolves. We describe the challenges we faced in applying smart casual verification to a complex existing codebase and how we overcame them to find six subtle bugs in the design and implementation before they could impact production.

1 Introduction

The Confidential Consortium Framework (CCF) [28, 61] is a general-purpose platform for developing trustworthy and highly available cloud applications. CCF combines centralized compute with decentralized trust, supporting deployment on untrusted cloud infrastructure and transparent governance by mutually untrusted parties. CCF achieves this by leveraging hardware-based trusted execution environments (TEEs) for remotely verifiable confidentiality and code integrity [77, 78], coupled with state machine replication backed by an auditable immutable ledger for data integrity and high availability. CCF is trusted in production by services such as Azure Confidential Ledger [57], a tamper-proof append-only ledger, which is utilized for storing critical data like digests for integrity-protection with SQL Server [3, 63] and Azure Immutable Blob Storage [35]. Open source applications of CCF range from code transparency [17, 58] and mediation of multi-party data sharing [43], to decentralized identity [59], privacy-preserving ad auctions [62], and confidential storage [32, 56].

This paper summarizes our experience with verifying the correctness guarantees of the distributed protocols in CCF, a large-scale, production distributed system, using TLA$^+$ [45, 47]. We have five primary requirements that guided our approach to verification:

(1) Verify high-level distributed safety properties. We aim to check the correctness of our custom distributed consensus protocol, including its dynamic reconfiguration logic. CCF's consensus logic, though based on Raft [74] has been sufficiently modified such that it is now based on an unproven algorithm. This is a common problem: the Chubby authors [8] similarly note that the additional requirements imposed by a real-world system over a vanilla Paxos [46] implementation require significant changes. Moreover, distributed consensus protocols are notoriously hard to get right, and even well-known protocols, including PBFT [9], Egalitarian Paxos [66], and Zyzzyva [39], as well as the previously mentioned Raft and Chubby, have been found to contain subtle bugs [1, 2, 4, 55, 72, 82, 90]. The chosen verification strategy must therefore be able to check properties across distributed nodes, handling asynchrony, concurrency, and non-determinism in the order that events, such as timeouts and message delivery, occur as well as expected failures, like nodes crashing and message loss.

(2) Document and communicate the behavior of the system. A formal specification can act as compact and unambiguous documentation of system behavior for potential users. This gives developers and users clarity about the guarantees they can expect and rely on. The existence of such a spec also offers a succinct mechanism to communicate changes to these guarantees. Due to resource constraints on early TEEs [14], the consistency guarantees offered by CCF to clients can be subtle, confusing users and paper reviewers alike. In fact, even when consistency guarantees are seemingly simple, they

can still be famously difficult to reason about [36]. We thus wish to formally define these guarantees, communicate them clearly, and check that these hold, even as failures occur.

(3) Increased confidence in the implementation & design. While many verification efforts focus solely on checking the design via reference specs, we also wish to validate that our concrete implementation corresponds to our specs. If, in the future, there were to be variants or even multiple implementations of CCF, we would like to verify that they are functionally equivalent in key areas.

(4) Integrates with the existing codebase. We do not wish, however, to rewrite CCF for the purpose of verification. At the time of writing, the implementation is already 63 kLoC in C++. Our support for Intel SGX [14] (via OpenEnclave SDK [19]) constrains us to C++. Moreover, since the project started seven years ago, we have invested significantly in adding functionality, improving performance, and supporting new hardware (AMD SEV-SNP [31]). We want our verification efforts to *improve* upon that existing investment, rather than impose a fresh implementation.

(5) Pragmatic and evolves with the implementation over time. CCF is an ongoing project which is continuously growing and evolving, with an average 16 pull requests merged every week. Since 1.0, the first release to be deployed to production, there have been four further major versions, with minor versions and patches released every 11 days on average. Any verification effort must thus be continuous, automatic, and sufficiently lightweight to integrate into the existing CI pipelines and software engineering workloads. The approach should also be approachable and pragmatic such that anyone contributing to the project can update the specs and debug discrepancies between the implementation and specs.

1.1 Approach

Full formal verification of distributed systems has been successfully applied in various research projects [21, 23, 24, 91], for instance, by synthesizing an executable implementation from a formally proven spec. Unfortunately, while formal verification is a powerful tool, it requires a significant upfront investment in time and expertise. We thus chose a different approach. We already used traditional testing techniques (*casual verification*), but wanted to augment them with an approach that was more rigorous and complete. We thus chose to adopt *smart casual verification*[1], a pragmatic yet systematic approach to verification that combines the rigor of formal methods with the easy-of-use and flexibility of more casual methods. We combine a rigorous TLA$^+$ specification which we *tie* to our existing production implementation using *trace validation*.

We chose TLA$^+$ for several reasons. TLA$^+$ has been successfully utilized to verify the design of a number of production distributed systems [7, 68, 81, 85, 92]. Most notably for us, TLA$^+$ has been used to describe both consistency guarantees [22, 26, 86], and distributed consensus protocols, namely Paxos [46, 87] and Raft [73]. The existence of the last of these was a significant factor in our decision, as it allowed us to start from a complete spec of Raft and adapt it to our protocol's specificities, rather than from scratch. Finally, the maturity of TLA$^+$ and its tools [15, 37, 42, 93], the extensive examples available [51], and its active community [12] assured us of ongoing support and resources. Our increased investment in TLA$^+$, following initial successes, was supported by the availability of a recurring, two-day TLA$^+$ workshop [40] to train our team.

However, achieving our goals is not simply a matter of writing some high-level specs as this would not provide any guarantees about the production code itself. We bridged this gap by applying trace validation to validate implementation traces against the formal specs. In this paper, we describe our experience applying smart casual verification to CCF using TLA$^+$, focusing on the challenges we faced and how we overcame them. First, we present our TLA$^+$ specs of CCF from the perspective of its nodes (§4) and its clients (§5). Next, we present how we validate traces generated from the CCF implementation against our TLA$^+$ specs (§6). Finally, we reflect on our experiences applying smart casual verification to CCF (§7), documenting the six bugs we prevented, and the lessons learned along the way (§8). Both our specifications and implementation are open source and actively maintained [64].

2 CCF

This section provides an overview of the distributed architecture of CCF, focusing on the components that are relevant to our verification efforts. Interested readers can find a more comprehensive description of CCF in [28].

At its core, CCF uses state-machine-replication (SMR) [79] and trusted execution to offer the abstraction of an always available application that remains robust to attacks, including from the nodes themselves. CCF assumes that neither node operators nor other applications running on the hardware can be trusted. The host, the OS, the hypervisor, the network and persistent storage are all assumed to be corruptible. Intuitively, SMR provides clients with the illusion that there is a single server that will, sequentially, execute individual application requests. SMR achieves this by replicating application logic on a set of nodes, a fraction of which may fail. The system maintains consistency across nodes by deciding on a totally ordered transaction log. Formally, SMR guarantees the following (def. from [74, Fig. 3]):

Property 1 (State Machine Safety) *If a node has applied a log entry at a given index to its state machine, no other node will ever apply a different log entry for the same index.*

Most SMR systems further ensure that the agreed-upon set of transactions will be applied in a way that guarantees *linearizability* [25] (or *strict serializability*): the resulting execution

[1] Smart casual refers to a style of dress that is neat and stylish, without the expense and discomfort associated with formal attire such as a business suit. Smart casual dress can easily be made more/less formal, for instance, with the addition/removal of a blazer or tie. [18]

will be equivalent (equal read and write sets) to an execution in which each transaction was executed in sequence, and in an order that matches the order in which they were issued. Though appealing, strict serializability can be costly to enforce. SMR systems thus often relax this guarantee to read-only transactions specifically. They offer only *serializability* and allow read-only transactions to read stale state. CCF is no different: it offers strict serializability for committed read-write transactions and serializability for committed read-only transactions.

Serializability is a gold standard in system design, but is fairly pessimistic: a client must wait until a transaction has committed to learn any information about that transaction and its effects. This design was unfortunately at odds with CCF's initial SGX-related design constraint, which precluded keeping potentially large amounts of application-defined responses in the limited amount of in-enclave memory (128 MB). CCF thus provides configuration settings that clients can use to achieve good performance. They are useful in practice, but make it more challenging to formalize the consistency guarantees that users can expect.

In CCF, the leader node executes transactions as soon as they are received, and prior to them being replicated to other nodes. The leader then directly replies to the client with the result of the transaction without waiting for confirmation that the request has been replicated. As a consequence, a leader failure can cause the transaction to fail, even after a response has been returned to the client. Clients can then, on a per-response basis, decide whether they wish to wait for the transaction to be committed before proceeding or not. Either way, this cuts down the number of open client connections and pending responses, reducing memory footprint significantly.

Transactions in CCF can be in one of the following client-observable states: COMMITTED, PENDING, or INVALID. A transaction is COMMITTED if it has been replicated by the leader to a majority of nodes in its current term. A transaction is PENDING if it has been executed but not yet replicated. If the leader fails before replication is complete, CCF will mark the transaction as INVALID.

PENDING transactions, can eventually become INVALID, but cannot return arbitrary results. They provide a guarantee akin to *fork-linearizability* [52] (or *fork sequential consistency* [6] when considering read-only transactions). A pending transaction observes a prefix of committed transactions and a sequence of pending transactions. Leader failures may cause the system to fork and generate multiple (locally linearizable) sequences of pending transactions. Only one forked sequence will eventually commit, thus ensuring that the set of committed transactions remains linearizable. All other sequences will be marked as invalid. In other words, if a pending transaction commits, the result it returned to clients is guaranteed to have been linearizable.

CCF makes extensive use of timestamps to help clients understand when transactions transition from PENDING to COMMITTED or INVALID. Each transaction is associated with a unique transaction identifier, consisting of a lexicographically ordered pair $\langle t.i \rangle$ of term t and log index i. The client can use this ID to quickly understand the system state. CCF, for instance, enforces *timestamp ordering*: if $txid < txid'$ and the two transactions are committed, then the transaction with $txid$ executed before $txid'$. Clients can further use this ID to learn the state of not only this transaction, but its ancestors. For instance, CCF guarantees that:

Property 2 (Ancestor Commit) *If $\langle t.i \rangle$ is committed then any transaction $\langle t.j \rangle$ where $j \leq i$ is also committed.*

Ensuring that CCF does indeed provide these specific guarantees requires care and adapting existing linearizability specs, which only reason about committed operations. They support neither reasoning about forks nor timestamp properties.

To tolerate node crashes and network asynchrony, SMR requires a crash fault-tolerant distributed consensus protocol or equivalent [10], such as Multi-Paxos [46] or Raft [74], to agree on a total-ordered transaction log. While the terminology varies, such protocols are typically leader-based and operate by electing one of the nodes to be the *leader* while the other nodes are *followers*. The leader is responsible for proposing new transactions for the log and the followers are responsible for replicating them. The leader will only consider a transaction to be committed once a strict majority of nodes have replicated the transaction at the same position in the log. When the leader fails, a new leader is elected from the remaining nodes and the protocol continues. We use *terms* to distinguish between the different periods of leadership and there should be at most one leader per term.

It is the responsibility of the leader-based consensus protocol to ensure that the new leader has knowledge of all previously committed transactions. In Raft, this is achieved by requiring followers to become *candidates* (transition ① in Fig. 1) before they can become leaders. A candidate will only become a leader (transition ② in Fig. 1) if it can obtain a strict majority of votes from the other nodes. A node will only vote for a candidate if it has not already voted in the candidate's term and the candidate's log is at least as up-to-date as its own log. The former ensures that at most one leader can be elected per term and the latter ensures that the new leader has knowledge of all committed transactions from previous terms. A more comprehensive description of Raft can be found elsewhere [74].

2.1 What makes CCF's distributed consensus protocol interesting?

CCF uses a custom consensus protocol, which evolved from Raft. Now we will outline some of the ways that the consensus protocol in CCF today differs from the description of the Raft protocol given the original paper. While some of these modifications may seem small, the combined effect is significant and the interactions between them have proven complex and subtle, leading to the bugs we later describe (§7).

Signature transactions Offline log integrity and transaction provenance are key requirements for CCF, neither of which is provided by Raft, nor by the AEAD mechanism used inside the CCF network. The offline guarantees crucially enable external audit, and disaster recovery. To implement them efficiently, CCF utilizes *signature transactions*, which include the root of a Merkle tree [54] over the whole log thus far, signed by the current leader. A transaction in the log is not considered committed unless a subsequent signature has been committed.

Messaging not RPCs CCF does not use RPCs to communicate between nodes, and instead it uses a uni-directional messaging layer. When a node receives a response to a message it has sent, it does not know which message the response corresponds to as we do not assume reliable or in-order delivery. Raft uses two main message types: AppendEntries (AE) and RequestVote (RV). AE messages are used to replicate transactions and RV messages are used to elect a leader. In the case of RVs, the term in the response is sufficient to handle the reply. In the case of AEs, the response in CCF contains an additional field, LastIndex. For positive responses to AE messages (AE-ACK), this is the index of the last transaction in the follower's log.

Optimistic acknowledgement In Raft, the leader replicates transactions to its followers using AE requests. The leader maintains a NextIndex for each node to record which log entry to send next to the follower. This index is updated when a follower responds positively to an AE request (AE-ACK). If a leader receives a new transaction from a client, before it has received a response from a follower, it must either (1) wait for the reply for the previous transaction, potentially impacting liveness and performance as AEs cannot be pipelined, or (2) send both transactions in the next AE request, even though the follower is likely to already have the first transaction. CCF avoids this problem by allowing the leader to update the index, known in CCF as the SentIndex, as soon the AE message is sent. This therefore means that if the leader receives a negative response to its AE request (AE-NACK), it might need to rollback the SentIndex.

Express node catch up AE messages include a previous log index and term, which allows a follower to determine if it diverged from the leader. If a follower does not have the previous log index and term, either because it does not have, or has a different transaction at that index, it then responds with an AE-NACK. CCF uses an express catch up mechanism, where a leader makes a conservative estimate of how far behind a follower is, and sends a batch of transactions to the follower.

Partition leader step down A known limitation of the base Raft protocol is that partial/asymmetric network partitions can cause a loss of liveness [27, 33]. For instance, if a leader can no longer make progress because it cannot receive messages from the other nodes, it continues to send AE heartbeats to followers, preventing them from timing out and from electing a new leader who can make progress.

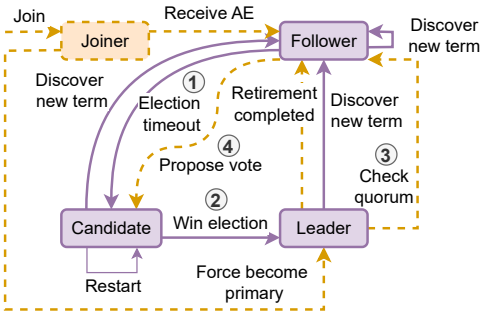

Figure 1: State transitions for CCF's consensus protocol. Solid boxes and lines show Raft's original states and transitions, CCF's additional states and transitions are shown with dashed lines.

CCF implements a known extension [71, pg. 69] to the Raft protocol, referred to as *CheckQuorum*, where a leader steps down if it does not hear back from a quorum of nodes within a specified time period (transition ③ in Fig. 1).

Bootstrapping to retirement Reconfiguration is the process by which the set of nodes participating in consensus can be changed. Raft support two reconfiguration protocols: *joint consensus*, described in the original paper [74], and single-server reconfiguration, subsequently described in [71]. CCF's reconfiguration protocol is more similar to the former. Reconfigurations are recorded in CCF's log with *configuration transactions*, and are therefore ordered in the same total order. Logs always begin with an initial singleton configuration transaction followed by a signature transaction. To change the configuration, the leader proposes a new configuration transaction specifying the new set of nodes, which may be different in cardinality to the current set of nodes and may or may not be disjoint. To commit this transaction, the leader must obtain a quorum of AE-ACKs from both the previous and new configurations. Once the transaction is committed, the leader no longer needs quorum agreement from the previous configuration. If a node has been removed from the configuration, we refer to it as *retiring*. In order to complete its retirement and permanently switch off the node, a *retirement transaction* must be committed to ensure that any future leader will know that the reconfiguration which removed the node has been committed, and thus the node will never be needed. CCF also adds a message to the protocol, *ProposeVote* which is utilized by a retiring leader to nominate a successor, fast-tracking the usual leader election process (transition ④ in Fig. 1).

3 Primer on TLA$^+$

TLA$^+$ [45, 47] is a formal modeling language widely used to verify concurrent and distributed systems. It is easy to learn and use, as well as agnostic about system frameworks or implementation languages.

TLA$^+$ is a variant of linear temporal time logic with only two operators, *Always* (□) and *Eventually* (◇). A system is defined by a set of *behaviors*, each a sequence of pairs of states called *actions*, beginning at one of the system's initial states. A *state* is an assignment of values to variables.

Syntactically, TLA$^+$ describes a system's state machine using a canonical (temporal) formula $Init \wedge \Box[Next]_{vars} \wedge L$. Here, $Init$ is a predicate defining the system's set of initial states. The system's next-state relation $Next$ is a first-order logic formula that is usually decomposed into a disjunct of actions which relates the values of the variables in the current state to the ones in the successor state. CHECKQUORUM (Listing 3), for instance, states that a node i can abdicate as a leader and become a follower; we change the value of the variable *role* to $Follower$ in the successor state, while the values of the other variables remain unchanged.[2] The tuple, $vars$, represents the spec's variables, and $[Next]_{vars}$ stipulates that either $Next$ is true, or the variable in $vars$ do not change. This asserts that TLA$^+$ specs are stuttering-insensitive, allowing a spec to always be refined by a more detailed, low-level one. The optional formula L is used to assert fairness, i.e., constraints on the system's behavior that ensure that certain actions eventually occur. Composition of actions allows us to change the *grain of atomicity* by defining more coarse-grained behaviors [47, §7.3]. Concretely, the composition $A \cdot B$ states that the two actions happen atomically; the intermediate state between A and B is not observable.

We also state desired safety (*something bad never happens*) and liveness (*something good eventually happens*) properties in TLA$^+$. For example, the safety properties LOGINV, APPENDONLYPROP, and MONOLOGINV (Listing 3, described in §4) assert properties of the *log*. Properties are checked and verified using, random state space exploration (simulation), model checking, or theorem proving. TLC [93], an explicit-state model checker, verifies that a *finite* model of a spec satisfies its properties by enumerating all reachable states. A symbolic model-checker [37] is especially well-suited for the verification of inductive invariants of finite systems. The TLA$^+$ Proof System [15, 88] mechanically verifies a deductive proof of the properties of an infinite system. These tools complement each other, enabling a combination of model-checking and deductive proofs to verify specs. This approach allows for varying levels of verification depth, from push-button model checking to fully mechanized safety and liveness proofs [38]. Our companion paper [11, §2.1] provides a more detailed summary of TLA$^+$.

4 Distributed Consensus Specification

Fig. 2 summarizes our consensus verification architecture. The consensus specification, shown as ① in Fig. 2, consists of 17 actions to describe the transitions over 13 variables. The first 12 variables are local and track consensus state (CURRENTTERM, LOG, COMMITINDEX, ...). The last variable instead tracks the set of in-transit messages, allowing support for different network abstractions (ordered/unordered delivery, etc.) and is shown as ② in Fig. 2. Each action models a node taking a single step within the protocol, updating its

[2]The value of the variable *role* is a mapping from all node identifiers to their roles such as *leader*, *follower*, and *candidate*.

Listing 3: Excerpt of our consensus spec.

local state and optionally the collection of in-transit messages, (i.e. CHECKQUORUM in Listing 3). Actions can either be initiated from a message receipt or by a node itself. Actions in the latter class include adding a signature transaction, stepping up as a candidate or stepping down as a leader. Such actions are always enabled, to model the fact that we make no assumptions about clock synchrony; each node's opinion of the progression of time is independent. Later we discuss how action-weighted simulation enabled us to find bugs in the prototype despite the state space explosion inherent with such an approach. The spec is parameterized by the set of nodes available in the service. The initial states of the spec include every non-empty subset of nodes in the initial configuration with any node in that initial configuration as an initial leader.

Our key correctness property is State Machine Safety (Property 1) which we check with invariant LOGINV and action property APPENDONLYPROP (Listing 3). LOGINV states that all pairs of committed logs must be consistent and APPENDONLYPROP states that each node can only extend its committed log. LOGINV checks for safety violations across nodes (in space) and APPENDONLYPROP checks for safety violations within a node (in time). We also checked a further 27 invariants/properties to ensure the correctness of our consensus protocol and of our understanding (see [64]). One such example is MONOLOGINV (Listing 3), which is a stronger

variant of the property that log terms are monotonically increasing which we depend upon extensively. More concretely, MONOLOGINV states that terms in the log can only increase after a signature and remains the same otherwise.

Our consensus spec is unbounded, there is always the possibility of a new transaction being proposed or a timeout triggering a new election. To exhaustively model check our spec, we extend our consensus spec, shown as ③ in Fig. 2, to restrict the state space by adding additional constraints to the actions limiting the max term, number of client requests, and the sequence of reconfigurations. We found exhaustive model checking too time-consuming to run with all but the strongest state constraints in our CI pipeline, particularly after the spec was updated to describe reconfiguration accurately (discussed further in §8). We therefore developed an extension to our spec for simulation as a lightweight alternative to exhaustive state exploration. Our simulation spec, shown as ④ in Fig. 2, takes a time quota and explores as many behaviors as possible, up to a given depth, within that time. To expand the coverage of simulation, specifically to explore behaviors where the system exhibits more forward progress, we manually weighted failure actions to reduce the likelihood of them being chosen. We also implemented Q-Learning proposed by [67] in TLC to automatically weight actions to increase coverage of simulation. However, we were unable to find the right set of variables as input to Q-Learning's state hash function $\mathcal{H}$ that achieved better coverage than manual weighting.

5 Client Consistency Specification

Following our success with the consensus spec and a discussion regarding the linearizability of read-only transactions [60], we decided to formalize the possible externally visible behaviors of a CCF service in TLA$^+$ to better understand the guarantees provided. Our aim with this spec was to keep it as high-level as possible, focusing solely on the possible safe interactions between clients and the service. By design this spec does not model the internal details of the service itself such as the state of individual nodes or the messages exchanged between nodes as such low level details are already modeled by our consensus spec.

Our consistency spec uses just two variables. The first is HISTORY, an append-only sequence which records the messages exchanges between clients and the services. Five messages are supported, read-only/read-write transaction requests and responses as well as a transaction status messages. Note that since we are focused on safety, we omit messages that cannot impact correctness but can increase the state space, for instance, we do not track when a client requested a transaction status, nor do we track status responses of PENDING. In order to stress the consistency guarantees, we modelled an application where all transactions operate on a simple value, reading the current value, appending a new identifier to the value and writing back the new value. All transactions conflict and each transaction observes every transaction that has been executed before it. To succinctly record the current state of the service we use LOGBRANCHES, an append-only two-dimensional sequence, where the sequence at index i corresponds with the local log of the leader of term i if such a node still exists. This representation does not therefore need to be parameterized over the number of nodes in the service and usefully models the fact that there can be multiple leaders at one time (although they will have different terms).

$$
\begin{aligned}
&PrevCommittedInv \triangleq \\
&\quad \forall i,j \in \{x \in \text{DOMAIN } history : history[x].type = Status\} : \\
&\quad \wedge history[i].status = Committed \\
&\quad \wedge history[i].term = history[j].term \\
&\quad \wedge history[j].index \leq history[i].index \\
&\quad \Rightarrow history[j].status = Committed
\end{aligned}
$$

$$
\begin{aligned}
&ObservedRoInv \triangleq \\
&\quad \forall i \in RwResCommitIndexes : \\
&\quad\quad \forall j \in RoReqCommitIndexes : \\
&\quad\quad\quad \forall k \in RoResCommitIndexes : \\
&\quad\quad\quad\quad history[k].tx = history[j].tx \wedge i < j \\
&\quad\quad\quad\quad \Rightarrow Contains(history[k].observed, history[i].tx)
\end{aligned}
$$

Listing 4: Two properties over histories checked by our consistency spec.

To populate these histories, we defined a set of actions to describe how the history can be extended depending on the log branches. Initially, the history and log branches are empty. The possible actions are: append a transaction request or response to the history, execute a transaction by appending it to any log branches, append a transaction status to the history, or starting a new log branch to simulate leader election. Note that when a transaction is executed, it can be appended to any log branch, this simulates the fact that a transaction can be handled by any node that believes itself to be the leader, even if it is not the latest leader. At any time, a new log branch can be started. This new log branch can be any prefix of any existing log branches, provided it includes the last committed transaction. Having established an approach to generate histories, we formalized in TLA$^+$ the properties that we expect to hold over these histories and check them with TLC. For instance, PREVCOMMITTEDINV (Listings 4) formalizes Property 2 by stating that for any pair of transaction status responses from the same term, if the one with the greater (or equal) index is COMMITTED, then the other status response must also be COMMITTED (as PENDING states are not modelled). OBSERVEDROINV (Listings 4) states that if a committed read-write transaction received an initial response (event i), before a committed read-only transaction was started (event j) then the read-only transaction response (event k) must observe the read-write transaction. Note that RWRESCOMMITINDEXES is the set of indexes for all read-write transaction response events, filtered to include only transactions that were subsequently committed. ROREQCOMMITINDEXES and RORESCOMMITINDEXES are similarly defined for read-only transaction requests and responses.

6 Trace Validation

Conceptually, trace validation checks that every observed implementation trace matches a behavior of the system's high-level specification. We must therefore first collect implementation traces before validating them against our high-level consensus TLA+ specification. A more formal discussion of trace validation, including insights from applying trace validation to systems other than CCF, is provided in [11].

6.1 Trace Collection

When we began the trace validation work, CCF already had extensive unit, functional, and end-to-end testing. Unit testing of CCF's consensus layer consisted of approximately 1.6 kLoC. End-to-end testing covered complex scenarios such as reconfigurations, node failover, and network partitions, spread over more than 2 kLoC of Python tests and infrastructure code. Consensus functional testing was done through a scenario driver, shown as ⑤ in Fig. 2, that serialized execution deterministically across nodes, and isolated the consensus layer by mocking unrelated CCF components, such as governance, networking etc. This driver allowed the injection of network faults such as partitions, delays, reorderings, and message loss, and provides observability. Core correctness invariants and properties were checked at designated execution steps in 13 manually written scenario tests exercising replication, election, and reconfiguration under controlled fault conditions. Additionally, an initial prototype to fuzz-test the consensus layer through generated inputs and faults was developed but ultimately abandoned since it failed to generate interesting behaviors that would achieve satisfactory coverage.

The driver allows us to replace the node's wall clocks with a single global clock. If this global clock had not been possible, a distributed clock, such as a Lamport or vector clock, would have also provided the necessary event ordering to establish the happen-before relationships. However, a distributed clock would have required changes to the network message format. We enhanced system observability by incorporating an additional 15 log statements to capture consistent system states at well-defined, side-effect-free linearization points including (i) the sending and receipt of network messages, and (ii) transitions in a node's high-level state, such as moving from candidate to leader[3]. It is important to note that the driver logs only those values that remain constant in space. For instance, the driver records the length of the logs but not the log entries themselves, which would become impractically large. Still, the logging is disabled at compile time for production builds, and thus does not impact CCF's performance.

Before validation, implementation traces, shown as ⑥ in Fig. 2, are preprocessed to exclude and de-duplicate events from the initial bootstrapping phase of a CCF network, as this phase is not modeled in our consensus spec.

[3] State changes are logged immediately after acquiring a global lock.

Listing 5: Excerpt of the *Trace* spec for trace validation.

6.2 Consensus Trace Validation

Trace validation, shown as ⑦ in Fig. 2, ensures that an implementation trace is consistent with the specification. More formally, it verifies whether the set of behaviors $\mathcal{T}$, which encapsulates the values and events from a trace, intersects with the set of behaviors $\mathcal{S}$ derived from the high-level spec, thereby checking that $\mathcal{T} \cap \mathcal{S} \neq \emptyset$. While TLC can construct $\mathcal{S}$, it cannot directly generate $\mathcal{T}$ from the trace. Thus, we write a new TLA+ spec, *Trace*, reusing many actions of the definitions from the high-level spec. However, the actions are only enabled iff the current event in the trace matches an action. Likewise, the actions are parameterized by the values taken from the trace, effectively constraining successor states.

Consider for example *IsSendAppendEntries* (Listing 5). This action is enabled iff the current line of the trace, denoted by *ln*,

is a *sndAE* event, and the *commitIndex* of the sending node (denoted by *ln.snd*) matches the trace's *commit_idx*. The action then reuses the definition of the *AppendEntries* action from the consensus spec, parameterized by *ln.snd* and *ln.rcv* from the trace. Given that the number of entries in the high-level action *AppendEntries* is chosen nondeterministically within defined limits, *IsSendAppendEntries* determines the successor state by asserting the existence of an additional *AppendEntriesRequest* in the network with a matching number of entries. Note that while the consensus spec modeled the network as a set of messages, thereby leaving the variable upon a resend of an *AppendEntriesRequest* unchanged, *Trace* redefines the value of the variable to be a multi-set. This allowed the spec to account for the addition of messages in the network, even during resend events. Subsequently, this approach to address the impedance mismatch was expanded to verify, with TLC, the impact of various message delivery guarantees, such as ordering, duplication, and other message loss patterns.

6.2.1 Aligning Grains Of Atomicity

The granularity of some actions in the consensus spec did not align with the granularity of events in the traces. The action *IsRcvAppendEntries* outlines the alignment of such different *grains of atomicity*. Like many Raft implementations, CCF minimize network round trips by piggybacking *term* updates on *AppendEntries* messages. This optimization was not reflected in the consensus spec. Instead, the spec modeled term updates with an action that increases the term upon a pending *AppendEntriesRequest*, while leaving the variable unchanged. In effect, a term update might nondeterministically occur before the receipt of the *AppendEntriesRequest*. To reconcile these different grains of atomicity, we composed the actions *UpdateTerm* and *HandleAppendEntriesReq*, allowing them to occur atomically, i.e., in a single action.

Another important application of action composition addresses events that are omitted from the trace, such as losing messages. Although our consensus specs explicitly modeled losing messages, message loss was not recorded in the trace. Therefore, to account for faults at any step of a behavior, we composed an *IsFault* action with *Trace*'s next-state relation. Conversely, aligning a single high-level action with multiple implementation events is addressed by introducing finite stuttering that does not change the high-level variables. For instance, the action *IsSendAppendEntriesResponse* is enabled iff *ln* is a *sndAER* event. However, it leaves the high-level variables unchanged.

6.2.2 Deriving Consensus Trace Validation

We began to derive *Trace* by mapping the trace of a straightforward happy-path test line by line to the consensus spec. To proactively catch discrepancies, we added as many assertions as possible to *Trace*. Whenever we discovered discrepancies, we investigated them by examining relevant sections of the implementation's source code. Adding cross-references between the implementation and the spec proved useful, particularly when the terminology——such as variable and function names——differed between the two. We further debugged the *Trace* using the TLA$^+$ debugger [41] in tandem with implementation debugging. Upon detecting discrepancies, we corrected either the implementation or the spec, subsequently rerunning verification on the revised consensus spec, and executing tests on the updated implementation.

6.3 Debugging Discrepancies

Bogus logging, incorrect mappings from implementation to spec state, or true discrepancies between the spec and the implementation, resulted in $\mathcal{T} \cap \mathcal{S} = \emptyset$, i.e., the verdict that a trace is invalid. In either case, contrary to ordinary model checking, a failure to validate a trace had no counterexample. However, the behaviors within $\mathcal{T}$ helped explain why a trace failed to validate. We typically compared the final state of the longest behaviors and the corresponding line in the trace to identify the source of the mismatch. The TLA$^+$ debugger was instrumental in this process, as it allowed us to step through the evaluation of formulas and compare variables at the current and successor states with the trace values. To determine if *Trace* is overly restrictive, we implemented a new *unsatisfied breakpoint*. It triggers for each state in $\mathcal{T}$ that is found to be unreachable. Furthermore, $\mathcal{T}$ can be visualized as a graph that not only includes all unreachable states but also references the subformula responsible for each state being unreachable.

6.4 Scalability of Trace Validation

The cardinality of $\mathcal{T}$, the set of potential system behaviors, can become prohibitively large due to nondeterminism resulting from incomplete traces. Recognizing that it suffices to find a single behavior in the intersection of $\mathcal{T}$ and $\mathcal{S}$ to check the validity of a trace, we implemented depth-first search (DFS) in TLC. This method mitigated the issue of state-space explosion, making trace validation orders of magnitude faster compared to enumerating all behaviors with breadth-first search (BFS). For instance, validating a trace against our consistency spec started to take less than a second using DFS, compared to about an hour with BFS.

6.5 Trace Validation Effort

The enhancements to the test driver and the addition of detailed logging were completed in approximately one day. The effort to derive a version of the *Trace* spec that validated the majority of the traces required approximately two engineer-months, spread over four months. The primary tasks included enhancing the TLC model checker to support trace validation, which involved implementing support for action composition, DFS, improved debugging support, and visualizing the state graph. The second major tasks was diagnosing if the root cause of discrepancies arose from bugs in the reverse-engineered spec, the implementation, or both. This frequently required consulting the original Raft paper and discussions with the CCF experts to elucidate differences between Raft

and CCF. In this context, the shared vocabulary developed during the TLA+ workshops, along with TLA+ counterexamples from trace validation, simulation, and model checking proved invaluable. The third major task involved finding modeling patterns to bridge impedance mismatches between the high-level TLA+ design and low-level implementation. Writing the 400 LoC *Trace* spec itself was a minor task. The introduction of trace validation resulted in 88 fine-grained commits to the *Trace* spec, while the consensus spec underwent 107 changes.

The discovery of a serious safety bug through trace validation (*Commit advance on AE-NACK* §7) led to increased investment in trace validation. Substantial changes were made to the consensus spec to accurately reflect the implementation. For example, the bootstrapping of a CCF network was modeled with greater fidelity. Additionally, the spec was expanded to include all node states, especially those related to node retirement. These comprehensive changes necessitated substantial revisions to the test driver and the development of new tests. This uncovered a serious liveness bug (*Premature node retirement* §7). Once the consensus spec was validated to accurately mirror the implementation, we transitioned to a spec-driven development, wherein the spec served as the source of truth. Notably, this phase included the integration of the *ProposeVote* messages (described in §4; used for transition ④ in Fig. 1).

Later, trace validation was also applied to the consistency spec, requiring significantly less effort. The consistency spec was considerably less complex, written with the implementation in mind, and we had already gained experience validating our consensus spec. Moreover, TLC had already been enhanced to support trace validation. No instrumentation of the CCF source code was required for consistency trace validation. Instead, the implementation state was observed by making calls to the system's REST API. As with consensus specification, we had to address impedance mismatches. For instance, the consistency spec assumed knowledge of the transactions of all clients, whereas a trace is limited to the transactions of a single client. This required defining a TLA+ action in the specification to reconstruct all transactions based on observed transaction IDs. Yet, applying trace validation to consistency was almost entirely carried out by the CCF experts, with minimal involvement from the formal methods expert. The effort required to apply trace validation to the consistency spec was approximately one engineer-week, spread over a two-week period.[4]

7 Results

This section summarizes the core results of our efforts, focusing on state coverage as well as the bugs found. Table 1 compares the sizes of the TLA+ specs against the implementation and test infra, to give a sense of scale and illustrate the level of detail necessary to execute trace validation. We find that verification of our TLA+ specs is an extremely efficient way to achieve state coverage. Comparing state exploration between implementation and specs is straightforward, because traces can also be collected in end-to-end tests, and one log line is largely equivalent to a spec action. It is immediately apparent that verification of our consensus spec explores orders of magnitude more states at a higher rate than implementation testing. While code size is not a direct measure of cost, the overall size of the spec and its models are not out of proportion compared to the tests. Importantly, the consistency spec required very little infrastructure to verify, and to validate traces against the implementation. The cost of writing formal documentation of the log's consistency guarantee was thus low, and validating it and keeping it in sync with the implementation is equally affordable.

Table 1: Scale of specifications and state coverage.

	Item	LoC	Vars	Approx states /min	Approx states Total

All numbers measured on an Azure DC8s v3 VM.

Table 2 lists the most serious bugs found in our consensus protocol as part of the verification work. These bugs affected both the safety and the liveness of CCF, and were uncovered at several stages of the process by each tool in our verification wardrobe. In the rest of this section we describe the bugs which were found and corrected during this process, explaining how they were uncovered by our combination of smart casual and classical testing methods. All these bugs were fixed before they affected any end-users or resulted in customer bug reports. Thus, although this formalization work took place after the system was initially developed and deployed, it still provided a core benefit of spec-driven development; the identification and removal of critical bugs before they impact production, proving that it is never too late to benefit from smart casual verification.

Incorrect election quorum tally 48 hours of exhaustive model checking of the consensus spec on a 128 core machine revealed that CCF was tallying election quorums against the union of active configurations (the current configuration plus any pending reconfigurations), rather than against each indi-

[4]The work on trace validation has been tracked in milestones 18 and 20 at https://github.com/microsoft/CCF/milestones/.

Table 2: Bugs found in CCF's consensus protocol before they could impact production.

Name	Violation	High-Level Description (Issues)
Incorrect election quorum tally	Safety	Quorum was tallied against union of active configurations, rather than against each individual active configuration. (#3837, #3948, #4018)
Commit advance for previous term	Safety	Leaders could advance commit for historical terms without extending log in the current term. (#3828, #3950, #3971, #5674)
Commit advance on AE-NACK	Safety	Variable reuse could cause the leader's commit index to advance when receiving an AE-NACK (#5324, #5325)
Truncation from early AE	Safety	Followers could roll back committed entries, after a sequence triggered by stale AE-NACK messages. (#5927, #5991, #6016)
Inaccurate AE-ACK	Safety	AE-ACK could report an index beyond the end index of AE received, despite the suffix potentially being incompatible. (#6001, #6016)
Premature node retirement	Liveness	Nodes could stop participating in consensus too early during retirement, leading to diminished fault tolerance. (#5919, #5973)

vidual active configuration (compare §2.1). The initial implementation had correctly used the majority in each term, as described in [74, §5.2], but had not been updated appropriately when reconfiguration was implemented. This meant that a node could be elected leader in a term without having a quorum in one of the active configurations, potentially allowing two leaders being elected in the same term, violating a core safety property. The issue was reproduced with functional and end-to-end testing, a fix was applied, and resolved the problem in both tests and model checking. This was the first bug identified by TLC and motivated our further investment in TLA$^+$.

Commit advance for previous term While assessing the work required to align the implementation and the spec, we discovered that the implementation omitted a check described in Raft. Our implementation allowed a leader to advance its commit index based solely on receiving a quorum of AE-ACKs confirming a given log entry, and missed the additional requirement that this entry must have been appended by the current leader. This restriction is fully explained in [74, §5.4.2], along with the corresponding risk to safety, but had been accidentally omitted in the implementation. We added a scenario test based on [74, Fig. 9] to confirm that the implementation was faulty. An initial fix emptied the node's set of indices eligible for commit (because they are signature transactions) when becoming a leader. This fix passed all existing and amended tests and was thus integrated into the codebase. Our work on trace validation, several months later, required us to revise the spec to represent committable indices accurately. Subsequent simulation revealed a safety violation caused by the initial fix; the *fix* broke an implicit property that committable indices contains *all* signatures. A second fix was implemented and tested as well as verified with TLC. This bug illustrated that even deterministic testing (compare §6.1) is insufficient to guarantee the correctness of changes. Moreover, it confirmed that trace validation is effective at guiding the alignment of the spec and the implementation to enable verification.

Commit advance on AE-NACK Trace validation discovered that the spec defined a leader's *matchIndex* to remain unchanged after receiving a follower's AE-NACK, whereas the implementation allowed it to decrease. This difference was due to an aggressive implementation of an optimization proposed in [74, §5.3, last paragraph]. After a single LoC change to align the spec with the implementation, subsequent simulation found a 34-state counterexample violating one of the spec's main correctness properties. This counterexample was manually translated into a 150 LoC functional test, confirming that the implementation could incorrectly advance its commit index. We also noted that [74, fig. 2, p. 4] implicitly states that *matchIndex* should never decrease, except after a leader election. Adding this property to the spec allowed model checking to find a shorter counterexample. The combination of functional testing and model checking allowed us to fix this bug quickly and confidently.

Truncation from early AE Once a subset of our initial scenarios passed trace validation, investigating why the remaining scenarios failed trace validation uncovered a safety violation. Log entries necessary to the persistence of committed transactions could be rolled back by a follower. This bug was introduced by an optimization, and existed in the implementation for some time. When the suffix of a follower's log is incompatible with that of the leader, there is a need to find the last agreement point. The Raft paper describes an iterative reverse search of the sequence numbers, but we instead implemented a suggested optimization to skip entire terms of divergence. CCF thus finds an agreement point after a sequence of round trips bounded by the number of divergent terms, rather than sequence numbers. We implemented this optimization by changing the semantics of the AE-NACK message, in which followers now include a safe best-estimate of an agreement point communicated using existing fields in the AE-NACK message.

Because the leader cannot distinguish these estimate messages from stale AE-NACKs emitted in previous terms,

it may respond with an AE starting before the end of the follower's log. This, coupled with an insufficiently defensive code path in the follower's code, would cause the AE to be treated as a conflicting suffix, and trigger a roll back preceding the application of the AE, potentially violating Leader Completeness (defined in [74, Figure 3]). The fix proved simple: rather than rolling back optimistically on an AE in a new term, the follower should only do so on true conflicts.

Notably, this bug was triggered by existing functional tests, producing output that did not pass trace validation, but the tests' assertions were not strong enough. The reproduction scenario we wrote produced a trace 305 events long at the point the bug manifests itself. This bug showed the important benefit of trace validation to check the invariants in every state, compared to the traditional approach of manually inserting assertions in scenarios at specific points.

Inaccurate AE-ACK Fixing this bug directly led to the discovery of the AE-ACK index issue. Because CCF uses unidirectional messages rather than RPCs (§2.1), the code responsible for responding to messages sends values from local state where possible, rather than values specific to the message they responded to. The AE-ACK handler did so for the LastIndex field, which is the index of the last entry in the appended entries, without correctly checking that the log was also compatible. This was discovered while conducting trace validation on the previous issue, and a specific scenario was added to test it in isolation. Here too, the fix was simple, and involved constraining the LastIndex in AE-ACKs to the last index contained within the received AE.

Premature node retirement Network configuration in CCF is stored in a map (compare §2.1). Adding or removing nodes happens through updates to this map, which produce write sets that are also replicated and handled like any other transaction, and are therefore part of the totally ordered log. The consensus logic is notified through hooks, which can be called when a transaction is ordered and/or committed. As a result, the reconfiguration logic is not isolated from the consensus code, and was initially mocked with low fidelity in the scenario driver, and correspondingly simplified in the TLA$^+$ spec. This was known to be a significant discrepancy between the implementation and the spec, which we decided to address by making the driver more realistic, and by improving the scenario coverage used for trace validation. As the spec was aligned, simulation produced counterexamples where a reconfiguration would leave the CCF network permanently unable to make progress; a retiring node stopped responding before all future leaders were aware of its retirement. We translated the counterexamples into new functional tests to reproduce the issue. A fix, leveraging an existing mechanism to shut down retired nodes safely, was proposed, verified, and implemented together.

Non-linearizability of read-only transactions Thus far we have described bugs founds in our consensus protocol. In this last example we describe how we identify an ambiguity in CCF's docs, aided by the consistency spec. Recall that linearizability requires that transaction execution is consistent with the real-time ordering of client requests and responses. Recall that ObservedRoInv (Listings 4) specifies that any committed read-only transaction must observe any previously committed read-write transactions. Model checking found a 12-step counterexample to ObservedRoInv in four seconds. A read-only transaction is handled by an old, yet active leader that has not added a read-write transaction to its log since the new leader was elected. This is rare in practice, a leader has to be falsely replaced when it is still active. The leader's logs must be identical, then, in the short window of time before the old leader retires, it needs to handle a read-only transaction.[5] Currently, we have no plans to change this behavior, as serializability for read-only transactions is sufficient for most applications, however, we hope that our consistency spec will help us to more clearly communicate this guarantee to developers.

8 Lessons Learned

We were surprised that, despite our extensive testing, *many bugs were first spotted during the development of the spec and subsequent alignment with the implementation.* The development and refinement of the consensus and consistency specs forced us to think deeply about our protocol and its invariants. During the process of spec development, the implementation was very closely scrutinized (with the target invariants in mind) and many bugs were first identified. In some cases, someone would become suspicious of a particular part of the code but would be unable to confirm that the current behavior led to a violation. This was particularly true for situations including multiple reconfigurations and failure handling (see Incorrect election quorum tally §7 and Commit advance for previous term §7), where counterexamples require many steps and were no longer feasible to work through on a whiteboard. This is where verification was invaluable, as it allowed us to quickly check the behavior against the expected invariants.

While finding implementation bugs by gradually and manually aligning a formal spec with its implementation is possible, we found that *trace validation is a more systematic and efficient approach*. Prior to our trace validation efforts, which began in Spring 2023, we were not confident that our consensus spec matched the implementation. Different team members worked on the spec and the implementation, and as such, they reflected different understandings of how the consensus worked. Moreover, we corrected safety violations present only in the spec, while the implementation contained bugs that spec verification could not find. Trace validation, and its inclusion in our CI pipeline, proved to be a turning point in our verification efforts, as it finally allowed us to systematically identify and fix these discrepancies.

Our results show that *that software verification is beneficial even for systems that have already been "proven in*

[5] The counterexample can be found and interactively explored online [65].

production". During the time that the incorrect election quorum tally (§7) was present in CCF, the operators added and removed nodes one at time. This meant that the bug did not lead to a safety violation and thus remained undiscovered, but could have surfaced if the operators had changed their reconfiguration strategy. Similarly, that the incorrect fix for the commit advance for previous term bug (§7) did not lead to a production incident can be attributed to chance.

Despite modern hardware and advances in tooling, we found that *exhaustive model checking, at our level of abstraction, took significant time to complete*. This led us to limit the state space more than we would have liked. We could have used a proof system, such as the TLA$^+$ Proof System, instead of a model checker. By opting for model checking, we chose to prioritize developer time and accessibility over compute time. As interactive theorem provers continue to advance [13, 75], along with AI-assisted verification [44], this trade-off may no longer be necessary. However, *simulation proved effective at quickly finding bugs*, especially when combined with action weighting (described in §4).

9 Related Work

Validating the correctness of distributed systems is a widely studied problem with approaches ranging from rigorously verified implementations, *formal verification*, to the many flavors of software testing, *casual verification*, including *smart casual verification* which sits between the two.

Formal verification of distributed systems provides the strongest guarantees of correctness, but is often impractical for real-world systems due to the high cost of development and expertise required. For example, IronFleet [24] and Verdi [91] both proved implementations of Raft correct, but, to the best of our knowledge, have not been used outside of an academic setting. Moreover, they are not easily amenable to systems already implemented in a general-purpose programming language. PGo [21] follows a related approach in which one could prove the correctness of a TLA$^+$ spec, and then extract a Go implementation using their PGo compiler. Again, an approach that works best for greenfield projects.

On the other hand, there is a broad spectrum of approaches to testing distributed systems (casual verification) [7, 34, 53], which tend to follow the same pattern: (i) orchestrate the creation of one or more configurations of the system, (ii) schedule workloads, and (iii) inject faults, such as network partitions, node failures, clock skew etc. As the extent of the system and its dependencies being orchestrated increases, it becomes more difficult to maintain determinism and repeatability. Test times for equivalent scenarios also tend to grow longer, and the likelihood of spurious failures goes up.

CCF's consensus spec is the latest addition in a recent tradition of modeling consensus in TLA$^+$. This began with Lamport's description of Paxos [46] in TLA$^+$, as a refinement of higher-level specs [87]. This was followed by the formalization in TLA$^+$ of other consensus algorithms [81, 85, 92] including Paxos variants [20, 29, 30, 48–50] and Raft [73, 80].

Tasiran et al. [84] were the first to extract and validate traces obtained from a hardware simulator against a TLA$^+$ spec, demonstrating the practical applicability of trace validation. The adoption of TLA$^+$ among distributed system practitioners, spurred by Newcombe et al. [69], and the formalization of trace validation as a refinement check by Pressler [76], caused trace validation to be applied to real-world distributed systems. For instance, Davis et al. [16] applied the technique to MongoDB, discovering a non-trivial implementation bug. However, they faced challenges in consistently logging implementation state, and aligning different grains of atomicity, which we attribute to them not leveraging TLA$^+$'s non-determinism to infer implementation state, and action composition to align atomicity. Niu et al. [70] also validated traces of Zookeeper, ensuring that its implementation corresponds to its spec. Similarly, Wang et al. [89] revealed several implementation bugs by replaying TLA$^+$ behaviors against instrumented implementations. Likewise, SandTable is capable of replaying behaviors but, additionally, provides a generic testing framework for distributed systems [83]. SandTable intercepts network communication at the POSIX layer, making it incompatible with systems like CCF that encrypt communications at the application layer. Furthermore, Wang et al. and SandTable serve as examples of the challenges of aligning the grains of atomicity, illustrated by the authors identifying two bugs in Ongaro's well-established Raft [73] spec. We contend that these are, in fact, common TLA$^+$ modeling patterns and can be handled with action composition. Nevertheless, all efforts found non-trivial bugs in real-world systems by comparing implementation traces to high-level TLA$^+$ behaviors; a testament to the effectiveness of this approach.

More pragmatic verification efforts are not limited to TLA+; Amazon's S3 ShardStore service was recently augmented with *lightweight verification* [5] using reference models written in Rust, which are simplified instantiations of program components that can be used to track program state under different input conditions. Like CCF, the primary goals are usability, and the ability to ensure correctness as both the implementation and the spec evolve over time. Unlike the CCF approach however, state exploration is limited to what the test harness is able to reach.

10 Conclusion

This paper details our journey with smart casual verification of the distributed protocols in CCF using TLA$^+$. Our experience demonstrates that TLA$^+$ can be used in industrial settings to verify extensive and nuanced distributed protocols, and that the verification process can be integrated into the development workflow of a production codebase. We have seen that TLA$^+$ can be effectively utilized to find bugs in both the design and implementation of these protocols and to communicate understanding of complex and subtle distributed systems like CCF.

Abstract

Extended Berkeley Package Filter (eBPF) is a revolutionary technology that can safely and efficiently extend kernel capabilities. It has been widely used in networking, tracing, security, and more. However, existing eBPF verifiers impose strict constraints, often requiring repeated modifications to eBPF programs to pass verification. To enhance programmability, we introduce VEP, an annotation-guided eBPF program verification toolchain. VEP consists of three components: VEP-C, a verifier for annotated eBPF-C programs; VEP-compiler, a compiler targeting annotated eBPF bytecode; and VEP-eBPF, a lightweight bytecode-level proof checker. VEP allows users to verify the correctness of their programs with appropriate annotations, thus enabling full programmability. Our experimental results demonstrate that VEP addresses the limitations of existing verifiers, i.e. the Linux verifier and PREVAIL, and provides a more flexible and automated approach to kernel security.

1 Introduction

Recently, eBPF [15] has gained significant popularity as a versatile technique. This innovative technology enables users to load programs into the Linux kernel dynamically, proving to be highly advantageous across various domains, including networking [2, 6, 29, 34, 46, 49],tracing [4, 43], security [3, 23, 47], storage [7, 51, 52], and more. In contrast to traditional Linux kernel modules, eBPF programs offer enhanced stability, as each program undergoes a rigorous verification process before attachment to the kernel. This verifier meticulously screens programs for unsafe behaviors, such as infinite loops and out-of-bound memory access, thus preventing potential crashes.

Existing eBPF verifiers (e.g., the Linux verifier [19] and PREVAIL [26]) often compromise programmability for security, sometimes rejecting safe eBPF programs. The Linux verifier [19] uses *register value tracking* to simulate the execution paths but limits programmability by imposing constraints such as maximum program size and loop complexity to prevent path explosion. PREVAIL [26] addresses this issue using *abstract interpretation* to merge paths, allowing variable-sized loops in eBPF programs. However, when loops involve complex, dynamic behaviors—such as termination conditions dependent on runtime data—PREVAIL's analysis could become imprecise, leading to safe programs being incorrectly rejected.

The eBPF maintainers have acknowledged this issue and have developed methods to mitigate these restrictions on program size and loop complexity. Since kernel version 3.18, the Linux verifier has employed *pruning* to eliminate redundant code paths [18, 19]. Kernel version 5.2 raised the instruction limit from 4096 to 1 million, and version 5.3 added support for bounded loops [16]. In version 5.13, map iterators were introduced to allow iteration through map elements [17], as loops are always unrolled by the verifier, which can lead to excessive code lengths when iterating over large maps. However, map iterators require a function pointer, which, while suited for functional languages, is cumbersome in C. Despite all these ad-hoc features, some safe programs remain impossible to pass the Linux verifier.

State-of-the-art verification tools have the potential to achieve full programmability. We broadly categorize modern verification tools into three types based on their design approaches when dealing with intricate algorithms, complex program properties, and the need for

*These authors contributed equally to this work.
†Corresponding authors.

high levels of automation: (1) Fully automatic verifiers. CBMC [12], a bounded model checker, verifies array bounds, pointer safety, and other properties in C programs by unrolling loops a fixed number of times. Infer [10], a static analysis tool developed by Meta, automatically checks memory safety in mobile and server-side code. These tools can automatically handle millions of lines of source codes. But their users have to tolerate false positives and negatives, especially when verifying complex programs with intricate algorithms and data structures. (2) Verifiers based on interactive theorem provers. This method can verify complex programs, but it requires significant manual effort in developing machine-checkable *proof code*. VST [24], as a representative of this type of tool, verifies properties of programs in the theorem prover Coq [48] by requiring users to describe the desired properties and manually write proof code to complete the proof. This approach lacks automation, and the time and memory consumption can be significant [1]. (3) Annotation verifiers based on SMT solver. This approach relies heavily on the SMT solver. VeriFast [31] allows users to provide assertions within the program that describe relevant properties, which are then evaluated by the SMT solver for correctness. Similarly, Dafny [33] leverages the Z3 [8] SMT solver to automate the verification of annotated programs. Unfortunately, even powerful and industry-standard SMT solvers such as Z3 and cvc5 [5] still encounter numerous unsolvable or incorrectly solved problems. Moreover, these SMT solvers are often of considerable scale, requiring substantial amounts of time and memory. In short, it is possible for verification tools to verify complex programs without posing any limitation (i.e. achieve full programmability) but with an additional cost such as requiring users to write annotations. Meanwhile, the tools must make trade-offs among efficiency, resource consumption, and potential false negatives and false positives (see Table 1).

For eBPF verification, the verifier must operate within the kernel, necessitating high efficiency, minimal resource usage, and the absence of false negatives. These requirements imply several constraints: First, despite the advanced capabilities of modern SMT solvers, their overhead and risk of false results make them unsuitable for kernel verification. Second, most eBPF programs are compiled with unverified compilers such as LLVM or GCC. We aim to minimize our Trusted Computing Base (TCB), avoiding including such monolithic components. Finally, verification tools must be highly automated and user-friendly to encourage widespread adoption by eBPF developers in practical settings.

Inspired by these considerations, we propose **v**erification toolchain for **e**BPF **p**rograms (VEP) based on an annotation-guided verification approach. The VEP toolchain comprises a C-level verifier, an annotation-aware compiler, and a bytecode-level proof checker. First, verification is conducted on the annotated C programs. To ensure they are free of undefined behavior(UB) per the C standard and only use limited resources. This phase also generates additional annotations and proof terms for later bytecode-level verification. Next, the verified C program is transformed into an annotated bytecode program by an annotation-aware compiler. In this step, the code, the annotations, and the proof terms are all converted to the bytecode level. Finally, a bytecode proof checker re-evaluates the proofs and the annotated bytecode to ensure compliance with eBPF standards, thereby completing the verification process. Our two-stage verification framework distributes substantial time and memory overhead to user space, while the kernel space contains only a proof checker with minimal time and space requirements.

In summary, we have developed a verification tool VEP for annotated eBPF programs, which offers the following advantages:

1. VEP achieves full programmability for eBPF programs, going beyond memory safety to verify the functional correctness of eBPF programs.
2. In user space, the verifier is highly automatic.
3. In kernel space, the proof checker is secure and efficient with lower time and memory consumption.
4. Our TCB is small, which includes only the proof checker in kernel space, excluding the C verifier and the compiler.

The structure of this paper is as follows: In Section 2, we describe the design of VEP, including the general framework and underlying design principles. In particular, we explain the design necessity of the two-stage verification scheme. In Section 3, 4 and 5, we introduce the detailed design of the three components of VEP respectively. In Section 6, we show our experiments and the performance of the proposed method. Section 7 and 8 introduce our future works and make a conclusion.

2 Overall Architecture of VEP

In this section, we will introduce the overall design of VEP and discuss the design choices of the two-stage

[1]The resource requirements of theorem-prover-based tools, such as VST, vary with implementation. Tools built entirely on theorem provers such as Coq and Isabelle [40] tend to have high time and memory demands, while implementations in languages such as C or Python such as VST-A [53] can greatly reduce these costs.

Tool	Full Programability	Automation	Small TCB	Low Time/Memory Cost
CBMC/Infer	-	+++	- - -	+++
VST	+	- -	+++	depend on implementation
VeriFast	+	+	- - -	+

Table 1: Comparison of different verification tools.

verification framework.

2.1 Two-stage Verification

We have developed the verification tool VEP for annotated programs to achieve full programmability, enabling users to write any safe and valid program. Specifically, the VEP toolchain verifies whether an eBPF program (1) is free from aborting behaviors such as null-pointer dereferences and division by zero and (2) adheres to strict memory safety properties, including program-owned memory (e.g., stack, eBPF maps) and kernel-owned memory (e.g., pointers passed via helper functions or context structures).

VEP begins with a C-level verifier, VEP-C, which performs initial checks on user-annotated C programs. Developers can iteratively refine their code using VEP-C until it passes verification. In this process, VEP-C applies symbolic execution to compute the strongest postcondition for each program statement and leverages an SMT solver to derive assertions and generate corresponding proofs automatically. Here, postconditions define the conditions that must hold after executing a program segment, while preconditions specify the assumptions made before execution begins. Symbolic execution systematically computes the strongest postcondition based on the given preconditions, ensuring that the program adheres to its safety and resource constraints.

```
/*@ 0 ⩽ x < 100 */
x = x + 1;
/*@ 0 ⩽ x ⩽ 100 */
```

In this example, the precondition is $P \triangleq 0 \leqslant x < 100$, and the postcondition to be checked is $Q \triangleq 0 \leqslant x \leqslant 100$. We need to verify whether, after executing $c \triangleq$`x=x+1` under the condition P, the postcondition Q holds. The first step is to compute the *strongest* postcondition; that is, the best we can tell about the program state after executing c given the initial condition P. In this case, the strongest postcondition is $\exists x_0, x = x_0 + 1 \wedge 0 \leqslant x_0 < 100$, where intuitively x_0 represents the value of x before the increment operation. During symbolic execution, such computation of strongest postconditions has its logic foundation in Hoare logic rules [28, 41]. The time complexity of the strongest postcondition computation is approximately linear with assertion length. So in general, the time complexity of symbolic execution is approximately linear with the product of the program length and the average assertion length.

Next, we use an SMT solver to determine whether $\exists x_0, x = x_0 + 1 \wedge 0 \leqslant x_0 < 100$ implies $0 \leqslant x \leqslant 100$. Although this example is simple, determining the validity of assertion derivations can be complex in practice. In fact, the decision problem is undecidable in general. Fortunately, existing research on SMT solvers has shown that modern solvers can produce correct results in many practical cases. VEP's built-in SMT solver is required not only to verify whether the derivations hold but also to provide (cvc5-style) proofs. Each proof consists of a list of proof steps. Every proof step derives a new conclusion from known propositions (including assumptions and conclusions proved earlier). Formally, a proof step contains one proof rule name, the associated parameters t_i, the premises φ_i, the resulting conclusion ψ, and its side condition C.

$$\text{RULENAME} : \frac{\varphi_1, \ldots, \varphi_n \mid t_1, \ldots, t_m}{\psi} \text{ if } C$$

In the example of $(\exists x_0, x = x_0 + 1 \wedge 0 \leqslant x_0 < 100) \Rightarrow 0 \leqslant x \leqslant 100$, the VEP's built-in SMT solver produces a 'YES' with a 138-line proof. It means that the code has been successfully verified by VEP-C, with both the corresponding proof and strongest postcondition generated.

Computed strongest postconditions and SMT-generated proofs are inserted back into the original annotated program. The annotation-aware compiler (VEP-compiler) then compiles the elaborated C program into annotated eBPF bytecode. Unlike traditional compilers, relevant assertions and proofs will also undergo corresponding compilation passes.

Finally, VEP uses a bytecode-level proof checker (VEP-eBPF) to perform a final verification. VEP-eBPF similarly uses symbolic execution to compute the strongest postcondition for each statement and then checks the corresponding proofs to derive the assertions, but without requiring SMT solvers: it only checks the proofs based on basic logic rules, using a minimal proof

checker. If the verification passes, the user-written program has successfully undergone VEP's verification process. In the end, the eBPF program will be loaded in the kernel, and its execution is guaranteed to be safe. This security assurance is achieved solely by verifying that the programs and proofs checked by VEP-eBPF are consistent. Therefore, the entire TCB of VEP is effectively reduced to the lightweight proof checker, VEP-eBPF.

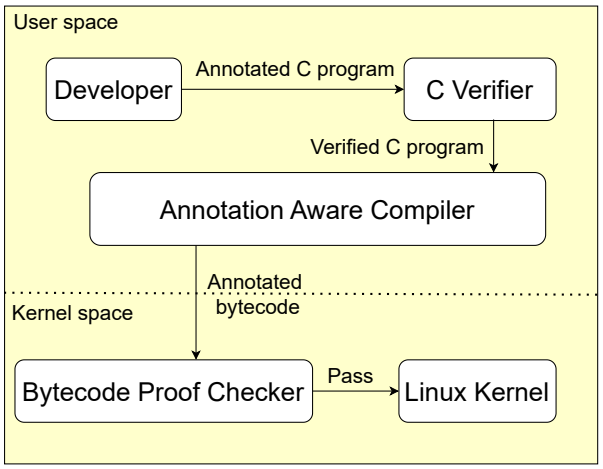

Figure 1: The framework of VEP.

All components of VEP were developed independently, without relying on existing tools. We aim for VEP to replace the current eBPF verification mechanism in Linux. Figure 1 shows the whole workflow of VEP. Our two-stage verification addressed the three requirements mentioned in Section 1.

- **Small and Efficient Kernel Integration.** Our two-stage verification process takes advantage of this by offloading complex SMT solver calls to VEP-C in user space while keeping a lightweight proof checker, VEP-eBPF, in kernel space. VEP-eBPF performs only straightforward logical deductions without complex SMT operations, ensuring the kernel component remains simple and efficient.
- **Minimal Final Trusted Computing Base (TCB).** The safety of loading eBPF programs depends solely on the correct implementation of VEP-eBPF. By isolating the critical verification logic in this small component, we minimize the TCB, thereby reducing risks associated with complex verification algorithms and enhancing overall reliability.
- **Highly Automated and User-Friendly.** While users must provide assertions to prove program safety, our approach leverages lessons from tools like VeriFast and VST by offering an annotation syntax that closely resembles C. This familiar syntax reduces the learning curve, making it easier for users to write and understand assertions.

2.2 Verification Capabilities

VEP is designed to verify critical properties of eBPF programs, ensuring they adhere to both safety and correctness guarantees. Here, safety refers to kernel safety, while correctness pertains to functional correctness verification—the assurance that program implementations precisely match their specified behaviors.

Safety Guarantees: Under the classification framework of KFlex [14], kernel safety consists of two core components: *kernel-interface compliance* and *extension correctness*. Since eBPF programs extend kernel functionality, *extension correctness* ensures safe memory accesses and guarantees program termination. Additionally, as eBPF programs often invoke kernel functions to perform specific tasks, *kernel-interface compliance* is equally critical. This requires that all kernel function calls are valid and that any resources acquired through these calls are properly released, preventing resource leaks.

VEP not only ensures *extension correctness* but also enforces *kernel-interface compliance*. VEP features an annotation language that enables users to formally specify program properties for verifying the following critical properties:

1. Enforcing memory access permissions for load/store operations and function calls.
2. Guaranteeing that all programs terminate within a finite number of steps.
3. Ensuring proper acquire-release ordering discipline for synchronization primitives (e.g., locks and semaphores).
4. Preventing resource leaks through comprehensive lifecycle tracking.

Correctness Guarantees: While the annotation requirements for functional correctness verification are indeed significantly more complex than those for safety verification, our annotation language has been specifically designed to facilitate the precise description of these complex properties. Since functional correctness verification fundamentally builds upon the foundation of safety verification, VEP enforces the requirement that all user-provided annotations must satisfy the four fundamental properties of safety guarantees. This ensures that verified programs maintain both safety guarantees and correctness guarantees throughout the verification process.

2.3 Discussion

In short, we believe an eBPF verifier should be powerful enough to reject unsafe programs and accept correct complex programs, and still be simple enough to be built in the kernel.

Why not use only the C verifier? In a single-phase C verification approach, users need to place a high level of trust in not only the C verifier but also the compiler. But even widely-used compilers such as GCC and LLVM continue to receive numerous bug reports daily. For instance, the LLVM bug tracker has numerous reports of bugs affecting various components of the compiler [22,50], such as the front end, the optimizer, and the code generator. These reports illustrate the necessity for users to trust the compiler while being aware of potential issues. Instead, we have a trustworthy bytecode verifier to ensure the final validation before loading, which is our only TCB.

Why not use only the bytecode verifier? Most importantly, if there is only one bytecode verifier, then it needs a strong SMT solver, which contradicts the simplicity goal of the whole verifier discussed above.

Second, the C verifier provides better computer-human interaction. An optimizing compiler may dramatically change the structure of a C program, making it impossible to convert verification results at the bytecode level back to the source level. If we only report failures at the bytecode level, users must understand how the whole toolchain works only to debug their code. Instead, the C verifier can directly generate C-level feedback, which is more understandable for developers.

A further reason is that writing an annotated bytecode program directly is challenging. Bytecode is very hard to comprehend, and thus it is even more difficult to write suitable assertions for it. Therefore, VEP provides a transformation from C assertions to bytecode assertions through an annotation-aware compiler, which enables users to write more readable assertions based on C code.

Unsafe C programs may be compiled to a safe bytecode program. Can such programs pass VEP? As the compiler is a black box for eBPF developers, we believe VEP should reject undefined behavior (UB) in C at the C verification level. For example, Figure 2 shows an unsafe eBPF program. Due to the insufficient space (size of 20) in *buffer* to store the information of comm, the Linux verifier rejects the function. However, a C program (shown in Figure 3) has out-of-bound array access. After being compiled into bytecode, that access may be a valid

```
1  int badhelpercall()
2  {   char buffer[1];
3      return bpf_get_current_comm(buffer, 20); }
```

Figure 2: Bad helper call A from PREVAIL benchmark.

```
1  int badhelpercall()
2  {   char buffer[1];
3      char buffer2[20];
4      return bpf_get_current_comm(buffer, 20); }
```

Figure 3: Bad helper call B from PREVAIL benchmark.

albeit unintended location, say, *buffer2*. The C standard does not require *buffer2* to be placed right after *buffer*. Compilers could choose to swap them for optimization. Advanced compilers may even detect this undefined behavior (UB) and aggressively exploit this fact by eliminating the whole C function. This program is accepted by version 5.10 of the Linux Kernel but is rejected by version 5.15. We believe that these programs need to be rejected as early as possible. VEP-C will reject all such programs at the C level. Even if such a program were to bypass VEP-C, VEP-eBPF would still reject it during bytecode verification due to the absence of required proofs generated from the C-level assertions.

How much additional efforts are needed for writing annotations? Typically, annotation-based verification tools require users to provide at least function specifications and loop invariants. For complex assertion derivations, users might also need to supply additional assertions to elaborate on the derivation steps. VEP offers some automation support for generating specifications and loop invariants, and we have found that, with this basic support, users can often complete program verification without *any* additional annotations. However, for complex programs, manual input is still required, particularly for verifying functional correctness.

If one manually modifies the generated annotated bytecode, is it possible to trick the VEP-eBPF checker and break the safety guarantee? Simply put: no. It is like you cannot modify the proof of $0 = 0$ to prove $0 = 1$.

In scenarios where a user modifies the annotated bytecode and/or its corresponding proofs, VEP-eBPF still meticulously verifies the alignment between them. If the modifications result in a correct match, meaning that the proof still validates the safety and correctness of the altered bytecode, VEP-eBPF will permit the bytecode to be loaded into the kernel. This ensures that even after modifications, as long as the integrity of the proofs is

maintained, the program remains secure and is considered safe for kernel execution.

Conversely, if a user alters the annotated bytecode and introduces incorrect or inconsistent proofs, VEP-eBPF will detect these discrepancies during the verification process. The proof checker is designed to ensure that only bytecode with valid, accurate proofs can be executed within the kernel. When erroneous proofs are encountered—those that fail to substantiate the safety or correctness of the bytecode—VEP-eBPF will reject the bytecode, preventing it from being loaded into the kernel.

How can we make sure that the pre/postconditions correctly describe the properties that we care? Regarding whether the modified code functions as the user intends, additional proofs related to functional correctness can be provided by the user to ensure this aspect. VEP-eBPF's primary focus is to guarantee that any code it approves is safe to execute. However, the tool will not automatically verify that the modified code behaves as desired; it will only ensure that the code can be safely run without introducing security vulnerabilities. Therefore, it is up to the user to include further assertions and proofs to confirm that the program's functionality aligns with their expectations.

2.4 Related Work

To the best of our knowledge, VEP is the first annotation-guided eBPF verification toolchain. In theory, for any correct eBPF program written by programmers, there exists a way to add annotations to pass VEP.

Most existing eBPF verifiers, including the Linux verifier [19], PREVAIL [26], etc., are automatic verifiers. Admittedly, automatic verifiers are easy to use. But in theory, checking whether an eBPF program can be safely executed and terminated is an undecidable problem. Indeed, both the Linux verifier and PREVAIL encounter problems when handling loops with complex data structures and may generate false positive results for certain eBPF programs, which limits eBPF programs from achieving full programmability.

We have identified ExoBPF [38] and Serval [37], which necessitate users to add specifications at the bytecode level. These tools conduct symbolic execution utilizing theorem provers and subsequently employ an SMT solver to resolve constraints. Specifically, ExoBPF utilizes Lean, while Serval leverages Rosette. Although these tools are indeed powerful, they require users to be familiar with eBPF bytecode and theorem provers to effectively write bytecode specifications.

Previous research in annotation-based verification has laid important theoretical foundations. Necula established a proof-carrying code (PCC) framework where code producers generate safety proofs that can be efficiently verified by the code consumer [35, 36]. While these PCC concepts have inspired later verification systems, existing annotation-based tools like Vale [9] and Ironclad Apps [27] demonstrate limitations when adapted for eBPF verification. Vale leverages Dafny's Z3-based verification to analyze annotated assembly code for cryptographic implementations, while Ironclad Apps streamlined Z3's capabilities for OS-level verification. Though effective for assembly code verification in specific domains, these approaches impose substantial learning overhead for eBPF developers who must reason about low-level memory semantics and instruction sets. Our methodology builds upon PCC's foundational principles but shifts the verification abstraction layer - rather than requiring assembly-level annotations or specialized proof generators, we enable developers to annotate directly at the C source level. This creates an end-to-end verification chain from high-level semantics to eBPF bytecode, crucially mediated by a lightweight verification engine optimized for kernel integration.

3 Detailed Design of VEP-C

VEP-C is an annotation-based verifier for annotated C programs, implemented based on traditional ***symbolic execution*** algorithm with an ***entailment solver*** to check the validity of the verification conditions. It uses separation logic assertions to represent program states and performs symbolic execution. The entailment solver is based on a separation logic elimination solver and an SMT solver. During the verification process, it generates proofs for assertion derivations. In this section, we will detail the design of VEP-C, focusing on the assertion syntax, the symbolic execution process, and the verified program.

3.1 Verification Process of VEP-C

Throughout this subsection, we use the annotated program *memset* in Figure 4 as an example[2]. In this example, we intentionally write "`i = 0; for (; i < n;) { ...; i ++ }`" (respectively in line 5, 8, and 19) rather than the commonly used "`for (i = 0; i < n; ++ i) { ... }`" to illustrate the verification steps more conveniently. This is not a requirement or restriction in realistic

[2]To facilitate the reader's understanding, we present a version of the annotated program that leans more towards functional correctness. Assertions in actual code are more straightforward.

verification tools.

```
1  void memset(char *p1, __u32 n, char v)
2  /*@ With l1
3      Require chars(p1,n,l1)
4      Ensure ∃ l2, chars(p1,n,l2) */
5  { __u32 i = 0;
6   /*@ i == 0 && chars(p1,n,l1) */
7   /*@ Inv: ∃ l2, 0 ⩽ i ⩽ n && chars(p1,n,l2) */
8   for (; i < n; ) {
9   /*@ ∃ l2, 0 ⩽ i < n && chars(p1,n,l2) */
10  p1[i] = v;
11  /*@ ∃ l3 l2, 0 ⩽ i < n &&
12        l3[0:i] == l2[0:i] &&
13        l3[i] == v &&
14        l3[i+1:n] == l2[i+1:n] &&
15        chars(p1,n,l3) */
16  i++;
17  /*@ ∃ l3 l2, 0 ⩽ i - 1 < n &&
18        l3[0:i-1] == l2[0:i-1] &&
19        l3[i-1] == v &&
20        l3[i:n] == l2[i:n] &&
21        chars(p1,n,l3) */ }
22  /*@ ∃ l2, i == n && chars(p1,n,l2) */
23  return ; }
```

Figure 4: Annotated memset.

Line 2-4*:* In the beginning, the user needs to provide a function specification, which indicates the condition that the arguments together with the initial program state need to satisfy when entering the function and the condition that needs to be satisfied when exiting the function. A function specification consists of a **With** clause, a **Require** clause, and an **Ensure** clause. The **Require** clause indicates the function precondition; the **Ensure** clause indicates the function postcondition; and the **With** clause indicates the list of logical variables mentioned in precondition which will be used in the whole program assertions. In this example, the precondition is `chars(p1, n, l1)` (line 3), which indicates that `p1` is an array of length `n`, with its data `l1` being a list of characters. The postcondition provided in line 4 specifies that the array stored at `p1` will be modified to a new character list `l2`.

Line 5-6*:* To verify the program in Figure 4, VEP-C initiates symbolic execution based on the preconditions of the function. For instance, after processing the variable declaration and initialization at line 5, the strongest postcondition in line 6 is computed. In this example, assertions generated through symbolic execution are highlighted in red, distinguishing themselves from the assertions provided by the user, which are displayed in blue.

Line 7-22*:* Before entering the loop, the user needs to provide a loop invariant, which indicates the property that the program state needs to satisfy at the beginning and end of each loop iteration. VEP-C will check whether the assertion before entering the function (lines 6) implies the loop invariant (line 7). If the above check passes, VEP-C will continue to symbolically execute the loop condition testing from the loop invariant. Thus, in its strongest postcondition (line 9), an additional proposition $i < n$ is added, comparing to the `Inv`. Moreover, symbolic execution will generate the strongest postcondition of the assignment statement (lines 11-15), and the strongest postcondition of the incremental step (lines 17-21). VEP-C will check whether the assertion entails the loop invariant `Inv`. The check is successful, thereby proving the correctness of the loop invariant. Subsequently, we can derive the strongest postcondition at the end of the loop, which is the strongest postcondition of `Inv` when the loop condition evaluates to false (line 22).

Line 23*:* Finally, we perform symbolic execution on the return statement. Unlike other statements, the return statement requires the calculation of the return value (although there is no return value in this example), followed by the deallocation of all declared local variables and corresponding updates of the assertions. In this case, the variable `i` is deallocated, and the assertion is updated accordingly into `∃ l2, chars(p1,n,l2)`. The final step is to check whether the updated assertion implies the postcondition of the function. The proof here is straightforward, thus completing the verification of this example.

3.2 Assertion Language of VEP-C

In the example of Figure 4, we used first-order logic to describe program states. For some C programs, such assertions are sufficient to capture time costs and the changes made to memory. However, most programs manipulate more than one data structure (array, linked list, tree, etc). These data structures are stored in disjoint memory locations and such disjointness is critical in verification. For example, the C standard says that *strncpy* copies strings from source to destination, while the source and destination memory space are disjoint [30, Section 7.24.2.4]. Therefore, some naive specification like the one in Figure 5 does not correctly describes strncpy's behavior.

```
1  void strncpy (char *p1, char *p2, __u32 n)
2  /*@ With l1 l2
3      Require chars(p1,n,l1) && chars(p2,n,l2)
4      Ensure chars(p1,n,l2) && chars(p2,n,l2) */;
```

Figure 5: A naive strncpy specification.

This specification appears to be very concise, but it overlooks a critical issue: whether the two arrays, `p1` and `p2`, overlap. If there is an overlap, the behavior of the program could differ significantly, leading to potential unintended side effects that are not accounted for by this

simple specification. Therefore, merely using first-order logic is insufficient to meet our needs.

State-of-the-art research has provided us with new insights, particularly through the introduction of separation logic into assertions. Tools such as VST, VeriFast, and Hip/Sleek [39] have demonstrated that using separation logic is an effective method for clearly describing properties and facilitating symbolic execution, especially in proofs related to memory properties.

Separation logic [41] uses a new connective *separating conjunction* to ensure that different names duplicate no identical addresses. The separating conjunction $P * Q$ represents the existence of two disjoint portions of the state, one that satisfies P and one that satisfies Q. Specifically,

$$m \models P * Q \Leftrightarrow \exists m_1, m_2 . m = m_1 \uplus m_2 \wedge m_1 \models P \wedge m_2 \models Q.$$

Here $\uplus$ means the disjoint union[3] and $m \models P$ means m satisfies P. A distinction between $*$ and boolean conjunction && is that $P * P \neq P$ where $P \&\& P = P$. In particular, if $\mathbf{store}(p, v)$ means that the value v is stored at address p, $\mathbf{store}(p, v) * \mathbf{store}(q, u)$ implies $p \neq q$, and thus $\mathbf{store}(p, v) * \mathbf{store}(p, v)$ is always false: there is no way to divide a heap that a cell p goes to both partitions.

Separation logic predicates can also be used to represent kernel resources [13,41], like semaphores and locks. Intuitively, when a helper function is used to gain a piece of resource, the corresponding predicate will be added to the assertion. When a helper function is used to release a piece of resource, the predicate are required to appear beforehand (which will be checked by VEP) and will then be removed. In separation logic, those resources act like memory. We show an example in Appendix E.

VEP-C uses separation-logic assertions in the canonical form of a symbolic heap. A symbolic heap is in the form $\exists \overrightarrow{x}.(P_1 \wedge \cdots \wedge P_n \wedge Q_1 * \cdots * Q_m)$, where the pure part P describes memory-irrelevant properties between terms (e.g. `e1`, `e2`), and the spatial part Q is a separating conjunction of spatial predicates. For example, `e1==e2` and `e1>e2` can appear as memory-irrelevant conjuncts; the empty heap predicate `emp` and the points-to predicate `store(e1,e2)` can appear as spatial conjuncts. Additionally, users can define their own predicates according to their specific needs. For example, a user can define a string array predicate such as `chars(a,e1,e2)`.

With the help of separation logic, we can write the specification shown in Figure 6, which describes the scenario stipulated by the C standard where `p1` and `p2` do not overlap in memory.

[3] $A \uplus B = A \cup B$ if $A \cap B = \varnothing$, Otherwise, $A \uplus B$ is undefined. For example, $\{1,2,3,5\} = \{1,3\} \uplus \{2,5\}$, but $\{1,3\} \uplus \{1,2\}$ is undefined.

```
1  void strncpy (char *p1, char *p2, __u32 n)
2  /*@ With l1 l2
3      Require chars(p1,n,l1) * chars(p2,n,l2)
4      Ensure ∃ l3,
5              chars(p1,n,l3) * chars(p2,n,l2) */;
```

Figure 6: A correct strncpy specification.

Traditionally, these terms (`e1`, `e2`, etc) above in pure parts and spatial parts should be memory-irrelevant expressions. For example, if `x` is a C variable of a struct type, then `&(x.tail)` is a memory-irrelevant expression, because computing its value does not include a load from memory. Many verification tools use this setting internally because this assertion language prevents a lot of ambiguity. For example, it may be unclear whether the predicate `store(*x, 0)` only claims the memory permission at address `*x`, or it claims the memory permission at addresses `*x` and `x` – if we take the address of storing variable `x` into consideration, it becomes even more complicated. VEP-C extends traditional symbolic heap and allows users to use memory-related expressions, which makes assertions more concise. VEP-C automatically transforms the expression to the traditional symbolic heap. In this way, users avoid a large portion of boilerplate[4]. For example, VEP-C allows users to write `*y==x→tail`, which is equivalent to:

```
∃ v yp,
store((field_addr(x,tail),v) *
store(y, yp) * store(yp, v)
```

Through the application of separation logic assertions, users gain the capability to formally specify function properties while simultaneously verifying both the fundamental safety guarantees (Properties 1 and 2 as detailed in Section 2.2) and comprehensive functional correctness properties within a unified verification framework.

Verification when helper functions involve in The acquisition and release of kernel resources of eBPF programs relies on helper functions, making the symbolic execution of helper function calls a critical component in the verification process. The VEP framework incorporates predefined specifications for most helper functions, formally characterizing their interactions with memory subsystems and kernel resource management. These specifications are derived from eBPF's official documentation [1]. Figure 7 presents the specifications for `bpf_sk_lookup_udp` and `bpf_sk_release`, while Figure 8 illustrates the symbolic execution behaviors of these two helper functions. The complete program is provided

[4] The detailed syntax and transformation algorithm can be found in Appendix A and B.

in Appendix E.

```
struct bpf_sock * bpf_sk_lookup_udp
    (void *ctx, struct bpf_sock_tuple *tuple,
     __u32 tuple_size, __u64 netns, __u64 flags)
/*@ xdp_version
    Require flags == 0 &&
      valid_size(tuple_size, tuple) &&
      store_xdp(ctx) * store_sock_tuple(tuple)
    Ensure store_sock(__return) * store_xdp(ctx) *
      store_sock_tuple(tuple) */;
```

```
int bpf_sk_release (void * sock)
/*@ sock_version
    Require sock != NULL && store_sock(sock)
    Ensure ∃ v, __return == v */;
```

Figure 7: The specification of `bpf_sk_lookup_udp` and `bpf_sk_release`

In Figure 7, the `valid_size` predicate ensures that the value of `tuple_size` correctly corresponds to `tuple`. Specifically, if `tuple` represents an IPv4 socket, then `tuple_size` must be `sizeof(tuple→ipv4)`, and similarly for IPv6. The `store_sock(sk)` predicate ensures that if `sk` is a null pointer, it corresponds to an empty memory region. Otherwise, if `sk` is non-null, it provides access to a valid socket. This definition guarantees that memory operations on `sk` can only be performed after checking whether `sk` is null.

```
1  /*[auto generated pre]
2      ipv4(tuple) && store_xdp(ctx) *
3      store_sock_tuple(tup) */
4  sk = bpf_sk_lookup_udp(ctx, &tup,
5          sizeof(tup.ipv4), 0, 0);
6  /*[auto generated]
7      store_xdp(ctx) * store_sock_tuple(tup) *
8      store_sock(sk) */
9  ...
10 /*[auto generated pre]
11     sk != NULL && store_xdp(ctx) *
12     store_sock_tuple(tup) * store_sock(sk) */
13 bpf_sk_release(sk);
14 /*[auto generated]
15     store_xdp(ctx) * store_sock_tuple(tup) */
```

Figure 8: The symbolic execution result of `bpf_sk_lookup_udp` and `bpf_sk_release`

In Figure 8, we assume that `tup` is an IPv4 socket before the helper function call in line 4. Therefore, the function call on line 4 satisfies the function specification of `xdp_version`, allowing us to obtain a `store_sock(sk)`. When execution reaches line 12, we know that `sk` is non-null. Consequently, the function call on line 12 satisfies the function specification of `sock_version`, enabling us to properly reclaim the allocated socket memory.

By leveraging these built-in helper function specifications, VEP automatically enforces the verification of safety guarantee Properties 3 and 4 (as specified in Section 2.2) during symbolic execution. The full list of helper function specifications can be found in our GitHub repository.

3.3 Output of VEP-C

After the symbolic execution and entailment solver processes, VEP-C completes the verification of the input program. Based on the verification process, VEP-C generates a verified C program, which is then passed to the VEP-compiler to be compiled into bytecode. Figure 9 illustrates the verified C program corresponding to the program in Figure 4. Due to space constraints, we have omitted the specific assertions and proof content.

```
1  void memset(char *p1, __u32 n, char v)
2  /*@ With l1
3      Require chars(p1,n,l1)
4      Ensure chars(p1,n,repeat(v,n)) */
5  { __u32 i = 0;
6   /*@ Assertion\_1 with Proof\_1 */
7   /*@ Inv with Proof\_2 and Proof\_6 */
8   for (; i < n; ) {
9   /*@ Assertion\_2 with Proof\_3 */
10  p1[i] = v;
11  /*@ Assertion\_3 with Proof\_4 */
12  i++;
13  /*@ Assertion\_4 with Proof\_5 */ }
14  /*@ Assertion\_5 with Proof\_7 */
15  return ; /*@ Proof\_8 */ }
```

Figure 9: Verified memset.

In this example, `Proof_1`, `Proof_3`, `Proof_4`, `Proof_5`, and `Proof_7` pertain to the verification of various safety checks during symbolic execution. These include range checks for array writes, as well as checks to ensure that there are no undefined behaviors during assignments. `Proof_2` and `Proof_6` are associated with the verification of the validity of loop invariants. `Proof_8` ensures that the function postcondition is satisfied upon completion of the function.

4 Detailed Design of VEP-compiler

An annotated C program undergoes several compilation passes before being converted into an annotated eBPF bytecode. While most of these passes are standard, modifications to assertions and proofs are necessary throughout the process. It's worth noting that the VEP-compiler contains only a few optimization passes at present, primarily for simplicity, which may not generate the most efficient bytecode. How to incorporate additional compilation optimizations while ensuring accurate transformation of assertions and proofs is a future work.

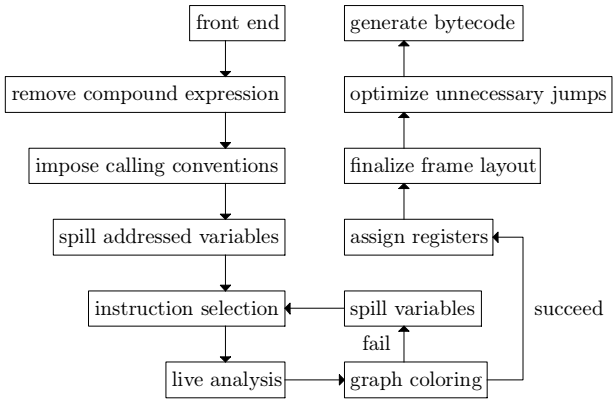

Figure 10: The nanopass-style compilation process

```
//@ ∃ v, store((field_addr(x,tail),v)
                ⇓ compile
        //@ ∃ v, store(x + 8,v)
```

Figure 11: IR Generation example

Figure 10 shows the whole compilation process. Every pass has a single simple and clear purpose, as in the nanopass framework [44]. We discuss the transformation during relevant passes in the rest of this section.

4.1 IR Generation

In our intermediate representation, we replace structure-member access by dereferencing the address of the structure plus the offset of the member. We do the same for assertions, as illustrated in Figure 11.

4.2 Calling Conventions

The BPF calling convention is defined as follows.

1. `R0` stores the return value.
2. `R1` to `R5` are used to pass arguments.
3. `R6` to `R9` are callee saved. Others are caller-saved.

All the helper functions obey the suggested calling convention. We adopt the same convention in compiling in-program functions, so the compiler modifies function specifications to reflect the calling convention as follows.

1. Return value `__return` is replaced by `R0`.
2. Function parameters are replaced by `R1` to `R5`.
3. State that `R6` to `R9` are preserved.

The generated code saves used callee-saved registers on the stack at the beginning of a procedure and restores them before returning. To convince the symbolic executor that callee-saved registers are indeed unchanged, we also modify each assertion in the procedure. They state that certain portions of the stack contain the original values of callee-saved registers.

```
strncpy:
/*@ With l1 l2 _R1 _R2 _R3 _R6 _R7 _R8 _R9
    Require
      _R1 == R1 &&
      _R2 == R2 &&
      _R3 == R3 &&
      _R6 == R6 && _R7 == R7 &&
      _R8 == R8 && _R9 == R9 &&
      chars(R1, R3, l1) * chars(R2, R3, l2)
    Ensure
      _R6 == R6 && _R7 == R7 &&
      _R8 == R8 && _R9 == R9 &&
      chars(_R1,_R3,l2) * chars(_R2,_R3,l2) */
```

Figure 12: Transformation of the function specification for strncpy. `p1`, `p2`, `n` and `__return` are replaced by `R1`, `R2`, `R3`, and `R0`, respectively.

Figure 12 shows the specification in Figure 5 produced by this pass. Besides the substitution defined previously, the compiler introduces auxiliary logic variables `_Ri`-s to relate the register values at function entry and those at the return point.

4.3 Register Allocation

We adopt a standard "iterated register coalescing" algorithm [25]. Most of the time, simply substituting variables in assertions with their corresponding registers (or their location on the stack, if it is spilled) is enough. The only exception is when the variable is not live (the value of the variable is not used later) at that point. In that case, the register does not necessarily hold the value of the variable: maybe another variable is using it. To make the assertion valid while retaining information, the variable should be substituted by an existentially quantified logic variable. Figure 13 shows a complete example. The third line in the source code takes the address of `x`, so `x` is spilled to the stack. `p` and `q` are assigned to the same register `R1` because they are unused.

In annotated code, register allocation can sometimes yield interesting results. Figure 14 shows one example.

In the previous example, the C code clearly fails VEP-C verification, but the compiler generates valid eBPF bytecode for it. This is due to liveness analysis determining that the value of x is not live at that point. We believe rejecting such code at the VEP-C level is reasonable and does not compromise programmability. Even if one only uses VEP-compiler and VEP-eBPF, he/she can still trust the safety of the C code, because (1) the precondition is unchanged, and (2) propositions related to resources (time, memory) are unaffected.

```
int x, y, *p, *q;
x = 0; y = 1;
p = &x; q = 0;
//@ y == x + 1 && p != q
return y;
```

⇓ compile

```
*(R10 - 4) = 0
R0 = 1
R1 = R10
R1 -= 4
R1 = 0 // p and q are not used
/*@ R1 == *(R10-4) + 1 &&
    ∃ _p _q, _p != _q */
ret
```

Figure 13: An assertion after register allocation.

```
int x = 0;          R0 = 0
//@ x == 1    ⇒     //@ ∃ _x, _x == 1
return;             ret
```

Figure 14: Example of register allocation.

4.4 Frame Layout

In annotated C programs, a variable is available after we declare it. But in bytecode, there are no such declarations. So the frame—which contains spilled scalar variables, structures, and so on—should be specified in the precondition so that the symbolic executor knows which addresses are valid. Knowing how much stack space a procedure consumes is also necessary to verify that the whole program does not exceed the stack space limit.

Figure 15 shows a complete example. In the example, we assume the compiler places `l` at `R10-16`. Consequently, `R10-16` stores an integer, and `R10-8` stores a pointer to a `struct list`. The underscores indicate that their actual values are not needed.

5 Detailed Design of VEP-eBPF and Proof Check

VEP-eBPF processes the annotated bytecode produced by the VEP-compiler and performs symbolic execution. During this execution, when it encounters assertion entailment or safety checks typically requiring an entailment solver, VEP-eBPF distinguishes itself from VEP-C by not invoking an SMT solver. Instead, it verifies whether the proofs, generated by the SMT solver and transformed by the VEP-compiler, correctly establish the required entailments. If all entailments can be validated through their corresponding proofs, it indicates that the bytecode is safe, allowing the program to be loaded into the kernel.

VEP-eBPF's proof language is designed to include

```
struct list {
  int x;
  struct list *next;
};
int f()
/*@ Require emp
   Ensure __return == 0 */
{ struct list l;
  l.head = 0;
  return l.head; }
```

⇓ compile

```
f: /*@ Require
     *(R10-16) == _ *
     *(R10-8)  == _
   Ensure R0 == 0 */
...
```

Figure 15: A precondition decorated with frame information. Assume `l` is located at `R10-16`, then the compiler guarantees that `R10-16` stores an integer and `R10-8` stores a pointer to a `struct list`. The underscores indicate that they are uninitialized.

both spatial parts derivation proofs and pure propositional parts derivation proofs. The spatial parts proofs are primarily syntactic transformations of the entailment using established separation logic properties. These properties have been formalized and proved within the Coq proof assistant, ensuring their correctness. On the other hand, the pure parts proofs are based on a proof language inspired by cvc5, a well-known SMT solver. In this process, no SMT solving is required. The spatial syntax transformation and pure proof checking are handled by highly efficient algorithms.

As a result, VEP-eBPF is an efficient, low-memory proof checker ideally suited for kernel-space deployment. The lightweight nature of these algorithms contributes to the overall performance, making VEP-eBPF a robust tool for verifying the safety of eBPF bytecode without the overhead of traditional SMT-based methods.

6 Evaluation

We evaluate the time cost, memory efficiency, and verification accuracy of VEP compared to the Linux verifier (Kernel 5.15) and PREVAIL (August 2024 version). Our benchmark selected a total of 41 programs across four categories of programs: Linux kernel samples, PREVAIL test cases, C standard library string functions, and unsafe programs with known vulnerabilities, such as out-of-bounds memory accesses and invalid function call. Detailed per-program results are provided in Appendix C (Tables 4 and 5), and all data is publicly available in our

GitHub repository[5].

6.1 Performance Analysis

The Linux verifier demonstrates superior stability with consistent sub-millisecond verification times (avg. 0.94 ms) and low memory consumption (<5.2 MB) across all benchmarks (Table 2). In contrast, VEP-eBPF achieves 3–5× faster verification than both PREVAIL (avg. 13.88 ms) and VEP-C (avg. 39.46 ms), while maintaining predictable memory usage of 2–3 MB – a 75% reduction compared to VEP-C's 8.5–32.6 MB footprint. This efficiency gain stems from our novel design choice discussed in Section 2.

6.2 Verification Accuracy

While all tools successfully reject 100% of unsafe programs (10/10 PR), critical deficiencies emerge in their handling of safe implementations. The Linux verifier demonstrates particularly severe limitations, accepting only 60% of safe programs (6/10 PR) with a 40% rejection rate - primarily stemming from inadequate loop verification (e.g., StringLib functions). PREVAIL exhibits even more erratic behavior, achieving wildly inconsistent acceptance rates from 10% (1/10 PR) on StringLib to 80% (8/10 PR) for its own test suite, a consequence of its SMT solver dependency introducing non-determinism.

This version-induced instability compounds the problem - 30% of PREVAIL samples and 20% Linux kernel programs that previously passed verification get rejected after updates, exposing fundamental flaws in their architectural design. Such brittleness severely undermines their reliability for production deployment.

In stark contrast, VEP achieves perfect verification outcomes across all benchmarks: 100% acceptance (10/10 PR) for properly annotated safe programs and 100% rejection of unsafe implementations. As long as the user provides correct annotations, VEP ensures there are no false positives and no false negatives. This deterministic behavior persists across kernel versions, demonstrating VEP's architectural superiority in balancing verification rigor with practical stability.

6.3 Annotation Efficiency

Tables 2 and 3 present the total lines of code, the number of user-written assertions, and the corresponding proof obligations generated by VEP. The comparison highlights that VEP requires a relatively modest number of assertions to verify programs effectively. For example, in the Linux samples with 618 lines of code, only 76 assertions were needed, resulting in 64,840 proof obligations. This indicates that a small number of high-level assertions can generate comprehensive proof coverage. Although the generated proofs are extensive, the verification process remains efficient because our proof checker is highly lightweight, ensuring minimal verification time.

Regarding the effort required to write annotated programs, we observe that adding annotations does not demand extensive modifications to the original code. Most assertions involve standard properties such as memory safety, resource bounds, and function preconditions, which can be specified with basic knowledge of program verification concepts. The expertise required is comparable to writing simple function contracts or preconditions in languages with contract support.

Furthermore, VEP supports the generation of specifications for several functions through lightweight methods, reducing manual effort. As VEP evolves, we aim to automate more of the assertion generation process, further minimizing the manual effort required and lowering the expertise barrier for new users.

6.4 Case Study : Key_Connection

The *Key_Connection* example (last row in Tables 2-3) demonstrates VEP's ability to verify non-eBPF network functions – specifically, an L7 filter mapping string keys to backend servers. Detailed code and the annotations for this example can be found in Appendix D. For this program, VEP generates 350 lines of annotated bytecode and 5,800 lines of proof.

This capability addresses critical limitations in current eBPF frameworks like Cilium [11], which must offload complex L7 logic to external proxies (Envoy [21]) due to verification challenges. By enabling verifiable L7 processing, VEP could eliminate proxy dependencies while maintaining safety guarantees.

7 Future Work

In advancing eBPF program verification, several critical areas offer promising research opportunities. This section outlines key directions for future work designed to enhance and expand the capabilities of our verification framework, aiming to make it more robust and applicable to real-world scenarios.

Table 3: Evaluation results for VEP. 'PR' refers to the acceptance rate for safe programs and the rejection rate for unsafe programs.

Towards Functional Correctness As our demands for programs increase, memory safety alone no longer meets our development requirements. We aim to go further by supporting the verification of the functional correctness of eBPF programs. From this perspective, VEP needs to enable users to directly write proofs within C annotations or provide an interface to incorporate external proofs.

Towards Less Annotations Given that VEP currently requires users to provide necessary C annotations, including function preconditions, postconditions, and loop invariants, we aim to introduce additional tools to automate the generation of these annotations and reduce the user's burden. Traditional verification tools [20, 32] have already made progress in this area, and recent advancements have been achieved by integrating large language models [42, 45]. In the future, VEP will be able to adopt similar approaches to automate the generation of some annotations, thereby minimizing the user's workload.

Towards Compilation Optimization Advanced optimization passes may dramatically change the control flow and data flow of a program, and assertion annotations should be modified accordingly. In our current compiler, one such compilation pass is register allocation, in which multiple variables may be represented by one register (as long as their lifetime does not overlap) — we translate all these variables to the register in assertions. In the future, optimization passes may be added to eliminate some redundant instructions or redundant variables. Then, corresponding algorithms need to be designed to compile assertion annotations.

8 Conclusion

Since its proposal, eBPF is widely used in various domains while its verification often comes with a trade-off between safety and programmability. In this paper, we propose a two-stage automatic formal framework that addresses this issue between verification and programmability. It empowers eBPF developers to write annotations regarding the memory to guide automatic verification. As far as we are concerned, this is the first approach that could verify the safety and resource constraints of eBPF programs without compromising programmability. Specifically, a safe eBPF program can always pass VEP's check, provided that it includes sufficient annotations.

Based on this, we implement a prototype toolchain VEP. Our evaluation further demonstrates that VEP can verify the safety of complex programs with moderate overhead, which highlights the potential of the two-stage framework as a practical solution for kernel security. We believe this will enable eBPF to support more flexible and powerful programs across a wider range of domains.

A Syntax of VEP-C Assertions

In this section, we discuss the syntax of VEP-C assertions, which are divided into two main categories: user assertions and internal assertions. User assertions enable developers to annotate C code with specific directives, whereas internal assertions support the tool's symbolic execution and reasoning processes.

A.1 Syntax of User Assertions

The primary design principle of user assertions is to align as closely as possible with the habits of C programmers, while also ensuring sufficient expressiveness for formal reasoning at the logical level. We begin by defining the expressions used in user assertions, followed by an explanation of how to construct a complete assertion. Lastly, we will discuss the structure of function specifications within this framework.

The expressions are inductively defined in Figure 16. The only thing unfamiliar is custom functions. They are functions in the *logic* world. For example, we provide a built-in function `rev`(l) that reverses a list (a list of values, not a data structure in C).

A user assertion can consist of several branches, each of which is divided into a section that describes pure facts and another that describes memory aspects. The syntax tree is defined in Figure 17. The semantics of user assertions is a little different from textbook separation logics, because of its HCI nature. To convince yourself that our transformation explained later makes sense, imagine we normalize every memory-related expression to a form $*l$. We assume two ls are different simply by their syntax. Then, each proposition—whether pure or spatial—describes such memory locations in addition to their spatial part, if any. When they are connected through conjunction `&&` or separating conjunction `*`, we union these locations; when connected through `||`, we keep them local to each case.

Just like custom functions, users can introduce custom predicates. For example, our built-in predicate `Ebpf_map`(m) denotes that an eBPF map is stored at a location m.

A function specification consists of three parts: logical variable list (**With** clause), precondition (**Require** clause), and postcondition (**Ensure** clause).

With clause. An implicit "∀" around the specification. They are sometimes essential to relate the program state at the function exit point to the one at the function entry. They can even appear in annotations inside the function so that developers have convenient access to the initial state. In general, their values should be "determinable" from the precondition.

Require clause. The precondition describes properties that the program state at function entry should satisfy.

Ensure clause. The postcondition describes properties that the program states when the function exits should satisfy. We use the keyword `__return` to refer to the return value, if any.

The syntax of function specifications is formally defined in Figure 18:

A.2 Syntax of Internal Assertions

We use a canonical form of assertions, internal assertions, actual symbolic execution, constraint solving, and everything. They have a simpler structure and clearer semantics (paradoxically, user-friendly assertions have *complex* semantics). Each internal assertion consists of several branches; each of which includes four parts: **Exist**, **Local**, **Prop**, and **Sep**. **Exist** is a list of existential variables, either explicitly written by developers or automatically generated during transformation (explained later). **Local** describes the relations between program variables and the logic world. For example, in C, `&`$v = e$ means that the address of the program variable v is expression e; in eBPF bytecode, $r = e$ means the register r stores value e. **Prop** stores pure facts. **Sep** stores memory-related facts. The syntax of internal assertions is defined in Figure 19.

We will use an example to clearly illustrate the distinction between user assertions and internal assertions. Consider the following annotation in a C program:

```
exists v, y = &x && x == 2 * v &&
          forall n, v != n * n
```

An equivalent internal assertion looks like this:

```
Ex    : v vx vy
Local : &x = px,  &y = py
Prop  : vy == px && vx == 2 * v &&
        forall n, n != n * n
Sep   : store(px, int, vx)
      * store(py, int, vy)
```

In this example, the user assertion describes an integer variable x, whose value is an even number that is not a perfect square; y is a pointer to x. The internal assertion introduces two new existential variables vx and vy to represent the current values of the program variables x

Expression	e	::=	$z \in \mathbb{Z}_{64}$	integer literal

and y, respectively. It is more structured and facilitates symbolic execution more conveniently.

B Transformation To Internal Assertion

In this section, we show how user assertions are transformed into internal assertions.

B.1 Step 1: Normalization

This phase puts an assertion in a sort of disjunctive normal form (DNF). Such a normal form is defined in Figure 20. The normalization procedure is described in Figure 21.

B.2 Step 2: Convert Expressions

In this phase, we convert expressions in user assertions to expressions in internal assertions, at the same time generating auxiliary **Local** and **Sep**. The procedure is defined in Figure 22. The judgement $\mathcal{V}(e,L,S,x) = (e',L',S',x')$ means that under context L,S,x, the value of e is e' and the context is updated to L',S',x'. $\mathcal{A}$ is similar, computing addresses (if valid) instead of values. The conversion is naturally extended to pure propositions $\mathcal{T}(P)$ and spatial propositions $\mathcal{T}(B)$, replacing each expression e in them with $\mathcal{V}(e)$, which we omit here.

B.3 Step 3: Sanity Check

Our pure propositions P can contain spatial expressions, so they are not really pure. Consequently, some user assertions cannot be transformed into internal ones. For example, the following user assertion is invalid.

$$\texttt{forall}\ i,\ 0 <= i \ \&\&\ i < 4 => a[i] == 0$$

A simple scope checking on internal assertions is enough to exclude such invalid cases. That is, every logic variable appearing in S should be bound by existential variables introduced in `exists` x,S.

C Full Evaulations

Full test results of previous work and VEP are shown in Table 4 and Table 5, respectively.

D Case Study : Key_connection

Figure 23 presents the complete Key_connection program, though only the assertions used to verify memory safety are shown here. In this program, `connt→conn_list` is a linked list of servers to connect to. To describe the memory structure related to this linked list, we introduce two predicates: `ConnListrep` and `ConnListseg`. These predicates are defined as follows:

```
ConnListrep(x) := x == 0 && emp ||
    ∃ n l num mark_v length,
      0 ⩽ n && n < 128 && l[n] == 0 &&
      x → num_packet == num &&
      x → mark == mark_v &&
      x → lengthsofar == length &&
      store_char_array(&(x→key), 128, l) *
      ConnListrep(x → next)

ConnListseg(x,y) := x == y && emp ||
    ∃ n l num mark_v length,
      0 ⩽ n && n < 128 && l[n] == 0 &&
      x → num_packet == num &&
      x → mark == mark_v &&
      x → lengthsofar == length &&
      store_char_array(&(x→key), 128, l) *
      ConnListseg(x → next, y)
```

In this definition, `store_char_array` corresponds to `chars` in Figure 4, representing a character array. This is purely a recursive definition describing the server list.

E Case Study : Acquire/Release example

Figure 24 presents an example that uses helper functions for acquiring and releasing resources. In this example, line 13 invokes the helper function `bpf_sk_lookup_udp` to obtain a socket. The success of this operation is checked at line 17, and if successful, the socket is released at line 19 using the helper function `bpf_sk_release`. As a result, this program maintains kernel-interface compliance level safety.

In this example, the user only needs to provide the annotations in lines 3 to 5 to successfully verify the program. VEP automatically generates the assertions in lines 13-15 and 19-20. Suppose the user omits the null check for sk at line 16 and directly returns. In that case, VEP will report an error due to the presence of an unverified

$$norm(P) = P \qquad norm(p(e_1,\ldots,e_n)) = p(e_1,\ldots,e_n) \qquad \frac{norm(S) = \exists\overrightarrow{x_1}.P_1 \,\&\&\, \overrightarrow{B_1},\ldots,\exists\overrightarrow{x_n}.P_n \,\&\&\, \overrightarrow{B_n}}{norm(\exists x,S) = \exists\overrightarrow{x,x_1}.P_1 \,\&\&\, \overrightarrow{B_1},\ldots,\exists\overrightarrow{x,x_n}.P_n \,\&\&\, \overrightarrow{B_n}}$$

$$\frac{norm(S) = \exists\overrightarrow{x_1}.P_1 \,\&\&\, \overrightarrow{B_1},\ldots,\exists\overrightarrow{x_n}.P_n \,\&\&\, \overrightarrow{B_n}}{norm(P \;\&\&\; S) = \exists\overrightarrow{x_1}.(P \,\&\&\, P_1) \,\&\&\, \overrightarrow{B_1},\ldots,\exists\overrightarrow{x_n}.(P \,\&\&\, P_n) \,\&\&\, \overrightarrow{B_n}} \qquad \frac{norm(S_1) = \overrightarrow{H_1} \qquad norm(S_2) = \overrightarrow{H_2}}{norm(S_1 \;||\; S_2) = \overrightarrow{H_1 H_2}}$$

$$\frac{norm(S_1) = H_1,\ldots,H_n \qquad norm(S_2) = G_1,\ldots,G_m}{norm(S_1 \;*\; S_2) = merge(H_1,G_1),\ldots,merge(H_1,G_m),\ldots,merge(H_n,G_m)}$$

$$merge(\exists\overrightarrow{x_1}.P_1 \,\&\&\, \overrightarrow{B_1}, \exists\overrightarrow{x_2}.P_2 \,\&\&\, \overrightarrow{B_2}) = \exists\overrightarrow{x_1 x_2}.(P_1 \,\&\&\, P_2) \,\&\&\, \overrightarrow{B_1 B_2}$$

Figure 21: Normalization procedure.

$$\mathcal{V}(z,C) = (z,C) \qquad \mathcal{V}(v_l,C) = (v_l,C) \qquad \mathcal{V}(\texttt{sizeof}(t),C) = (\mathsf{sizeof}(t),C) \qquad \mathcal{V}(\&e,C) = \mathcal{A}(e,C)$$

$$\frac{\mathcal{V}(e,C) = (e',C')}{\mathcal{V}(\odot e,C) = (\odot e',C')} \qquad \frac{\mathcal{V}(e_1,C) = (e_1',C') \qquad \mathcal{V}(e_2,C') = (e_2',C'')}{\mathcal{V}(e_1 \oplus e_2,C) = (e_1' \oplus e_2',C'')}$$

MeshTest: End-to-End Testing for Service Mesh Traffic Management

Naiqian Zheng Tianshuo Qiao Xuanzhe Liu Xin Jin
School of Computer Science, Peking University

Abstract

We present MeshTest, the first end-to-end testing framework for traffic management of service mesh. The key idea of MeshTest is to automatically generate input configurations with end-to-end semantics, and then create real test request suites on each input. There are two technical challenges. First, the input space of service mesh configurations is large and complex. The input configurations should be carefully orchestrated to form end-to-end service flow paths. Second, the abstract output network behavior cannot be directly checked for correctness, and we need to generate a set of real requests that are capable of checking possible behaviors. To address these challenges, we model the service flows of traffic management in service mesh, and propose a novel *Service Flow Exploration* technique to enumerate all possible configuration resources and interactions between them in the input configuration. We design and implement MeshTest, which contains an automatic input configuration generator based on *Service Flow Exploration* and a *Service Mesh Oracle* which leverages formal methods to generate test request suites. MeshTest has found 23 *new* bugs (19 confirmed and 10 fixed) in two popular service mesh systems, Istio and Linkerd.

1 Introduction

Cloud computing systems are growing with larger scale and more complex functionalities. Many cloud computing systems choose to be architected in a microservice-alike [1] manner, with each collection of microservices performing some discrete business functions. Service mesh systems are designed to process network requests and manage the communication between microservices. The widely-used open-source and commercial service mesh systems, such as Istio [2], Linkerd [3], Canal Mesh [4] and AWS App Mesh [5], provide rich traffic management functionalities for service traffic. Traffic management decides how service requests are transmitted through the service mesh system, and establishes the foundation for other functionalities. It provides declarative API for developers to define service routing, load balancing, A/B testing [6], and access control with just a few lines of configurations. Service meshes have been widely-used in industry [7], and there are also academic proposals such as application-defined networks [8, 9] to improve performance and simplify management of service meshes.

The rapid evolution and increasingly popular use of service mesh systems have raised higher demands on their reliability. Reliable traffic management is critical in service meshes, as it directly controls the service traffic and thus affects the correctness and performance of the entire application. The complexity in both implementation and functionality of service mesh traffic management makes it difficult to systematically test or verify. For example, Istio [2], one of the most widely-used service mesh systems, contains over 1,000 components and 3×10^5 lines of code. It provides more than 10 custom resources with extensive configuration options to define traffic management policies. Each custom resource is able to define a specific network function, and an actual service mesh configuration contains multiple custom resources. These resources are orchestrated to describe full end-to-end network functions, including traffic entrance, service routing, and workload dispatching (shown in Figure 1). The interactions between resources create more complex functionalities, such as priority competition on resources with the same matching conditions.

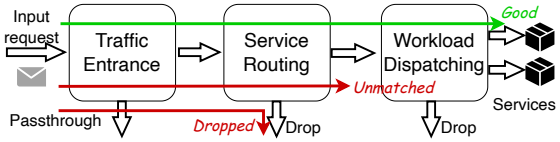

Figure 1: Network request processing stages in service mesh traffic management.

Figure 2 shows a real bug that our technique detects in Istio [10]. When two `service entries` (a custom resource in Istio to define service entrance rules) are defined with the same hostname but different ports and workloads, one of them will be unreachable. This bug is caused by the incorrect implementation in service entrance, which fails to merge the two `service entries` correctly and makes the service listening on port 9080 unreachable. Similar to this bug, traffic management bugs lead to severe issues, such as service unavailability and incorrect service routing, which subsequently degrade the entire application. These bugs escape from existing testing suites because existing service mesh systems rely most on unit tests which can not check traffic management correctness end to end. Some systems include a few end-to-end tests, but they only check basic functionalities and do not cover complex resource interactions.

Creating end-to-end tests for traffic management of service mesh is not trivial, since the test input should be carefully orchestrated to form service flow paths from the sources to the destinations. Figure 1 shows three stages of request processing in the traffic management of service mesh systems. Each stage receives and forwards requests based on the fields and

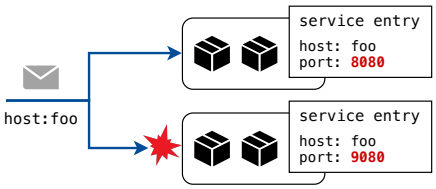

Figure 2: A bug [10] discovered by MeshTest. When two `service entries` are defined on the same host but different ports and workloads, one of them will be unreachable.

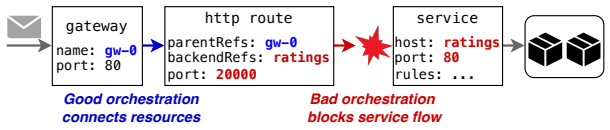

Figure 3: An example configuration snippet of Linkerd [3]. It demonstrates that resource orchestration is necessary for end-to-end test cases; otherwise, it would break the service flow and make the cases not end-to-end.

metadata of the request (*e.g.*, hostname, destination). An end-to-end test case should build up service flow paths through these stages, while a basic test input may drop the request in some stages or fail to hand over between stages. To orchestrate resources and forward the service flow from one resource to another, developers need to set up connectors fields in the entry and exit of each resource to specify what kind of service flow to accept and where to forward. Figure 3 shows a good and a bad example of service flow forwarding between different resources based on a configuration snippet of Linkerd [3]. In the good case (highlighted in blue), the `gateway` hands over the service request to the `http route` via the matching connector fields. In the bad case (highlighted in red), the `http route` fails to forward the request to the service due to a mismatch in port, and blocks the service flow, causing the test case to be not end-to-end. Notably, the real end-to-end test cases can be much more complex than this example, as the types of resources and their connections are more diverse, allowing service flow splitting and merging in various ways.

We seek for a systematic approach to automatically perform end-to-end testing for traffic management of service mesh. Existing techniques like symbolic execution [11] and fuzzing [12] do not model service flows, and cannot be directly used to generate end-to-end input configurations for service mesh systems because of state explosion and low validation pass rates. Besides, the automatic testing tool requires an automatic testing oracle to check the correctness on each input configuration, which existing tools cannot achieve.

Our solution. In this paper, we present MeshTest, the first automatic end-to-end testing framework for traffic management of service mesh. MeshTest automatically generates end-to-end input configurations based on an explicit model on service flows and a novel *Service Flow Exploration* technique. MeshTest's *Service Mesh Oracle* checks whether the service mesh correctly implements functionalities specified in the input configuration by sending real network requests. MeshTest is highly usable. It does not require hypotheses about vulnerable regions in the code nor implementation details. MeshTest is not tied to any specific service mesh system, and can be retrofitted among different systems by its generic API.

MeshTest is a service flow centric approach. It gradually models service flow at a finer granularity on a smaller scale in four stages: service flow exploration, service flow filling, fine-grained service flow modeling and service flow execution. The first two stages compose the input generator, which automatically creates end-to-end input configurations. The last two stages compose the *Service Mesh Oracle*, which automatically generates real network requests to check whether the service mesh system behaves correctly under the input configuration. These stages are designed to be loose-coupled so that they can work individually and can be extended to other tools.

The key insight of MeshTest's input generator is that in an end-to-end input configuration, the resources are orchestrated by end-to-end service flows. Specifically, MeshTest models the input space of end-to-end configurations as *Service Flow Skeletons* (representing interactions among configuration resources) and *Service Flow Bodies* (representing the detailed rules inside each configuration resource). The MeshTest input generator firstly conducts a domain-specific *Service Flow Exploration* technique to create service flow skeletons (§ 4.1), which depict end-to-end layouts of resource orchestration. *Service Flow Exploration* additionally objectives testing vulnerable resource interactions, comprehensively covering all possible resource interactions in the service flow skeleton suites. Then, MeshTest fills in the service flow bodies based on the skeleton with fuzzing-based domain-specific techniques to generate ready-to-use end-to-end input configurations with various network configuration options (§ 4.2).

The *Service Mesh Oracle* in MeshTest is a powerful testing oracle to check whether the service mesh system correctly implements the input configuration. The key idea of *Service Mesh Oracle* is to select a comprehensive set of requests to represent possible service traffic based on a domain specific model, and then check whether the results are as expected. To do so, *Service Mesh Oracle* first supplements the service flow model with more fine-grained and accurate rules (§ 4.3), and transforms the input configuration into a control flow graph (CFG) which is capable of inferring the correct effects on arbitrary requests. Then, *Service Mesh Oracle* conducts symbolic execution on the control flow graph, and generates a set of test requests where each request represents a unique path in the CFG, thereby representing a specific behavior of the input configuration (§ 4.4). These requests are then sent to and captured from the service mesh system hosted in a testbed to check whether the system behaves as expected under the input configuration. Besides, *Service Mesh Oracle* also checks negative cases, such as rejecting invalid inputs, and inspects whether the system raises exceptions.

Key results. We implement MeshTest for service mesh systems. MeshTest requires no expert knowledge on the implementation code base. MeshTest's input generator can effectively enumerate possible layouts of configuration resources orchestrated by service flows, and generate corresponding end-to-end input configurations. MeshTest's *Service Mesh Oracle* can automatically generate a real network request suite which is comprehensive to represent arbitrary service traffic and check behaviors of the service mesh system under the input configuration. We evaluate MeshTest on two most widely-used service mesh systems, Istio [2] and Linkerd [3]. To date, MeshTest has detected 23 *new* bugs that have not been reported previously. 19 out of these 23 bugs have been already confirmed and 10 have been fixed by developers. Notably, a large number of these bugs occur due to interactions between resources, leading to deep semantic violations that are difficult to detect using existing approaches. MeshTest can generate 2500 end-to-end input configurations per second, and check correctness with an average of 29 varying network requests for each input configuration.

Contributions. The paper makes three main contributions.

- We propose a service flow centric approach to model the end-to-end semantics of traffic management of service mesh in gradually finer granularity, and design a novel *Service Flow Exploration* technique to create input configurations with end-to-end service flows.
- We design and implement MeshTest, the first automatic end-to-end testing technique for traffic management of service mesh. MeshTest consists of an input generator empowered by *Service Flow Exploration* and a *Service Mesh Oracle* based on formal methods.
- MeshTest has already improved the quality of two most widely-used service mesh systems by finding 23 *new* bugs. The code of MeshTest is open-source and publicly available `https://github.com/pkusys/meshtest`.

2 Background and Motivation

2.1 Service Mesh Systems

Traffic management of service mesh. Service mesh systems provide a set of network functions to manage and control network traffic in a microservice architecture. Traffic management is the core and most important function, which includes fine-grained service routing, load balancing, and advanced traffic control such as A/B testing. The input of the service mesh is a high-level configuration file that describes the desired network behaviors with custom resources, such as service routing rules and workload discovery. The configuration file (usually written in YAML or JSON) is declarative and highly-abstracted, *i.e.* it only specifies the desired network behaviors, but not how to implement them. The main goal and challenge of service meshes is to correctly implement the abstract network behavior specifications into concrete request processing logics on each nodes.

Interactions between input configuration resources. Although each configuration resource specifies an individual network function, the end-to-end network traffic transmission requires orchestrated interactions between these resources to build end-to-end service flows. The resources define different network functions in different request processing stages, and interact with other resources via connector fields. The blue resource orchestration in Figure 3 allows the service traffic to be forwarded from traffic entrance rules to service routing rules. In contrast, the red resource interaction blocks the service flow, and drops the service request before reaching the destination workload. Besides the orchestration, competition and conflicts also appear between configuration resources. For example, two resources on routing can share the same host key but conflicting routing behaviors. In this case, the service mesh system has to resolve the priority competition and arrange the correct routing rule for arbitrary service traffic. This problem orients from the declarative nature of the input configuration, which makes resource interactions implicit.

Abstract service mesh output. The goal of service mesh is to correctly implement desired network functions specified in the input configuration for arbitrary service traffic. The output of service mesh is the abstract traffic processing behaviors in the system, which are not directly observable or measurable. Judging the correctness of the output has to rely on sending and capturing real network requests to infer the abstract traffic processing behaviors. Thus, a reliable testing oracle has to select a comprehensive network request suite which is limited in size but capable of representing various service traffic in the service mesh system. In particular, it should cover all possible individual network functions and their complicated interactions specified in the input configuration.

2.2 Testing Service Mesh Systems

The lack of existing end-to-end tests. Most popular service mesh systems already have a mature ecosystem, including unit tests and continuous integrations, but they usually have only few end-to-end tests. For example, Istio [2] has 10891 unit tests and has already been widely-used in production. However, it only has 168 end-to-end tests and 217 assertions. Most of these end-to-end tests are simple and the assertions are basic. They do not reason about complex network behaviors caused by the interactions of resources. Another popular service mesh system, Linkerd [3], also has only 31 simple end-to-end tests. The lack of high-quality end-to-end tests is a common problem in traffic management of service mesh systems, mainly due to the difficulties of creating test inputs with end-to-end semantics and the challenges of creating a strong testing oracle. On one hand, the end-to-end service flow path costs a lot of manual work to generate configuration resources and connect them with proper connector fields to form reasonable service flow paths. On the other hand, the extensive functionality combinations raise the complexity of

determining the vulnerable input patterns and code regions. Thus, the lack of end-to-end tests reveals an urgent need to develop a comprehensive end-to-end testing framework for traffic management of service mesh, more specifically, to create more complex end-to-end input configurations and stronger correctness checkers.

Difficulties on applying existing techniques. Existing testing techniques, such as fuzzing [12, 13], symbolic execution [11], cannot be directly applied to service mesh systems. The main reason is that the input configuration is composed of a set of configuration resources, which are very large and have to be carefully orchestrated to form end-to-end service flow paths. Symbolic execution suffers from the path explosion problem, since each resource has a large number of detailed rule options and the combination of these resources explodes the input space exponentially. Specifically, `virtual service` includes more than one million of different configurations, and the number explodes when combined with other resources. Fuzzing does not model the service flows, so the generated resources are usually isolated and do not form end-to-end service flow paths. Another solution is to fuzz individual resources and then combine them by setting connector fields. On one hand, it is not easy to decide what resources are generated and how to connect them. On the other hand, the modified resources may not pass the configuration validation for violating constraints.

Recent works on reliability of Kubernetes controllers [14] and operators [15] cannot be directly applied to service mesh. The main reason is that these works rely on the state-centric property of Kubernetes, while service mesh traffic management is service flow centric. Specifically, state reconciliation is not the main concern in service mesh, since the network policies are completely recalculated on configuration changes. Besides, the input generation technique proposed by Acto [15] is not suitable for traffic management of service mesh, since many of the core resources in service mesh systems do not have a direct mapping to Kubernetes resources.

2.3 Challenges

Our goal is to develop a comprehensive end-to-end testing framework for service mesh traffic management. It should (1) automatically generate orchestrated input configurations with end-to-end service flow paths and (2) automatically checks the correctness of the abstract network behaviors by sending and checking real network requests. We identify two main challenges:

Challenge 1: End-to-end input generation. The first challenge is to create input configurations that have end-to-end semantics. More specifically, the resources in the input configuration have to be orchestrated and carefully connected to form complete service flow paths. Additionally, the input generator should be able to handle complex interactions and interleaving between resources, and strive to create complex combinations of configuration resources, such as service flow priority competition.

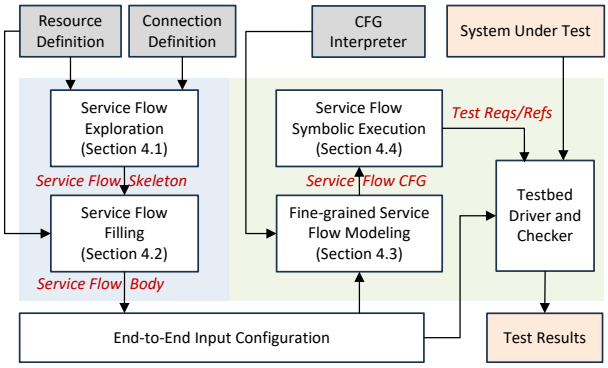

Figure 4: The workflow of MeshTest. The manual parts are gray, the automatic parts are white, and the system input and output are orange.

Challenge 2: Oracle for complex end-to-end inputs. The second challenge is to create a strong testing oracle that can judge whether the service mesh system correctly implements the input network configuration. The testing oracle has to create a limited but comprehensive network request suite which is able to represent various service traffic in the service mesh system. It also has to infer the expected output of arbitrary input requests as a reference to compare with the actual output.

3 Overview

MeshTest centers on service flows, which indicate how the service traffic flows through network functions specified in configuration resources. Specifically, MeshTest explicitly models the service flow in different granularity levels, in order to balance the need of covering larger input space and judging the correctness of service mesh behaviors. First, MeshTest's input generator models the input space of end-to-end configurations as service flow skeletons and service flow bodies, respectively representing the high-level combination layouts and detailed rules of resources. Second, MeshTest's oracle generates a comprehensive set of real requests based on a precise model of the service flow, and checks the correctness of the target system.

3.1 Workflow

Figure 4 shows the full workflow of MeshTest. MeshTest gradually creates and completes test cases in four stages: (1) it generates service flow skeletons by leveraging a domain specific *Service Flow Exploration* technique, indicating the high-level layout of service flows; (2) it fills service flow bodies with detailed rules and options and creates ready-to-use input configurations; (3) it automatically models the input configuration into a fine-grained service flow CFG; and (4) it checks the service mesh system with real requests generated. The first two stages focus on the input generation, and the last two stages focus on the output checking.

Through the four stages, the service flow modeling is gradually refined in finer granularity, and corresponds to a smaller scope. Each service flow skeleton specifies a high-level combination layout of resources, but does not contain detailed rules inside resources. Each service flow body (and its equivalent input configuration) is one of the possible fuzzing results of the service flow skeleton, and fills detailed rules inside resources. Each service flow CFG is a formal model for one input configuration, and contains precise priority selection and any other implicit effects of configuration. Each test request corresponds to a specific service flow path in the CFG, and is used to check a detailed effect. The less detailed modeling in MeshTest's input generator focuses on service flow layouts and reduces the complexity of input space without loss of generality. The fine-grained modeling in *Service Mesh Oracle* provides better correctness checking ability and covers more subtle explicit and implicit effects.

Usage. To use MeshTest, one needs to provide (1) the definition of the configuration resources used in the service flow, including constraints and the range of values, (2) connection rules between different resources, such as possible predecessor and successor resource types, and (3) an interpreter to automatically convert the input configuration to its equivalent service flow CFG, which includes system-specific detailed rules such as priority selection and implicit routes. On this basis, MeshTest automatically generates ready-to-use input configurations, creates a comprehensive service request suite, and applies the test on a testbed environment. Figure 4 illustrates the various components, system inputs, and outputs of MeshTest, where the manual parts are indicated in gray and the automatic parts are shown in white. The definition of the configuration resources and connection rules can be directly obtained from the documentations of the service mesh system. The interpreter requires users to utilize system-specific knowledge to develop and provide to MeshTest, thus requiring some manual efforts when updating the target service mesh or applying MeshTest to a new service mesh system. MeshTest provides a user-friendly interface, facilitating generalization across various service mesh implementations. These interfaces include configuration template definition and connection rule matrix for the input generator, and domain specific primitives used in CFG and symbolic execution for the testing oracle. In our practice, adapting MeshTest to another service mesh system costs less than two person-weeks. After the adaptation, MeshTest can work automatically and continuously until the input constraints or rules change.

3.2 Technique

Collecting service flow skeletons. The goal of this stage is to generate service flow skeletons which depict a high-level layout of service flows. We model a service flow skeleton as a directed acyclic graph (DAG). Each node represents a configuration resource, and each edge represents a connection between two resources. To ensure the end-to-end service flow, the service flow skeleton contains end-to-end service flow paths for all internal resources, making it ready for end-to-end testing. To do so, we leverage a domain specific *Service Flow Exploration* technique to systematically build service flow skeletons with end-to-end service flows. The *Service Flow Exploration* starts from a skeleton seed with resource interactions, and gradually connects more resources on the predecessor side and successor side. In this way, the skeleton seed is extended to larger size, and eventually connects the start and the end points to form a complete end-to-end service flow skeleton. Additionally, we heuristically explore all possible interactions of three typical types for any two resources to be the skeleton seed, in order to check the service meshes on more service flow orchestrations.

Filling service flow bodies. The goal of this stage is to fill detailed rules and options for each resources in the service flow skeleton, and then create ready-to-use input configurations. The service flow body describes (1) the detailed rules and options for each resource in the service flow skeleton, and (2) which pair of fields connects the resources. The main challenge of this stage is how to realize the connectivity defined in the service flow skeleton into real field values. To do so, MeshTest leverages a two-stage approach in which the first stage fills the connector fields to ensure connectivity, and the second stage extends the configuration with more detailed rules and options with fuzzing. As shown in the second part of Figure 4, one abstract service flow skeleton is filled with various detailed options, and becomes a set of corresponding input configurations. The configurations realize service flows designed in the skeleton, and cover more options on non-connector fields.

Fine-grained service flow modeling. The goal of this stage is to build a precise fine-grained model for each input configuration. The model describes the expected behaviors of arbitrary service request under the input configuration. The model depicts the fine-grained control flow of processing the service requests in the service mesh, and considers all explicit and implicit effects of the input configuration. Compared to the service flow skeleton and body, the fine granularity is mainly reflected in considering the complete role of resources, the priority competition between resources, and other implicit intrinsic rules in the service mesh. The design of the structure of the service flow CFG is based on the intrinsic three-stage structure of the service processing model (traffic entrance, service routing, and workload dispatching). We embed each resource's effects to these three stages, and resolve the priority competition and implicit routes carefully.

Checking by real requests. The goal of this stage is to check if the service mesh system correctly realizes the input configuration by sending and checking real service requests. The service request suite is a comprehensive set of real service requests, which is capable to represent arbitrary possible request. Specifically, it should cover all individual and combined rules

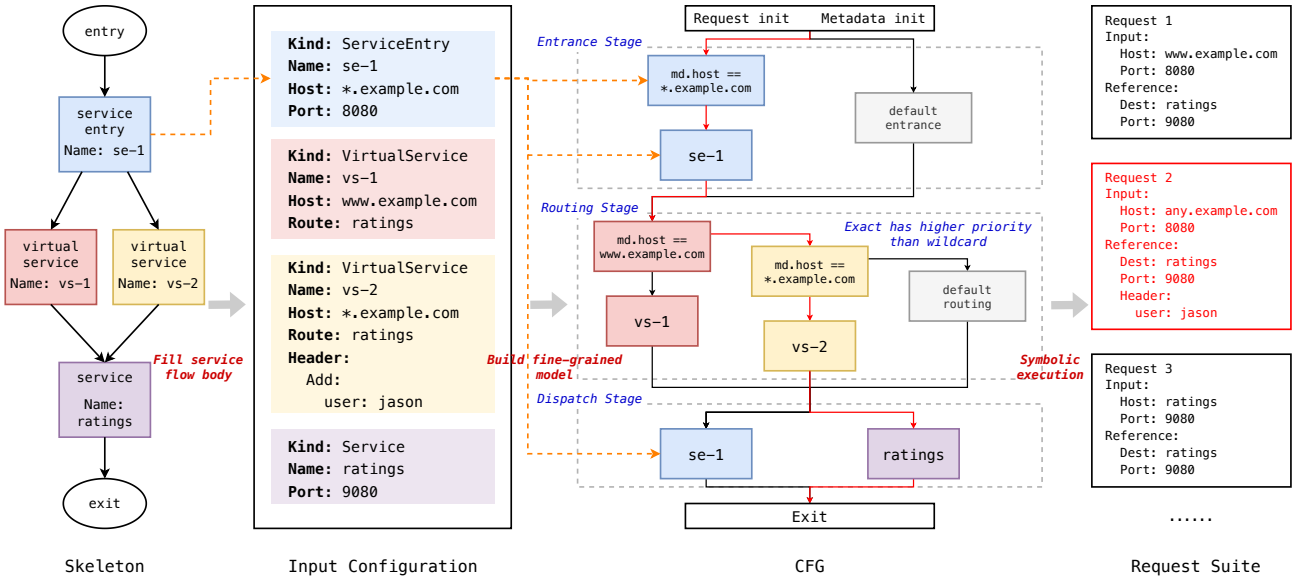

Figure 5: An illustrative example on the creation and evolvement of test cases for Istio [2]. The process starts from a service flow skeleton, evolves to a detailed input configuration, models the full effects to a CFG, and finally composes a real test request suite.

specified in the input configuration, and infer the expected outputs of those requests. To get a comprehensive test request suite, MeshTest leverages symbolic execution and traverses all possible paths on the service flow CFG. Each service flow path in the CFG corresponds to a specific test request, and further corresponds to a specific rule in the input configuration. After that, these test requests are sent to and captured from the testbed environment, and compared with the expected results.

4 Design and Implementation

This section explains the design of MeshTest and how we implement it. Figure 5 shows an illustrative example of the whole test campaign. It shows how a test case is created and evolved in the testing workflow. Specifically, we explain how MeshTest explores the resource combinations to orchestrate end-to-end service flow skeletons(§ 4.1), fills all fields to compose ready-to-use end-to-end input configurations (§ 4.2), models full fine-grained effects of the configuration (§ 4.3), and tests the target system with real service requests (§ 4.4).

4.1 Service Flow Exploration

Generating end-to-end service flows to guide the orchestration of resources is the first step of the workflow and the key to end-to-end test input generation. As shown in the first part of Figure 5, the service flow skeleton depicts how the service flow passes through resources. Further, it serves as a backbone indicating the resource orchestration structure. Service flow skeletons are high-level and not ready for system input, since they do not contain detailed rules and options. To find all possible service flow structures, MeshTest models and then explores the service flow skeletons with a domain specific *Service Flow Exploration* technique.

Service flow model. To get a formal definition, we model the resources as nodes, and the service flow between resources as directed edges. Further, we model the service flow skeleton as a directed acyclic graph (DAG) $G = (V, E)$. Each resource is of one resource type $R(v) \in \{R_0, R_1, \cdots, R_n\}$. The connectability between two kinds of resources is modeled by an adjacency matrix $\mathcal{A} = [A_{ij}]$. The acyclic property of the graph is intrinsic in the service mesh traffic management, because any request has to be processed in bounded steps. We model the end-to-end service flow path as a sequence of resources connected by edges, which starts from the start point and ends at the end point. We define that the service flow skeleton does not contain any dangling resources, *i.e.* each resource is covered by at least one end-to-end service flow path.

Generating service flow skeletons. The goal of *Service Flow Exploration* is to generate end-to-end service flow skeletons which depict the layouts of resource orchestration. The key insight of *Service Flow Exploration* is to first explore resource interactions as skeleton seeds and then explore the end-to-end service flow paths traversing the seeds to compose end-to-end service flow skeletons. The skeleton seed describes the resource interactions used in the service flow skeleton. Other resources are orchestrated to establish end-to-end service flow paths that traverse through the skeleton seed, thereby enabling the composition of complete service flow skeletons. The inputs of *Service Flow Exploration* are the types of resources $\mathcal{R}$ and the adjacent matrix $\mathcal{A}$ describing the connectability of resources. They can be inferred from the documentations and specifications of traffic management of service mesh. The output is a set of end-to-end service flow skeletons showing orchestrations and interactions of resources.

Algorithm 1 *Service Flow Exploration*

Inputs:
- $\mathcal{R} = \{R_0, \cdots, R_n\}$: resources for traffic management of service mesh
- $\mathcal{A} = [A_{ij}]$: adjacency matrix for resource connection compatibility

Outputs:
- $\mathcal{S}keleton$: end-to-end service flow skeletons

```
1:  function ExploreSkeletonSeeds(R, A)
2:      // Enumerate resource interactions as seeds
3:      seeds ← ∅
4:      for res1, res2 ∈ R do
5:          if A_{res1,res2} then
6:              seeds.add(Connect(res1, res2))
7:          if ∃res3 s.t. A_{res3,res1} ∩ A_{res3,res2} then
8:              seeds.add(Split(res3, res1, res2))
9:          if ∃res3 s.t. A_{res1,res3} ∩ A_{res2,res3} then
10:             seeds.add(Merge(res3, res1, res2))
11:     return seeds
12: function ServiceFlowExploration(R, A)
13:     skeletonSeeds ← ExploreSkeletonSeeds(R, A)
14:     Skeleton ← ∅
15:     for seed ∈ skeletonSeeds do
16:         partialSkeleton ← seed
17:         seedResourceSet ← seed.getResourceSet()
18:         queue ← Queue(seedResourceSet) // init with seed resources
19:         while queue ≠ ∅ do
20:             res ← queue.pop()
21:             if res ≠ R_entry and res has no predecessor then
22:                 pred ← GetPossiblePred(res, R, A)
23:                 partialSkeleton.connect(pred, res)
24:                 queue.push(pred)
25:             if res ≠ R_exit and res has no successor then
26:                 succ ← GetPossibleSucc(res, R, A)
27:                 partialSkeleton.connect(res, succ)
28:                 queue.push(succ)
29:         Skeleton.add(partialSkeleton)
30:     return Skeleton
```

Algorithm 1 shows the *Service Flow Exploration* algorithm, which consists of two steps: exploration of skeleton seeds and exploration of end-to-end service flow paths. First, *Service Flow Exploration* explores the skeleton seeds by enumerating all possible interactions between resources (line 1-11). We limit the interactions to be pairwise, since the documentation and implementation of traffic management of service mesh typically split large interactions into several pairwise interactions. *Service Flow Exploration* explores three types of interactions: direct connection (line 5), service flow splitting (line 7), and service flow merging (line 9), since the direct connection is the most common interaction in traffic management of service mesh, and the splitting and merging interactions challenge correctness of complex priority competition and conflict resolution. Notably, the interactions are not limited in scale and type, and they can be extended to more complex interactions in practice, such as increasing the number of interleaving resources or adding more complex interactions.

Second, *Service Flow Exploration* explores end-to-end service flow paths for each skeleton seed to construct end-to-end service flow skeletons (line 16-29). The key idea of the exploration is to extend the service flow path from the skeleton seed to the designated entry and the exit points. For the entry side, the algorithm initializes a queue with seed resources (line 18), recording resources without predecessors. It then iteratively pops a resource from the queue, appending any possible predecessor if the resource lacks one (lines 21-23). This predecessor is subsequently re-enqueued for further exploration. This iterative process drives the service flow path towards the entry point, continuing until every service flow path includes the entry point (line 21). The exit side is explored analogously, ensuring that the service flow paths remain connected from end to end. The correctness of the algorithm and its property of not falling into an infinite loop are guaranteed by an intrinsic property of traffic management for service mesh: any type of resource has an end-to-end service flow path that passes through it, and the length of the path is bounded. Thus, the algorithm will not fall into a loop, since a service flow with unbounded length is not permitted in the system. Importantly, the algorithm does not seek to enumerate all possible service flow skeletons for a given skeleton seed, since the interaction among resources outside the initial seed can be later considered as new seeds to construct new service flow skeletons. *Service Flow Exploration* prioritizes maintaining simplicity in service flow skeletons to facilitate bug determination and localization.

4.2 Filling Service Flow Bodies

Filling service flow bodies is the second stage of the testing workflow. It extends service flow skeletons to complete input configurations which are ready for the system input and following testing steps. Compared with the service flow skeleton, filling the service flow bodies requires more considerations on the configuration formats and detailed constraints. Besides, MeshTest needs to realize the connectivity described in the abstract service flow skeleton in concrete service mesh configurations. To do so, MeshTest leverages a two-step approach to fill the service flow bodies. The first step fills the connector fields to ensure the connectivity of resources. The second step extends the configuration with more detailed rules and options.

The main challenge of the first step is how to connect resources as specified in the service flow skeleton. The service flow skeleton only describes the connectivity of resources, but does not specify the specific connector fields. MeshTest automatically sets connector fields to realize the connectivity of resources. For example, MeshTest connects a routing resource and a workload dispatching resource by setting related values on connector fields in both resources. Further in some cases, connecting adjacent resource pairs does not guarantee the connectivity of the whole service flow path. Taking a practical Istio test case as an example, the service flow skeleton specifies a service flow path that sequentially passes through routing rules, workload dispatching rules, and service definitions. Since the routing rule specifies the host and port fields, the service definition has to specify the same host and port fields though they are not directly connected.

To ensure the connectivity of the whole service flow path, MeshTest tracks the core keys of service flow (such as host and port), propagates among resources from the entry, and fills the connector fields in a topological order.

When the connectivity is ensured, the second step fills other fields with a constraint-aware fuzzing technique. The constraints include ranges of values for each field (*e.g.*, the type of `StringMatch` has to be one of `EXACT`, `PREFIX`, `REGEX`) and field conflicting (*e.g.*, if `resolution` is set to `DNS`, host can not be wildcard). Besides, this step has to guarantee newly filled fields do not conflict with the connector fields. Moreover, we intentionally set some fields with invalid values (prohibited in the documents) or some special values (*e.g.*, empty string, wildcard domain) to challenge the robustness of the service mesh systems. To summarize, the service flow body filling transforms each abstract service flow skeleton into many concrete and detailed input configurations, meanwhile enriches the input configurations with more random options and rules.

4.3 Fine-grained Service Flow Model

The first two stages of the testing workflow focus on creating various end-to-end input configurations for the service mesh system. With the generated input configurations, the next two stages build a strong *Service Mesh Oracle* to check whether the service mesh system correctly realizes the network functions defined in the input configurations.

Gaps between skeletons and facts. Although first two stages are service flow centric, they do not build a precise and fine-grained model to reason about the accurate effects of the input configuration. The first three parts of Figure 5 show the gap between the service flow skeleton, input configuration and the real network behaviors. On one hand, the service flow skeleton does not model the full effects of resources. For example, in the service flow skeleton, the `se-1` is only used to define the traffic entrance, but in real service mesh systems the `service entry` also influences the dispatching stage as a supplementary endpoint provider. On the other hand, the service flow skeleton does not model fine-grained rules such as priority selection and default routes. For example shown in the third part of Figure 5, `vs-1` has higher priority than `vs-2` since exact matching has higher priority than wildcard matching. Another example is the grey blocks, which represent the default routes on port 80.

Modeling fine-grained semantics with CFG. In order to provide a precise and fine-grained model for the whole semantics specified in the input configuration, MeshTest uses a control flow graph (CFG) to describe the processing logics of an arbitrary network request. The CFG is a directed acyclic graph (DAG), which is composed of `action` nodes and `predicate` nodes. Each `action` node represents setting a field or metadata in the network request. Each `predicate` node represents a condition that determines whether the following nodes adapt to the specific request. The CFG inherits intrinsic three-stage structure of service mesh systems: traffic entrance, service routing, and workload dispatching. Each resource acts as a subgraph in the CFG, and the priority selections are modeled as the priority comparisons between different subgraphs.

An example of the fine-grained service flow CFG is shown in the third column of Figure 5. MeshTest uses interpreters (provided by developers) to convert the input configurations into service flow CFGs. The interpreters vary with different service mesh systems, require domain specific knowledge, and cost manual efforts. Notably, the manual efforts are inevitable: on one hand, different service mesh systems have varying input APIs and specific rules, making it infeasible to develop a universal interpreter; on the other hand, the interpreter must accurately represent the functionalities of the service mesh, which is difficult to infer automatically from documentation or code.

MeshTest provides general CFG APIs to aid the users and reduce manual efforts in developing the interpreter. First, MeshTest provides a set of universal CFG primitives, which are common in all service mesh systems. The primitives include nodes and edges in the control flow graph, basic three-stage CFG backbone structure, and expressions and statements to describe the semantics of service mesh resources. Second, MeshTest provides universal abstraction of network requests and service mesh metadata, which is applicable to all service meshes. The network request abstraction includes host, headers and other contents in the TCP and HTTP request. The metadata depict the status of the request, such as source and destination. MeshTest also provides APIs to effectively encode hosts and URIs by splitting them into substrings and further encoding them to integers. Third, MeshTest provides common utility functions, which are frequently used in all service mesh systems. The utility functions include string matching, priority comparisons, default routes, and so on.

MeshTest also provides strategies and guides to build the interpreter. First, the interpreter should build up the backbone structure with its CFG API, set entry and exit nodes, and initialize request fields and metadata. Second, the interpreter needs to encode each resources in the input configuration to individual subgraphs. Each subgraph contains a `predicate` node as the entry guardian, and other following nodes for the detailed semantics of the resource. Third, the interpreter should connect the subgraphs into the holistic CFG, resolve priority competitions between different resources, and add default routes to the CFG. In the example of Figure 5, the `vs-1` and `vs-2` are in different priority levels due to different matching types. The interpreter also utilizes other detailed rules to resolve priority conflicts, such as resource sequence and resource name. After initial development, the interpreter might be incorrect due to bugs or misunderstandings. To address this issue, MeshTest adopts an iterative development approach, conducting tests on the interpreter and the target service mesh system simultaneously, ultimately obtaining an interpreter without false positives (§ 5.4).

With these APIs and strategies, developing and maintaining the interpreter for specific service mesh systems become much easier for the developers. In practice, we have developed interpreters for Istio and Linkerd, and the manual effort is less than two person-weeks. After that, the interpreter is reusable for further development and evolvement

4.4 Testing with Real Network Requests

Judging whether the service mesh system correctly realizes the input configuration is the final step of the testing workflow. The realization is highly abstracted network behavior and cannot be directly observed or compared. The only way is to send real network requests into the mesh network and judge the correctness of output requests. Because of the infinity of network requests, we have to select a finite set of network requests which is comprehensive enough to represent arbitrary network requests. In particular, the test request suite should cover all detailed rules and corner cases appeared with subtle interactions of resources. It should also produce reference results for each output request. After that, we design a test driver which is able to set up the testbed environment, apply the input configuration to the service mesh system, send the network requests, capture output requests, and check results with the expected behaviors.

To produce the test request suite, we leverage symbolic execution [11, 16] on the service flow CFG. The symbolic execution enumerates all types of network requests by exploring all possible paths in the CFG. During the execution, the symbolic execution engine tracks and updates the states and path conditions on each nodes. When the execution reaches a `predicate` node, it evaluates the condition with a SMT solver [17] and decides whether the path is reachable. When the execution reaches an `action` node, it updates the request fields and metadata based on the action. After exploring all paths in the CFG, the symbolic execution engine evaluates the corresponding input requests and reference results, and thus forms a comprehensive test request suite. Notably, since the input configurations obtained from the MeshTest's input generator are not large in scale, symbolic execution here will not encounter scalability issues (§ 5.3).

After that, the test driver automatically conducts tests on a real service mesh testbed. The input of each test campaign contains an input configuration and a set of network requests and reference results. The test driver converts the test suite into real requests by supplementing arbitrary values (unrestricted in the symbolic execution), attaching a test magic number to distinguish test requests and other network requests, and setting indexes to classify individual tests. It then sends the requests to the service mesh system, captures and parses the results, and compares the results with the reference results. The test driver also analyzes system status and logs to check for crashes and internal errors. Finally, the test driver reports the test results, identifying the failed input configurations and their corresponding network requests.

4.5 Implementation

We implement MeshTest with roughly 8300 lines of JAVA and Python code, among which 1400 lines for configuration resource descriptions (850 lines for Istio, 350 lines for Linkerd and 200 lines of shared codes), 1800 lines for the input generator, 3600 lines for CFG modeling and symbolic execution (1700 lines for Istio, 500 lines for Linkerd and 1400 lines of shared codes) and 1500 lines for the test driver. To enhance the generality and extensibility of MeshTest, we architect the system components in a loosely-coupled manner and delineate a suite of domain-specific interfaces within the shared codebase. Specifically, the shared code responsible for resource descriptions incorporates a parser tailored for domain-specific resource templates. Similarly, the shared code dedicated to CFG modeling furnishes a comprehensive set of interfaces for constructing the CFG, including nodes and edges, domain-specific expressions and constraints, and utility functions designed to encapsulate common semantic operations such as string matching and priority selection.

5 Evaluation

We conduct extensive evaluation on two most popular service mesh systems, Istio [2] and Linkerd [3], to demonstrate the effectiveness of MeshTest in finding new bugs and improving the reliability of service mesh systems. Our main evaluation results are summarized as follows:

- MeshTest has found 23 *new* bugs that escape from existing test cases. Among them, 19 have been confirmed and 10 has been fixed.
- MeshTest covers all properties specified by single resource and pairwise interactions between resources.
- MeshTest is efficient in end-to-end test case generation and oracle checking. The input generator produces 2500 end-to-end test cases per second. On average, the *Service Mesh Oracle* checks each test case using 29 distinct real-world requests within 15 seconds.
- MeshTest reports no false positives. Each test alarm during the test campaigns points to a violation of the specification of the target service mesh system.

5.1 Finding New Bugs

As shown in Table 1, MeshTest has found 23 previously unknown bugs in two most popular service mesh systems. We reported the bugs to developers and they confirmed 19 of them and fixed 10. Many of them stand in the critical path of request processing and can lead to severe failures, including incorrect state, load imbalance and security vulnerabilities. Figure 6 shows a real bug found by MeshTest, where the service request mistakenly skips the routing stage. This bug may lead to imbalanced load, and more seriously, it may disable security policies in the routing stage, and cause security vulnerabilities. It is noteworthy that the primary reasons for the majority of bugs being found in Istio [2] are twofold. On one hand, Istio

Index	Implementation	Bug Description	Status
1 [18]	Istio 1.19–1.21	Empty prefix in specific fields causes an internal error	Fixed
2 [19]	Istio 1.19–1.21/dev	Port 80 is not open by default when Istio gateways are not installed	Reported
3 [20]	Istio 1.19–1.21/dev	Traffic passthroughs cluster when `service entry endpoints` set to an internal IP	Reported
4 [21]	Istio 1.19–1.21/dev	`Service entry` with wildcard host makes traffic skip service routing	Confirmed
5 [22]	Istio 1.19–1.21/dev	`Service entry` defined on port 80 disables `virtual service`	Confirmed
6 [23]	Istio 1.22dev	Routing fails under multiple interleaved resources	Fixed
7 [24]	Istio 1.19–1.21/dev	Traffic is not dropped when port not matched in `virtual service`	Confirmed
8 [25]	Istio 1.19–1.21	`WithoutHeaders` matching fails without target header	Fixed
9 [26]	Istio 1.19–1.21	Delegation influences the priority between `virtual services`	Fixed
10 [27]	Istio 1.19–1.21/dev	Match conditions influence the choice of `virtual service` for gateway	Confirmed
11 [28]	Istio 1.19–1.21/dev	`Service` defined on port 80 disables `virtual service`	Reported
12 [29]	Istio 1.19–1.21	Update on `targetPort` does not trigger update on `EDS`	Fixed
13 [30]	Istio 1.19–1.21/dev	Wildcard matching fails on destination host	Reported
14 [10]	Istio 1.19–1.21	Collision between `service entries` with same host but different workloads	Fixed
15 [31]	Istio 1.19–1.21/dev	`EDS` missing for `service entry` defined on the same host as `service`	Confirmed
16 [32]	Istio 1.19–1.21/dev	`WorkloadSelector` takes effect at wrong place	Confirmed
17 [33]	Istio 1.19–1.21/dev	Header manipulation fails when the value is empty string	Confirmed
18 [34]	Istio 1.19–1.21/dev	Special headers are not ignored in match conditions	Confirmed
19 [35]	Istio 1.19/1.20	Header manipulation fails on pseudo headers	Fixed
20 [36]	Linkerd 2.14	Linkerd extension drives specific pods crash	Fixed
21 [37]	Linkerd 2.14	Routing error under rules with the same matching conditions	Fixed
22 [38]	Linkerd 2.14	Routing error under `http routes` bound on the same `gateway`	Fixed
23 [39]	Linkerd 2.14/dev	Incorrect `hostnames` effects	Confirmed

Table 1: Bugs found by MeshTest. Istio [2] and Linkerd [3] are two most widely-used service mesh systems. All bugs are newly discovered in supported versions or main branch (dev version). All bugs had escaped from existing test suites.

provides more complex and flexible features compared to Linkerd [3], which inherently raises the risk of encountering bugs. Istio exhibits significantly more issues than Linkerd. On the other hand, due to Istio's widespread adoption and rich feature set, MeshTest has implemented more configuration resources and more detailed service flow modeling specifically for Istio. Table 2 demonstrates categories and sources of these new bugs: entrance error, routing error, dispatching error, internal error and others.

Entrance error. These bugs indicate that requests are not captured correctly by the service mesh system. Entrance errors can cause the system to capture the wrong traffic or miss some traffic. Issue #2 in Table 1 shows a typical entrance error found by MeshTest. When no gateway is explicitly set, the default traffic entrance on port 80 is not added for internal requests to the virtual service. These bugs usually result in traffic loss and disable other functionalities.

Routing error. These bugs are rooted in the complex routing rules, including those specified by users and those generated by default. They are usually related to some complicated functionalities, such as priority competition and wildcard matching. Figure 7 describes a bug when two `virtual services` share the same host but have different routing behaviors. The correct priority should follow the creation order of the `virtual services`, but the `delegation` causes incorrect priority. Previous approaches cannot detect this bug, since it is triggered by specific combinations of routing rules. MeshTest generates test cases to cover the priority competition of routing rules with the *Service Flow Exploration* technique, and successfully detected this bug.

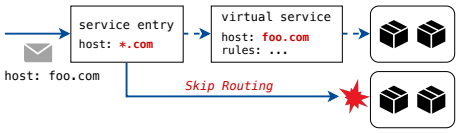

Figure 6: A real bug [21] in Istio discovered by MeshTest, where `service entry` with wildcard host makes the request skip the routing stage.

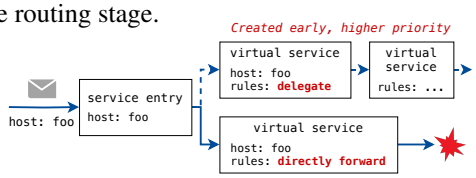

Figure 7: A real bug [26] in Istio discovered by MeshTest, where delegation causes incorrect priority.

Dispatching error. These bugs occur in dispatching the service requests to the concrete workloads. They are usually caused by incorrect assignment of the traffic to the workloads or wrong attributes of the services. Figure 2 shows a severe dispatching error, where two `service entries` with the same host collide with each other when they refer to different workloads. This bug is caused by the incorrect transformations from workloads to services, and it makes the system fail to dispatch traffic to partial workloads. It is confirmed by the developers and fixed in the next release.

Internal error. These bugs occur with an unhandled exception or an undesired state due to the absence of exception handling or internal conflicts. Although internal errors are not the primary target of MeshTest, we still detect some of them by simple but effective techniques such as setting invalid values for configuration properties, checking logs, and

	Istio	Linkerd	Total
Entrance error	1	0	1
Routing error	9	3	12
Dispatching error	5	0	5
Internal error	1	1	2
Others	3	0	3
Total	19	4	23

Table 2: Classification of the bugs found by MeshTest.

monitoring component liveness.

Others. Besides the above four types of bugs, MeshTest also finds some other bugs, such as manipulation failure and inconsistency between specification and implementation. We reported them to developers and received positive feedback.

5.2 Coverage

MeshTest achieves 100% coverage on the functionalities specified in single resource and functionalities indicated by the interactions between pairwise resources. Both coverages are critical for the correctness of service mesh traffic management, and are not fully covered with existing test suites. Even the coverage of functionalities in resource interactions is rarely considered in the design of test suites. MeshTest traverses all possible value types (exact, wildcard, etc.) for each resource field when filling the service flow bodies. MeshTest leverages the domain specific *Service Flow Exploration* technique to enumerate all possible pairwise interactions between resources to cover the functionalities rooted within. For the results, MeshTest detects many bugs related to resource interactions based on the full coverage, including Issue #4, Issue #5 and Issue #9 in Table 1. Besides, MeshTest also finds some bugs related to functionalities specified by single resource, such as Issue #8 in Table 1.

MeshTest improves code coverage by enumerating all possible resource interactions with the *Service Flow Exploration* technique and fuzzing detailed options with service body filling. We conduct code coverage analysis on the controller of Istio (`pilot-discovery`). The results show that: (1) MeshTest achieves 41.2% statement coverage for traffic management packages and 32.2% statement coverage for the entire controller; (2) MeshTest increases the statement coverage of existing test suites from 74.1% to 78.8% for traffic management packages and from 73.1% to 77.0% for the entire controller; and (3) *Service Flow Exploration* is effective in testing resource interactions, increasing the corresponding statement coverage from 70.9% to 79.4%.

5.3 Test Efficiency

The efficiency of MeshTest is evaluated in two aspects: how fast MeshTest can generate diverse end-to-end test inputs and how long it takes to execute and check each test case. We evaluate MeshTest in a virtual Kind [40] cluster on a lightweight host machine. On one hand, the input generator of MeshTest is efficient and effective. MeshTest leverages *Service Flow Exploration* to create service flow skeletons and fills service flow bodies to generate diverse end-to-end test cases with different service flows. MeshTest produces 2500 end-to-end test cases per second, and the cases need to be tested with an average of 29 different service requests. On the other hand, the *Service Mesh Oracle* checks whether the target system behaves consistently with the input configuration efficiently. For each test input, the *Service Mesh Oracle* builds the CFG, performs symbolic execution, and sends and receives requests in less than 15 seconds on average. As shown in Table 3, more than 99% of time is spent on environment setting, request sending and receiving, which is inevitable in the end-to-end testing. The environment setting time includes applying and deleting the end-to-end test configuration on the testbed environment, and cannot be reduced by testing tools. It is possible to set up multiple test environments in parallel to significantly improve the efficiency of *Service Mesh Oracle*.

	Set Env	Build CFG	Symbolic Execution	Send/Recv Requests	Total
Istio (Sidecar)	5.405	0.008	0.046	5.913	11.372
Istio (Ambient)	4.793	0.009	0.03	5.605	10.437
Linkerd	9.92	0.08	0.043	4.895	14.938

Table 3: Average time (in seconds) for each test input spent in *Service Mesh Oracle*.

5.4 False Positives

MeshTest prevents false positives under the assumptions of *Service Mesh Oracle* correctness. Each test alarm during the test campaign points to an inconsistency between the exprected behavior (specified in documentation) and actual behavior of the target system, and further indicates a bug or undefined behavior. To make sure the correctness of *Service Mesh Oracle*, we develop the service flow CFG model iteractively when we are detecting bugs in the target system. Specifically, we develop a basic service flow CFG model based on the documentation of the target system, and then we run the test campaigns to find violations. Then we determine whether the violations are caused by the bugs in the target system or the incorrectness of the CFG model. If the violations are caused by the CFG model, we refine the model and iteratively repeat the process until there are no more model errors. It is not feasible to develop a universal CFG model for all service mesh systems, since they have different functionalities and no standard specifications. We respectively developed the CFG model for Istio and Linkerd with less than two person-weeks of effort and finally made it reliable. We argue that although we cannot prove the correctness of the CFG model, it stops producing false positives quickly just after several iterations.

6 Discussion

Limitations and future work. MeshTest is a first step towards automatic end-to-end testing for traffic management of service mesh. Like other testing techniques, MeshTest is

incomplete and it can miss bugs. MeshTest does not cover all possible input configuration space. Both the input generator and the testing oracle rely on the domain specific service flow model, which can not cover implementation specific details. This design aims to balance efficiency and coverage—it covers all pairwise interactions between resources and requests specified in the documentation. The results show that MeshTest can find bugs in real-world service mesh systems, but the coverage and scope of testing can be further improved. MeshTest relies on domain knowledge to provide the adjacency matrix in *Service Flow Exploration* and build the fine-grained CFG model for *Service Mesh Oracle*. Although most of the knowledge can be obtained from the documentation, there are some details that are not well documented and require experience as system users. The soundness of test results rely on the correctness of the service flow CFG model. MeshTest does not test service mesh performance, security, or network topologies. MeshTest does not aim to test the state reconciliation of the service mesh system.

Generality. The approach of MeshTest is not tied to the specific implementation of service mesh systems and can be generalized to other service mesh systems with different functionality models and configuration resource definitions. The generalization requires domain knowledge of service mesh for *Service Flow Exploration* and service flow CFG model construction. The generalization cost is inevitable due to the absence of a standard for service mesh systems. To reduce the effort of generalization, MeshTest introduces the universal principles of service mesh traffic management into the design and implementation, and provides a set of domain specific interfaces to facilitate generalization. These interfaces includes template resource definitions, domain specific expressions and constraints, and utility functions designed to encapsulate common semantic operations. Besides service mesh, the approach of MeshTest can be extended to other service flow centric systems with a high level declarative input specification for network behaviors, such as application defined networks [8] and software defined networks [41].

7 Related Work

Application defined networks and service meshes. Both service mesh [42] and application defined network (ADN) [8, 9] provide a way to decouple the network communication and the application logic, and releases the burden of development and maintenance. Besides industry practices [7], service mesh systems can be used to empower secure microservice applications [43], API managements [44], tracing systems [45], and so on [46]. Some works focus on the performance and efficiency of service mesh systems [9, 47, 48], which is orthogonal to our work. Application defined networks (ADN) [8] share the similar goal with service meshes, and it has more flexibility and better performance than service mesh [9]. ADN is also service flow centric and is expected to be a potential alternative of service meshes. We believe MeshTest can be easily retrofitted to ADN systems.

Reliability of microservice systems. There is rich literature on improving microservice systems by testing clusters [14, 49–52], RPC communication [53], system operators [15], and so on [54–64]. Among them, Sieve [14] and Acto [15] focus on the state reconciliation in the microservice systems. MeshTest focuses on the service flow and the end-to-end communication in service mesh systems, which is orthogonal to the state change reconciliation. The input generation technique in Acto [15] does not suit for service mesh systems since it relies on a mapping between the input resources and the system state resources. The traffic management of service mesh mainly focus on network communication rules and do not have a direct mapping to the system state.

Checking system correctness with formal techniques. Formal methods have been used to improve the system correctness in various domains, such as verification on system codes [65–75], system configuration verification [76–84]. Ucheck [85] is a tool to check whether a given invariant would hold based on modular microservice models. Ucheck [85] mainly focuses on the correctness of application logic, which is orthogonal to the communication correctness in service mesh systems. Model based testing builds a model of the system and creates test cases covering the model rather than the system code. It is lightweight and has been widely-used in testing large and complex systems [86–91]. *Service Mesh Oracle* is inspired by the art of model based testing, and builds a common model for service mesh functionalities.

8 Conclusion

We present MeshTest, an automatic end-to-end testing framework for traffic management of service mesh. MeshTest centers around an explicit service flow model, generates end-to-end test inputs with a domain specific *Service Flow Exploration* technique, and checks correctness with a *Service Mesh Oracle* which leverages formal methods to generate test request suites. MeshTest is proved to be practical for detecting 23 *new* bugs in real service mesh systems.

Acknowledgments. We thank our shepherd, T. S. Eugene Ng, and the anonymous reviewers for their valuable feedback. We thank all the Istio, Linkerd, and Kubernetes developers who engaged with us and reviewed our reports. Abstract

Datacenter network hotspots, defined as links with persistently high utilization, can lead to performance bottlenecks. In this work, we study hotspots in Google's datacenter networks. We find that these hotspots occur most frequently at ToR switches and can persist for hours. They are caused mainly by *bandwidth demand-supply imbalance*, largely due to high demand from network-intensive services, or demand exceeding available bandwidth when compute/storage upgrades outpace ToR bandwidth upgrades. Compounding this issue is *bandwidth-independent task/data placement* by datacenter compute and storage schedulers. We quantify the performance impact of hotspots, and find that they can degrade the end-to-end latency of some distributed applications by over 2× relative to low utilization levels. Finally, we describe simple improvements we deployed. In our cluster scheduler, adding hotspot-aware task placement reduced the number of hot ToRs by 90%; in our distributed file system, adding hotspot-aware data placement reduced p95 network latency by more than 50%. While congestion control, load balancing, and traffic engineering can efficiently utilize paths for a fixed placement, we find hotspot-aware placement – placing tasks and data under ToRs with higher available bandwidth – is crucial for achieving consistently good performance.

1 Introduction

Distributed cloud applications and services rely on high-bandwidth networks to provide high-throughput, low-latency data transfers. Ideally, the datacenter network provides applications with the illusion of an *unconstrained network* — one in which applications receive high throughput independent of the placement of their components across the network. Techniques such as topology design [41] and/or topology and traffic engineering [32] can support this ideal.

In practice, however, the datacenter network is not unconstrained at all places and all times. In our study of production networks (§2), there exist *network hotspots* — links with persistently high utilization — both within the datacenter interconnect and at top-of-the-rack (ToR) switches (§3). At Google, most hotspots occur at ToR switches and can persist for tens of minutes to hours. ToRs are split between compute hosts managed by Borg [45] and storage hosts. A dominant fraction of traffic in our clusters[1] can be attributed to our distributed storage stack. This includes the Colossus distributed file system [17], the *RamStore*, an in-memory store similar to RamCloud [29], *QuerySys*, an internal query processing system similar to [5, 27, 36, 44], and Bigtable [18]. Colossus places chunks on storage racks, and *QuerySys* worker tasks (§4.2) access these over the network.

Datacenter network planning balances ToR bandwidth supply with anticipated compute and storage traffic demand. Due to the high cost of non-blocking bandwidth provisioning, statistical multiplexing is employed, resulting in an oversubscription ratio – the ratio of ToR downlink to uplink bandwidth. This ratio, set at deployment, typically remains fixed throughout a ToR's multi-year lifespan, based on initial workload forecasts. Consequently, hotspots emerge from two primary, interconnected causes (§3). The first is rack *bandwidth demand-supply imbalance*: an imbalance between bandwidth demand from compute or storage provisioned on a rack, and the provisioned ToR bandwidth supply. This imbalance may occur under specific extreme traffic patterns, such as large incasts, due to the inherent oversubscription ratio. Alternatively, it can arise unexpectedly from deviations in either demand or supply compared to initial provisioning forecasts. Demand-side changes might stem over time from inorganic increased bandwidth demands of network-intensive workloads or other workload efficiency improvements. Supply-side changes could be triggered by incremental upgrades that increase compute or storage capacity without corresponding ToR uplink upgrades, or by planned/unplanned ToR uplink outages that reduce available bandwidth temporarily. The second reason is *bandwidth-independent task/data placement* by datacenter compute or storage schedulers assuming an unconstrained network. Datacenter scheduling is primarily focused on host resources, like compute and storage, that can be evaluated independently for each scheduling decision (because the network was designed to typically not be a bottleneck). Scheduling for network load is a much harder problem, since a hotspot is a property of a set of hosts and not attributable to any individual host. Further, characterizing the bursty communication demands of a distributed job is

[1]In this paper, our scope is traditional compute and storage, excluding ML clusters.

challenging relative to the per-task CPU and memory requirements. Hence, for simplicity, our initial job schedulers did not consider network requirements in scheduling decisions. This could in turn lead to situations where the tasks or storage chunks on a rack had sufficient traffic demand to exceed the provisioned ToR bandwidth supply.

Highly utilized ToRs can degrade the performance of our distributed storage systems (§3.4). For instance, Colossus hard disk drive (HDD) write latencies are inflated by 2× relative to an unloaded ToR even at 40% ToR utilization. Higher levels of the storage stack are also sensitive to ToR hotspots; for example, query latencies in *QuerySys* are inflated by 1.5× at utilizations ranging from 75–95%. It is surprising that these systems are so sensitive to ToR utilization. They access high-latency storage devices like HDDs and can incur significant compute latency when, for example, aggregating query results. Clearly, the increased network latency due to high ToR utilization starts to dominate these other latency components at some utilization level.

Application impact from ToR hotspots cannot be avoided with traditional network performance techniques like congestion control and traffic engineering, since these solutions cannot provide more ToR bandwidth. Hotspots *can*, in theory, be addressed by maintaining ToR resource-balance at every instant but is hard and expensive to do in practice (§3.3). It is much easier to replace a few failed disks on a rack with new higher-capacity disks (resulting in an imbalance) than it is to upgrade ToR capacity to restore balance. Instead, we have to change the input traffic matrix by placing work in a hotspot-aware manner.

In this paper, we modified compute and storage schedulers (Borg and Colossus) to account for resource-imbalance and ToR utilization when making task and storage chunk placements. This is challenging because the scheduler and file system are complex software systems that simultaneously balance a range of competing objectives: ensuring performance for applications with diverse workloads, high utilization, load balance, failure tolerance, and so on.

Despite this, for two reasons, we were able to introduce relatively simple modifications to the scheduler and the file system to mitigate the latency impact of high ToR utilization. First, end-to-end application-perceived query performance is only sensitive to ToR utilization above 75% or so. Second, across our fleet, the *average* ToR utilization is low, so many ToRs are well below 75% utilization. Our *hotspot-aware* task placement (§5) on Borg proactively places tasks on low utilization ToRs, and reactively migrates them away from hotspot ToRs. Similarly, our *hotspot-aware* chunk placement biases storage chunk placement away from those imbalanced racks with less capacity.

These mechanisms reduced the number of hotspot ToRs by 90% in our network without regressing scheduler and file system objectives. Furthermore, they significantly reduce storage access and query latency. We reduced Colossus p95 network latency by 50–80% and p95 total latency by 30–60%. Similarly, *QuerySys* shuffle flush and materialize benchmarks achieve latency reductions of 13% and 9%, respectively.

This paper makes three key contributions:

1. We demonstrate that ToR hotspots remain an unsolved but critical problem, originating from rack bandwidth demand-supply imbalance in dynamic network environments with evolving workloads, incrementally increasing compute/storage resources, and ToR uplink bandwidth prone to planned/unplanned outages. The ToR ↔ aggregation block cross-section is the most common location for hotspots inside our datacenters, and these hotspots can persist for extended durations, ranging from minutes to days. (§3).
2. We show that these hotspots can significantly impact application performance, even for operations dependent on disk or compute latency. Specifically, ToR hotspots can double the latency of both simple storage read/write operations and complex application operations (§4).
3. We find that simple augmentations to existing compute and storage schedulers to better balance network load in a best-effort manner significantly reduce ToR hotspots and their impact on application latency without the added complexity of treating the network as a fully managed resource (§5).

2 Background

2.1 Datacenter Network

Clos topology. Google's datacenter network is based on a hierarchical design (Figure 1) that uses Clos topologies to provide high-bandwidth interconnectivity between servers [41]. The lowest level of the network consists of servers mounted on racks. A top-of-rack (ToR) switch connects to all the servers within the rack. Each ToR switch connects to an aggregation switch. A group of interconnected aggregation switches forms an aggregation block. In turn, aggregation blocks connect to the datacenter network interconnect (DCNI). The DCNI provides links that directly connect different aggregation blocks or indirectly connect them through spine blocks [32, 41]. The DCNI connects to a fabric border router (FBR) that provides connectivity to other datacenters or WAN.

Rack types. To simplify procurement, deployment, and subsequent lifecycle management, Google's datacenters contain different types of racks. A *Disk* rack contains only storage appliances, servers dedicated to I/O using hard disk drives (HDDs) or solid-state drives (SSDs). Optimized for high-capacity storage, they store and serve data for Google's entire suite of user-facing services, as well as analytics, backup, and archival applications. A *Compute* rack contains compute resources, such as servers, with minimal local storage. Finally, a *Mixed* rack contains both compute and storage resources.

2.2 The Storage Stack

Several storage systems provide Google's applications with a range of interfaces to storage hardware. These systems

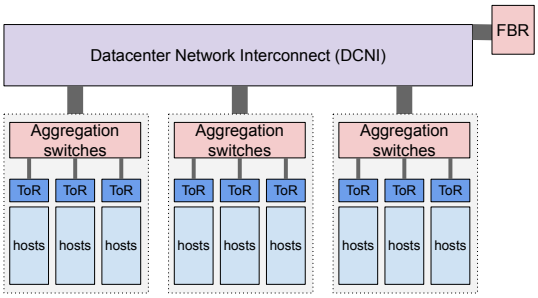

Figure 1: The typical topology of a datacenter network deployed at Google.

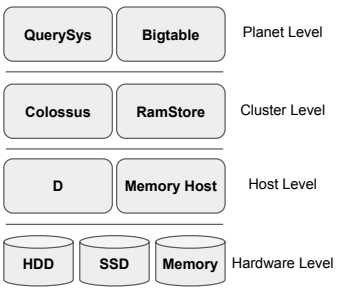

Figure 2: The storage stack at Google.

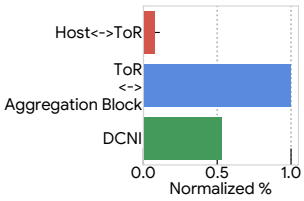

Figure 3: The percentage of hot links at different cross-sections of the network, normalized by the percentage at the ToR ↔ aggregation block layer.

collectively constitute the *storage stack* (Figure 2).

At the lowest level, *D* provides access to chunks of data residing on a single server, but it does not have an API to access user-level files or provide reliability guarantees.

Colossus [17], a distributed file system, is a successor to, and shares some architectural heritage with, the Google File System [16]. It breaks files up into encoded units called *stripes*. Each stripe has a particular encoding, perhaps replicated or erasure-coded, and is comprised of *chunks*, which it stores on *D*. Colossus transparently manages chunk replication and/or encoding, scalably updates filesystem metadata, and ensures adherence to consistency semantics during concurrent writes and appends. Clients access Colossus through a client library which obtains metadata from Colossus and directly accesses chunks, or parts of chunks, from *D* servers.

RamStore, a distributed in-memory file system (similar to [29]) built upon *memory hosts*, is primarily used to stage data during a *shuffle* [10]. Database grouping and join operations frequently use this form of collective communication, and an in-memory file system enables fast shuffles.

At the top of the stack, *QuerySys*, an internal query processing system similar to [5, 27, 36, 44], provides a query interface to distributed storage. *QuerySys* stores persistent data in Colossus, and uses *RamStore* to stage intermediate data during query execution. Multiple such systems with varying APIs and features exist, including Bigtable [18], another database service built on the same infrastructure.

3 Hotspot Characterization

In this section, we characterize the prevalence and duration of network hotspots in Google's network, discuss their causes, and present examples of their impact. We begin by defining hotspots and describing our methodology.

3.1 Methodology and Metrics

To characterize hotspots, we use telemetry data from switches, which provides the average utilization of each network link over 5-minute intervals. A link is a *hotspot* in an interval if its utilization during that interval is higher than 75%. Since a hotspot might occur on either of the two directions of a given link, we treat each direction separately in our characterization.

We choose a 75% threshold for two reasons. First, we [32, 41, 50] and others [14, 39, 47] maintain a 25% capacity headroom to minimize application impact during maintenance, upgrade, and failure mitigation. For this reason, we use a 75% threshold to determine a hotspot. Second, applications we study in this paper exhibit significant latency increases when network utilization exceeds this threshold (§4.1).

3.2 Prevalence

Figure 3 shows the percentage of hot links (i.e., the *hotspot rate*) across three types of network links in different cross-sections: host ↔ ToR, ToR ↔ aggregation block, and links within the DCNI, aggregated from the link utilization data over a month across the entire fleet.

ToR uplinks have the highest hotspot rate. As we have observed that ToR ↔ aggregation block links are ∼10x more likely to be hot than host ↔ ToR links and ∼2x more than DCNI links, ToR ↔ aggregation block hotspots have the highest traffic impact and are the main focus of this paper. Moreover, ToR hotspots are evenly divided across upstream and downstream directions (results omitted for brevity), so solutions cannot focus on a specific traffic direction. In what follows, the term hotspot always refers to a ToR uplink (i.e., ToR ↔ aggregation block) hotspot in either direction unless otherwise stated.

ToR hotspots span a large range of durations. Figure 4 shows the distribution of the duration for all ToR hotspots in a month. Here, the *duration* of a hotspot is defined as the total length of successive 5-minute time intervals during which the ToR uplink is consistently hot. About a third of the hotspots last less than 1 hour, while nearly 40% of them last 1–12 hours. Other timescales show non-trivial persistence as well; for example, about 13% of hotspots last between 1 day and 2 weeks. This wide range of persistence suggests that a variety of approaches might be necessary to address hotspots: reactive job migration at smaller time scales (minutes), proactive placement of data and network-intensive long-running jobs at medium timescales (hours), and capacity planning and re-provisioning at longer timescales (days or longer).

Storage traffic accounts for most ToR hotspots. Figure 5 shows the distribution of hotspots across different types of racks in the same month. *Mixed* racks, which contain both storage and compute (§2), account for nearly 50% of hotspots,

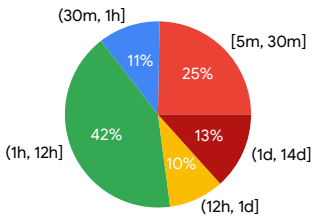

Figure 4: The distribution of the duration of hotspots.

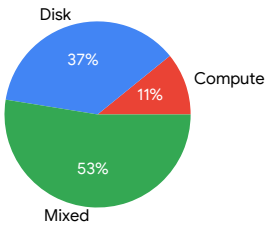

Figure 5: The distribution of hotspots by rack type.

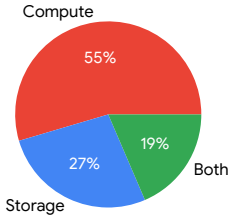

Figure 6: The attribution of hotspots to different workloads on *Mixed* racks.

and *Disk* racks for nearly 40%. Thus, between them, racks with storage devices account for about 90% of hotspots.

To understand which type contributes more to hotspots on *Mixed* racks, we first calculate the share of the capacity provisioned for storage and compute for a given rack based on the configured CPU and disks on the rack. Then, we attribute a hotspot on a *Mixed* rack to storage (compute) if the average throughput of storage (compute) traffic divided by the corresponding provisioned capacity is larger than 75%. From Figure 6, both compute and storage jobs contribute significantly to hotspots on *Mixed* racks; nearly 45% of hotspot traffic on a *Mixed* rack can be attributed to storage.

Taken together with Figure 5, this data suggests that storage traffic contributes significantly to hotspots. Prior work [49] also observes that storage read/write traffic constitutes 75% of the application traffic in Google's datacenters.

3.3 What Causes ToR Hotspots

ToR hotspots occur in our network because of a combination of two factors: *bandwidth demand-supply imbalance* on racks, and *bandwidth-independent task/data placement* by cluster schedulers and distributed storage systems.

Rack bandwidth demand-supply imbalance. Datacenter network planning involves *balancing* ToR bandwidth supply with anticipated traffic demand. For compute racks, bandwidth provisioning targets a specific bandwidth per normalized compute unit. For storage racks, link capacity is provisioned based on HDD capacity on the rack.

Over time, as datacenter ecosystems evolve, demand and supply can diverge from targets, resulting in *bandwidth demand-supply imbalance*. On a compute rack, new network-intensive applications with unprecedented network demands, efficiency improvements in existing applications, or server hardware refreshes can increase bandwidth demand beyond design targets and result in *compute bandwidth demand-supply imbalance*. On a storage rack, increases in installed storage capacity, or incremental replacement of existing or failed disks with faster ones, can increase storage supply without increasing bandwidth supply proportionally, likewise increasing bandwidth demand beyond design targets and resulting in *storage bandwidth demand-supply imbalance*.

These imbalances can persist for days, weeks, or months until network operators restore balance. We argue that these imbalances are inherent to cost-effective datacenter management. It is easier to upgrade or replace a few servers or disks on a rack, but harder to upgrade ToR capacity, since the latter requires taking all ToR-hosted compute and storage offline, and may require aggregation block upgrades as well.

Bandwidth-independent task and data placement. By themselves, rack resource imbalances do not necessarily cause ToR hotspots. ToR hotspots arise, additionally, because our cluster scheduler and our distributed file system make *bandwidth-independent task/data placement* decisions. This was a deliberate choice. At the scale of our datacenters, designing bandwidth-aware cluster scheduling and file systems while also satisfying performance, reliability, and utilization objectives was (and is) considered extremely hard. We have instead attempted to provide the illusion of an unconstrained network to these systems (§1).

As a result of bandwidth-independent task/data placement, these systems can create ToR hotspots. Consider our cluster scheduler, Borg, which schedules, on compute racks, worker tasks belonging to storage systems like *QuerySys*, *RamStore* and Bigtable. Making bandwidth-independent task placement decisions, Borg can schedule a large number of these network-intensive workers on a single rack, resulting in significant traffic demand and triggering a hotspot. Figure 7 shows the distribution of bandwidth per compute unit across all the jobs on our fleet. The distribution is wide, with some network-intensive jobs using more than 10× the median value. Figure 8 plots ToR utilization as a function of the ratio of the number of all network-intensive tasks, including those from *QuerySys*, *RamStore* and Bigtable, per unit network bandwidth for each rack. There is a clear correlation between utilization and the number of these tasks per bandwidth unit.

Bandwidth-independent data placement in a distributed file system can place a large number of storage chunks on racks. When applications access these chunks concurrently, bandwidth demand can approach or exceed supply, and ToR hotspots can arise. Figure 9 quantifies the storage bandwidth demand-supply imbalance in our network; the normalized amount of link capacity divided by HDD capacity for *Disk* racks across our fleet exhibits a more than 2× difference between the smallest and largest values.

3.4 Hotspot Incidents

Network hotspots can cause significant production incidents, including SLO (service-level-objective) violations, user expe-

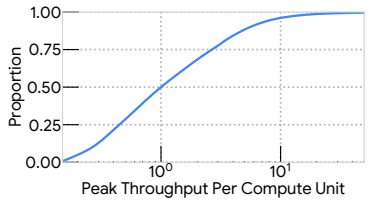

Figure 7: The distribution of outbound peak network throughput per compute unit for jobs across the fleet with non-trivial network usage, normalized by the median value.

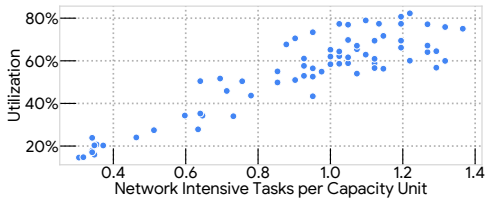

Figure 8: The correlation between ToR utilization (maximum of outbound and inbound directions utilization) and the number of network-intensive tasks on a *Compute* rack per unit of ToR capacity. The x-axis is normalized by the median value. ToRs with a higher number of network-intensive tasks run hotter.

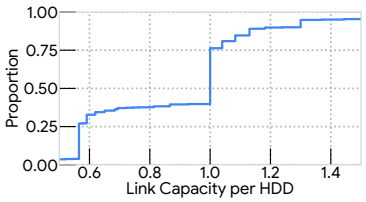

Figure 9: The distribution of the link capacity per HDD capacity for all *Disk* racks across the fleet, normalized by the median value.

rience degradation, and can require extensive troubleshooting effort. This section details several hotspot-related incidents.

Unintended capacity reduction causes ToR hotspots. Temporary hotspots can occur from reduced ToR uplink capacity during maintenance or failures. In a specific instance, a software rollout issue during network maintenance caused a 50% uplink capacity reduction on multiple ToRs. Unaware of this reduced capacity, Borg scheduled too many network-intensive jobs, including crucial batch jobs for Ads analysis, based only on compute resources. This demand-supply mismatch resulted in a 2–3x increase in task completion time.

Unintended network imbalances from scheduling constraints. While serving their intended purpose, Borg scheduling constraints can inadvertently create network imbalances. For instance, an I/O-intensive service implemented a custom constraint to avoid scheduling workers on machines with D servers, aiming to reduce network congestion. However, this constraint unintentionally excluded the majority of available machines, concentrating a large number of these same workers onto the remaining servers. This concentrated load resulted in persistent ToR hotspots and a 1.5x increase in read latency. This incident underscores the need for a more comprehensive approach to mitigating network hotspots.

Colossus degraded reads exacerbate ToR hotspots. During reads, a Colossus client initially attempts to read data directly from the disks storing the required chunk(s). If one or more of these are temporarily unavailable (due to overload on the disk, CPU, or network), and the file is erasure-encoded, the client performs a degraded read: retrieving the other chunks in the erasure-coded stripe and reconstructing the unavailable chunk. However, this mechanism is ineffective when the client resides on a ToR hotspot — it increases network demand on an already congested link. For example, in one incident, ToR congestion caused by incast traffic to Bigtable led to high Colossus read latencies. The resulting degraded reads significantly exacerbated ToR congestion.

Storage ToR hotspots cause high-level applications pain. There are many applications that are built on top of storage services. Therefore, hotspots impacting storage services ultimately translate into impact on users. For example, YouTube relies on storage services (e.g., Bigtable) to store, retrieve and display watch history. In one incident, a ToR hotspot led to increased packet losses and slowed reads from an SSD-backed Bigtable partition. As a result, Bigtable replication latency of user data doubled, resulting in stale or missing watch histories for some users, impacting user satisfaction.

4 Impact of Hotspots on Storage Systems

In this section, we present measurements of the impact of hotspots on the performance of our distributed storage systems. Because ToR hotspots occur predominantly on racks with storage elements, they impact the performance of access to distributed storage. In our infrastructure, applications access distributed storage via queries to a distributed database (*QuerySys*), or by performing reads/writes on a distributed file system (Colossus). In this section, we study how ToR utilization affects the latency of *QuerySys* query completion and Colossus file reads and writes.

4.1 Approach and Methodology

At a high level, to understand the impact of ToR utilization on storage access, we associate the latency of a *storage operation* (a file system read/write, or a database query) with the ToR utilization observed during the operation.

Latency. We use extensive logs to measure the latency of each storage operation, relying on production workloads for measurements of file system accesses and common benchmarks for database queries. These systems are instrumented to break down the time spent on the server versus on the network. The total operation time is measured from initiation to response, including network latency, which encompasses the time for underlying Remote Procedure Calls (RPCs) to traverse the network (including ToR switches).

Utilization. Each file system read or write, and each query, produces a *latency sample*. To understand how these latency measurements depend on ToR utilization, we associate each latency sample with a ToR utilization value. We do this as follows. A file system read/write, or a database query involves many ToR uplinks and downlinks, since these operations may involve multiple servers. We associate each latency sample with the maximum utilization of all ToR links involved in a storage operation, since that lies on the critical path of

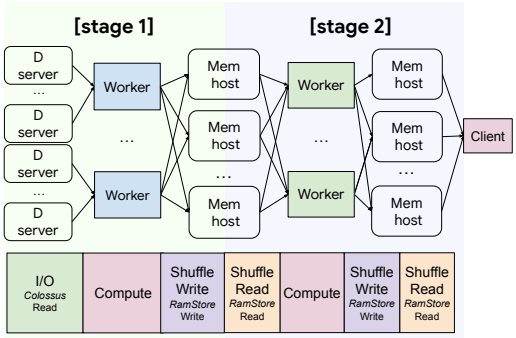

Figure 10: The data flow for an aggregation query in *QuerySys*.

an operation's completion. We obtain network utilization from a network telemetry system which reports the average throughput of each ToR during each 30 second window. For each latency sample, we use the average utilization during the time window containing the operation.

Metrics. To understand and quantify how storage access latency is affected by utilization, we divide utilization values into buckets in increments of 5%. For each bucket, we compute the *p95* latency of the samples within that bucket. We define the p95 *latency inflation* at a given utilization bucket as the ratio of the p95 latency in that bucket to the p95 latency of the lowest utilization bucket for which we have data. Latency inflation characterizes how storage access latency is affected by increasing ToR utilization.

We use a tail measure (p95) because tail performance is critical for many of our applications. We have also measured median latency inflation (defined similarly). This shows qualitatively similar results, so we omit this for brevity.

To understand how ToR utilization inflates storage access latency, we define *Load-tolerance*: the utilization at which p95 (or median) latency inflation is τ. In this paper, we consider two values of τ, 1.5 and 2. At $\tau = 2$, the storage access latency is double that at the lowest utilization which we consider unacceptable. For simplicity, we currently define unacceptable latency based on this fixed threshold. In future work (§6), we plan to define it based on application latency SLOs, which directly characterize the sensitivity of storage access to utilization.

4.2 Database Queries

A significant component of the offered load in our datacenters is traffic from queries of a distributed database, *QuerySys*. Query execution consists of a series of stages, and each stage runs multiple *workers* in parallel. Each worker (running on compute racks) processes a *partition* by reading data initially from a distributed file system, Colossus (or, in later stages, from an in-memory file system *RamStore*), performing some computation, and writing data to *RamStore*. Figure 10 depicts this for an *aggregation* query which produces statistics across one or more columns in a large relational table.

As discussed in §3, imbalanced infrastructure upgrades or network-intensive workloads can result in a *network/compute imbalance* that can increase ToR utilization and, in turn, affect query completion times. When infrastructure used for databases is upgraded such that compute on a rack increases (*e.g.,* because servers are upgraded) without a corresponding increase in ToR capacity, ToR utilization can increase. Database workload network-intensiveness can grow in several ways: *e.g.,* the rate of queries can increase, queries can become more complex, and queries can process larger tables; any of these factors can require more workers. More workers concurrently accessing distributed storage from a rack can increase ToR utilization.

In this section, we seek to quantify how the end-to-end query completion time, as well as the latency of each read or write operation, is affected by ToR utilization. When a query is issued, its completion time is affected by the concurrent workload (other queries and other application traffic) using the network. Some queries may traverse highly utilized ToRs. This gives us an opportunity to study how database queries are affected by ToR utilization.

Methodology. While most database queries execute in stages (*e.g.,* Figure 10), they differ widely in terms of the number of stages they use, the number of workers they employ, and the tables they access. We cannot thus assess ToR utilization impact on a single query, because each query may be affected to different extents at different utilization levels.

We use seven *benchmark* queries that our *QuerySys* team runs periodically to assess performance. These benchmarks include canonical queries (aggregations, materializations, etc.) that reflect real-world usage patterns, as well as industry standard benchmarks (*e.g.,* TPC-H and TPC-DS [46]), and thus capture the shape and semantics of most common queries against *QuerySys*. The breakdown of latency at each worker and each stage is logged for these benchmarks. This enables us to understand and quantify the extent to which network, compute, and storage affect end-to-end performance.

The rest of this section presents the impact of ToR utilization on these benchmarks.

Aggregation is the most common query in *QuerySys*: computing aggregates (*e.g.,* sum, count, average) from one or more columns in a large relational table. To scale to large tables, *QuerySys* employs multiple workers each of which processes distinct partitions of the table. This query executes in two stages (Figure 10). Both stages involve networked storage access and computation.

In this query, networked storage (Colossus) access account for approximately 30% of the query's total time. The time difference between Colossus reads and the query total time is primarily computation time, representing roughly 50% of the query's total time.

Figure 11 shows the p95 latency inflation and the varying *Load-tolerance* of these operations for $\tau = 1.5$: The *Load-tolerance* of the end-to-end query latency can be quite high (85%). For this query, the component which accounts for half the overall query latency, the computation time, is largely

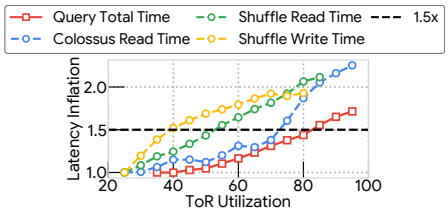

Figure 11: The query latency inflation vs. ToR utilization for the aggregation query.

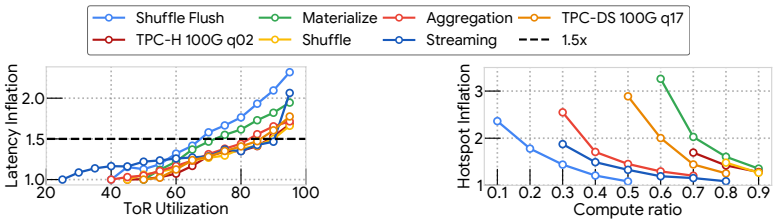


(a) The query latency inflation vs. ToR utilization. **(b)** The CPU ratio of a query vs. the latency inflation at utilization 75%.

Figure 12: The query latency inflation of different *QuerySys* benchmarks.

independent of network hotspots, resulting in a higher *Load-tolerance*. The other components of the storage stack have a lower and widely varying *Load-tolerance*: shuffle writes at 40%, shuffle reads at 52%, and Colossus reads at 72%. Shuffle read/write have lower *Load-tolerance* because they don't involve compute and storage operation on the *RamStore* hosts. Colossus read is slightly higher because it involves storage but minimal compute.

Figure 12a shows p95 latency inflation and Table 1 shows *Load-tolerance* of the other queries in the benchmark. **Shuffle flush** is most sensitive to ToR utilization, primarily because it triggers an intensive data-flush from *RamStore* memory hosts to Colossus when the host runs out of memory to complete the write. This operation increases the share of network transfer time in the total query time, resulting in the lowest 1.5× *Load-tolerance* among all benchmarks (70%). **Materialize** writes results through Colossus; its *Load-tolerance* of 75% is similar to that of shuffle flush and Colossus reads during aggregation. The remaining benchmark queries are less network-intensive, so have a *Load-tolerance* of 90–95%.

The impact of computation. Queries access storage, but also process the retrieved data (*e.g.,* aggregate the data). This processing time affects the tolerance of a query to hotspots.

To illustrate this, we defined *Hotspot-inflation*: the latency inflation at the hotspot threshold (75% utilization, §3). We explored *Hotspot-inflation* for different queries as a function of *query compute ratio* — the ratio of the sum of the processing time for the 10 slowest workers[2] within each stage by the sum of their worker time (aggregated across all stages).

Figure 12b depicts the relationship between these two quantities. To understand this figure, it helps to understand that different samples from a single benchmark query may exhibit different compute ratios (because storage operations and networking take different amounts of time). The figure groups samples by compute ratio, and plots the *Hotspot-inflation* for each group. Thus, for example, samples of the shuffle flush benchmark which have a compute ratio of 0.1 have a *Hotspot-inflation* of about 2.25. The figure demonstrates a clear negative dependence between compute ratio and *Hotspot-inflation*. This explains why higher compute ratios result in higher *Load-tolerance*s. In other words, the more compute-bound a query is, the less sensitive it is to network hotspots.

[2]Currently, our telemetry system tracks processing times only for the 10 slowest workers.

	Load-tolerance (1.5×)	*Load-tolerance* (2×)	*Hotspot-inflation* (75%)
Shuffle Flush	70	90	1.67
Materialize	75	–	1.55
Aggregation	85	–	1.38
TPC-DS 100G q17	90	–	1.35
TPC-H 100G q02	90	–	1.34
Shuffle	95	–	1.29
Streaming	95	95	1.37

Table 1: *Load-tolerance* and *Hotspot-inflation* of different *QuerySys* benchmarks.

Different queries have different *Hotspot-inflation* at the same compute ratio because they may, for example, use different storage operations. For example, when the CPU ratio is 0.8, *materialize* prober has more *Hotspot-inflation* than *streaming* prober because the former incurs Colossus writes while the latter incurs Colossus reads. For Colossus, writes are more sensitive to ToR hotspots than reads (§4.3).

Summary. In Table 1, we compare the *Load-tolerance* and *Hotspot-inflation* across queries. Most queries also have high *Load-tolerance*; many did not reach 2× inflation. For these, their high *Load-tolerance* comes from the significant time spent on compute — ranging from 10% to 90% (Figure 12b).

This discussion implies that for some *QuerySys* benchmarks substantial tail latency reductions can be had by reducing the occurrence of ToR hotspots. §5 discusses hotspot-aware placement mechanisms we use to achieve that.

4.3 File Access

In a distributed file system like Colossus, files are split into chunks, with each chunk replicated across multiple servers. Consider a rack with servers that host chunks. If these servers are upgraded to add more storage I/O capacity (e.g.,new storage hardware that increases the storage read/write rate), but the ToR's capacity is not correspondingly upgraded, a network/storage imbalance can result. This imbalance can result in a ToR hotspot, which can, in turn, affect the latency of reads and writes to the file system. In this section, we (a) study how Colossus read/write latency is impacted by ToR hotspots and by ToR utilization, and (b) quantify the prevalence of network/storage imbalance across our fleet.

Methodology. We collect the total latency of datacenter HDD chunk read and write requests on racks with HDD stor-

age (§2.1) with chunk sizes between 100KB and 1MB from the Dapper tracing system [40] from production workloads over one day.

HDD reads. Figure 13a shows the p95 latency *inflation* (ratio against latency at lowest utilization, §4.1) for network and total latency. Both network and total latency increases with ToR utilization. At the 75% hotspot threshold, network latency is inflated by 4×, but Colossus HDD reads have a *Hotspot-inflation* (the inflation at the hotspot-threshold of 75%, §4.1) of only 1.5×. This is because only the network portion of the Colossus read time is inflated. In all but the last utilization bucket, network accounts for less than 20% of the total HDD read latency; in the last utilization bucket, network doesn't contribute more than 40%. *Load-tolerance* (§4.1) is another way to depict the impact of ToR utilization on storage access latency. For Colossus reads, the 2× *Load-tolerance* is 95%; this means that read latency is less than 2× for all ToR utilizations lower than 95%.

HDD writes. Colossus HDD writes show a qualitatively different behavior than HDD reads because Colossus employs write-back caching on *D* servers (§2.2): writes are cached in battery protected server-side memory and later flushed to persistent storage. Thus Colossus HDD write latency is dominated by network latency, and hence is impacted significantly by increases in network latency as a result of high ToR utilization. Network contributes to 30–40% for low utilization buckets and more than 50% for higher utilization buckets (>75%). By contrast, though Colossus caches reads, read cache hit rates are low, because our workloads mostly access large files sequentially, resulting in little read locality. Hence similar behavior is not observed on reads.

Writes are very sensitive to ToR utilization. As Figure 13b shows, their 2× *Load-tolerance* is a mere 50%, so, even in a lightly loaded network, write latency can be twice the latency when compared to an unloaded network. Their *Hotspot-inflation* is around 4; writes to a rack with a ToR hotspot can be 4 times slower than writes to a rack with an unloaded ToR.

While HDD write operations are impacted more than reads due to the amount of storage access, the network portion of the latency is similarly affected in both operations. The network latency components include round-trip delay (RTT), serialization delays, and congestion control shaping traffic to fill the ToR link capacity. Measurements of RTT and packet losses (not shown here) remain consistently low across utilizations as expected from our deployments of congestion control and load balancing techniques [22, 25]. The shape of the network latency curve reflects the workload's inherent burstiness relative to the available capacity.

The impact of imbalanced infrastructure. Having characterized the impact of network utilization on reads and writes, we now show how network/storage imbalance impacts file reads and writes in Figure 14. To derive this figure, we classified each rack in a datacenter into one of three categories based on its level of resource balance: *High-Uplink* if its installed ToR uplink capacity exceeds provisioning guideline relative to installed storage, *Medium-Uplink* if the capacity matches the guideline, and *Low-Uplink* if the capacity is lower than the guideline. Figure 14 shows the fraction of storage reads and writes to each type of rack across different ToR utilizations, across all of our datacenters. The figure dramatically illustrates the impact of network/storage imbalance. Storage requests that experience low ToR utilization access *High-Uplink* ToRs (in green). Conversely, storage requests that experience extremely high ToR utilization almost exclusively access *Low-Uplink* ToRs (in red).

5 Hotspot-Aware Placement

As discussed in §3, ToR hotspots occur as a result of an interplay between network supply and demand for compute and storage resources. As such they cannot be resolved by *in-network* mechanisms *e.g.,* in switches or host networking stacks. Therefore, we integrate *hotspot awareness* into our cluster scheduler and distributed file system. We've specifically developed two hotspot-aware placement strategies:

1. *ToR-utilization aware task placement and migration* (UTP) takes ToR utilization into account when placing tasks (such as query workers §4) on servers, or migrating tasks away from them, thereby improving the balance between network demand-supply for compute resources.
2. *ToR-capacity aware chunk placement* (CCP) takes the imbalance between ToR capacity and rack storage capacity into account when making storage chunk placement decisions. Thereby improving the balance between network demand-supply for storage resources.

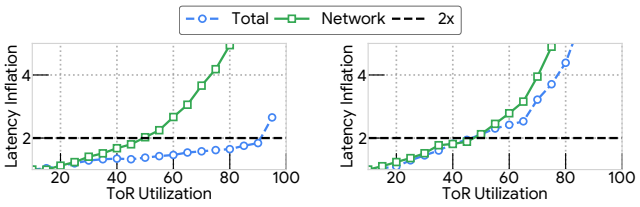
As we describe below, the design of these hotspot-aware placement strategies is informed by the measurements presented in §3 and §4. Moreover, neither of these placement decisions is trivial, since each needs to balance complex, competing objectives. At the same time, avoiding hotspots is important, since doing so can potentially improve network utilization and applications' perceived latency.

5.1 Task Placement and Migration

We modified the Borg cluster scheduler to bias task placement away from, and reactively migrate tasks from, ToR hotspots. Before describing this technique, abbreviated UTP, we briefly describe Borg; see [9, 45] for details.

Background. Borg selects the server on which to place each task (e.g., worker) in a job. It utilizes historical measurements to estimate task resource requirements, and uses this to select suitable servers. When an estimate is inaccurate or workload changes, Borg can reactively migrate affected tasks to improve job performance, but task migration must be careful to avoid impacting availability SLOs offered to service owners.

In practice, a cluster scheduler must (a) scale to clusters with a large number of servers and (b) satisfy many other, often competing, objectives. It must: balance load between servers, prevent over-subscription to resources such as CPU



(a) HDD read. **(b)** HDD write.

Figure 13: The total latency and the network latency inflation (*i.e.,* p95 latency values normalized against the latency at the lowest utilization).

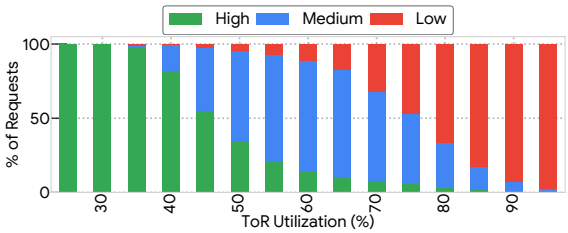


Figure 14: The distribution of chunk read and write request by uplink categories (*High-*, *Medium-* and *Low-Uplink*) for ToRs at a given level of utilization.

or memory, over-commit resources to take advantage of statistical multiplexing, spread tasks of a job across racks to minimize the likelihood of correlated failure, enable memory access locality, and pack jobs into as few servers as possible.

Borg addresses the first challenge by choosing a random sample of placement candidates from amongst servers in the cluster, rather than considering all servers. It addresses the second challenge by assigning a vector of scores to each server based on multiple objectives. Borg prioritizes server selection objectives, with lower-ranked objectives taking precedence. For instance, if load balancing is deemed more critical than bin packing, Borg may choose a server that optimizes load distribution even if it leads to suboptimal bin packing efficiency.

Requirements. Before we designed and implemented UTP, Borg made *bandwidth-independent task placement decisions* — its decisions did not take network utilization into account. Its primary task — to find a set of servers to satisfy application requirements and potentially competing infrastructure constraints — was complex enough that no attempt was made to add network as a resource to Borg earlier, since that would require imposing constraints on group of servers beneath each ToR rather than individual servers. Given that hotspots can degrade performance, and that Borg is a mature infrastructure, we imposed two requirements on UTP: (a) it should be designed as a minimal change to Borg (i.e., not requiring network as a full-fledged new resource type), and (b) it should not adversely impact any existing cluster objective.

Design. To make minimal changes to the scheduler, ideally we should minimally modify an existing objective so that it does not regress any other existing objective. This is hard to do for ToR utilization. Borg can easily determine if placing a task on a server would over-run the server's CPU resources; this depends only on the resources currently committed by the server to other tasks. It is harder to determine how placing a task on a server would impact the server's ToR utilization, since that depends on *other* servers on the rack (that may or may not be in the randomly chosen candidate set) and how their workload changes. Reasoning about this impact correctly would require Borg to consider a large number of servers, which can impact scaling.

Proactive UTP placement. Fortunately, UTP required a relatively simple change to Borg for the following reason: at any given instant, there are relatively few ToR hotspots in each cluster, since the average ToR utilization in our datacenters is low. Given this, UTP tweaks a low-priority objective in Borg, that of ensuring load-balance across servers: it prefers servers that would balance ToR-utilization across the cluster more evenly. Specifically, UTP achieves this by assigning a score to each candidate machine that reflects the ToR utilization for that machine should the task get placed on that machine. In computing this score, we take into account instantaneous ToR utilization as well as peak task demand.

This methodology works well even on a random sample of servers; given the low average ToR utilization, there are likely to be many servers in the sample with low ToR utilization, so in most of the cases Borg can satisfy other cluster-level objectives while finding a suitable candidate server which also improves better balancing of ToR utilization.

Reactive UTP migration. Even with ToR-utilization aware task placement (UTP), ToR hotspots can develop. This is because the placement decision is based on historical estimates, which can be incorrect as the usage pattern of a workload changes, or may not be available for new workloads. To address this, UTP migrates tasks away from ToR hotspots. Borg already supports the infrastructure to orchestrate this for other dimensions (e.g., cpu, memory bandwidth, etc) and we extended it toward network. To this end, UTP must make two decisions: (a) how to determine if a ToR is a hotspot, (b) which task(s) to migrate and when.

UTP employs a 75% utilization threshold to identify hotspots. This aligns with the load tolerance of common workloads, including those discussed in §4.2 and Colossus reads up to 1MB. It also adheres to the fleet-wide requirement of reserving 25% capacity for in-place upgrades and expansions. It then greedily finds the latency-tolerant tasks with the largest network bandwidth usage on a rack to migrate. This ensures the fewest possible migrations and avoids migrating latency-sensitive tasks when possible. Finally, UTP migrates tasks only if availability budgets would permit.

Results. Figure 15 shows the efficacy of UTP in addressing ToR hotspots after its fleetwide rollout. Specifically, it shows that the number of hot ToRs was reduced by 90% after deploying these features in the scheduler. The remaining hot

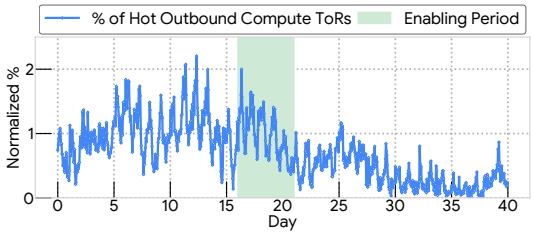

Figure 15: The fleet-wide percentage of compute ToRs hot in the outbound direction before and after deploying UTP, normalized by the average value before the deployment.

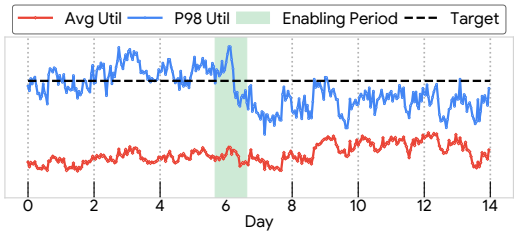

Figure 16: The change of the p98 outbound utilization of compute ToRs as well as the average cell level utilization, defined as the total egress throughput from compute ToRs divided by their total uplink capacity, after UTP was enabled in a pilot cluster.

ToRs are likely due to cases where higher-priority objectives in task placement would prefer a hot ToR rather than cold ToRs. As expected, given the low average ToR utilization in our datacenters, such cases are not common. Future work can consider ways to improve scoring and the relative order of objectives to further reduce the occurrence of hot ToRs.

Figure 16 shows a time series of the evolution of the p98 outbound utilization of *Compute* ToRs during the pilot of UTP in one of our clusters before the fleetwide rollout. It also depicts a timeseries of the average cell level utilization in the cluster (§5.2) during that same window. UTP reduces the tail of the ToR utilization to below the hotspot threshold (75%) after the deployment of UTP. This benefits comes despite a higher average utilization due to an unrelated workload change after UTP was enabled.

In theory, UTP could have been purely reactive: it could have omitted ToR-aware initial placement, and merely invoked task migration when a hotspot was detected. Figure 17 shows that a purely reactive design can increase task migrations by nearly 2×, relative to our design. Moreover, with a purely reactive approach, network-intensive jobs are 7× more likely to be scheduled on hot ToRs (Figure 18).

UTP enables significant reductions (up to 13%) in p95 latency across many of our *QuerySys* benchmarks (Figure 19). The shuffle flush and materialize benefit the most from UTP because they are the most sensitive to ToR utilization with the lowest *Load-tolerance* (Figure 12a). On the other hand, the improvement on the TPC-H benchmark is not significant, which is expected because the workload is not sensitive to ToR utilization.

As discussed in section §3.4, ToR hotspots were a recurring cause of service incidents. Enabling UTP resulted in a 70% reduction in the monthly occurrence of such incidents. The remaining incidents post-UTP were primarily attributed to either resolved bugs within UTP or occurred in specific clusters where UTP had not yet been deployed.

Metric	Change
Percentage of hot ToRs	−44.6%
p98th utilization	−18.5%
Average utilization	10.9%

Table 2: The change of the median value of the metrics reported in Figure 15 and Figure 16 in a 5-day window before and after UTP was enabled. We also used the Student's t-test on the metrics samples in the two periods to confirm that the change was statistically significant.

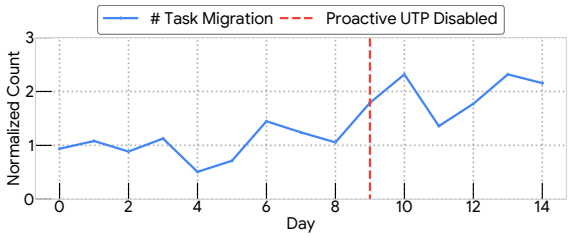

Figure 17: The number of task migration events in a day due to UTP before and after the disabling of the proactive UTP placement, normalized by the average value before.

Lastly, as discussed earlier, a key constraint that we needed to satisfy in the design of UTP was to not adversely impact any existing cluster objective. We didn't observe any regression in key Borg objective after the rollout of UTP. Corresponding graphs are omitted for brevity.

5.2 Storage Chunk Placement

ToR-capacity aware chunk placement (CCP) addresses imbalanced infrastructure upgrades by steering Colossus chunk placement away from racks whose storage capacity has grown out of balance with provisioned ToR bandwidth.

Background. Distributed file systems use heuristics to determine where to place new file chunks. These heuristics are designed to achieve several, often competing, objectives to determine the most appropriate storage servers at which to replicate these chunks. These objectives are similar to that of task placement: spreading for reliability, load balancing, access locality, and so on.

Design. As with UTP, CCP was designed to ensure minimal changes to the existing Colossus distributed file system. These changes were similar in principle to those for UTP, so we omit the details for brevity but describe the key idea underlying the approach.

In §4.3, we showed that storage requests to *High-Uplink* ToRs experience low ToR utilization. Conversely, storage requests that experience extremely high ToR utilization almost exclusively access *Low-Uplink* ToRs. Based on this observation, CCP prioritizes High-Uplink ToRs over Medium-Uplink and Low-Uplink ToRs for new chunk placement.

Results. We now discuss latency reduction resulting from

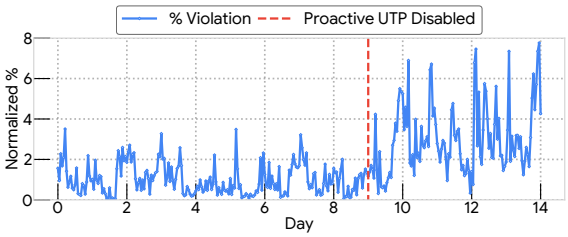

Figure 18: The percent of job scheduling events where a network-intensive job is scheduled on a hot ToR before and after the disabling of the proactive UTP placement, normalized by the average value before.

Metric	Change
Number of task migration events	−41.0%
Percentage of scheduling violations	−74.1%

Table 3: The change of the median value of various metrics reported in Figure 17 and Figure 18 in a 5-day window with ToR utilization-aware placement enabled against in a 5-day window without the feature. We also used the Student's t-test on the metrics samples in the two periods to confirm that the change was statistically significant.

this approach, using measurements from a 15-day pilot in one of our clusters. Figure 20 shows the relative reduction in Colossus p95 total storage access and network latency in the pilot cluster. As CCP biases storage accesses towards high-capacity ToRs, p95 network latency reduces by 50–80% and p95 total latency reduces by 30–60%.

6 Future Directions

Automation techniques for hotspot mitigation. Hotspot mitigation in our storage systems required significant manual intervention, leveraging service owner knowledge of application metrics, dependencies, and request prioritization within the application. To scale mitigation to more applications, automation techniques must be developed. Future work can explore declarative methods for service owners to define application characteristics, dependencies, and constraints, enabling automated backend systems to identify and implement mitigation opportunities. Alternatively, more robust profiling techniques can extract network communication requirements from live deployments and map them to a range of system deployment conditions.

Service Level Objectives (SLOs). Our current placement strategy, which is hotspot-aware but best-effort, cannot guarantee performance under every network and workload condition. To ensure consistent performance, we must define SLOs and implement mechanisms to guarantee them. This necessitates substantial scheduler enhancements, moving beyond simple load spreading to include strict network constraint enforcement, thereby mitigating SLO risks.

Network fault tolerance for ML. The distinct characteristics of Machine Learning (ML) workloads, such as single points of failure and sensitivity to worker performance, necessitate novel network fault tolerance strategies. Placement and rescheduling techniques discussed in this paper can be

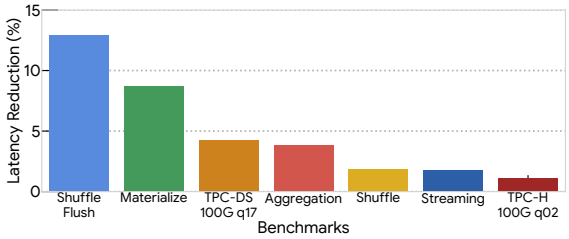

Figure 19: The relative improvement of the p95 query latency for each of the seven *QuerySys* benchmarks studied in Section 4.2 in a 5-day window before and after UTP was enabled in the pilot cluster.

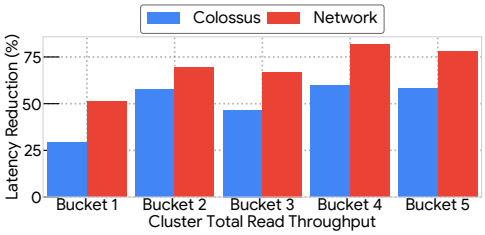

Figure 20: The reduction of the p95 Colossus and network latency of HDD reads in a pilot cluster with CCP enabled, compared with those at the time when the cluster is in the same bucket of total read throughput but with CCP disabled.

adapted for ML workloads to minimize the impact of faulty network components, such as NICs and ToRs. This is particularly crucial for jobs that rely on synchronous communication between numerous accelerators.

Network-awareness across layers. While we tackled persistent network hotspots with infrastructure-level network awareness, shorter-lived hotspots (seconds to few minutes) can make use of application-level load balancing. Application control further allows for customized hotspot handling based on request sensitivity and required quality of service. Future investigations can focus on determining optimal hotspot resolution timescales for various mitigation strategies (proactive/reactive) and layers (infrastructure/application), and developing coordinated decision-making frameworks.

Connecting placement and provisioning. Future work can explore the interplay between hotspot-aware placement and resource (re-)provisioning. While hotspot-aware placement can extend the lifespan of network infrastructure and allow for more conservative uplink:downlink oversubscription to deliver network efficiency, capacity planners need tools to determine when and where to upgrade network, storage, and compute resources to address capacity mismatches. A key area for future research is determining the optimal utilization target for provisioning and identifying utilization values to inform changes in job and data placement, enabling safely operating network at higher utilization while meeting application SLOs.

7 Related Work

Reducing network congestion. To reduce datacenter congestion, the literature explored various solutions, including congestion control [3, 4, 19, 25, 26, 28, 31, 51], network load balancing [1, 2, 8, 21, 22], and traffic engineering [7, 35]. These solutions mitigate packet drops and queuing delays by distributing traffic over time (congestion control) or across different paths (load balancing and traffic engineering), but they are bounded by bandwidth limits in ToR hotspots in which all the uplinks of a ToR are persistently hot. By contrast, hotspot-aware scheduling makes more bandwidth available, by modifying the traffic matrix.

Datacenter scheduling. Datacenter job scheduling can influence traffic patterns, but it traditionally prioritizes local resources like compute, memory and storage, assuming the network isn't a bottleneck. Various research has explored incorporating network attributes like latency, bandwidth, and reliability into storage systems to make them network-aware [6, 15, 42, 43]. Several storage systems attempt to mitigate network congestion. For instance, Sinbad [12] dynamically adjusts replica placement based on real-time link utilization to address imbalances. However, it is restricted to replicated file encodings and requires live network data, unlike our ToR-capacity aware chunk placement (CCP), which is encoding-agnostic and relies on simpler, static ToR uplink information. NetHint [11] proposes an interactive cloud tenant-provider mechanism to optimize application performance by identifying network hotspots. Yet, this approach necessitates application-level network awareness and is confined to single-tenant environments, contrasting with our infrastructure-level, multi-tenant hotspot management. Furthermore, systems like Diktyo [37] and Kubernetes [13] optimize service placement for latency by considering network bandwidth and topology, primarily focusing on microservice environments.

High-Performance Computing (HPC) and Machine Learning (ML) have long incorporated network awareness into job scheduling, as exemplified by CASSINI [34] and Corral [20]. This paper demonstrates that network awareness is equally critical for traditional compute and storage services, especially in mitigating application tail latency.

Network capacity planning. Recent research has explored leveraging application-specific information to enhance bandwidth allocation: Saba [23], for example, uses ahead-of-time profiling to distribute network bandwidth based on how sensitive applications are to changes in bandwidth. Jupiter's networks [41] employ both traffic engineering and topology engineering, which operate at different timescales. Traffic engineering swiftly adapts to changes in topology and traffic, whereas topology engineering is a slower, planned process for implementing new network structures. However, capacity planning alone cannot eliminate network hotspots due to the fundamental causes discussed earlier (§3.3). Our work focuses on analyzing how sensitive applications are to network hotspots, and how network-aware placement can reduce the occurrence and duration of these hotspots.

Characterizing application performance. Prior research has explored the impact of various factors on application performance. Ousterhout *et al.* [30] proposed a methodology for quantifying performance bottlenecks and used it to analyze the Spark framework's performance, concluding that network optimizations can only reduce job completion time by a median of at most 2%. Their conclusions are not in contradiction to this paper because (1) the network utilization in their datacenters is low and below 50%, so they do not observe the effect of hotspots, and (2) workloads in our datacenters are able to fully parallelize the execution, which magnifies the impact of the worst straggler. Seemakhupt *et al.* [38] analyzed latency bottlenecks in Remote Procedure Calls (RPCs), identifying network performance issues using passively-sampled RPCs [33] at Google. Zambre *et al.* [48] broke down the time involved in small message communication into CPU, I/O, and network usage. More recently, Kong *et al.* [24] modeled how NIC resource usage affects RDMA performance. Our work complements these studies by focusing on how ToR utilization influences performance, ranging from basic storage operations to complex application operations in *QuerySys*.

8 Conclusion

This paper demonstrates the need for hotspot-aware scheduling to mitigate the impact of network hotspots on application performance in datacenters. Traditional solutions like congestion control and traffic engineering prove insufficient; instead, directly managing workload placement is essential for reining in elevated tail latency. Our work reveals two surprising findings: first, even disk- or compute-bound application operations are vulnerable to elevated network utilization levels, with ToR hotspots capable of doubling their latency. Second, adding simple hotspot awareness to existing compute and storage schedulers dramatically reduces application tail latency and eliminates most ToR hotspots. This approach, while simpler than incorporating network as a fully schedulable resource, yields significant gains.

These results highlight the need for datacenter schedulers to comprehensively consider network demand and supply. Future research shall investigate holistic scheduling frameworks accounting for network bandwidth, topology, and compute and storage resources to pave the way for balanced datacenter environments with predictable application performance.

Acknowledgement

This work wouldn't have been possible without the contributions of many individuals and teams across Google, particularly within the Networking Infrastructure, Compute, and Storage organizations. We are especially grateful to to Arjun Singh, David Wetherall, Ian Whalley, Milo Martin, Thomas Wenisch, Larry Greenfield, Gaurav Dhiman, Flo-

rentina Popovici and the anonymous NSDI reviewers for their invaluable feedback and to our shepherd Ravi Soundararajan for guiding us through the revision process. This research was in part supported by NSF CNS NeTS 2211383.

Appendix

A *QuerySys* Dataflow

Aggregation queries involve two stages (Figure 10), communicating via a shuffle primitive provided by *RamStore*. In the first stage, workers read data from *D* servers using the Colossus read API, perform parallel computations, and write intermediate results to *RamStore* memory hosts. Second, workers read these results, perform further computations, and write final results to memory hosts.

This process involves many-to-many communication between workers, *D* servers, and memory hosts, making it difficult to correlate ToR utilization with operation latency (§4.2). To simplify this analysis, we focus on the maximum ToR utilization observed across all ToRs[3] involved in each worker's operation (Table 4). This approach allows us to capture the impact of the worst hotspot on the operation's performance.

B Impact of Chunk Sizes

Figure 21 shows how chunk sizes impact the *Load-tolerance*. We look at 3 different operation size buckets: *10KB – 100KB*, *100KB – 1MB*, and *1MB–10MB*, and measure the 2× *Load-tolerance* for HDD reads and writes. A larger *Op size* decreases *Load-tolerance*, *i.e.,* making it more sensitive to the utilization. Thus, for example, reads of small chunks of 10-100 KB can tolerate fully loaded ToRs with a latency inflation of less than 2. For these small chunks, read access time is dominated by disk read latency (disk seeking), and so should, in general, offer worse performance than larger reads. In contrast, large reads of a MB or more incur a latency inflation of 2 even with a 50% ToR utilization, because they are bottlenecked by the network. HDD write operations have a low *Load-tolerance* even for small chunks, since writes do not wait for disk accesses, and hence are dominated by network latency at any size.

[3] Except for Colossus read operations we only consider the ToR utilization of workers but not *D* servers due to telemetry limitations.

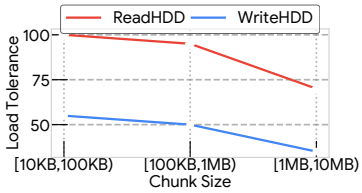

Figure 21: The impact of chunk sizes on the *Load-tolerance*.

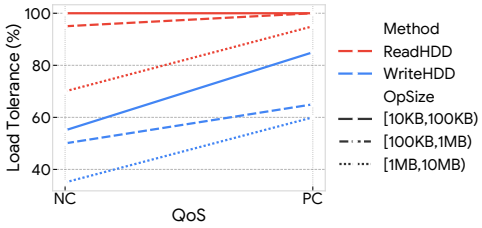

Figure 22: In all Op sizes, moving from NC QoS to PC QoS increases the *Load-tolerance*.

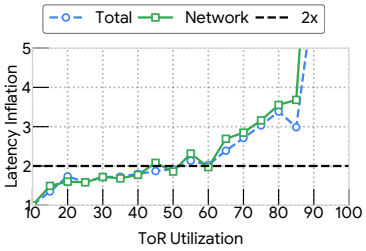
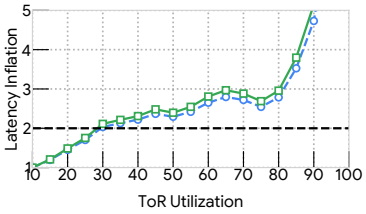


(a) SSD read.



(b) *RamStore* read.

Figure 23: The latency inflation of SSD and *RamStore* reads as a function of ToR utilization.

C Impact of QoS

Typical cluster applications in public clouds, including storage, classify their traffic into three priority classes: performance-critical (*PC*) traffic is associated with user-facing applications, non-critical (*NC*) traffic such as bulk storage operations generally cares about sustained rate, and best-effort (*BE*) traffic such as background analytics and backup traffic has the lowest priority. *PC*, *NC*, and *BE* traffic are mapped to high, medium, and low QoS classes respectively [49].

We measure network utilization every 30 seconds at each ToR for each quality of service (QoS) level. In our results reported below, the utilization always refers to the weighted-effective utilization of the given QoS class. The weighted-effective utilization is defined by the utilization of each

Operation	Description	Associated Network Utilization
Colossus Read	Read data from Colossus to worker	worker downlink
Shuffle Write	Write output from a worker to *RamStore*	**MAX**(worker uplink, *RamStore* memhost downlink)
Shuffle Read	Read the result generated by the previous stage from *RamStore* to worker	**MAX**(worker downlink, *RamStore* memhost uplink)

Table 4: The time of individual *QuerySys* worker's operation and the associated network utilization.

QoS and the weight ratio between QoSes. In practice, a flow of higher QoS can still be impacted by traffics of a lower QoS due to the weighted queues at the network devices. The weighted-effective utilization is capturing this subtlety with a weighted sum of all QoSes traffic occurs in the given ToR for each interval. Lower QoS contributions have smaller weight (< 1) and higher QoS traffic will have a larger weight (> 1).

Figure 22 shows that both HDD read and write has higher *Load-tolerance* when move from *Non-critical* (NC) to *Performance-critical* (PC) QoS. This is because traffic of the higher QoS observe less queuing time than that of the lower QoS. This less queuing delay will behave as a higher *Load-tolerance*.

D SSD and *RamStore*

SSD reads are much faster than HDD reads, and thus are more sensitive to network utilization. As shown in Figure 23a, SSD reads are more sensitive to high ToR utilization than HDDs. The *Hotspot-inflation* for SSD read is about $2.5\times$, and the $2\times$ *Load-tolerance* is about 55%. Thus, even when ToR utilization is not high enough to be classified as a hotspot, SSD read latency can be more than double the latency on an unloaded network.

RamStore reads have lower latency than Colossus since it stores the data in RAM. For this reason, *RamStore* is more sensitive to higher utilization and hotspots than any of the storage subsystems discussed so far. As shown in Figure 23b, *RamStore*'s $2\times$ *Load-tolerance* is 30%, and its *Hotspot-inflation* is 3.

Enhancing Network Failure Mitigation with Performance-Aware Ranking

Abstract– Cloud providers install mitigations to reduce the impact of network failures within their datacenters. Existing network mitigation systems rely on simple local criteria or global proxy metrics to determine the best action. In this paper, we show that we can support a broader range of actions and select more effective mitigations by directly optimizing end-to-end flow-level metrics and analyzing actions holistically. To achieve this, we develop novel techniques to quickly estimate the impact of different mitigations and rank them with high fidelity. Our results on incidents from a large cloud provider show orders of magnitude improvements in flow completion time and throughput. We also show our approach scales to large datacenters.

1 Introduction

Datacenter networks often incur a variety of (concurrent) failures ranging from failed or lossy links to localized, persistent congestion. Repairing these failures takes time [1]. For example, operators require days to replace optical links and hours to fix hardware-induced packet corruptions [11, 21, 63, 71]. As a result, cloud providers install mitigations to reduce the impact of failures while they work on repairs. In this paper, we focus on *network-level* mitigations[1] such as disabling links or switches and re-routing traffic. These are effective because of the path and resource diversity in datacenter networks.

Given the economic importance of cloud services and the increasing likelihood of failures at scale, it is essential to find and implement effective mitigations quickly. Today, cloud providers are increasingly using automation to mitigate each incident. For example, Azure uses automation for nearly 80% of its incidents. An auto-mitigation system allows an operator to pre-define a limited set of potential mitigations for each type of failure. The system then chooses the "best" mitigation for each individual incident. At its core, an auto-mitigation system ***ranks mitigations*** based on one or more criteria, and it must do so ***quickly*** to be effective. At Azure, mitigations must be in place within 5 minutes [21] of failure localization.

Azure uses *local* criteria to assess mitigations.[2] For example, disabling a link is acceptable if it leaves sufficient functional uplinks at the corresponding switch. The state of the art either uses *global proxy* metrics, such as the residual path diversity from the top-of-rack (ToR) switches to the spine of the datacenter [71], or *global non-end-to-end* measures like packet loss and network utilization [63]. However, these methods can negatively impact customers by suggesting inadequate mitigations (§2).

SWARM	FCT/Tput	✓	✓	✓	✓	✓	✓

TABLE 1: SWARM is the only method that mitigates failures based on **E**nd-to-end **G**lobal **P**erformance metrics, considers **U**ncertainty in future networking behaviors, supports a **B**road range of actions and failure, and **S**cales to large datacenters. (**E**: End-to-End, **G**: Global, **U**: Uncertainty, **B**: Broadly applicable, **S**: Scalable, **P**: based on Performance)

In this paper, we explore a new mitigation ranking criterion (Table 1): the impact on the *end-to-end* connection-level performance (CLP) metrics, throughput and flow completion time. We can quantify the *global* impact using distributional measures of these quantities (averages and percentiles) across all connections in the datacenter. Failures adversely impact these global end-to-end metrics, and an ideal mitigation is the one that minimizes the impact. For instance, if our goal is to optimize 1st percentile (1p) throughput, the best mitigation is the one with the least impact on 1p throughput (§3).

From a cloud operator's perspective, this criterion reflects the network performance that customers experience and is preferable to local or non-end-to-end metrics that may not correlate with customer-visible network performance. However, at the scale of modern datacenters, the feasibility of quickly ranking mitigations based on global end-to-end CLP measures is unclear.

We introduce SWARM, a service for operators and auto-mitigation systems that quickly ranks mitigations while scaling to large clusters. SWARM leverages the insight that ranking mitigations only require an estimate of CLP distributions to produce an effective *ordering*. Its *CLP estimator* models traffic, routing, and transport behavior in sufficient detail to ensure ranking fidelity and, at the same time, produces results in just a matter of minutes.

To approximate CLP, SWARM must estimate *per-flow* performance not just for the current network state (topology and

*The author contributed to this work while at Microsoft.

[1] We use network-level mitigations and mitigations interchangeably. We briefly discuss application-level mitigations in §3.4.

[2] Its auto-mitigation system uses local criteria to determine whether taking a fixed action is better than taking no action.

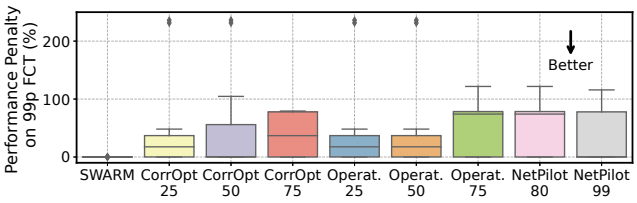

FIGURE 1: Our solution (SWARM) takes orders of magnitude better decisions by ranking mitigations using approximates of flow-level metrics and by accounting for uncertainties. The results are from scenario 1 in Mininet, see §4.2 (Operat. = Operator).

routing) but for potential (unknown) future network states that may manifest while mitigation is in place. Flow performance can depend on other concurrent flows as well as flow arrivals and departures. The central challenge in SWARM is producing an estimate quickly while accounting for all these factors.

SWARM overcomes these challenges as follows (§3):

- It takes flow arrivals, sizes, and communication probabilities as input distributions. It then samples a set of flow-level traffic traces to ensure statistical significance. For each demand, it generates routing samples to capture uncertainty in flows' paths. SWARM estimates CLP for each sample and then combines these estimates to create a composite distribution that succinctly captures traffic and routing variability. It uses this distribution to rank mitigations.
- SWARM estimates CLP separately for long and short flows. Estimating CLP for short flows is easier since they experience less time-varying network behavior. SWARM takes care in modeling long flows along two dimensions: (1) whether their throughput is limited by loss or contention, and (2) how this limitation changes over time as flows arrive/depart and network bottlenecks shift.
- It uses a suite of aggressive scaling methods, which include pipelining, parallelism, topology downscaling, and careful data structure design to estimate CLP quickly.

Using CLP estimates allows SWARM to explicitly account for failure characteristics (*e.g.,* packet drop rate), reason about a broader range of mitigations (taking no action or bringing back a previously disabled link), and model failures (*e.g.,* packet drops below the ToR) that previous methods [63, 71] cannot (see Table 1).

In summary, we make the following contributions:

- We propose CLP-aware failure mitigation, which finds the mitigation with the least impact on network performance. This is a significant departure from state-of-the-art.
- We identify sufficient approximations that allow us to build a robust and scalable CLP estimator that helps rank mitigations effectively (Fig. 1) and support a broader range of failures and mitigations compared to prior work (Table 1).
- We show SWARM is fast at scale and useful. For common failure scenarios (Scenarios 1 and 2 in §4), it picks either the best mitigation or one that is at most 9% worse than the best mitigation. It also outperforms the state-of-the-art by orders of magnitude. In more complicated failure cases which many prior work [63, 71] do not support, SWARM picks an action that is only 29% worse than the best mitigation.

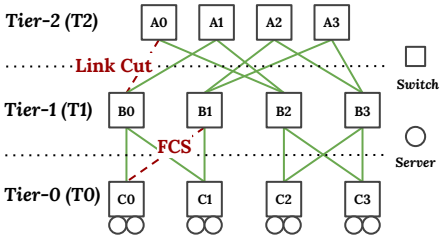

FIGURE 2: An example of two consecutive failures. First, the link between C0 and B1 experiences frame check sequence (FCS) errors. After mitigating, but before fixing this failure, a fiber cut between A0 and B0 causes congestion-induced packet drops.

2 CLP-Aware Mitigation

We use simplified versions of real-world incidents at Azure (Fig. 2) to explain the limitations of state-of-art auto-mitigation techniques and to illustrate the benefit of CLP-based impact assessments.

Failure scenario. Multiple link failures are common in cloud providers [7, 31, 55]. We emulate this in the Clos topology in Fig. 2. First, frame check sequence (FCS) errors [71] appear on a link. Operators mitigate this failure, but before they can physically replace the link, a fiber cut on another link (LINK CUT) causes congestion and packet loss.

We emulate (in Mininet [37], details in §4) a sequence of flow arrivals and successively apply each mitigation (or a combination of them) for FCS and LINK CUT. We use HIGH FCS and LOW FCS to denote the drop rate of $\sim 5\%$ and 0.005% respectively. For this example, our goal is to maximize the 1st percentile (1p) throughput [3]. We show how using Azure's troubleshooting guide, CorrOpt [71], and NetPilot [63] lead to substantial and unnecessary performance degradation.

Troubleshooting guides in Azure disable any failed link (with drop rate $\geq 10^{-6}$) if at least half of the switch uplinks are healthy. This mitigation for FCS achieves a 1p throughput of 3.6 Mbps and is optimal when the drop rates are high (HIGH FCS). However, it is conservative and static, and ignores the failure pattern, link location, and traffic demand. For example, leaving the lossy link in place in LOW FCS and taking no action has a higher 1p throughput (14.2 Mbps), while disabling the link causes congestion and impacts tail performance. For LINK CUT, Azure's guidelines do not do anything in the face of congestion, which results in a 1p throughput of 2.7 Mbps. In this case, the 1p throughput is higher if we adjust WCMP [70] weights to reduce traffic on congested links (3.2 Mbps).

CorrOpt [71] disables the link in FCS if there is sufficient path diversity. This is sub-optimal for the same reason dis-

[3] SWARM can optimize quantiles of both throughput and FCT.

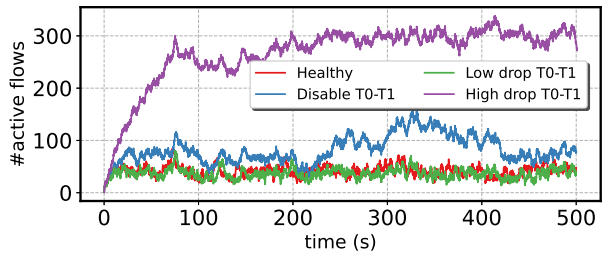

FIGURE 3: Failures and mitigations can increase flow durations, resulting in more active flows. (Fig. 2 topology in in Mininet)

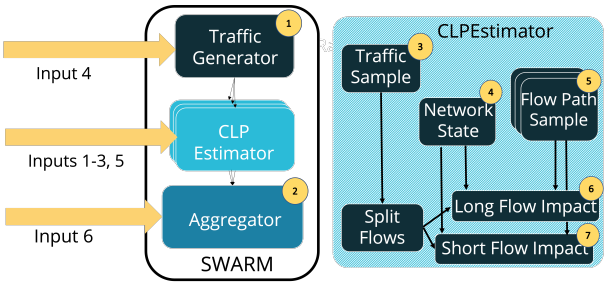

FIGURE 4: SWARM Design.

cussed above: depending on the failure properties (*e.g.,* drop rate and location), taking no action may lead to a higher 1p throughput. CorrOpt focuses on FCS errors and does not consider congestion induced by capacity drops, like LINK CUT.

NetPilot [63] always disables the faulty link to optimize one of its health metrics (loss rate). This may not be the best option. In a LOW FCS scenario, disabling the link drops the 1p throughput from 15 Mbps to 3.6 Mbps. After the LINK CUT, NetPilot disables the congested link or switch to avoid additional drops. This exacerbates the problem and reduces the 1p throughput to 3.17 Mbps. A better strategy is to undo the previous mitigation and re-enable the LOW FCS link when LINK CUT occurs, which results in 1p throughput of 14.2 Mbps.

Takeaways. While this is a simplified example, operators can negatively impact customers in practice and cause extended outages if they fail to find an effective mitigation [2]. Rules with static thresholds in troubleshooting guides cannot capture correct mitigations because CLP impact depends on traffic demands. Path diversity measures (as in CorrOpt) cannot capture customer impact since they do not account for the failure characteristics. Non-end-to-end metrics like packet loss or utilization (as in NetPilot) often suggest disabling links, which discounts better mitigations. In contrast, SWARM ranks mitigations based on impact on end-to-end global measures.

3 SWARM Design

Network operators seek to improve flow completion time (FCT) and throughput in their datacenters [5, 6, 41, 44, 61]. These CLP metrics evaluate the performance properties of importance for short and long flows. Moreover, operators express their objectives as distributional statistics over the entire datacenter (*e.g.,* tail or average performance). In this section, we describe how SWARM ranks mitigations in terms of their impact on CLP metrics, throughput and FCT.

3.1 Challenges and Insights

Challenges. To optimize CLP objectives, SWARM must quickly estimate the distributions with sufficient accuracy to ensure effective mitigation ranking. This is hard:

Traffic characterization. SWARM requires information about traffic demands to estimate CLP distributions for a given failure and mitigation. Instantaneous flow or ToR-level traffic matrices (TMs) can provide this information. However, fine-grained flow-level TMs are impractical to capture at datacenter scales and are sensitive to failures and mitigations. For example, packet drops often extend the flow durations, resulting in 3 - 4× more concurrently active flows (Fig. 3). ToR-to-ToR TMs, as in NetPilot [63], are too ambiguous since they aggregate flows with different characteristics (*e.g.,* capacity drops impact long flows more than short flows).

Routing determines the contention level at each link, which impacts throughput and FCTs. It depends on ECMP hash functions, as well as any existing failures in the network. The ECMP hash functions can change when links fail or switches reboot [56]. SWARM must consider these factors.

Transport behavior. SWARM needs to model transport behavior since CLP measures depend on congestion control algorithms (*e.g.,* BBR vs. Cubic), their parameters (*e.g.,* initial window size), and their reaction to failures (*e.g.,* packet drops). However, it is hard to model transport behavior while maintaining scalability. Accurate simulations over-index on specific protocols and are slow [29]. Faster approximate simulators do not account for lossy links [67, 68] or require a prohibitive amount of compute [67]. Existing formal models have limitations (see §6). For instance, fluid models [36] capture steady-state for long flows, but datacenter flows are often short and do not reach a steady state [44].

Temporal and spatial dependencies. CLP measures depend on the time-varying number of flows competing for bandwidth at a link. They also depend on where and for how long these flows experience congestion. For example, a flow bottlenecked at a link does not need its full fair share at other links. These bottlenecks may shift frequently due to flow arrivals and departures, and SWARM must capture them.

Approach. At the core of SWARM (Fig. 4) is a *CLPEstimator* that estimates the *distribution* of throughput and flow completion time (FCT) for a given network, failure pattern, and mitigation set.

SWARM avoids the limitations of fine-grained flow-level TMs and uses an *approximate* TM distribution (§3.2). It generates multiple (①) TM samples (③) from three inputs that cloud providers like Azure already collect: the flow arrival rates, the flow size distributions [44], and the probability of server-to-server communication [9].

Failure	Mitigation	Works that consider these failures/actions
Packet drop above the ToR	Take down the switch or link	NetPilot, CorrOpt, Operators
	Bringing back less faulty links to add capacity	×
	Changing WCMP weights	×
	Do not apply any mitigation	×
Packet drop at ToR	Disable the ToR	Operators
	Move traffic *e.g.,* by changing VM placement	×
	Do not apply any mitigation	×
Congestion above the ToR	Disable the link.	NetPilot, Operators
	Disable the device	NetPilot, Operators
	Bring back less faulty links to add capacity	×
	Change WCMP weights	×
	Do not apply any mitigation	×

TABLE 2: List of failures and mitigations in SWARM. Disabling a device is a common mitigation for congestion [63], see §E.

SWARM addresses routing uncertainty by evaluating CLPs on enough flow path samples (5) to reach a target statistical confidence (§3.3). It generates these samples based on the network state (4).

The trickiest challenge is to model the impact of losses and dependencies between concurrent flows on throughput and FCT. To this end, SWARM uses three techniques.

Epoch-based flow rate estimator. SWARM uses a fast, scalable epoch-based flow rate estimator to handle temporal bandwidth changes and flow dependencies. It divides time into multiple epochs, recomputes CLPs in each epoch, and *combines* the results to find an overall estimate.

Traffic Classification. SWARM needs to quickly find effective mitigations at scale rather than accurately estimating the flow performance, which can be slow [29]. Therefore, SWARM divides traffic into long (6) and short flows (7) based on their sizes [5, 44]. In each epoch, it estimates throughput and flow completion time separately. This approach results in significantly better mitigations (§4) for three reasons:

First, failures affect short and long flow differently. Longer flows are exposed to network variations, while shorter flows only experience a snapshot of the network and have more predictable FCTs.

Second, congestion control algorithms [12, 28] typically have a start-up phase to find available bandwidth. Short flows with few packets may finish during this phase. Therefore, they experience queueing delays caused by switch buffer occupancies rather than bandwidth limits [5, 44]. Accounting for these factors improves the effectiveness of our approach.

Third, previous studies [5, 6, 44] have shown that datacenter traffic is a mixture of short and long flows. Short flows are delay-sensitive, while long flows are throughput-sensitive. SWARM reports these separately and allows operators to adjust their mitigations based on their requirements. For example, they can prioritize short flows if their workload mainly consists of latency-sensitive short flows. Modeling these two classes separately also helps with scalability. Future work can explore modeling more than two classes of flows, such as those that are not short enough to ignore startup behavior.

Transport protocol abstraction. SWARM uses an approximate model of transport protocols that is effective and scalable: (1) it assumes long flows are TCP-friendly [4, 20], which means each long flow grabs a fair share of the bottleneck bandwidth in the absence of failures. (2) under failures and packet drops, SWARM determines if long flows are *capacity-* or *loss-limited*. For capacity-limited flows, it computes their fair share of bandwidth. For loss-limited flows, it estimates the bandwidth at which the control loop converges under loss. SWARM extends existing max-min fair algorithms [34, 45] to detect and estimate both simultaneously. (3) SWARM assumes short flows do not reach steady-state and are impacted by packet drops or queueing delays rather than the bandwidth limits.

SWARM aggregates distributions (2) from each traffic and routing sample. Operators use these to rank mitigations and set priorities based on one or more distributional metrics (*e.g.,* prioritize average throughput over FCT).

3.2 SWARM: Inputs and Outputs

Inputs. Operators or auto-mitigation tools can invoke SWARM with the following inputs:

1. Datacenter topology.
2. List of ongoing mitigations (if any).
3. Failure pattern (*e.g., estimated* loss rate) and location.
4. Data center traffic details (*e.g.,* TMs distributions).
5. Candidate mitigations to evaluate.
6. A *comparator* that ranks mitigations by CLP estimates.

Inputs 1-2-3. Cloud providers use monitoring systems [13, 40] and automated watchdogs [21] to detect incidents and use different techniques [8, 63, 66] to localize the failure. They then create incident reports [1, 2, 21] that contain details of the incident. On-call engineers or automation systems use these reports to install mitigations that are active until the operator finds the root cause and repairs the failure. These reports contain the information SWARM needs, such as the failure

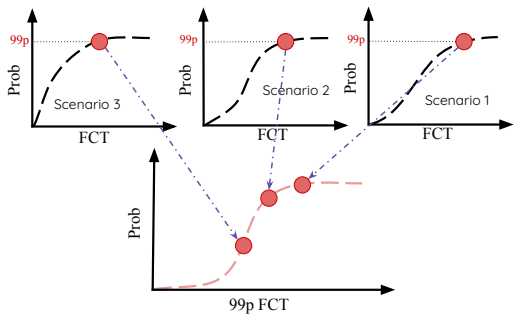

FIGURE 5: The composite distribution of 99p FCT obtained from the FCT distributions of different traffic and routing samples.

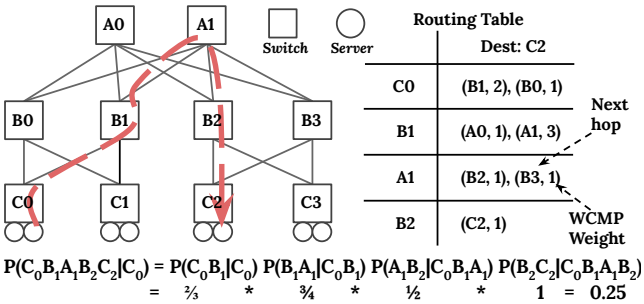

FIGURE 6: The probability of a flow taking a particular path.

location or pattern. The failure characterization (*e.g.,* packet drop rate) is sometimes imperfect, and operators may not be able to accurately localize the failure. SWARM can tolerate errors in packet drop rate (§4), and operators can incorporate the probability of different locations (§5) and iteratively refine mitigations to deal with imperfect localization.

Input 4. SWARM requires simple characterizations of datacenter traffic: the flow arrival distribution, the server-to-server communication probability, and the flow size distributions. From these, it extracts a set of flow-level demand matrices (§3.3). These probabilistic characterizations of the inputs allows SWARM to be robust to traffic variability and ensure a desired level of statistical confidence in its estimation.

Input 5. SWARM requires a mapping from the failure types to a list of mitigations or a combination of mitigations. Cloud providers [33, 57] already document possible mitigations for each type of incident in their troubleshooting guidelines and can use these documents to create the mapping. Certain actions may require additional information, such as VM placements or WCMP weights. We assume operators use existing techniques [26, 60] to find values for these inputs. Table 2 shows a sample of failures and associated mitigations.

Input 6. Operators can customize the *comparator*. We currently support two types of comparators, and we can easily extend to others (see §4). The *priority* comparator considers throughput-based and FCT-based metrics in a pre-specified priority order. The *linear* comparator is a linear combination of two or more of these metrics, where the operator specifies the weights. This flexibility enables operators to adjust their mitigation strategy based on their workloads. For example, if delay-sensitive short flows [5, 44] are the dominant workload, they can choose to prioritize the impact on short flows.

Outputs. SWARM outputs the mitigation (or mitigation combination) with minimal impact as ranked by the comparator.

3.3 SWARM: Internals

The CLPEstimator (Fig. 4) takes a demand matrix $\mathcal{T}$ and a mitigation $\mathcal{M}$ as inputs and estimates: (a) the distribution of average throughput across all the long flows in $\mathcal{T}$ and (b) the distribution of FCT across all the short flows in $\mathcal{T}$. SWARM can compute average throughput from FCT and vice versa using FCT $= \frac{\text{flow size}}{\text{throughput}}$ if necessary. SWARM calls the CLPEstimator for each candidate mitigation and ranks these mitigations based on the estimates (see Alg. A.1).

How SWARM uses CLPEstimator. SWARM samples K different demand matrices (1 in Fig. 4) and invokes the CLPEstimator to evaluate a given mitigation on each of them. The CLPEstimator then internally generates N different *routing samples* (5), where each sample describes the path for every flow in the demand matrix. We choose K and N to ensure a desired confidence level (see below).

Depending on the comparator, SWARM estimates the *distribution* of the *percentiles* of throughput and FCT across the traffic and routing samples (Fig. 5). For instance, if the comparator uses 99p FCT, SWARM would extract the 99p from FCT distributions of the $N \times K$ samples and form a *composite distribution* of the 99p FCTs. The variance of this distribution captures the uncertainty in our estimates, which we can reduce by increasing the number of samples [14] (Fig. A.4).

SWARM uses the composite distribution (2) to compare and rank mitigations. This approach allows it to handle uncertainty explicitly and provide robust mitigation rankings.

Network state representation. SWARM models the network state (4) using a graph $G = (\mathcal{V}, \mathcal{E})$, where each edge e has a capacity and a drop rate (0% = healthy and 100% = down), each node v has a drop rate and a routing table, and each server s maps to a switch. Before each invocation, SWARM *updates* this state to reflect the mitigation (line 2 in Alg. A.1). It uses data structures to ensure this step is efficient (§3.4).

Modeling traffic variability. The demand matrix $\mathcal{T}$ includes the arrival times, flow sizes, and their corresponding source and destinations. To create $\mathcal{T}$, SWARM uses input 4 (1): for each flow, it randomly samples the arrival time from the flow arrival distribution, the source-destination pair from the server-to-server communication probabilities, and the flow size from the size distribution. SWARM then invokes CLPEstimator with K demand matrix samples. It uses the Dvoretzky–Kiefer–Wolfowitz (DKW) inequality [18] to determine K based on a given confidence level α. DKW provides confidence for the difference between an empirically sampled distribution and the ground truth distribution.

Modeling routing uncertainty. The CLPEstimator handles

routing uncertainty by generating N different flow path samples (5), each representing a different routing of the flows (§3.1). First, it uses the DKW inequality [18] to determine the N to achieve a confidence level of α. Then, it samples from the distribution of possible paths between source-destination pairs. It computes the probability of a specific path for a given source-destination pair based on routing tables and associated WCMP weights at each node (Fig. 6).

Modeling the throughput of long flows. SWARM models long and short flows separately (Line 6 and Line 7 in Alg. A.1). Long flows typically reach their steady state, and their throughput depends on network variations and packet drops.

Varying network conditions. SWARM approximates network variations and the arrival and departure of flows that compete on a link by dividing time into discrete epochs (Alg. 1). It assumes stable conditions within each epoch (no flow arrival/departure) but allows for variations across them. At the beginning of each epoch, SWARM adds the newly arrived flows to the set of active flows (Line 6). Then, it computes their bandwidth share (Line 7). At the end of each epoch, SWARM updates the number of transmitted bytes for each flow, removes the completed flows, and records their overall throughput estimates (Line 8-Line 16).

Computing bandwidth share. SWARM finds the rate of each flow within an epoch in two steps (Line 7 in Alg. 1):

1. It computes the loss-limited throughput of each flow, as described below.
2. It executes a demand-aware extension of the water-filling approach [34], which uses the loss-limited throughput estimates as an upper bound on the flow throughput and provably converges in O(number of edges). We have developed this extension (see §A.2).

Modeling loss-limited throughputs. It is possible to compute the throughput under packet drop analytically, but these models are specific to certain congestion control protocols and cannot easily extend to other variants (*e.g.,* [5]). SWARM overcomes this limitation by using an empirically-driven distribution of the loss-limited throughputs. To find this distribution, SWARM measures the average throughput of a long flow under different network conditions (*e.g.,* drop rate, latency) through experiments in a small testbed. In each experiment, it ensures that link capacities are high enough so that they never become bottlenecks, and the drop rate is the only limiting factor. SWARM repeats the experiment multiple times for each network condition to create a robust distribution [18]. Depending on the uncertainty in transport protocols running in the data center, we can also change the mix of transport protocols we use. SWARM then uses this distribution to sample the drop-limited throughputs. See §B for details.

Modeling the FCT of short flows. Prior work [42] develops an analytical model for the average FCT across flows. We are unaware of any models that can estimate the distribution. In developing SWARM, we observe that short flow are more predictable since they do not stay in the network long enough to be affected by network variations. Thus, a simple empirical model is sufficient to estimate their FCT distribution.

Algorithm 1: Impact on Long Flows.

Input: G. current network state.
Input: $\mathcal{T}$ = {<source, destination, size, start time>}.
Input: $\mathcal{R}$. the sampled routing of each flow.
Input: $\mathcal{I}$. measurement interval.
Input: ζ. epoch size.
Output: β_l. distribution of throughput of long flows

```
1  K ← {}
2  time ← 0
3  β_l ← []
4  while ∃ f ∈ T : f.start ≥ time or K ≠ ∅ do
5      time ← time + ζ
6      K.add({f ∈ T : time − ζ ≤ f.start < time})
7      θ_f ← compute_throughput(G, K, R)
8      for flow f in K do
9          f.sent ← min(f.sent + ζθ_f, f.size)
10         if f.sent = f.size then
11             K.remove(f)
12             if f ∈ I then
13                 β_l.append(f.size / f.dur)
14             end
15         end
16     end
17 end
18 return β_l
```

SWARM finds a short flow's FCT distribution (6) by estimating (a) its RTT and (b) the number of RTTs to deliver its demand. A short flow's FCT is equal to the average duration of RTTs multiplied by the required number of RTTs. We derive the distribution of each metric separately and then combine them to compute the FCT distribution.

We compute the distribution of the number of RTTs to deliver a flow's demand by conducting offline experiments in a small testbed. We repeat the experiments for different configurations (flow size, slow start threshold, initial congestion window) and network settings (drop rates, RTT) and store the results in a table that maps the setting to the measured distribution.

Next, we estimate the RTT, which is equal to the sum of the propagation delay (a constant determined by the flow's path) and the queueing delay along the flow's path. To estimate queueing delay, we collect data from sending small flows on links with different utilization and active flow counts (§B).

SWARM combines these distributions to derive the FCT distribution for short flows. It multiples the number of RTTs by the sum of the propagation delay and queueing delay.

3.4 Expressivity, Scaling, and Robustness

Expressivity. SWARM supports any failure or mitigation as long as we can model it as changes to the network state or the traffic. SWARM does not need the root cause of a failure or details of a mitigation but only needs to understand their observable impact (*e.g.,* packet drop, port down). This flexibility allows SWARM to support a wide range of failures and mitigations (Table 2). Existing production and state-of-the-art systems [63, 71] do not support many of these failures, while cloud providers [7, 24, 31, 55, 63, 71]) commonly observe them.

Robustness. SWARM's network-level mitigations should ideally mask network failures. However, this masking is not always perfect, and a cloud service might react to a mitigation (or the failure in general) by changing the traffic demand (*e.g.,* using retries). For this reason, SWARM does not model a fixed traffic demand. Instead, it draws multiple traffic samples from the historical distribution of flow arrivals, sizes, and communication probabilities to ensure statistical significance (§3.3). When operators do not have such statistics (*e.g.,* after a previously unseen failure or a data center expansion), SWARM uses a distribution that captures maximum uncertainty [51].

SWARM carefully models uncertainty, but its CLP estimates may not align with what operators observe after installing the mitigation. This can happen if an uncommon failure manifests itself that was not captured during the sampling process or if the traffic changes and the historical distribution is not representative anymore. In such instances, the auto-mitigation system that uses SWARM must update its inputs and invoke SWARM again to revise the mitigation. In other words, mitigation does not have to be a single-shot process and can be adjusted over time, especially since failure diagnosis might take hours to days [21, 63].

Scaling. SWARM must find a mitigation action quickly, even on large clusters. We scale it using the following techniques:

An ultra-fast max-min fair computation algorithm. We use an approximate computation of network-wide max-min fair share rates [45], which provides significant speedup over the state-of-art methods [34] without affecting quality.

Efficient network state and traffic update. The traffic trace is independent of the network state. This means SWARM can compute the traffic samples offline. However, when SWARM invokes CLPEstimator, it must update network state to reflect each mitigation and then re-compute routing samples. To scale, SWARM separates the topology representation from the traffic representation. It models the former as a graph (§3.3) and sorts the latter into a list of tuples (source and destination server, flow size, and flow start time). This design enables, for example, disabling a link by changing the drop rate in G to 100% or updating the traffic if a mitigation such as VM migration modifies a flow.

Parallelism and pipelining. SWARM (a) evaluates demand and routing samples in parallel, and (b) parallelizes and pipelines routing sample generation with epoch execution.

Reducing the number of epochs. After these steps, the bottleneck is the number of epochs in Alg. 1. We use two techniques. Firstly, we initialize on an already warmed-up network instead of starting from an empty network. This eliminates the need for a set of epochs at the beginning to mimic the cold-start effect. Secondly, the residual impact of flows that compete within an epoch diminishes over time. Therefore, epochs with large time differences present independent network snapshots. This observation allows us to compute their CLPs independently in parallel and combine the results to form an overall distribution.

Traffic downscaling. Following POP [47], SWARM downscales the demand matrix with minimal impact on throughput. It splits a network with link capacity c into k sub-networks with link capacity $\frac{c}{k}$ and divides traffic randomly across these sub-networks. POP [47] recommends choosing a value for k that is much smaller than the number of flows, which allows each partition to capture the network contention. This approach works with any flow arrival distribution. We use Poisson distributions [23, 35, 41], where assigning flows randomly is the same as downscaling the arrival rate based on the Poisson splitting property.

4 Evaluation

Our prototype of SWARM has 1500 lines of Python. We evaluate it on three categories of incidents and show it outperforms existing methods. We also show it scales and finds the best mitigation for a 16K-server topology within 5 minutes.

4.1 Methodology

Metric. We evaluate each approach by computing the *Performance Penalty (%)*, which is the relative difference between the CLP metrics that result from the best possible mitigation and the one each technique suggests. This metric captures the unnecessary performance degradation caused by a technique choosing sub-optimal mitigation. Often, the difference between the best mitigation and the "runner-up" is insignificant, resulting in a small penalty. In contrast, the difference between the best mitigation and the one the baselines choose can be as high as 200%.

Experimentation setup. We evaluate SWARM using Mininet [37], NS3 [29], and a physical testbed. Here is the summary of our setup (see §C for more details):

Traffic characterization. We use Azure production logs to derive the flow inter-arrival time, a commonly used distribution from DCTCP [5] for our flow size distribution, and [38] for server-to-server communication probability. We ensure that the trace duration is long enough to capture all flow sizes and that we do not capture an empty network's effect. Finally, we run on 30 different traces to ensure robustness.

Emulation Setup. We mainly use Mininet for our evaluation since it leverages a real TCP/IP stack from the Linux

kernel. We extend it to improve the fidelity of our results (monitoring systems, queueing disciplines). We report results on 57 scenarios (over 4000 hours of experiment) across 3 types of common incidents in cloud providers [7, 24, 55, 63, 71] (Table 2). We describe these scenarios in §4.2 and Table A.1. We use the Clos topology from Figure 2.

We seek to emulate 1500 flows arriving per second per server, which results in 12,000 flows every second. These are on links with 40 Gbps bandwidth and 50 μs propagation delay. However, running Mininet on a VM with 64 cores and 256 GB cannot emulate this demand. Instead, we use [48, 50] to downscale the traffic and link capacities by 120×(see §C.4). We run each emulation for 500 s and measure the performance for flows that start within [50, 150) s to avoid capturing effects from an empty network. We report results for both Cubic [28] and BBR [12] (and DCTCP [5] in our simulation).

Simulation Setup. We use a Clos topology with 128 servers, 32 ToRs, 32 T1s, and 16 T2s, all connected by 20 Gbps, 100 μs links. We use DCTCP [5] as the congestion control algorithm to show generality. Each of our traffic traces is 10 s long, and we measure the flows that start within [0.5, 1) s[4]. We use DCTCP [5] and FbHadoop [54] flow size distributions.

Testbed Setup. We use a different variant of Clos (see §C.3) with 32 servers, six TORs, four T1s, and two T2 switches, all connected by 10 Gbps 200 μs links. All switches are Arista 7050QX-32. We introduce random packet loss in the testbed using a user-defined access control list (ACL) to match bits on the IP ID field in packet headers and directly modify the Broadcom firmware to drop packets the ACL matches. Thus, packet loss rates in the testbed are powers of two based on the number of bits the ACL matches on. We evaluate the impact of the failure and each mitigating action on the testbed with a traffic load of 3000 flows per second. Each trace is 30 seconds long, and we measure across flows that start within [2, 5) s.

SWARM *Parameters.* We use 32 different random traffic traces and 1000 routing samples based on §3.3. For our baseline comparisons (with Mininet), each trace is 200 s long. We compute the performance over all the flows that start within [50, 150) s. Each epoch is 200 ms. We also consider any flow with a size ≤150 KB short.

Baselines. We compare SWARM to:

NetPilot [63] iterates through each possible mitigation, computes the maximum link utilization, and picks the action that minimizes utilization. NetPilot does not model link utilization on faulty links, so it always disables corrupted links. We report these results as NetPilot-Orig. We also extend NetPilot to mitigate only if the resulting maximum link utilization is below a threshold. We report these results as NetPilot-80 for an 80% and NetPilot-99 for a 99% utilization threshold.

[4]We adjust the duration based on the flow arrival rate and link bandwidths. When these values are smaller as in our Mininet experiments, it will take longer for a certain number of flows to arrive, and each flow remains in the network for a longer period. Thus, we need to cut a longer duration at the beginning to ensure we are not capturing the effect of the empty network.

CorrOpt [71] only considers link corruption failures. It disables a link if the number of remaining paths to the spine after taking the action is above a threshold. We consider three thresholds: CorrOpt-25, CorrOpt-50, and CorrOpt-75, which use a threshold of 25%, 50%, and 75%, respectively.

Operator playbooks. When an FCS error occurs above the ToR where there is path redundancy, the Azure playbook will disable the affected link if the number of remaining uplinks at the switch is above a certain threshold. We consider three thresholds: Operator-25 uses a 25% threshold, Operator-50 uses 50%, and Operator-75 uses 75%. When there is packet loss of more than 10^{-3} at or below the ToR, the playbook will drain the affected nodes, which is expensive and risks VM reboots or interrupts. Otherwise, it would take no action.

Some baselines cause a partitioned network under certain scenarios in part due to the smaller scale in our Mininet evaluations. Unless noted otherwise, we only report cases where all baselines keep the network connected for a fair comparison.

Comparators. Most experiments use two priority comparators (§3.2) (§D.4 shows SWARM achieves low penalty across two other comparators including a linear one as well):

PriorityFCT minimizes the 99p FCT. It uses two tiebreakers, 1p throughput followed by average throughput.

PriorityAvgT maximizes the average throughput first, using two tiebreakers, 99p FCT, followed by 1p throughput.

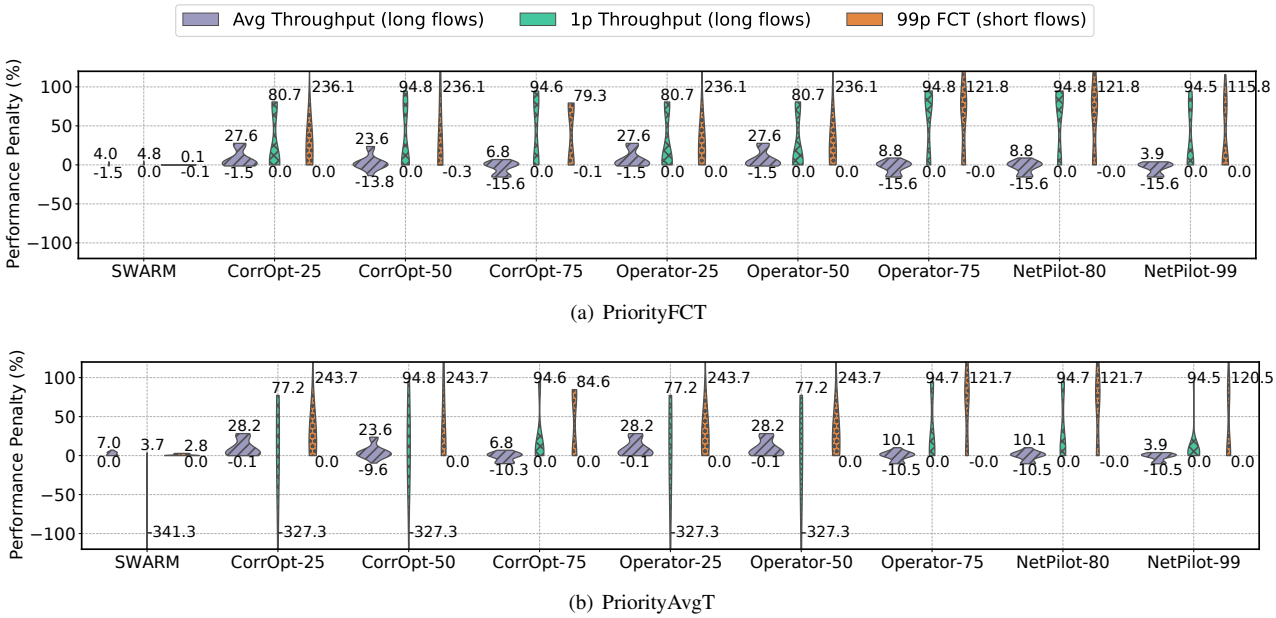
Two mitigations are tied on a particular metric if they are within 10% of each other on that metric.

4.2 Baseline Comparisons

We evaluate SWARM over three different failure scenarios, which are common in production incidents at Azure.

Scenario 1: Link-level packet corruption with network redundancy. In this scenario, we evaluate different combinations of two links consecutively experiencing FCS errors with a drop rate of $\sim 5\%$ (*high*) or $\sim 0.005\%$ (*low*). This is the most common failure pattern at Azure, and both drop rates are detected and reported as incidents. In this case, the viable mitigations are doing nothing, disabling the link, undoing past mitigations, changing WCMP weights, or any feasible combination of these. All baselines support this scenario because the link failure is above the ToR, and there is path redundancy.

In Fig. 7, we compare the performance penalty of SWARM to the baselines for both comparators. We do not compare to NetPilot-orig in this scenario since it partitions the network in 16 out of 32 failure pairs, and the results on the remaining failures are not statistically significant. We use violin plots to show the performance penalties' distribution across all incidents for each candidate approach and each metric. A tall violin plot indicates that performance penalties span a wide range, while a short and wide plot indicates that penalties are clustered within a small set of values. Even though the baselines do not explicitly use comparators, the best mitigation depends on the comparator, which causes the penalty to change for the baselines across different comparators.



(a) PriorityFCT

(b) PriorityAvgT

FIGURE 7: Comparison of SWARM and other baselines under Scenario 1 in Mininet. SWARM achieves 793× lower performance penalty on 99p FCT in the worst case compared to the next best baseline on PriorityFCT. SWARM is the only technique that achieves near-optimal performance across all three metrics and performs equally well across both comparators.

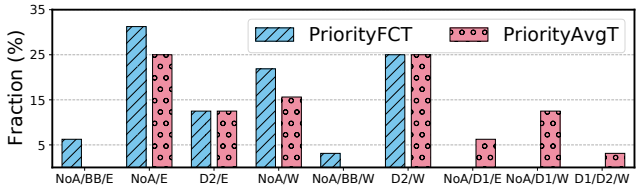


FIGURE 8: SWARM's actions in Scenario 1 (see §4). It chooses from nine action combinations and decides to take no action in more than 25% of the time. (NoA: No Action on link 2, D2: Disable link 2, BB: Bring Back link 1, D1: Disable link 1, W: WCMP Routing, E: ECMP Routing)

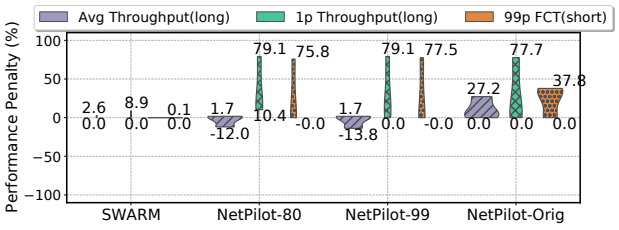
SWARM outperforms all baselines with a performance penalty consistently close to zero. When using the PriorityFCT comparator, SWARM has a maximum FCT performance penalty of 0.1%, compared to 79.3% penalty of the closest baseline, CorrOpt-75 (Fig. 7(a)). For the Priority-AvgT comparator, SWARM's maximum penalty on average throughput is similar to several of the baselines, such as NetPilot-99 and CorrOpt-75. However, SWARM reduces the performance penalty across *all three* CLP metrics while the baselines suffer from high performance penalties across at least one (Fig. 7(b)). SWARM's superior performance is due to its ability to analyze a broader set of mitigations and to choose one that reduces performance impact on all CLP metrics (see §F).

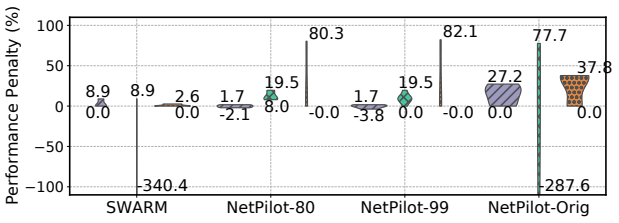
The negative penalty in some cases is because of the inherent trade-off between different metrics. For instance, the primary objective in Fig. 7(a) is to minimize short flows' 99p FCT. The optimal mitigation is the one that has the best FCT, even if it worsens other metrics. For example, CorrOpt-75 selects actions that increase the 99p short flow's FCT (highest priority) by up to 80% compared to the optimal action but achieve better average throughput (lower priority).

We show the diversity of SWARM's proposed mitigation under each comparator in Fig. 8. We focus on the mitigation for the second failure since the action space is larger and includes options such as bringing back a previously disabled link. We find SWARM chooses from nine different possible mitigations and decides to take no action in more than 25% of the cases. In two scenarios under PriorityFCT, it not only takes no action on the second failure but also *reinstates* the faulty link it previously disabled from the first failure (action NoA/BB/E). SWARM considers the failure locations, their intensity, and the traffic demands and decides to preserve those links rather than eliminate their capacity and cause congestion. Under PriorityAvgT, SWARM chooses combinations of mitigations such as disabling both links and adjusting WCMP weights.

Scenario 2: Congestion on a link. Operators shut down several faulty links (prior failures), causing the network to become over-subscribed. Meanwhile, an aggregation-core layer starts operating at half capacity (due to fiber cuts). CorrOpt and operator playbooks do not support this as they ignore traffic dynamics. NetPilot can reason about congestion but assumes the rest of the network is under-utilized. We evaluate SWARM and NetPilot under two failure patterns: (i) where the network is under-utilized and (ii) where a second link drops packets and reduces network capacity (Table A.1).

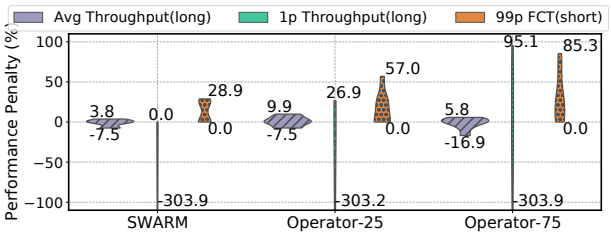


(a) PriorityFCT

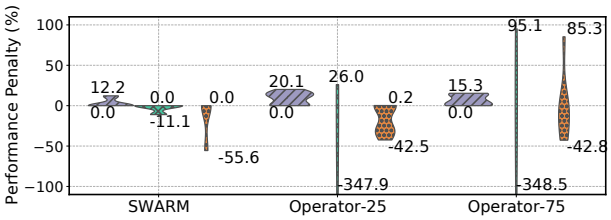


(b) PriorityAvgT

FIGURE 9: Comparison of SWARM and NetPilot variants under Scenario 2 in Mininet. Under the PriorityFCT comparator, SWARM always chooses a mitigation with near-optimal FCT performance ($\leq 0.1\%$), while the next best approach chooses mitigations up to 37.8% worse than optimal. SWARM is also the only approach with low performance penalty across all three metrics.



(a) Priority FCT



(b) Priority AvgT

FIGURE 10: Comparison of SWARM and operator playbooks on Scenario 3 in Mininet. Under PriorityFCT, SWARM has 2× lower 99p FCT penalty in the worst-case compared to operator playbooks. It also protects other non-priority metrics while optimizing for the priority metric (it outperforms baselines in both average throughput and 99p FCT under PriorityAvgT).

Fig. 9 compares the performance penalty of SWARM to the NetPilot variants for both comparators across both failure patterns. SWARM achieves consistently low penalty for its target CLP metric: 99p FCT in Fig. 9(a) and average throughput in Fig. 9(b). Since NetPilot assumes the rest of the network is under-utilized, it aggressively disables links and causes a large performance impact. Under PriorityFCT, SWARM chooses a mitigation with near-optimal performance on FCT, while the next best approach suffers an FCT penalty of 38%. Under the PriorityAvgT comparator, the NetPilot-80/99 variants result in lower impact on average throughput, but at the cost of increased performance penalty in at least one other metric (*e.g.*, NetPilot-80 achieves 7.2% less penalty in terms of average throughput at the cost of 80% penalty on 99p FCT) while SWARM is the only technique that performs well across both comparators and all three metrics.

Scenario 3: Packet corruption at ToR. In this scenario, we consider (Table A.1) failure patterns in which a ToR drops packets at either *high* 5% or *low* 0.005% rates. We also consider cases where both the ToR and a core link drop packets. CorrOpt and NetPilot do not support this failure as they can only account for scenarios where the network has redundant paths. The operator playbook makes a local decision on whether to mitigate the failure based on the severity of the packet loss, without considering the overall network condition. When the second failure occurs above the ToR, it reduces the capacity in the network core, causing the operator's approach to incur higher performance penalties.

Both playbook-based approaches suffer from performance penalties at least 2× higher than SWARM under PriorityFCT (Fig. 10). SWARM has a worst-case FCT penalty of 28.9% while the best operator approach has a worst-case FCT penalty of 57%. SWARM is again the only approach that achieves low penalty across all three metrics for both comparators.

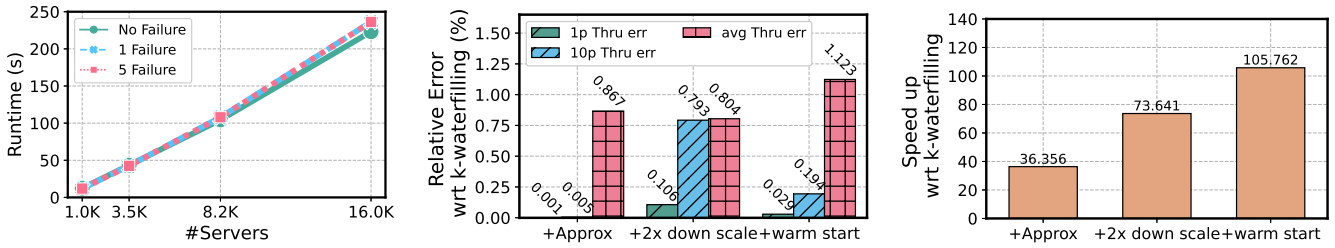
4.3 Other Results

Scalability. In Fig. 11(a), we show the time SWARM needs to find the best mitigation. SWARM's runtime scales linearly with the number of servers. Even on large-scale Clos topologies with 16K servers, SWARM needs less than 5 minutes, a fraction of the mitigation times operators report today [1, 21].

SWARM employs several approximation techniques to scale §3.4. In Fig. 11, we quantify the error and speed-up of these methods compared to a version of SWARM without these approximations. Each technique in §3.4 contributes significantly to speedup: (a) the max-min fair algorithm improves run-time by 36.3× and only introduces $\leq 0.9\%$ error; (b) downscaling traffic by 2× does not introduce additional error but produces 73.6× speedup! (c) adding warm-start and reducing the number of epochs results in 105.7× speedup and $\leq 1.2\%$ error. Future work can further speed this up by increasing the scale factor or reducing the number of epochs.

Sensitivity analysis. We evaluate SWARM's sensitivity to various inputs, including the drop rate estimates and the flow-arrival rates (see §D.1 for details).

As the inputs to the system vary, there are a few inflection points where SWARM is sensitive. These points are where SWARM can make mistakes and pick sub-optimal mitigations



(a) Runtime for different topology sizes (b) Estimation Error of different scalability choices (c) Speed up of different scalability choices

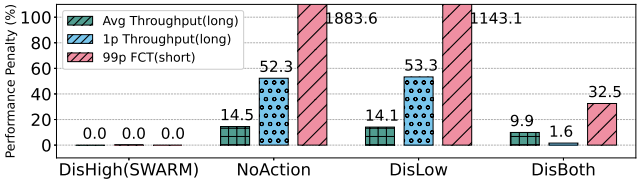
FIGURE 11: Scalability. (a) SWARM scales almost linearly with the number of servers. (b) Error introduced by each of our scaling techniques (approx refers to the ultra-fast max-min fair algorithm). (c) Speed-up from each of our scaling components. We compare with a version of SWARM that does not use the methods from §3.4, instead relies on extended 1-waterfilling [34] to compute max-min fair rates.

if the inputs are noisy. However, we find the difference between the impact of the mitigations is small around these inputs. Outside of these areas, the choice of better mitigation is clear. Thus, SWARM can tolerate large errors in the input distribution: the difference between mitigations is either large enough around that point so the choice of mitigation is clear or it is small enough where a mistake is not too costly.

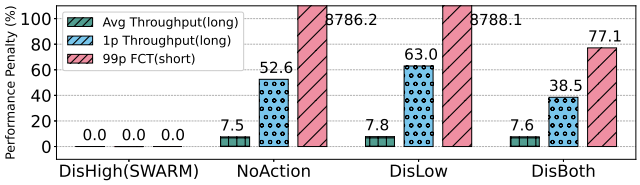
SWARM can also pick the best mitigation under different congestion control protocols (see Fig. A.3). For this, we compare two protocols with different behaviors under loss: (1) Cubic [28], which drastically reduces its sending rate under packet loss, and (2) BBR [12], which does not. SWARM picks the best mitigation irrespective of which protocol we use. However. its approximations of the 1p throughput distribution are more accurate when the mix of protocols is known (it can explicitly account for their differences in handling loss).

Simulation validation. To show SWARM's effectiveness at larger scales with realistic link speeds and latencies, we conducted a simulation using NS3 [29] on a 128-server topology with 20 Gbps 100 μs links. NS3 alone takes over a day to complete one simulation run (one sample). We invested significant effort in parallelizing NS3 using MPI and reduced the time to run one sample to 6 hours. On this topology, we induce a failure in which two links drop packets (one ToR-T1 at 0.005% and one T1-T2 at 0.5%). This scenario shows the complex effect of different packet drops at different levels of datacenters and the trade-off between causing congestion by disabling the links versus incurring packet drops by taking no action. Apart from the DCTCP distribution, we also simulated FbHadoop [54] that has more short flows. These experiments required over 2100 hours to complete.

Fig. 12 shows the performance penalties of different actions. SWARM is able to identify if the congestion introduced by disabling the link would impact the flows more than the packet drop or vice-versa. In contrast, prior work (NetPilot, CorrOpt, and Operator) ignores the impact of traffic and failure characteristics on the mitigation. SWARM finds the best mitigation (only disabling the high drop rate link). In contrast,



(a) DCTCP Traffic Distribution



(b) FbHadoop Traffic Distribution

FIGURE 12: NS3 evaluation with different flow size distributions. (Dis=Disable, High=High drop link, Low=Low drop link)

the baselines either disable both links or keep both links and incur 32% – 78% penalty on 99p FCT. Note that the performance penalty of not taking any action is the same as only disabling the link with a low packet drop since they both keep the link with a high drop rate in the network. This link ends up dropping many packets and determines the tail FCT.

Testbed validation. To demonstrate SWARM makes high-quality decisions even on a physical testbed, we induce a failure pattern from Scenario 1 in which a ToR – T1 link randomly drops 6.25% ($\frac{1}{16}$) of the packets, while a link from a different T1 to a T2 also drops packets at 0.39% ($\frac{1}{256}$).

SWARM picks an optimal mitigation for Priority-FCT and a mitigation with less than 1% penalty for PriorityAvgT (Fig. 13). In contrast, the FCT performance penalty for choosing the worst action under PriorityFCT is over 1000%. While the average throughput performance penalty is low across all mitigations in this incident, SWARM picks an action with a low penalty across all three metrics under the PriorityAvgT comparator. It avoids the 93% penalty in 1p throughput and

(b) Priority AvgT

FIGURE 13: Physical testbed validation with two links dropping packets. We consider four mitigation strategies (disable or take no action). Optimal mitigation has zero penalty.

1095% penalty in 99p FCT for the worst action.

Impact of the comparator. We also observe that SWARM adjusts its decision based on the comparator. Across all the single link failures from Scenario 1 (Table A.1), SWARM takes no action more often under the PriorityAvgT comparator than the PriorityFCT. This is because average throughput is sensitive to the remaining capacity in the network, so SWARM is more likely to keep the lossy link up.

Justifying design choices. We also conducted several experiments to justify the special treatment of loss-limited flows, estimating distributions of FCT and throughput, using multiple epochs to capture flow dynamics, using distributional measures to determine the best mitigation, and the importance of accounting for queueing delay (see §D.3).

5 Discussion and Limitations

SWARM is a first step towards CLP-aware incident mitigation. It has limitations that future work can address.

Support for loss-less transport. Cloud providers increasingly use RDMA [22, 58] for internal traffic. We can modify SWARM's CLPEstimator to (a) detect and account for pauses and (b) model loss-recovery approaches when losses happen.

Support for other routing protocols. SWARM applies to any datacenter that relies on ECMP or WCMP for routing. These are commonly used in Clos topologies. Our experiments show the effectiveness of SWARM on different variants of Clos. Future work can extend this to topologies that use traffic engineering (*e.g.,* direct-connect [49, 61])

Mitigations with transient effects. Some actions introduce transient risk. For example, a switch may drop packets during reboot, causing a non-steady-state impact on long flows.

Approximate failure localization. SWARM waits for operators or automation to localize the failure. It can instead use a spatial failure distribution which is available much sooner. This lowers the mean time to repair. SWARM relies on the correct input of the *type* of failure.

Impact on wide area network traffic. WAN traffic is a small fraction of the datacenter traffic [10, 19], so we ignore its impact. When WAN traffic increases, we would need to account for larger RTT.

Other extensions. Future work can extend SWARM to other metrics such as jitter and failures of software components such as load balancers. It can also account for estimated repair time in ranking mitigations, which can be challenging as incidents with vastly different repair times often have similar symptoms [25]. Future work can also explore the benefits of modeling more than two classes (short and long) of flows.

6 Related Work

Impact or risk estimation in networking. No prior work considers CLP-aware failure mitigation but several estimate the impact or future risk of management operations. Janus [4] focuses on risk estimation for datacenter management operations. RSS [64] estimates the risk for backbone management. TEAVAR [11] and [17, 62] route traffic in production wide area networks to minimize long-term impact. [43] models the risk of demand uncertainty and its impact on revenue in a WAN. Other approaches minimize the impact of failures without explicitly accounting for risk [39, 69].

NetPilot [63] and CorrOpt [71] are closest to SWARM. These can fail to produce mitigations with minimal CLP impact (see §2) because they (a) ignore the failure pattern, (b) do not account for traffic changes, (c) use proxy metrics (*e.g.,* maximum utilization) that only loosely correlate with CLPs, and (d) estimate impact on a healthy network, which limits the set of mitigations they support.

Computing fair share. Prior work assumes flows follow max-min fairness, which matches the objective of TCP [20], and either employ optimization [16, 30, 45, 46, 59], use simulations [68], or iterative algorithms [15, 32, 34, 45, 52, 53] to find the fair share. These approaches are limited; they assume flow rates are only limited by the network capacity and ignore packet drops.

7 Conclusion

Failure mitigation is crucial in running datacenters at scale, but operators often find it hard to choose the right action. SWARM ranks mitigations based on their impact on well-known CLP metrics. Our evaluation shows approximating these mertics is possible at scale and results in mitigations with orders of magnitude lower performance penalty.

Acknowledgments. We thank our shepherd, Sergey Gorinsky, and the anonymous reviewers for their insightful comments. A Algorithm Details

A.1 CLPEstimator Function

Alg. A.1 shows the CLPEstimator in detail. It first uses the DKW inequality [18] to compute the necessary number of samples to achieve a certain confidence level. It then adjusts the topology and the traffic based on the mitigation $\mathcal{M}$. Finally, it divides the resulting traffic into short and long flows, and computes their CLPs separately on multiple routing samples (§3.3).

Algorithm A.1: CLPEstimator Function.

Input: $\mathcal{T}$. traffic matrix (src, dest, start time, size).
Input: G. network state (location, type, failures).
Input: $\mathcal{M}$. mitigation.
Input: α. confidence threshold
Output: $\beta_l = \{\beta_l^{\mathcal{R}}\}$. $\beta_l^{\mathcal{R}}$ is the distribution of impact over all the long flows for routing sample $\mathcal{R}$.
Output: $\beta_s = \{\beta_s^{\mathcal{R}}\}$. $\beta_s^{\mathcal{R}}$ is the distribution of impact over all the short flows for routing sample $\mathcal{R}$.

1 $N \leftarrow$ num_samples(α)
2 $G_a, \mathcal{T}_a \leftarrow$ apply_mitigation($G, \mathcal{M}, \mathcal{T}$)
3 $\mathcal{T}_s, \mathcal{T}_l \leftarrow$ split_traffic($\mathcal{T}_a$)
4 **for** $n \in 1 \ldots N$ **do**
5 $\mathcal{R}_n \leftarrow$ get_routing_sample(G_a)
6 $\beta_l^{\mathcal{R}_n} \leftarrow$ impact_long_flows($G_a, \mathcal{T}_l, \mathcal{R}_n$)
7 $\beta_s^{\mathcal{R}_n} \leftarrow$ impact_short_flows($G_a, \mathcal{T}_s, \mathcal{R}_n$)
8 **end**
9 **return** β_l, β_s

A.2 Demand-Aware Max-Min Fair

CLPEstimator computes the impact of a given mitigation $\mathcal{M}$ on the throughput of long flows in two steps. (1) it estimates the drop-limited throughput for each flow (Line 1 in Alg. A.2), assuming there is no congestion and the packet drop enforces the maximum possible rate. (2) CLPEstimator computes the max-min fair rate of each flow and enforces these drop-limited throughputs as an upper limit on the rate (demand) of each flow (Line 2). This ensures that a flow does not receive more than its drop-limited throughput unless it is limited by its fair share when congestion is more severe than the drop rate.

Algorithms to compute max-min fairness [34] assume demands are unbounded and are only limited by the network capacities. In SWARM, we develop a demand-aware extension of these algorithms that can enforce limits on each flow's rate (Alg. A.3). To achieve this, we augment the topology and add one virtual edge per flow with capacity set at the drop-limited rate. Then, we use existing algorithms to compute the network-wide max-min fair rates on this augmented topology. We can use the same method to enforce congestion control rate limits in the first few epochs of each flow in cases where the protocol's congestion window limits the flow's rate.

We can use any of the variants of the k-waterfilling algorithm [34] in the network-wide-max-min-fair function in Line 6 (but some can result in O(|E| + |F|) number of iterations where |E| is the number of edges and |F| the number of flows). Instead, we use a faster variant of max-min fairness [45] that speeds up k-waterfilling by 30× with minor degradation in the quality of the estimated rates (Fig. 11(c), Fig. 11(b)).

Algorithm A.2: Compute throughput.

Input: G. current network state.
Input: $\mathcal{T}_{1\times n}$. source destination pairs (long flows).
Input: $\mathcal{R}_{1\times n}$. the (sampled) routing for each flow.
Output: F. max-min fair rate

1 $\theta \leftarrow$ get_drop_limited_throughput($G, \mathcal{T}, \mathcal{R}$)
2 $F \leftarrow$ demand_aware_max_min_fair($G, \mathcal{T}, \theta, \mathcal{R}$)
3 **return** F

Algorithm A.3: Demand-Aware Max-Min Fair.

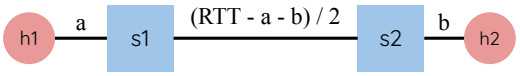
Input: G. current network state.
Input: $\mathcal{T}_{1\times n}$. source destination pairs (long flows).
Input: $\mathcal{R}_{1\times n}$. the (sampled) routing for each flow.
Input: $\theta_{1\times n}$. the drop-limited rate for each flow.
Output: $\hat{\theta}_{1\times n}$. max-min fair rates after applying congestion.

1 **for** $\forall f \in \mathcal{T}$ **do**
  /* add one virtual link per flow */
2 $e \leftarrow G$.add_virtual_edge()
  /* set capacity to drop-limited rate */
3 e.capacity $= \theta_f$
  /* add to the route of flow f */
4 $\mathcal{R}_f$.add(e)
5 **end**
6 $\hat{\theta} \leftarrow$ network_wide_max_min_fairness($G, \mathcal{T}, \mathcal{R}$)
7 **return** $\hat{\theta}$

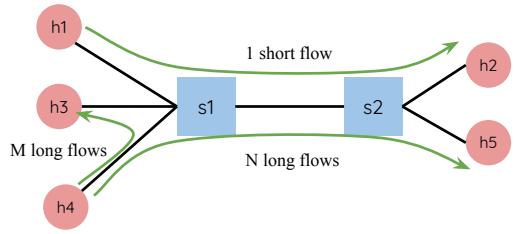
B Details of Offline Measurements

We measure three empirically driven distributions offline and use them to estimate CLPs in SWARM: (1) the upper bound on the throughput of long flows in a lossy network, (2) the necessary number of RTTs to deliver short flows, and (3) the queueing delay. In this section, we describe how we gathered these distributions. We also show a sample in Fig. A.8.

Throughput of long flows in a lossy network. We use Topol-



(a) Topology 1



(b) Topology 2

FIGURE A.1: Topologies for offline measurements.

ogy 1 in Fig. A.1 where h1 sends a long flow f to h2. We use iperf3 to measure throughput under different network conditions (*e.g.,* by inducing packet drops in s1 – s2 or changing the RTT by adjusting the delay on s1 – s2). We ensure that link capacities are sufficiently high so that the drop rate always dictates the rate. We also repeat each experiment multiple times to create a statistically significant distribution [18].

Number of RTTs for short flows. We send a short flow from h1 to h2 in Topology 1 (Fig. A.1) under different settings (*e.g.,* flow size, slow start threshold, initial congestion window) and network conditions (*e.g.,* packet drop rate, RTT). We repeat each experiment multiple times, measure the FCT of the flow in each experiment, and construct an FCT distribution. We ignore the queueing delay since we only have one flow in this experiment and divide the FCT distribution by the two-way propagation delay to derive the necessary number of RTTs.

Queueing delay for short flows. Queueing delay is harder to measure as it depends on network load and the number of competing flows. We use Topology 2 in Fig. A.1 to estimate the queueing delay distribution under various network conditions. We route M long flows from h4 to h3 and N additional long flows from h4 to h5. After these long flows reach the steady state, we route a flow small enough to finish within an RTT from h1 to h2 and measure its FCT.

In this experiment, we can control the number of flows that compete on the s1 – s2 link using N and the utilization of the s1 – s2 link using M and N. The latter is because the h4 – s1 is the main bottleneck in the network and determines the rate of the N long flows that go through s1 – s2. We vary both M and N to model different network conditions and measure the FCT of the short flow. We subtract the two-way propagation delay from the FCT to derive the queueing delay. Once again, we repeat these experiments to ensure statistical significance in the resulting distributions.

C Additional Experiment Details

In this section, we describe the details of how we evaluate SWARM using emulation, simulation, and testbed experiments on a set of representative and common incidents.

C.1 Traffic Traces

We evaluate our approach using many traffic traces to ensure our results are reliable. Each trace includes several network flows, each of which has 4 pieces of information: source, destination, size, and start time. We ensure these traces are long enough to capture the impact of mitigation on a wide range of flows with various sizes. To prevent capturing the impact of an empty network, we discard the performance of flows that begin in an initial window of the trace. Note that the duration of this window and the trace itself depend on the network bandwidth and delay in each setup.

Flow sizes. We follow recent works [38, 65] and sample flow sizes from a well-known and widely used distribution from DCTCP [5].

Flow start time. We generate flow start times using a Poisson distribution [35,38,41,61] with inter-arrival time derived from Azure to ensure the load on the network is reasonable (unless otherwise specified).

Source and destination. We follow [38] in picking the source and destinations.

C.2 Failures Types

We evaluate our approach on different types of failures (see Table 2). These failures (*e.g.,* packet drop on multiple links or capacity drop due to fiber cut) are common in Azure and other cloud providers, as several studies confirm [7, 24, 31, 55, 63, 71].

We use Mininet (a network emulator) as our primary evaluation framework for the reasons outlined below. We provide specific details on the failure cases in Table A.1. These 57 cases represent a wide range of potential issues that could arise in a datacenter. For instance, we evaluate two scenarios per packet drop rate for single-link failure incidents, which cover all possible single-link failures that can occur in a data center. This is because (a) the target link is either between ToR and an aggregation or between an aggregation and a core switch [3], and (b) Clos is a symmetric topology. Therefore, all ToR-aggregation and core-aggregation links are equivalent [4]. This means it is enough to only look at two cases, which are representative of a wide range of possible incidents.

The same logic applies to other cases. For example, one of our two-link failure scenarios considers the case where two ToR-aggregation links in the same pod drop packets. This scenario represents any two ToR-aggregation links that may fail in any of the pods over the entire datacenter.

C.3 Emulation, Simulation, and Testbed

Emulation Setup (Mininet). Mininet uses a real, production-grade TCP/IP stack from the Linux kernel. This allows us to evaluate our methods on production-grade implementations of congestion control algorithms such as BBR [12] or Cubic [28]. However, scaling Mininet is challenging [52]. We use the Clos

		Details	#scenarios

	1 other link failure	one T1 – T2 with capacity reduced to half, another T0 –T1 link with 3 levels of failure (two packet drop levels + completely down), and all possible ordering of failures.	6
Scen. 3	no link failure	One T0 with two levels of packet drop rate ∼5% and 0.005%	2
	1 link failure	One T0 and One T0 – T1 in the same cluster connected to a different T0, with all combinations of packet drop rates (ToR with two levels of packet drop rate and link with three levels of failure (two packet drop rates + completely down)), and all the possible ordering of failures.	12
		total number of evaluated scenarios	57

TABLE A.1: Mininet Experiment Details.

topology from Fig. 2 with 8 servers, 4 ToRs, 4 aggregation switches (T1), and 4 spine switches (T2). Even with this setup, we required a server with 64 cores and 256 GB memory to achieve the desired load level. We include results from *4000 hours experiments (over 5 months)* to cover all 57 scenarios, all combinations of possible mitigations, and running each multiple times.

Emulating a network with gigabit-level bandwidth (40 Gbps) and microsecond-level propagation delay (50 μs) is impossible in Mininet. Therefore, we downscale the traffic and the link properties following [48, 50]. This involves (1) reducing the link capacities and increasing the link delay to ensure the network bandwidth-delay product remains the same and (2) increasing the inter-arrival time between flows by the same factor (in our case, 120×). Our testbed and simulation experiments compensate for this.

We tested our approach with both Cubic [28] and BBR [12] congestion control algorithms in Mininet (and DCTCP [5] in our NS3 simulations). Our findings suggest that the choice of mitigation depends less on the congestion control, and a common abstraction that ensures these flows receive max-min fair rates is enough (TCP objective [20]).

For our evaluation, we use traffic traces that last 500 seconds (around 9 minutes) to capture enough samples from different flow sizes. We only measure the impact on flows that start within [50, 150) seconds to avoid including the start-up phase and to ensure all the captured flows finish before the end of the traffic trace. We repeat each experiment for 30 different traffic traces (§C.1).

Simulation Setup (NS3). We use a Clos topology with 16 cores (T2), 32 aggregations (T1), 32 ToRs, and 128 servers. Each link has 20 Gbps bandwidth and 100 μs propagation delay. We use DCTCP [5] as the congestion control algorithm.

We consider an example where two links drop packets (one at a high rate ∼0.5% and the other one at a low rate ∼0.005%). This scenario captures the impact of both the drop rates and the network load on the decision. We also find the packet drop rate impacts the scalability of the simulation. Thus, we had to slightly reduce it compared to our Mininet experiments. Even with this drop rate, it takes NS3 one day to compute the performance of one mitigation on a single traffic trace. We use MPI to speed up NS3 and reduce the runtime.

Each of our traffic traces is 10 s long, and we measure the impact on flows that start within [0.5, 1) s. We repeat each experiment for 30 different traffic traces.

Testbed Setup. Our testbed has 32 servers connected using a Clos topology with six ToRs, four aggregation switches (T1), and two core switches (T2). Each link in our testbed has 10 Gbps bandwidth and 200 μs propagation delay. The topology is a Clos [3] where all T1 and T2 switches are connected to each other (different from Mininet and NS3 simulations).

Due to hardware limitations, we can only inject packet drops at the power two. We consider an example where we have two links dropping packets (one at a high rate $\frac{1}{16}$ and the other one at a low rate $\frac{1}{256}$).

C.4 Other Details

SWARM. We use 32 traffic traces and 1000 routing samples in SWARM (unless mentioned otherwise). For our baseline comparisons in Mininet, we set the duration of each traffic trace to 200 s, and as in Mininet, we compute the CLP metrics over all the flows that start within [50, 150) s. We also use 200 ms as the epoch size for Alg. 1. Note that an ideal epoch size should be in the order of the flow inter-arrival time (1 ms in Mininet). However, we find that SWARM can still find good mitigations even when we use a much larger epoch size.

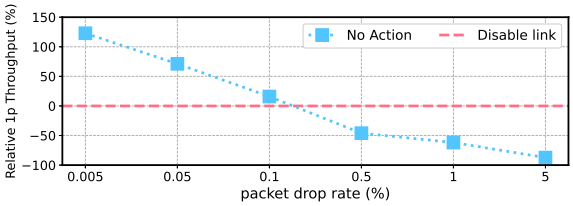
Routing. We assume either ECMP or WCMP routing [27, 70], which are typical in data centers.

D Extended Evaluation

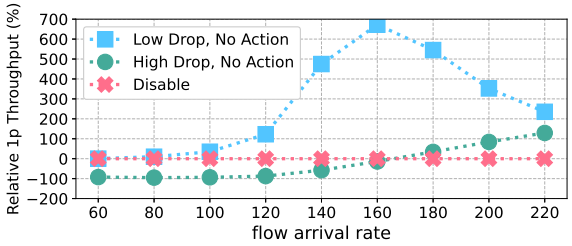
In this section, we present an extended evaluation of SWARM.

D.1 Sensitivity to Inputs

Packet drop rates. We compare the relative difference between the 1p throughput of taking no action and disabling a



(a) Sensitivity to packet drop rate



(b) Sensitivity to flow arrival rate changes

FIGURE A.2: Evaluating sensitivity of SWARM to errors in the input packet drop rate and flow arrival rate using Mininet. All experiments are in a scenario where a T0 – T1 drop packets.

link in a failure scenario where a T0 – T1 link drops packets at different rates (Fig. A.2). We find the choice of the right decision to be bi-modal with a wide room for error. It is better to take no action for all the drop rates below $\sim 0.1\%$ while the best action is to disable the link beyond that point. Also, the penalty close to this transition point (0.1% drop rate) is rather small. In other words, the error in the input packet loss rate has to be an order of magnitude for SWARM to make the wrong decision, an unlikely possibility in today's clouds.

Flow arrival rates. We investigate how SWARM's decisions change under two failure severities and different flow arrival rates (Fig. A.2). We observe that the gap between the two decisions is significant outside of a few inflection points, which means SWARM will pick the best mitigation in most cases.

For instance, in the high drop rate scenario, disabling the link is better than taking no action for arrival rates ranging from 60 to 160 flows per second (fps). Taking no action is better once we pass 160 fps as bringing down the link causes network congestion. This means SWARM has a wide margin of error. At small and large arrival rates, the difference between the two actions is consistently large, which means SWARM would pick the right action. At medium arrival rates, the difference is very small, so whichever action SWARM picks results in almost the same impact.

D.2 Sensitivity to Congestion Control

We conduct a limited experiment to evaluate whether SWARM is resilient to the choice of congestion control. We consider a scenario where a T0 – T1 and a T1 – T2 are dropping packets at low and high drop rates, respectively. We use two example congestion control protocols (CUBIC [28] and BBR [12]), which behave differently under loss. Cubic significantly reduces its rate under loss while BBR does not.

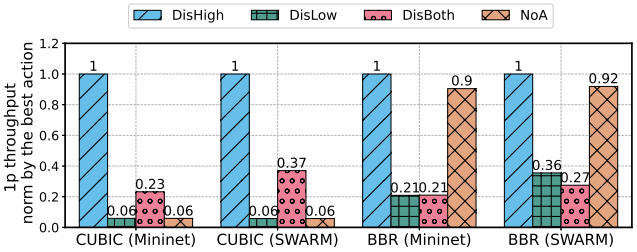


FIGURE A.3: Evaluation of SWARM on multiple congestion controls in Mininet. In general, SWARM is able to correctly order the mitigation actions and approximately capture the relative difference between different mitigation actions on both congestion controls (BBR [12] and Cubic [28]).

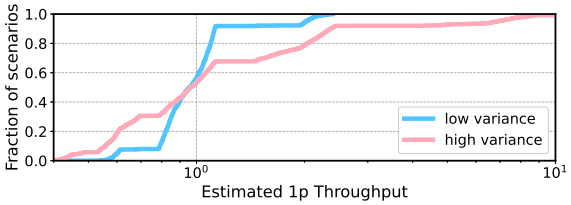

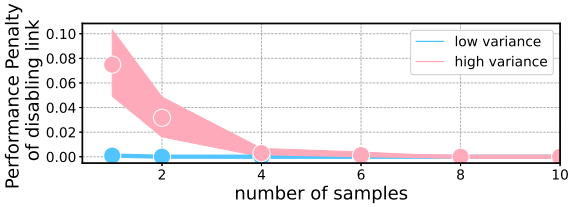

FIGURE A.4: Variance in the input flow arrival rate and its impact on the performance penalty of mitigation actions in Mininet.

We compare SWARM's estimated 1p throughput with Mininet under four mitigations (Fig. A.3). We find (1) SWARM can estimate throughput adequately enough to pick the best mitigation and (2) the choice of the best action remains independent of the congestion control protocol. SWARM's estimates are more accurate when it operates on the same congestion control protocol. This means it is more robust when operators correctly input the likelihood of different protocols being used inside their datacenters.

D.3 Assumptions and Design Choices

We also validate our assumptions and design choices.

Capturing the impact of drop-limited flows. We account for drop-limited flows by computing an upper bound on their rate and then enforce these bounds during max-min fair rate computations. We evaluate this assumption in an experiment where a single link delivers a varying number of flows and drops packets at different rates (Fig. A.5). We observe our observation is valid: each flow takes the minimum of its fair share rate and its drop-limited throughput.

We next evaluate our design choices for estimating the

distribution of the flow completion time and throughput (Fig. A.5). Specifically, we show the quality of SWARM's approximations compared to Mininet measurements. We use a scenario where two links drop packets at different rates, and the mitigation is to disable the link with the higher drop rate.

Single Epoch vs. Multiple Epochs. In SWARM, we use epochs to capture the shift in network bottlenecks as flows arrive or depart over time. We observe that not capturing these dynamics leads to more than 50% estimation error on average (this is equivalent to running SWARM with only one epoch). Instead, SWARM uses multiple epochs to model flow arrival/departure and avoids this error.

Distributions vs deterministic estimates. In SWARM, we pick the best mitigation based on CLP distributions. This method increases confidence in the final decision and has less error compared to relying on a single CLP sample. SWARM can efficiently compute these distributions in parallel.

Queueing Delay. We show the importance of accounting for queuing delay using an example scenario where the link C0 – B0 in the Fig. 2 topology drops packets at a high drop rate and the operator prioritizes 99p FCT of short flows. In this case, the best action is to disable the link. After we apply the mitigation, the link C0 – B1 starts to drop packets at a high drop rate. Disabling C0 – B1 is not feasible anymore as it partitions the network, so we have to either take no action or bring back C0 – B0. If we ignore the queuing delay, both of these options have the same approximate 99p FCT. However, bringing back C0 – B0 is a better mitigation since it increases the path diversity and reduces the queuing delay (Table A.5).

D.4 Results for Other Comparators

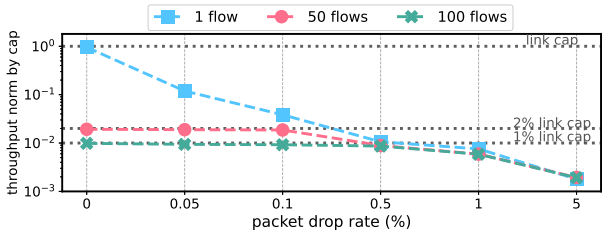
Priority1pT. This comparator minimizes the 1p (1st percentile) throughput. It uses two tiebreakers in the following order: average throughput and 99p FCT.

Linear combination. This comparator minimizes a weighted combination of the three CLP metrics (99p FCT, 1p throughput, and average throughput);

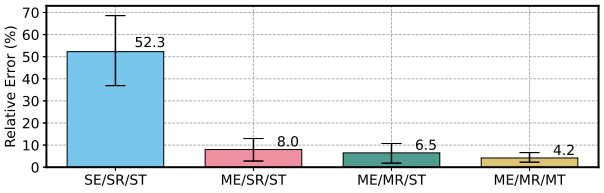
$$w_0 \frac{\text{99p FCT}}{\text{99p FCT}_\text{h}} + w_1 \frac{\text{1p Thru}_\text{h}}{\text{1p Thru}} + w_2 \frac{\text{avg Thru}_\text{h}}{\text{avg Thru}}$$

where w_i is the assigned weight and Metric_h is the metric measured in a healthy network. Note that we prefer lower FCT but higher throughput. Therefore, we use their inverses in our definition of the linear comparator. SWARM admits any combination of weights, but we evaluate for the case where all weights are set to 1. This is different from all the other comparators as it does not set any preference for any metric.

Summary of the results. Fig. A.6 and Fig. A.7 compare the performance penalty of SWARM against other baselines across the three types of failures for Priority1pT and Linear combination comparator. In summary, SWARM's performance penalty is low across all the scenarios and metrics.



(a) Drop-limited vs Capacity-limited



(b) Impact of different design choices on throughput estimation (E=Epoch, R=Routing Sample, T=Traffic Sample, S=Single, M=Multiple). For example, SE/SR/ST refers to using a single epoch, with a single routing sample, and a single traffic sample. We run each method with 10 different seeds.

Approach	Best Action	FCT Penalty
Ignore Queueing	Disable C0 – B0	48 %
Model Queueing	Bring back C0 – B0	0 %

(c) How queueing delay influences the mitigation choice.

FIGURE A.5: Validationg assumptions and design choices using Mininet. (a) shows flows are capacity- or loss-limited. A flow is loss-limited when its rate drops below its fair share of the link capacity (marked as dashed lines) (b) shows the impact of our design choices and the relative error with respect to Mininet. (c) the importance of accounting for queuing delay.

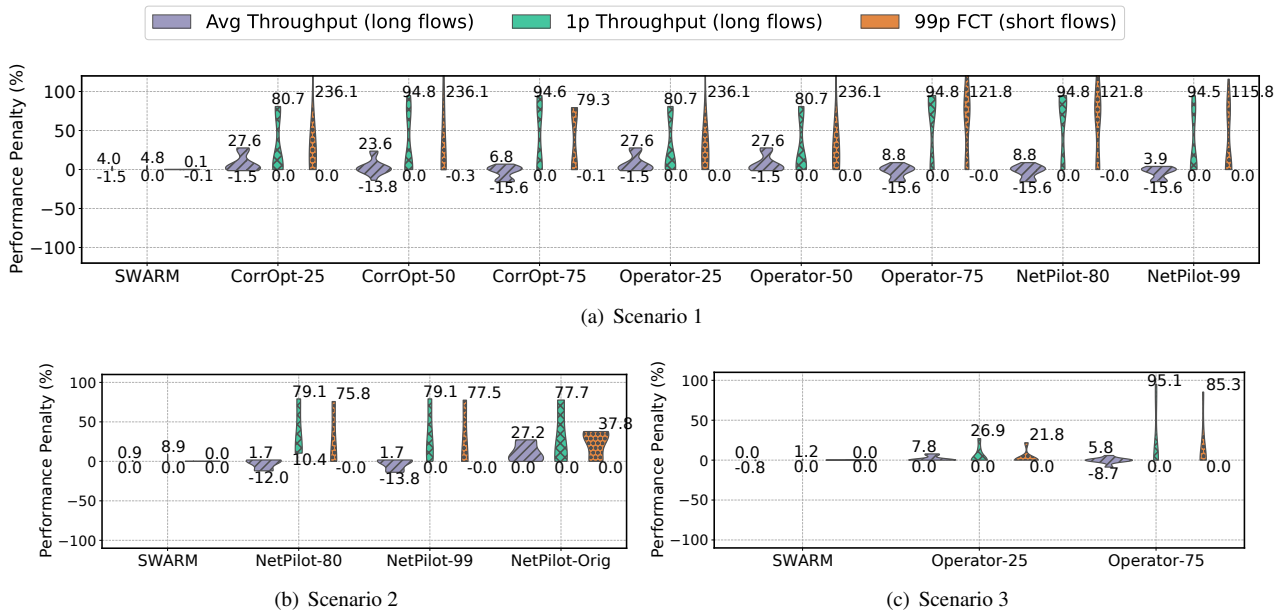
E Disabling the Congested Device

The routing protocols such as ECMP ignore the asymmetry in the datacenters, which can cause congestion. We can mitigate this by disabling the congested link or device so the routing can utilize other paths. For instance, each logical link between two switches [63] consists of multiple physical links. A control protocol multiplexes the packets over these physical links by hashing the packet's header. When a cut happens in any of these physical links, the link capacity decreases and can cause congestion on the remaining physical links. To mitigate this, we can disable the logical link to enable ECMP/WCMP to use other paths with healthy links.

F SWARM's Benefits

The reason behind SWARM's benefit depends on the scenario. In some incidents, SWARM chooses the actions that are already supported but ignored by prior work. In some other cases, the benefit is due to the larger action space of SWARM. We show this using two example failures on the topology in Fig. 2.

Scenario 1 (same action space). In this case, a link between a tier-0 and tier-1 switch start dropping packets (*e.g.,* C0 – B1). Existing threshold-based methods [63, 71] will take no



(a) Scenario 1

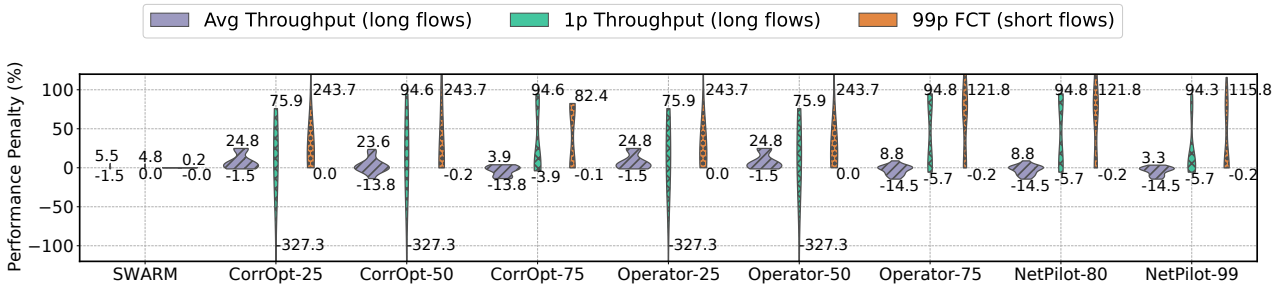
(b) Scenario 2

(c) Scenario 3

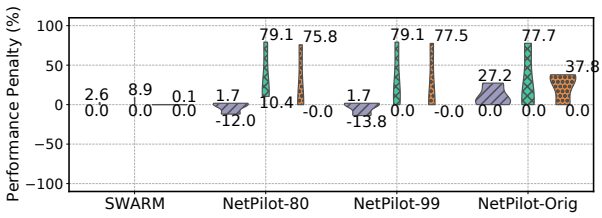
FIGURE A.6: SWARM outperforms other baselines under Priority1pT comparator in Mininet. It is the only method with a low penalty across all the metrics and all the scenarios.

action if they use a large threshold. This decision process completely ignores the impact of the packet drop rate. If the packet drop rate is high, we should disable the link. If these threshold-based methods use a smaller threshold, they end up always disabling the link. This decision completely ignores the impact of traffic load and the packet drop rate. Therefore, it can cause severe congestion. SWARM takes all these factors into account and finds much more effective mitigations (even though the action space is the same).

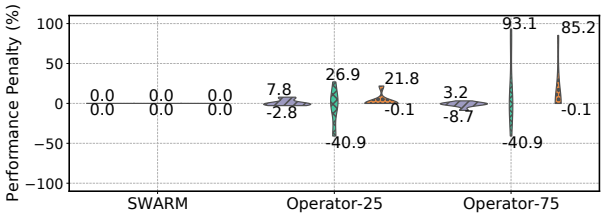
Scenario 2 (larger action space). Imagine a sequence of failures. First, a link between a tier-0 and tier-1 switch starts dropping packets at a moderate rate. SWARM would decide to disable the link. Later, another link between the same tier-0 switch and another tier-1 switch starts dropping packets at a much higher rate. In this case, SWARM disables the new link and re-enables the old link (undoing its previous action). This is because disabling both links would reduce the capacity of the network substantially, causing severe congestion. SWARM can reason about these cases, which enables exploring a broader set of actions, such as bringing back less faulty links.



(a) Scenario 1



(b) Scenario 2



(c) Scenario 3

FIGURE A.7: SWARM outperforms other baselines under Linear combination comparator in Mininet. SWARM consistently achieves low penalty (always $\leq 8.9\%$) across all the metrics and all the scenarios.

One-Size-Fits-None: Understanding and Enhancing Slow-Fault Tolerance in Modern Distributed Systems

Ruiming Lu[1,2] Yunchi Lu[1] Yuxuan Jiang[1] Guangtao Xue[2] Peng Huang[1]

[1]*University of Michigan* [2]*Shanghai Jiao Tong University*

Abstract

Recent studies have shown that various hardware components exhibit fail-slow behavior at scale. However, the characteristics of distributed software's tolerance of such slow faults remain ill-understood. This paper presents a comprehensive study that investigates the characteristics and current practices of slow-fault tolerance in modern distributed software. We focus on the fundamentally nuanced nature of slow faults. We develop a testing pipeline to systematically introduce diverse slow faults, measure their impact under different workloads, and identify the patterns. Our study shows that even small changes can lead to dramatically different reactions. While some systems have added slow-fault handling mechanisms, they are mostly controlled by static thresholds, which can hardly accommodate the highly sensitive and dynamic characteristics. To address this gap, we design ADR, a lightweight library to use within system code and make fail-slow handling adaptive. Evaluation shows ADR significantly reduces the impact of slow faults.

1 Introduction

The reliability of distributed systems hinges on their robust fault tolerance mechanisms. While deployed distributed systems today have been designed to tolerate crashes well using techniques such as state-machine replication, recent studies [36, 50] show that, *fail-slow* behavior is prevalent in different hardware components (*e.g.*, disk, NIC, switch) of systems at scale. For example, a NIC can suddenly experience a 50% packet loss. Such behavior occurs due to firmware bugs, driver bugs, external temperature, etc., and leads to severe incidents.

These studies have motivated a few recent research solutions [49, 54, 57, 64]. For example, Copilot is a consensus protocol designed to tolerate one slow replica by introducing proactive redundancy and parallel processing [54]. Developers also become increasingly aware of this overlooked failure mode. For instance, HBase developers introduced an enhancement feature [9] to detect and mitigate slow syncs.

Despite the progress, the characteristics of slow-fault tolerance in distributed systems remains ill-understood. The most notable existing insight comes from a 2013 study [32], which shows that slow hardware can cause severe cascading failures and "limplock" of the entire cluster. This study, while illuminating, focuses on demonstrating the existence of limplock in *worst-case* scenarios. For example, it demonstrates that when the disk throughput on the HDFS master node is permanently slowed down by 1000×, HDFS experiences a cluster limplock. Moreover, the landscape of both hardware and software has evolved significantly since 2013. Hardware is now more powerful, holds larger capacities, and integrates new technologies. Software adopts asynchronous programming, event-driven designs, chaos engineering, observability tools, *etc.* These changes have potentially altered the status quo.

To address this gap, this paper presents a study that comprehensively examines how modern distributed software reacts to slow faults. Our goal is to provide insights for developers to enhance their systems' slow-fault tolerance. The key challenge developers face is that, unlike crash faults, slow faults are not binary but rather have great varieties. Even defining slow tolerance is not easy. Indeed, when a hardware component has a slow fault, the software execution inevitably gets impacted. For distributed software, it can leverage its redundancy and concurrency to minimize the overall performance degradation.

Our study thus focuses on examining the nuances of fail-slow tolerance. We develop a testing pipeline that uses fault injection to systematically explore various slow faults and measure how a system reacts to the varieties. We also examine the current practices of slowness detection and mitigation.

Our study reveals many interesting findings. For example, we find that the sensitivity to different configurations of slow faults varies significantly across the studied systems. In some systems, a 1 ms network slow fault can cause 25% performance degradation, while other systems need a 100 ms delay to show a similar level of performance degradation. In almost all studied systems, we observe the existence of a *danger zone*, where a slight increase in slow-fault severity results in a significant increase in degradation. However, the range of these danger zones is often narrow, which poses challenges for early alerting. Moreover, a milder slow fault can cause more harm than a severe one. We also find that while the latest solutions or recent versions of a mature system have added slow handling mechanisms, these mechanisms are not effectively triggered.

A unifying theme in our study's findings is that slow faults not only are non-binary but also have highly dynamic and sensitive impacts (depending on workload, severity, duration, etc.). However, developers' existing efforts only try to address the non-binary nature but miss the dynamic and sensitive characteristics. The existing slowness handling mechanisms are controlled by static, over-conservative thresholds, which are only triggered by the most severe slow faults. Even when

System	Language	Version	Benchmarks
Cassandra	Java	4.0.10	YCSB [30]
HBase	Java	2.5.6	YCSB
HDFS	Java	3.3.6	MRBench, TeraSort
etcd	Go	3.5.10	YCSB, v3 benchmark [6]
CRDB	Go	23.1.11	YCSB, sysbench [19]
Kafka	Java, Scala	3.5.0	OpenMessaging [12]

Table 1: Studied systems. *CRDB*: CockroachDB.

the thresholds are exposed as parameters, it is hard for users to tune these parameters and they cannot be changed dynamically once set. Fail-slow handling needs to be made more dynamic.

Motivated by this takeaway, we design ADR, a lightweight *adaptive* fail-slow handling library that developers can easily use as a plug-in in their *code*. ADR will replace the static logic with an adaptive one and determine the levels of mitigation actions. ADR is robust against varying slow faults and workloads by monitoring both the value and update frequency of traced variables. We implement ADR with two distributed systems. We demonstrate that by using this library, the system performance degradations under different slow faults and different workloads are significantly reduced by 65% on average with low overhead, compared to using static thresholds.

Besides code enhancement, developers start to introduce test cases when they add slowness handling mechanisms. However, they only perform unit tests that use a worst-case setting to validate the basic code correctness. The effectiveness of these mechanisms in practice remains unchecked. Thorough fault injection testing is needed to measure the realistic effectiveness. The testing pipeline we develop addresses this gap and provides a continuous measurement tool for developers to understand and improve their systems' slow-fault tolerance level.

Our testing pipeline and ADR are available at `https://github.com/OrderLab/xinda`.

2 Methodology

We examine six large-scale distributed systems (Table 1). We choose them because they are representative and widely deployed in many companies. They are developed in different programming languages and support critical services, including distributed storage, databases and streaming. We select their latest stable versions at the time of our study.

We also study three state-of-the-art *solutions* tackling slow faults. We examine their effectiveness in Section 5.

Benchmarks. Measuring slow-fault tolerance requires representative workloads. Prior work uses manually crafted microbenchmarks (e.g., creating thousands of empty files to exercise the logging protocol) [32]. Such benchmarks provide localized views of individual features in the system. However, deployed systems receive many more complex and mixed requests. Thus, we use comprehensive benchmarks to better reflect the system responses under real deployments.

Table 1 lists the benchmarks we use to measure each system. For database systems, we use YCSB [30] to generate workloads with distinct access patterns, including read-only, write-only, and mixed reads and writes. For etcd, we also use the official benchmarking tool [6] to test other operations (*e.g.*, range queries and transactions) and etcd-specific requests (*e.g.*, leases and watches). For CRDB, we also use sysbench [19], a popular benchmark for relational database systems, to test delete, insert and range query operations. For HDFS, we use MRBench and TeraSort: MRBench executes a set of MapReduce jobs while TeraSort evaluates the system's capacity to sort large volumes of data. For Kafka, we use OpenMessaging [12] to generate message streams under different configurations (*e.g.*, partitions, batch size, and linger time).

Load stress. We adjust the benchmark load intensity to ensure all nodes are highly utilized: if one node crashes, the throughput of the remaining nodes does not increase significantly. We achieve this by tuning the concurrency levels of the benchmarks (*e.g.*, thread count in YCSB).

Fault Injection. Prior studies [32, 36, 49] show that slow faults can originate from hardware, software (*e.g.*, drivers), or environment issues. Regardless of their root causes, slow faults will ultimately affect a distributed system through the underlying interfaces. Thus, instead of injecting hardware-level faults, we inject slowness directly to the filesystem and network layer to minimize influences of uncontrollable factors. We use blockade [2] to inject network faults and charybdefs [3] to inject filesystem ones (Appendix A).

Since slow faults have wide varieties, we examine them by the following fault attributes:

• *Severity.* We study three major types of slow faults: network packet loss, network delay, and filesystem delay.

For packet loss, we choose 1%, 10%, 40%, and 70%. This is evidenced by prior empirical studies in data center networks and Internet service providers (ISPs) [36,52,61]: faulty links/devices could lead to 2% to 100% packet loss in Microsoft Azure [61]; 1-50% packet loss is observed from 12 institutions including NetApp and Twitter [36]; 0.1% to 100% packet loss is used to test a gray failure detector in ISPs [52].

For network delays, we choose 100 us, 1 ms, 10 ms, 100 ms, and 1 s. This is backed by a study from Microsoft data centers [37], where the tail network latency varies from several milliseconds to hundreds or even thousands of milliseconds.

For filesystem delays, we choose 1 ms, 10 ms, 100 ms, and 1 s. This is based on an empirical study on fail-slow disks in Alibaba data centers [50], where faulty device latency ranges from hundreds of microseconds to nearly a second.

• *Location.* We inject faults to only one node per experiment. For leader-based systems, faults are injected to either the follower or the leader: master or regionserver for HBase, namenode or datanode for Hadoop, leader or follower node for etcd. Although there is a concept of *leader* in CRDB (one leaseholder per range) and Kafka (one leader per partition), such leader roles are dynamic and are changing at runtime; for Cassandra, node roles do not differ after cluster initialization (gossiping). Thus, we inject faults to only one (arbitrary) node of the CRDB, Kafka, and Cassandra clusters.

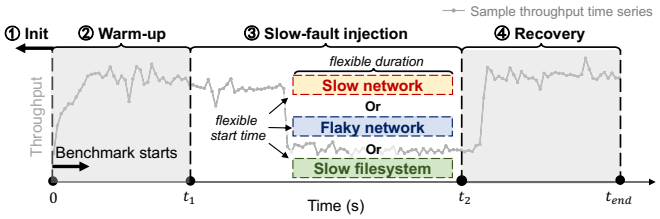

Figure 1: Our slow-fault tolerance testing pipeline.

Multiple slow faults could occur simultaneously. However, prior work suggests that fail-slow is a rare yet independent event [49, 57]. For example, Alibaba monitors 248 K SSDs for 10 months [49], only to find 304 fail-slow drives and they all come from different nodes; Nutanix monitors distributed services on 39 K nodes over 7 months [57], only to collect 232 *independent* fail-slow tickets. Therefore, in our experiments, we inject faults to one node at a time to capture the most common and realistic fault scenarios while maintaining focus on a representative fault model.

• *Duration.* We explore faults of varying durations, from transient issues lasting 30 seconds to long-lasting ones that cover the whole experiment.

2.1 Testing Pipeline

We develop a general and automated slow-fault tolerance testing pipeline that streamlines the aforementioned components: deploying a system, ensuring comparable experiment setup, running cloud benchmarks, injecting diverse slow faults, and collecting and summarizing key metrics. Figure 1 shows the diagram of our testing pipeline. It has four main stages:

① **Initialization.** Upon each test, we first bring up a cluster of the tested system. We wait until the cluster is fully initialized and ready to serve any requests. Test data in a benchmark is also loaded in this stage. We use a small cluster of 3–6 nodes for the testing. We also validate our major findings using a larger cluster size of 10 nodes and 20 nodes in Appendix B.

② **Warm-up.** We let the benchmark run for a warm-up period (30 s) before we start injecting any faults. This is to ensure that the system has reached a steady state so that the statistics we collect are representative. The benchmark client is connected to the system via a dedicated node to avoid interference with the system under test. We also make sure the client connects to all nodes of the system so that the benchmark will not stop in case of a node failure. Moreover, the performance records during the warm-up period will be excluded from our analysis.

③ **Slow-fault injection.** After the warm-up period, the pipeline is ready to inject faults. It enumerates distinct fault attributes and their combinations, injects one setting of slow fault per experiment, and records the setting for later analyses.

④ **Recovery.** The pipeline clears the injected faults, after which the system performance will gradually recover.

2.2 Data Collection

Our pipeline collects performance logs from ongoing benchmarks and system logs throughout the testing process. After each test concludes, the pipeline processes these logs to extract critical system responses, such as tail latency and throughput time series. We then utilize these responses to calculate *performance degradation*, which serves as the primary metric for quantifying the system's nuanced tolerance to slow faults.

Specifically, we first calculate the average throughput before fault injection (denoted as *avg_normal*) and during slow faults (denoted as *avg_slow*). We then derive the performance degradation as $\frac{(avg_normal - avg_slow)}{avg_normal} \times 100\%$, where a higher percentage indicates more severe degradation. Analyzing how degradation and latency vary across different fault scenarios provides insights into the system's tolerance to slow faults.

3 Nuanced Slow-Fault Tolerance

A key challenge distributed systems developers face in addressing slow faults is that they often cannot anticipate the specific slow faults their systems might encounter in the wild, particularly when the systems are deployed on hardware or workloads that differ from their testing environment. In this section, we delve into this nuanced nature by injecting diverse fault scenarios (§3.1), enforcing different hardware resource limits (§3.2), and simulating distinct workload patterns (§3.3).

3.1 How Systems React to Varying Slow Faults?

Figure 2 presents the performance degradation of the studied systems under different slow faults with varying *types*, *severities*, and *locations*. We also validated the observations and findings below using a larger cluster size (Appendix B.1).

Finding 1. *The same slow fault incurs radically different consequences across systems. For example, some systems degrade by more than 25% with a* 1 ms *network delay, while others remain robust until faced with delays 100× greater.*

All the evaluated systems use network and filesystem extensively. They all have extensive fault-tolerance mechanisms. Despite these similarities, their slow-fault tolerance still exhibits **high variability**. For example, CRDB and etcd require a delay as high as 100 ms to yield a notable degradation (>25%), while Cassandra, HBase and Kafka only need 1ms. Moreover, systems like Cassandra, HBase, and Kafka can even experience an unbearable degradation of 70% with only a 10 ms network delay, while the other systems (except for the etcd leader case) never degrade to this extent even with a 1 s delay.

The discrepancy arises from the differences in their fault tolerance mechanisms, at both the design and implementation levels. We further discuss their practices in Section 4.

Implication. Infrastructures (*e.g.*, network) and systems (*e.g.*, a database) are often monitored independently and use one-size-fits-all alerts. This can easily miss seemingly minor slow fault that turns out to be damaging for certain systems. System-specific and cross-layer slowness monitoring is needed.

Finding 2. *The relation between performance degradation and fault severity is non-monotonic. In half of the studied systems, higher packet loss leads to lower degradation.*

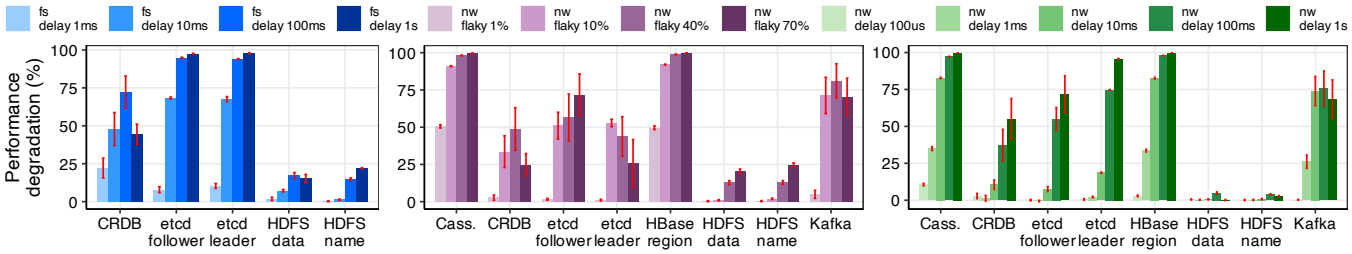

Figure 2: Performance degradation under filesystem delay (left), network packet loss (middle), and network delay (right). The darker the colors, the more severe the faults are. Each experiment was repeated 50 times for generalizability. Error bars refer to 95% confidence intervals.

In CRDB, as Figure 2 shows, the degradation only increases as the filesystem delay increases from 1 ms to 100 ms; however, with a 1 s delay, the resulting degradation (44%) is surprisingly smaller even than the case of 10 ms delay (48%). In Kafka, degradation under a 1 s delay (68%) is also smaller than that under a 10 ms delay (74%). In etcd, the performance becomes better when we inject a higher packet loss (i.e., a *negative* trend) to the leader. The underlying cause lies in whether leader re-election is triggered: a slow leader degrades performance until heartbeat loss triggers re-election (see Section 4.2.1).

Finding 3. *Even within the same system, the performance impact of different slow-fault types varies by up to 10×.*

In CRDB, the average degradation with different filesystem delays is 47%, which is 3.6× that of a delayed network (13%). In etcd, the average degradation under a delayed network is 45%, which is 1.7× than that under packet loss.

Implication. System architects need to consider the distinct impact of different slow-fault types when deciding which infrastructure component to prioritize and optimize. Developers should introduce tailored handling for sensitive fault types.

Finding 4. *Slow faults in followers can impose a more severe (1.5×) performance penalty than similar faults in leaders.*

It is commonly assumed that faults in leader nodes are more impactful than those in followers. However, our study shows a surprising twist in etcd: a slow follower incurs severe (up to 68%) and higher degradation than slow leaders. For example, under flaky networks, the degradation by slow followers (45%) is 1.5× that of slow leaders (31%). This is counter-intuitive as only one slow (even crashed) follower in a 3-node quorum-based system like etcd should at most degrade the overall performance by a third. We investigate and find that the root cause lies in the mismatched awareness of slow faults from the gRPC client and etcd endpoints (elaborated in Section 4.2.2). In contrast, a slow master in HBase does not bottleneck the system, as the YCSB benchmark only interacts with the region servers. In HDFS, both namenodes and datanodes exhibit a similar impact. Since leader roles in Kafka and CRDB are dynamic and change at runtime, the performance impact of a slow leader or follower can be hardly traced or compared.

3.2 Do Resource Limits Amplify Slow Faults?

When a distributed system gets deployed, it can run on different hardware. Does the system's slow-fault tolerance change under varying hardware resource limits? Figure 3 presents the performance degradation of an etcd cluster under four fault scenarios. Each node is subject to the same limits on CPU (1-5 cores) and memory (8-32 GB) based on hardware recommendations provided by the developers [8].

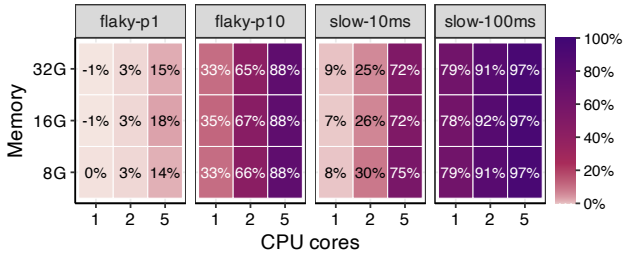

Figure 3: Degradation of etcd under different CPU and memory limits. Each cell corresponds to the average degradation of the same experiment repeated 50 times. Faults are injected to the leader.

Finding 5. *Scaling up resources improves normal performance but paradoxically exacerbates the impact of slow faults.*

For example, for etcd, under a network delay of 10 ms and a per-node memory limit of 32G, degradation increases from 7%, 26%, to 72% with a per-node CPU core limit of 1, 2, 5, respectively. This is because the baseline request latency becomes lower with more CPU cores (from 74 ms to 10 ms), thus the same delay worsens the degradation. This is also the case for packet loss, where latency increase is more pronounced with more CPU cores. However, degradation does not vary much as memory changes. This is because etcd tends to be CPU-bound under heavy load [8]. We validate these observations with a larger cluster size (Appendix B.2).

Implication. More hardware resources do not equate to better fault resilience. Developers need to test their systems' slow tolerance mechanisms under different hardware constraints. The slow-fault alerting and actions need to be resource-aware and recalibrate upon resource changes.

3.3 How Workloads Affect Slow Tolerance?

Deployed distributed systems need to handle diverse and often unpredictable workloads, which can cause developers to overlook slow-fault tolerance in a specific workload. Figure 4 shows the performance impact of network delays for Cassandra and etcd under different workload patterns (read only, balanced mix, and write only). We also validate the following observations with a larger cluster size (Appendix B.3).

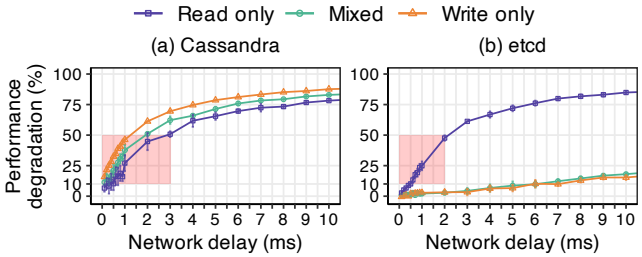

Figure 4: Performance degradation of (a) Cassandra and (b) etcd under distinct workload patterns and network delays. Each set of experiments was repeated 50 times for generalizability. The shaded area highlights the "danger zone" where performance degradation escalates dramatically. Mixed: 50% reads and 50% writes.

Finding 6. *The performance impact of slow faults is highly dependent on the workload, particularly in Raft-based systems (etcd, CRDB, and Kafka), which show up to 7.2× differences.*

Under a 10 ms network delay, the performance degradation of etcd under read-only, balanced mix, and write-only workloads is 85%, 18%, and 15% (up to 5.7× differences). For CRDB, the degradation can vary up to 7.2× differences. For Kafka, the degradation under the asynchronous [1] and synchronous [18] schemes is 20% and 3% (6.7× differences), respectively. For Cassandra and HBase, the degradation under the three workload patterns has lower variances (an average of 1.3× and 1.1× differences, respectively). Also, different systems are sensitive to different workload patterns. In Cassandra, write-only workloads yield the highest degradation, while read-only ones yield the highest degradation in etcd.

Finding 7. *Danger zones commonly exist in the studied systems, where a small increase in slow-fault severity leads to a significant increase in performance degradation.*

Danger zone. The sensitivity to workload patterns and fault severities prompts us to investigate the presence of a "*danger zone*", where degradation escalates dramatically from a moderate 10% to an unbearable 50% as the severity of the fault increases. Identifying the danger zone could potentially help system administrators to proactively monitor and mitigate slow faults, before they escalate and incur catastrophic degradation.

Figure 4 highlights the danger zone. Etcd displays a danger zone from 1 ms to 2 ms network delays only under read-only workloads. In Cassandra, however, danger zones exist under all workloads: 0.2 ms ~ 3 ms, 0.1 ms ~ 2 ms, and 0.1 ms ~ 1 ms for read-only, mixed, and write-only workloads, respectively.

We also apply the danger zone analysis to the other systems. Table 2 summarizes the results. The notion of a danger zone exists in almost all studied systems. However, in systems like etcd and CRDB with write-dominant workloads (≥ 50% write), the danger zones are not obvious. This is because slow writes can be alleviated by their Raft-based protocols. Thus, degradation does not increase drastically as the fault severity increases. Kafka, under batch workloads, does not exhibit obvious danger zones, as batched requests can alleviate the impact of slow faults. HDFS also shows no clear danger zone

	Network delay (ms)			Packet loss (%)		
	R	**M**	**W**	**R**	**M**	**W**
CS	0.2~3	0.1~2	0.1~1	0.2~2	0.2~1	0.2~0.7
HB	0.2~2	0.2~2	0.2~2	0.1~1	0.2~1	0.2~1
CR	4~5	N/A	N/A	2~5	N/A	N/A
EF	1~3	N/A	N/A	0.2~2	N/A	N/A
EL	0.5~2	N/A	N/A	0.2~2	N/A	N/A
	Async	**Sync**	**Batch**	**Async**	**Sync**	**Batch**
KF	0.7~2	0.6~6	N/A	1~5	1~5	N/A
	MRBench	**TeraSort**		**MRBench**	**TeraSort**	
HD	N/A	N/A		N/A	N/A	

Table 2: Danger zone of Cassandra (CS), HBase (HB), CRDB (CR), etcd leader (EL) and follower (EF), Kafka (KF), and HDFS (HD) under different workloads. We denote N/A for cases where the danger zone does not exist. R: read-only; M: mixed; W: write-only.

as it is optimized to support batch processing workloads.

Implication. Early alerting, based on the danger zones associated with sensitive workload patterns, is useful for effectively and proactively managing slow faults. However, the range of these danger zones is quite narrow, typically spanning only a few milliseconds of delay or less than a few percentage points of packet loss. Therefore, the utility of danger zones for early alerting may be limited without fine-grained monitoring.

3.4 Does Tuning Configurations Help?

To ensure consistency and avoid overfitting, we use default configurations of the studied systems. Does tuning a system help its slow-fault tolerance? We use HBase as an example, tuning its configurations for tolerating a 100 ms network delay.

To locate configurations related to slow-fault handling, we search the HBase codebase for keywords such as "slow" and "timeout". In total, there are 120 places matched. Most of them are `TimeoutException` and not configurable. We then manually inspect the rest of them and find 10 configurations (invoked in 43 different files) that are most related to slow faults (*e.g.*, RPC timeout, retry limit). Then, we assign different values for them, making sure that they will always be triggered under a 100 ms network delay. For example, we configure the RPC timeout to be either 10 ms, 50 ms, or 100 ms. Together, we explore 7,776 different combinations of configurations.

We then iterate through each combination and test HBase by injecting a 100 ms network delay with fixed workload settings. This already adds up to *540 machine hours*. As a result, the optimal one yields an average degradation of 27%, which is indeed much lower than that of the default configuration (98%). Finally, we test HBase with this optimal configuration under the same slow fault but different workload settings.

Finding 8. *Fine-tuning system configurations enhances tolerance to specific slow faults, but only within controlled environments. Even worse, it may harm system availability when faced with diverse, real-world workloads, leading to severe degradation or even system failures.*

Figure 5a shows the average degradation under different

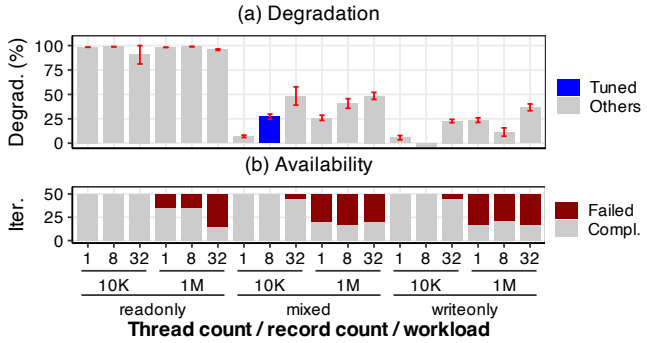

Figure 5: Degradation and availability of HBase with fine-tuned, optimal configurations to tolerate a 100 ms network delay. The x-axis corresponds to combinations of workload settings. The blue bar corresponds to the workload that HBase is fine-tuned on. The red bars indicate the number of failed runs out of 50 iterations. Error bars refer to 95% confidence intervals. *Compl.*: completed runs.

workloads. We iterate through different numbers of client threads, number of records (10K and 1M), and workload patterns. The blue bar corresponds to the workload setting that we previously fine-tuned on. The previously optimal configuration does not always perform well. For example, it causes severe degradation (>90%) under read-only workloads. Also, the degradation jumps to 48% with 32 clients, while a previously suboptimal configuration yields 34% degradation.

When analyzing the results, we find that the HBase cluster would sometimes fail and disconnect from the clients. Thus, we further check the availability of HBase, measured by the number of completed runs. As Figure 5b shows, among 18 workload settings, HBase fails at least once in 11 of them (the red bars), which are all heavier than what we previously fine-tuned on. The worst case is a read-only workload with one million records and 32 client threads: 35 out of 50 runs fail. After investigation, we find that the previously optimal configuration overfits the specific fault and workload, making HBase over-sensitive to and thus fail under heavier workloads.

Implication. Fine-tuning systems for slow faults is not only time-consuming but also does not generalize well across different workloads. Relying on static, fine-tuned configurations makes a system's slow-fault tolerance fragile.

3.5 Can Tail Latency Capture Slow Faults?

Tail latency is a widely used metric for performance monitoring and identifying potential slowdowns. Is tail latency always reliable for capturing slow faults? Figure 6a presents the tail latency of etcd, under a 10 ms network delay in the leader. Each experiment lasts for 150 s with faults extending from 30 s (20% service length) to 150 s (100% service length).

Finding 9. *Tail latency is not always reliable in capturing slow faults. The latency measurements are prone to under-representing the severity of slow faults due to the dilution by abundant measurements from the normal (fast) period.*

The measured tail latency does not exhibit significant variations as fault duration increases. For example, as the duration

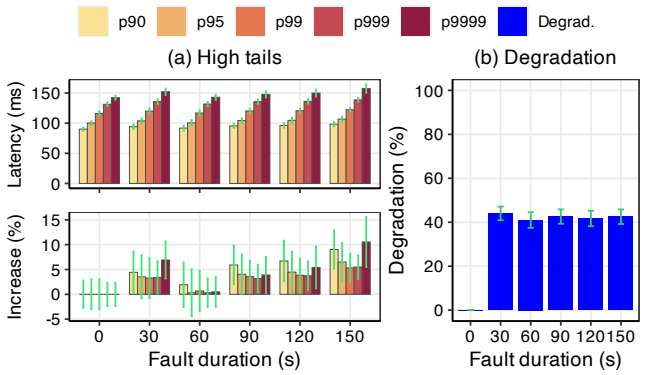

Figure 6: Tail latency and performance degradation of etcd. A 10 ms network delay is injected to the etcd leader with fault durations ranging from 30s to 150s. Each experiment lasts for 150 s.

increases from 30 s to 150 s, the increase in 99.9^{th} latency only ranges from 0.4 ms to 7.2 ms compared to the baseline, which translates to a 0.3%~5.5% relative increase. This is counter-intuitive as we are injecting a 10 ms delay but in return only observe an increase in the 99.9^{th} as minimal as 0.4 ms.

This phenomenon illustrates a limitation of relying on tail latency to detect slow faults. When a system suffers from a slow fault, much fewer requests are processed, hence fewer latency measurements are collected during the slow period. They can be outnumbered by those gathered in the normal period, leading to a misleading perception of low impact for the fault. We observe this pitfall when attempting to repeat the evaluation of MultiPaxos [44, 51] in Copilot [54] (Section 5). Even when the injected fault lasts 90 s in a 100 s experiment time, the 99^{th} latency is still not indicative, because the 90 s slow period only produces 900 latency measurements, while the 10 s normal period produces 300K measurements. Other systems exhibit similar phenomena. For example, the 99^{th} latency is only indicative when the degradation is severe ($\geq$ 83% in Cassandra, $\geq$ 68% in Kafka, $\geq$ 98% in HBase) and persistent ($\geq$ 90 s in Cassandra, $\geq$ 120 s in Kafka and HBase).

This highlights the need to use additional metrics to more comprehensively capture slow faults. For example, throughput degradation, regardless of fault durations, is more indicative of the impact of slow faults on the system (Figure 6b).

3.6 Other Findings

Besides performance degradation, we also study other aspects of slow-fault tolerance. First, we study the time to recover from slow faults (Appendix E). We find that systems recover fast (typically within 2 s) from filesystem and network delays but slower (sometimes more than 20 s) for flaky networks. Moreover, we study the residual impact of slow faults (Appendix F). We find that severe slow faults incur notable residual performance impacts on several systems. Lastly, we examine how slow-fault tolerance evolves across different versions of the same system (Appendix G). We find the improvement in slow-fault tolerance is limited over time.

System metric		Static threshold WT	WC	FT
Cassandra	Execution time of last query [16]	500 ms	-	-
CRDB	Execution time of last disk write [14]	5 s	-	20 s
CRDB	Time to flush pending logs [15]	10 s	-	20 s
etcd	`/livez` to check raft loop execution [7, 13]	5 s	3	-
HBase	Time to flush WAL to disk [9]	100 ms	100	10 s
HDFS	Time to read responses (ACK) from datanodes [17]	30 s	-	-
Kafka	Execution time of last request [10, 11]	30 s	-	2 min

Table 3: Examples of static thresholds used in all studied systems for slow detection. WT: warning threshold; WC: warning count; FT: fatal threshold.

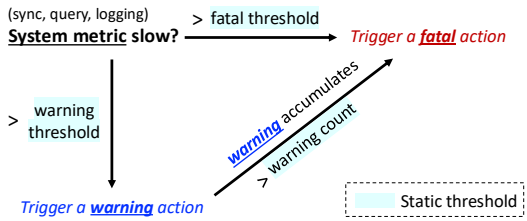

Figure 7: Summary of the common slow detection logic in all studied systems.

4 Current Practices to Handle Slowness

In this section, we study the current development and testing practices of handling slowness in the studied systems.

4.1 Slowness Detection Method

Finding 10. *All studied systems use static timeouts.*

Table 3 summarizes developers' efforts of slowness detection in the codebases of the studied systems. For example, HBase uses a few static thresholds such as `DEFAULT_SLOW_SYNC_TIME_MS=100`ms [5] to identify slow syncs. It also counts the number of slow syncs in a one-minute window: if the total number exceeds a default value of 100 [4], additional actions (log rolls) will be triggered [9]. We will further study the effectiveness of this approach in Section 4.2.3.

Another example lies in the storage engine of CRDB (*i.e.*, pebble), where disk health checks enforce a fixed `diskSlowThreshold` (set as 5 s) to detect disk slowness, and adopts `maxSyncDuration` (set as 20 s) to trigger a service crash [14]. Similar logic is also applied to detect slow logging [15].

Moreover, Cassandra uses `slow_query_log_timeout_in_ms=500`ms for slow queries [16]. HDFS uses `dfsclient SlowLogThresholdMs=30`s to trigger a slow read processor warning [17]. Kafka uses `request.timeout.ms` and `delivery.timeout.ms`, set as 30 s and 2 min respectively, to retry operations [10, 11]. etcd detects stalled writes by checking raft loop execution and exposes a `/livez` endpoint that supervisors can use to restart etcd if needed [7, 13].

Summary. Figure 7 summarizes the common logic of two-staged slow detection in the studied systems. For a monitored system metric, developers first set a warning threshold (WT) to detect slowness. If WT is exceeded, all studied systems will print warning messages. Moreover, if WT is exceeded multiple times (warning count, WC), or the metric exceeds a more severe threshold (fatal threshold, FT), escalated actions like log rolls or service kill will be triggered.

4.2 Slowness Mitigation Action

Besides detection and alert, current systems also trigger different mechanisms in reaction to slow faults. We study the following four major mechanisms: *leader re-election, client-side reconnection, log roll, and escalation to fail-stop*.

4.2.1 Leader Re-election

Systems like CRDB, etcd, and Kafka employ Raft, the leader-based consensus protocol [55]. If a leader encounters failures, either fail-stop or fail-slow, it will be unable to send out heartbeats in time. Subsequently, a healthy follower node will become the new leader and take over the workload.

Finding 11. *Leader re-election is only effective when slow faults are severe enough to impair heartbeats or lease liveness.*

In Section 3.1, we observe that, a slow etcd leader yields less degradation under intensive slow faults (70% packet loss) compared with milder ones (10% packet loss). This is also the case for CRDB. After further investigation, we discover that both systems recover from intensive faults a few seconds after injection. In etcd, the heartbeat timeout is 100 ms. Under milder slow faults, the degraded leader is still responsive to heartbeats. Thus, re-election will not be triggered, leading to continuous slowdowns. Conversely, under more severe slow faults, the leader may fail to respond. Therefore, a new leader will be elected and the system will be no longer bottlenecked by slow faults. The logic is similar in CRDB due to the lease interval (6 s). Appendix C provides more detailed illustrations.

4.2.2 Client-Side Reconnection in gRPC

In replicated systems, it is common for clients (or a load balancer) to maintain a pool of servers. When a server becomes unreachable, the client can reconnect to another server.

Finding 12. *The client side and server side can have different awareness of a slow fault, causing a single slow follower to degrade the cluster performance.*

We observed in Section 3.1 that, a slow etcd follower can also degrade system performance, even if its peer nodes are both healthy and underloaded in the meantime.

Root cause. Clients use a gRPC balancer to connect to and distribute requests across the etcd cluster. Initially, the balancer maintains a simple keepalive ping with one of the endpoints. This connection persists unless the keepalive fails. If the endpoint is a mildly slow follower, the keepalive may not break and thus the slow follower still degrades system performance. Conversely, if severe slow faults break the connection, the balancer will switch to another endpoint, and the performance is restored. Appendix D provides a more detailed illustration.

Essentially, there is a mismatch of information between the server and the client. Although the server side can detect the slow follower, the gRPC balancer lacks this insight. This calls for enhanced protocols to exchange slowness information.

4.2.3 Slowness-triggered Log Roll in HBase

HBase employs Write-Ahead Log (WAL) to record all data modifications. After a write operation is logged, HBase tries to flush WAL to disk (i.e., called *sync*). When WAL reaches a certain size or age, HBase closes the current WAL and starts a new one (i.e., called *log roll*) on a random datanode. Log roll was designed as an efficient mechanism to constrain the WAL file size and ensure fast log replay during recovery.

Interestingly, HBase developers later leverage log roll to also address slow faults. Recall that HBase will randomly select new datanodes after a log roll, thus the log rolling can help mitigate slow faults by avoiding the slow datanode. Starting from Version 2.3 (July 2020), developers add log roll into the slow-fault handling pipeline [9]. It detects slow syncs, and triggers a log roll when syncs exceed 10 s or there are more than 100 slow syncs in one minute.

Finding 13. *The conservative thresholds prevent log roll from being triggered even under severe slow faults.*

Despite the new slow-fault handling mechanism, HBase still suffers from severe performance degradation under slow faults as evidenced in Section 3.1. The empirical thresholds developers choose limit this mechanism's effectiveness.

The current threshold of slow sync, 100 ms, is excessively conservative. As evidenced by our evaluation, a mere 100 ms network delay on the HBase region server already leads to a drastic performance degradation (see Figure 2). By the time a slow sync is detected, the system has already been significantly impacted. Similarly, the condition to initiate a log roll—incurring 100 slow syncs within 60 seconds—is too strict. Under such a condition, HBase is likely to have already collapsed. To verify this, we inject a network delay of 1 s that lasts for 60 s (yielding a degradation of more than 98%). As a result, only 32 slow syncs are reported during the 60 s injection window, failing to trigger a log roll.

4.2.4 Escalation to Fail-Stop

As previously shown, allowing slow nodes to continue serving can worsen the system performance. Recent systems adopt the *fail early principle*, choosing to kill the corresponding process or node in the face of unexpectedly severe slowness [15].

Finding 14. *Recent practices adopt fail early principle to handle the severely slow processes and nodes.*

For example, in CRDB, if a sync operation exceeds `maxSyncDuration=20s`, the process will be killed. In etcd, if we inject persistent yet slight network delays, the system keeps logging warnings and error messages, and kills the slow endpoint in minutes. For HBase, if the slowness-triggered log rolls coincide with a flaky network, there are also chances these log rolls fail and escalate to crash failures of nodes.

While such actions can be beneficial, they need to be applied carefully, because they can impair the system reliability, *e.g.*, leading to cascading failures [38]. Distinguishing a truly severe slow fault from noisy ones is also challenging.

4.3 Testing

In all the studied systems, the tests for their slow-fault handling take the form of unit tests instead of integration tests. In unit tests, developers use the `sleep` function to exceed static detection thresholds, and assert-check the triggered actions. For example, in etcd, developers simulate stalled disk writes by calling `sleep("30s")` [20]; in Cassandra, developers fabricate a slow operation, by calling `Thread.sleep()` [22], then assert-check whether the operation is detected as slow, completed, or aborted [21]. Yet upon reviewing the code and documentation, we find that none of the systems employ an injection tool to test slow faults in an end-to-end manner. This raises concerns about whether preset static thresholds are appropriate and whether the mechanisms can be reliably triggered in a real deployment, particularly as different deploying environments and workloads incur varying system responses.

Finding 15. *Current testing of slow-fault handling mechanisms focuses on the functionality instead of the effectiveness and robustness of their triggering conditions in practice.*

5 State-of-the-Art Solutions

Researchers have recently proposed advanced fail-slow solutions, which have not yet been incorporated into the studied systems. Are these latest techniques effective? In this section, we evaluate three state-of-the-art solutions.

Perseus. Perseus [49] uses machine learning techniques to detect fail-slow storage devices. It relies on device-level telemetry data to train a regression model that infers the normal latency of a device, and detects a slow one if its latency is much higher. The training and detection are both offline.

We re-implement Perseus strictly following its original design. Since Perseus's core idea is to model device-level throughput with latency, we adapt it to model the end-to-end latency and throughput of the studied systems. Figure 8a shows the latency-vs.-throughput (LvT) distribution of HBase under a 50/50 read-write workload. The blue points refer to the LvT distribution of HBase without slow faults. First, we apply the same outlier detection algorithms [23, 59] to filter out biased samples. Then, we train a similar polynomial regression model and calculate the 99.9% prediction upper bound (the blue line): any LvT points above the line are considered slow. Finally, we inject different levels of network delays (the green points) and check if the upper bound identifies any slow faults or not.

This solution fails to detect slow faults in HBase even under our most severe delay of 1 s. The main reason is that the LvT patterns of distributed systems are different from those of storage devices, making the model rather biased. In the original context, slow faults in NVMe SSDs cause latency to jump from tens of microseconds to milliseconds or seconds, while throughput remains moderate. In contrast, in HBase, a mild delay like 10 ms already degrades the throughput by 83%. We evaluate other systems and test different workloads. The results all show that this approach is not robust against

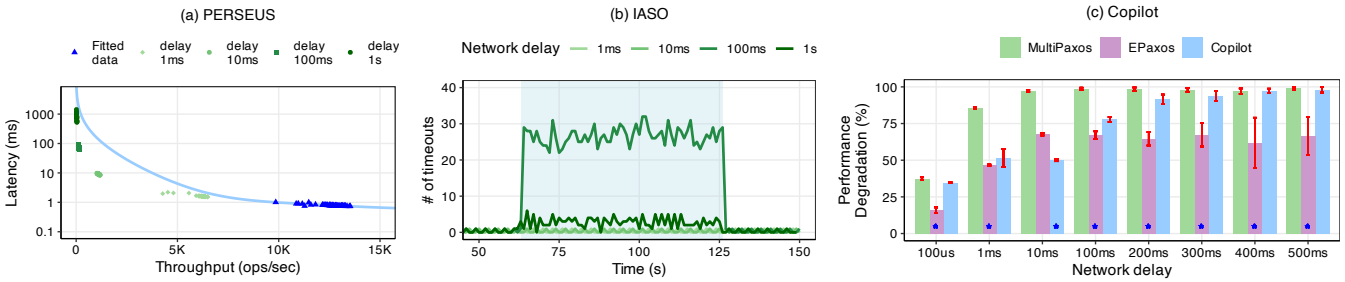

Figure 8: Evaluation of advanced fail-slow solutions. In Copilot (c), we mark the system with the smallest degradation using a blue asterisk.

slow faults in distributed systems.

IASO. IASO [57] is a peer-based, node-level fail-slow detection and mitigation framework for distributed systems. It relies on the deployed systems to emit timeout signals, converts them into a score, and compares the scores across nodes to detect slow ones (*i.e.*, nodes with higher scores than their peers).

However, since these timeouts are mostly static and over-conservative (Section 4.1), the effectiveness of IASO is limited. Figure 8b shows the number of timeouts per second as we inject different network delays to HBase (during the blue-shaded area). Clearly, HBase only emits notable timeouts when the delay reaches 100 ms. This coincides with our prior study in Table 3, where HBase has employed a 100 ms warning threshold for slow syncs. Tuning timeout thresholds may help IASO detect milder delays (e.g., ≤10 ms), yet it is time-consuming to do so and does not adapt to different workloads, as evidenced in Section 3.4.

Copilot. Copilot [54] is the first 1-slowdown-tolerant consensus protocol for quorum-based systems. It introduces two leaders that proactively add redundancy to all stages of the execution flow, so that any one slow replica (be it leader or follower) will not bottleneck the performance.

We evaluate Copilot and its two baselines (MultiPaxos [44, 51] and EPaxos [53]) using its original benchmark. Figure 8c presents their performance degradation under different network delays. Faults are injected to one of the pilots for Copilot, the leader in MultiPaxos, and one arbitrary node in EPaxos. We outline the following observations.

First, even under the mildest delay of 100 us, Copilot still incurs a degradation of 35%. Second, Copilot only yields the smallest degradation under a 10 ms delay. The root cause lies in two sets of static configurations. ❶ Copilot lets the fast pilot take over the work of the other slow pilot if the latter does not respond within 10 ms (*i.e.*, fast-takeover timeout). When the slowdowns are less than 10 ms, Copilot simply waits. This explains why Copilot is not optimal until 10 ms. ❷ When the delays are above 100 ms (*i.e.*, heartbeat sending interval), normal replicas will not receive heartbeats from the slow pilot in time. However, the slow pilot will not be marked as dead and still function until heartbeats are missing for more than 1 s (*i.e.*, heartbeat missing interval). This explains why Copilot still has a higher degradation when delays are above 100 ms.

6 An Adaptive Fail-Slow Detection Library

A consistent theme among our study's findings is that slow faults have highly diverse and dynamic characteristics. Changes (even small ones) in the workload, deploying environment, fault severity, location, *etc.*, can lead to dramatically different consequences. While developers become increasingly aware of the fail-slow problem and start to address it, the current practice of using static thresholds can hardly accommodate the characteristics of slow faults. We advocate for introducing *adaptive* designs [39] into slow-fault handling.

6.1 Limitations of Existing Solutions

As Section 5 shows, recent work does not address the dynamic nature of slow faults. Additionally, solutions such as Perseus and IASO are designed for *operators* to monitor systems as black boxes. They do not offer built-in support to help *developers* implement adaptive slow-fault handling within a system at the code level. An intrinsic adaptive design tackles the problem directly at the scene. It monitors slowness at fine granularity, such as a function call. It also invokes targeted actions to quickly mitigate slowness. However, realizing this design can require significant developer efforts. A library to reduce these efforts is desirable.

6.2 ADR: Adaptive Detection at Runtime

To address the gap, we design ADR, a lightweight adaptive fail-slow detection library for distributed systems. Developers use ADR as a plug-in when adding fail-slow handling code. ADR traces some built-in variables (*e.g.*, `syncOpLatency`), automatically adapts the associated threshold variables to decide slowness, and invokes different levels of defined actions. We aim to achieve the following goals: (1) ease of use; (2) accurate and fast detection; (3) low overhead; (4) robustness.

ADR can be integrated into a system by adding only few changes. Developers have added extensive tracing code for different operations (*e.g.*, write) and compared these tracing variables with static thresholds to detect slow operations. ADR leverages such existing code and replaces the static logic in place to make the detection adaptive.

ADR is directly motivated by the takeaways from our study. It replaces static timeouts (§4.1) with percentile-based detection to adapt to varying slow faults (§3.1), deploying environment (§3.2), workloads and danger zones (§3.3). Since percentile-based monitoring like tail latency can be diluted

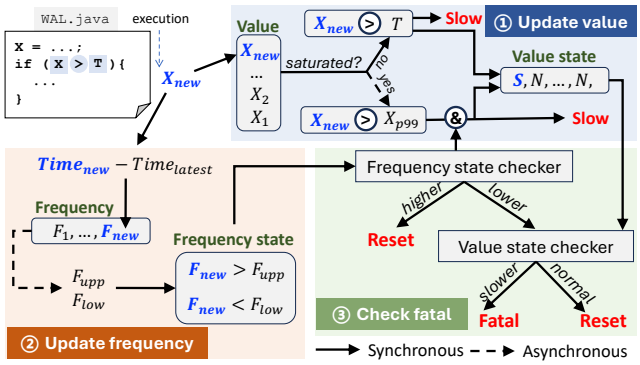

Figure 9: Overview of ADR.

by normal records (§3.5), ADR analyzes how frequently the tracing variables get updated for more reliable cross-validation. As systems employ different mitigation actions (§4.2), ADR outputs a slowness level (slow, fatal) for developers to trigger appropriate actions.

As shown in Figure 9, ADR monitors both the value and the update frequency of some tracing variables defined in the system code using sliding windows. The high-level idea is to adapt the original thresholds used in comparison based on historical values to identify slow data points, and distinguish workload changes from slow faults by checking how often the variable gets updated, *i.e.*, update frequency.

It employs two state checkers to make decisions, which either trigger internal actions (*reset windows*) or return a slowness level (slow or fatal) for the system code to act upon. If it detects a sudden increase in the update frequency, it assumes the system is under a heavier workload and resets all sliding windows to adapt. Conversely, if the update frequency drops, due to either a slow fault or a lighter workload, ADR further checks the values of the traced variable: if they show a sustained slowdown, ADR identifies a slow fault and triggers a fatal action; otherwise, it adapts to a lighter workload in the same manner. We describe each step below.

❶ Update value. When a new value of the tracing variable is updated (X_{new}), ADR stores it into a sliding window of historical values. Initially we use the original threshold T, preserving the default behavior, until the sliding window is saturated. We then calculate the 99^{th} percentile as the adaptive threshold (X_{p99}). If the new response is higher than the threshold (potentially slow), we further query the frequency state checker in Step 3. If the frequency is decreasing, we mark this response as slow and store its state in a sliding window of historical states (to check for continuous slowdown later).

❷ Update frequency. When a new value is updated, ADR also calculates the timestamp difference between the new and last value. We divide 1 s by the difference to get the update frequency of the tracing variable (unit: response/second), stored using a sliding window. Then, ADR calculates the average and standard deviation of the frequency window and derives *average* + *stdDev* (*average* − *stdDev*) as the upper (lower) bound. A frequency higher than the upper bound indicates a potential workload increase (*e.g.*, a burst of requests or heavier workload), while a frequency lower than the lower bound indicates either a decrease in workload intensity or a slow fault. We maintain another sliding window of frequency states to check for continuous frequency changes later.

❸ Check fatal. Finally, ADR checks the frequency and value state windows to distinguish workload changes from continuous slow faults. If the frequency is continuously higher, the system may experience a workload increase and ADR will reset all sliding windows and be ready to adapt new workload. If the frequency is continuously lower, ADR would cross-validate with value states: if the value state indicates a continuous slowdown, ADR would trigger a fatal action if needed; otherwise, the system may experience a workload decrease and all windows will be reset.

Adaptive threshold. ADR calculates the 99^{th} percentile as an adaptive threshold. This does not mean ADR will always treat 1% of total responses as slow. Instead, ADR cross-validates with frequency states to check if the frequency is continuously decreasing. In this case, ADR can accurately detect slow faults while not emitting false alarms due to workload variations.

Dynamic window length. The length of all sliding windows is set to be positively correlated with the frequency (i.e., 10 × current frequency). This is to make sure that the window size is always proportional and adaptive to any frequency change.

State checkers. ADR uses two state checkers to monitor continuous slowdown and workload changes. The value state checker inspects the most recent n value records, and checks if more than half of them are slow; the frequency state checker examines the most recent n frequency states (which represent heavier or lighter workloads) to see if more than half of them are persistent. We choose n to be equal to the current update frequency (*i.e.*, the number of updates in the last second). For example, when the frequency drops from 1 K records/sec to 100, the checkers will only use the most recent 100 data points instead of 1 K. This allows ADR to quickly adapt to workload changes while avoiding the dilution of slow fault records.

ADR also considers the case when slow faults occur during the data collection phase: when the value window is not populated yet to draw a X_{p99} adaptive threshold. In this case, ADR relies solely on the frequency state checker and resets all windows when the update frequency changes notably.

Example. Figure 10 shows the use case of ADR in HBase. Originally, HBase already included tracing code for the WAL sync. The latest sync time is stored in `timeInNanos` (a tracing variable). It further defines two static threshold variables, `slowSyncNs` (line 2) and `rollOnSyncNs` (line3), and uses two statements (lines 5 and 8) to check if the sync time exceeds the thresholds. Different actions would be taken accordingly, emitting a warning (line 7) or rolling WAL (line 10).

With ADR, the original parameters inside the "if" conditions are retained but wrapped up using ADR's APIs. Specifically, we call `isWarn()` in line 6 to compare the latest sync time

```
1  // Default static thresholds
2  long slowSyncNs = TimeUnit.MILLISECONDS.toNanos(100);
3  long rollOnSyncNs = TimeUnit.SECONDS.toNanos(10);
4  void postSync(final long timeInNanos, ...) {
5  -  if (timeInNanos > slowSyncNs) {
6  +  if (ADR.isWarn(timeInNanos, ">", slowSyncNs)) {
7        LOG.info("Slow sync detected.");
8  -     if (timeInNanos > rollOnSyncNs) {
9  +     if (ADR.isFatal(timeInNanos, ">", rollOnSyncNs)) {
10         requestLogRoll(SLOW_SYNC);
11       }
12   }
```

Figure 10: Applying ADR in HBase. Lines with '-' correspond to HBase's original slow-fault detection using static timeouts. Lines with '+' show how ADR is integrated into HBase.

Setup	Warning threshold	Fatal threshold
Static-1	1 ms	10 ms
Static-2	10 ms	100 ms
Static-3	100 ms	1 s

Table 4: Evaluation setups for the three static schemes.

with an adaptive threshold. Then we use `isFatal()` in line 9 to check if there is a continuous slowdown and frequency change (or if the latest value exceeds the default threshold). If so, a log roll would be triggered per developers' design.

Limitations. ADR cannot detect slow faults that appear during system start-up. Operators at the scene are typically able to monitor and handle such cases manually. Additionally, since ADR relies on update frequency to distinguish workload changes from slow faults, it may misclassify slow faults that occur precisely during workload transitions. Finally, ADR assumes developers already know where to check for slow faults. We believe a keyword-based search of potential code locations for instrumentation (§6.3) can be a useful addition.

6.3 Evaluation

Our evaluation aims to answer: (1) can ADR effectively detect and mitigate slow faults of varying severity? (2) is ADR robust to different and dynamic workloads? (3) what is the overhead of ADR at runtime?

Implementation and Baselines. We implement ADR in both Java and Go (~400 lines), and integrate it into HBase and CRDB. We use a keyword-based approach to automatically search for potential variables that can be traced. For example, in HBase, we first identify 57 variables. Among them, 9 exactly match the use case of ADR (comparing with a default static threshold) and are traced; the rest are either not timeouts, part of external APIs (*e.g.*, timeouts in protobuf), or triggering no mitigation action (*e.g.*, only logging the event).

We use the testing pipeline (Section 2.1) to inject slow faults with varying severity and workloads. Each experiment runs for 5 minutes and we inject a fault of 2 minutes starting from 90 seconds. Each set of experiments is repeated 50 times.

We compare ADR with both the original implementation (*i.e.*, vanilla) and three sets of static schemes (see Table 4). Since most studied systems (including HBase and CRDB) employ a typical two-stage timeout mechanism (§4.1), we

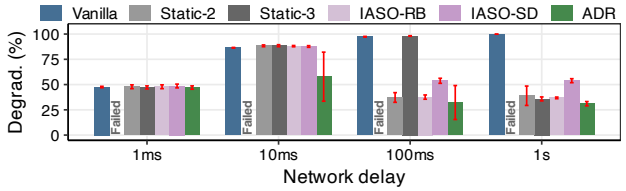

Figure 11: Degradation of HBase using ADR and the baselines under different network delays. Static-1 is too sensitive and fails the cluster. *IASO-RB*: IASO with reboot; *IASO-SD*: IASO with shutdown.

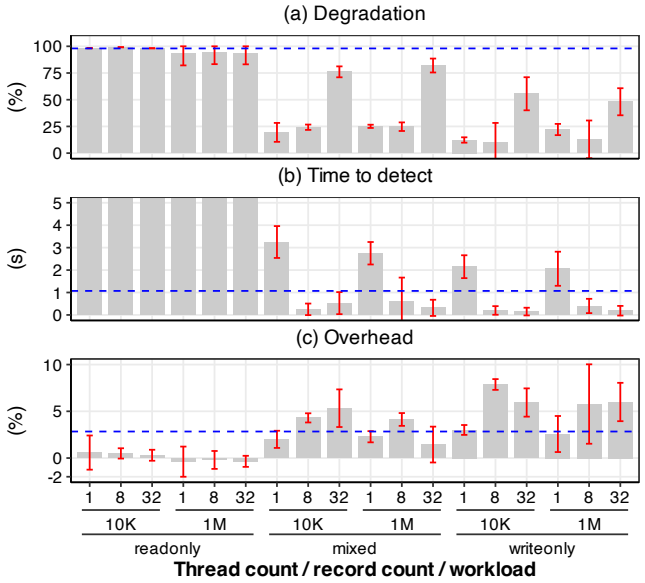

Figure 12: HBase using ADR under different workloads. The blue dashed line in (a), (b), and (c) corresponds to the degradation of vanilla HBase, the average time to detect in mixed and write-only workloads, and the average overhead, respectively.

set two thresholds (a warning and a fatal one) for each setup. The threshold values of the three static schemes are chosen according to the delays injected, so that they are the optimal ones for the corresponding slow faults. For example, Static-1 with a warning threshold of 1 ms would be the optimal one to detect a delay of 1 ms.

We also compare ADR with IASO [57] (see Section 5). We have fine-tuned IASO's parameters and chosen the optimal ones under our testing pipeline. IASO employs its own mitigation: upon detecting fail-slow, it will first try to reboot the service instance (*i.e.*, IASO-RB). If the reboot does not work, IASO will then try to shut down the slow node (*i.e.*, IASO-SD). Perseus [49] is not chosen as it is an offline detection solution.

Tolerance of Varying Slow Faults. Figure 11 shows the degradation of HBase under different network delays. ADR helps mitigate slow faults under all injected delays and is always better even than the optimal static settings. For example, under a 100 ms delay, ADR reduces the degradation from 97% (vanilla) to 32% (65% reduction). In comparison, the optimal Static-2 case, IASO-RB, and IASO-SD yield a higher degradation of 37%, 38%, and 54%, respectively.

Similarly in CRDB, the average degradation of the vanilla,

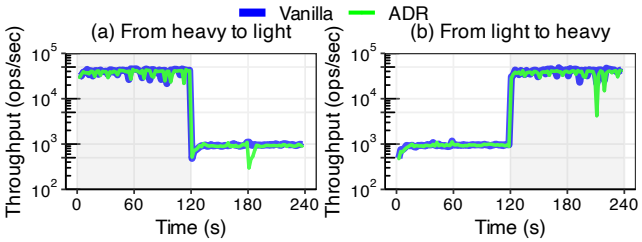

Figure 13: HBase under dynamic workloads. The light (heavy) one refers to mixed (write-only) workloads with 1 (32) YCSB client thread(s) and 10K (1M) records. Workload changes at 120 s.

Static-2, and Static-3 are 52%, 3%, and 44%, respectively, while ADR results in a 7% performance *gain*.

Tolerance Under Varying Workloads. Figure 12 shows the performance of HBase with ADR under diverse workloads. We inject a 100 ms network delay.

ADR decreases the degradation from 98% (vanilla) to as low as 10% (Figure 12a). Note that ADR does not mitigate read-only workloads. This is because the variables that ADR trace are all related to write operations, due to the fact that the system's fault-tolerance mechanisms are not engaged or required as much for reads. Nevertheless, we believe ADR will still work well given any critical read variables are traced. As a result, ADR helps reduce the degradation in mixed and write-only workloads by 16–80% and 43–90% in HBase, and by 20–96% and 5–66% in CRDB, respectively.

Recall the fine-tuned HBase incurs cluster failures under other workloads (Section 3.4). ADR, however, not only yields lower degradation than the optimal static settings, but also maintains system availability with zero failures.

As Figure 12b shows, the average time to detect in mixed and write-only workloads are 1.3 s and 0.9 s, respectively. This shows that ADR detects slow faults in a timely manner.

ADR is robust to dynamic workloads. As shown in Figure 13, system throughput is on par with or without ADR. This indicates that ADR can adapt to workload changes with minimal impact on system performance.

Overhead. Figure 12c shows the overhead of ADR. The average overhead across all workloads is 2.8%. With this low overhead, ADR can be integrated into even more modules.

7 Related Work

Since faults are frequent in distributed systems and fault tolerance is crucial, understanding failures has been a constant theme in distributed system research. Numerous empirical studies [24, 25, 27, 28, 32, 34–36, 41–43, 46, 47, 56, 65] have characterized failures in various settings. They generally have different focuses and are complementary to each other.

One common category is to analyze why certain systems fail and identify the high-level causes. For example, an early prominent study by Oppenheimer *et al.* [56] examined the root causes of failures in commercial Internet services. The findings pointed out that operator errors caused most failures. Yuan *et al.* [65] studied user-reported failures in open-source distributed systems and found that more than half of the catastrophic failures could have been detected by simple testing of error-handling code. Other studies in this category were conducted on Hadoop cluster [58], Microsoft Azure services [46], jobs in Google computer cluster [29], SCOPE jobs in Microsoft Bing [45], cloud servers [62], etc.

More recent studies analyze complex failure modes that are under-explored yet increasingly common in large distributed systems, such as gray failures [42], partial failures [47], metastable failures [41], limplock [32], and silent semantic violations [48]. These studies focus on software failures. Several other studies focus on failures related to hardware, such as network partitions [25], fail-slow hardware [36, 49, 50], and silent data corruption in CPUs [31, 40, 63]. Our study is motivated by recent fail-slow hardware studies. We shift the focus to the impact of fail-slow events on software. Our work revisits the early limplock study [32], which discusses the worst-case scenarios using microbenchmarks. In contrast, we focus on the operational impact of slow faults for modern distributed systems under realistic workloads. We explore a broad spectrum of failure space. For example, we analyze how nuanced slow faults with diverse severity (not just worst case), location, *etc.*, degrade system performance. We measure how varying cloud benchmarks, danger zones, deploying environments, tail latency measurements, and fine-tuning configurations impact slow-fault tolerance. We also evaluate the effectiveness of latest fail-slow detection and mitigation solutions.

A number of solutions have been proposed to tolerate slowness (performance issues) in distributed systems. A typical technique is speculative execution [26, 60, 66], which launches a backup task when a task is slow (straggling). Copilot [54] enhances the consensus protocol by using two distinguished replicas to tolerate slow faults. DepFast [64] provides programming interfaces for developers to implement slow-tolerant protocols. Our study aims to provide insights for distributed systems designers to improve slow-fault tolerance solutions.

8 Conclusion

Recent studies have increased the community's awareness of the fail-slow problem. Nevertheless, fail-slow tolerance remains a challenging topic to approach. We present a comprehensive study that analyzes the nuances of fail-slow tolerance in current systems. Our study reveals that existing efforts do not accommodate the highly dynamic and sensitive characteristics of slow faults. We showcase how adopting a simple adaptive design can significantly increase the effectiveness of a system's existing slow-fault handling mechanisms.

A Fault Injection Tools

We use blockade [2] to inject network slow faults and charybdefs [3] to inject filesystem ones.

Blockade is a network testing tool based on Docker utilities, allowing users to inject network failures in distributed applications. In essence, it employs Linux traffic control (`tc`) to inject network delays, packet loss, and partitions. In conclusion, our testing pipeline leverages blockade to inject delays and packet loss to running distributed nodes.

Charybdefs is a FUSE-based fault injection filesystem with a Thrift RPC interface for instrumentation. It simulates various filesystem faults, such as delays, read/write errors, and disk full. We use charybdefs to inject filesystem delays to the running distributed systems.

B Larger Cluster Size

In Section 3, we discuss the nuanced fault tolerance of distributed systems against diverse slow faults (§3.1), different resource limits (§3.2), and varied workloads (§3.3). However, the discussion is based on a small cluster size (3–6 nodes). In this section, we evaluate the impact of cluster size and check whether our findings and observations still persist. We validate the findings (Findings 1-7) presented in Section 3 using CRDB and etcd under a 10-node and 20-node setup.

B.1 How Systems React to Varying Slow Faults

Figures 14 and 15 present the performance degradation of etcd under a 10-node and 20-node setup, respectively. Although the absolute numbers of degradation do not exactly match with those in Figure 2, they still vary across systems as in Finding 1. For example, under a mixed workload with delayed network in the leader node, the degradation of 3-node etcd cluster is 0.5%, 2%, 19%, 75%, and 96% for 100 us, 1 ms, 10 ms, 100 ms, and 1 s delays, respectively. In comparison, the corresponding degradation of a 10-node etcd cluster is 0.5%, 1%, 9%, 51%, and 88% for the same delays, while that of a 20-node etcd cluster is 0.1%, 0.3%, 7%, 46%, and 74%.

Regarding different fault types, the average degradation of a 10-node etcd cluster (mixed workload, injected on the follower) under network packet loss and network delay is 10% and 37%, respectively. This indicates that etcd is much more sensitive (3.7× differences) to packet loss than network delay, which is consistent with Finding 3.

Moreover, slow faults still impact systems differently conditioned on the fault locations. In a 10-node etcd cluster, when we inject a 100 ms network delay to either the leader or the follower, the degradation is 8% and 51%, respectively. This translates to a 6.4× difference. As a result, Finding 4 also holds in a larger cluster size.

Previously, we summarized in Finding 2 that the performance degradation does not always increase as slow-fault severity increases. We find this finding also holds for CRDB with a larger cluster size. Figure 16 presents the degradation of 10-node and 20-node CRDB under different filesystem delays. As we can see, in a 10-node CRDB cluster under the read-only setup, the degradation under a 100 ms delay (82%) is 2.4× that of a 1 s delay (34%). We also observe a similar

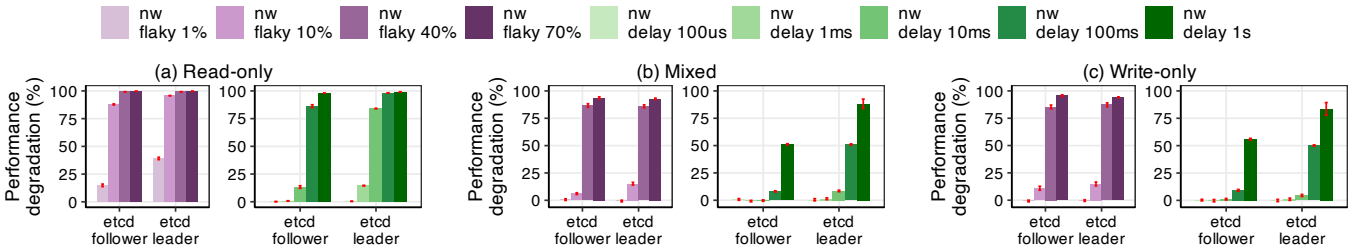

Figure 14: Performance degradation of 10-node etcd under different network packet loss and network delay. The darker the colors, the more severe the faults are. Each experiment was repeated 50 times for generalizability. Error bars refer to 95% confidence intervals.

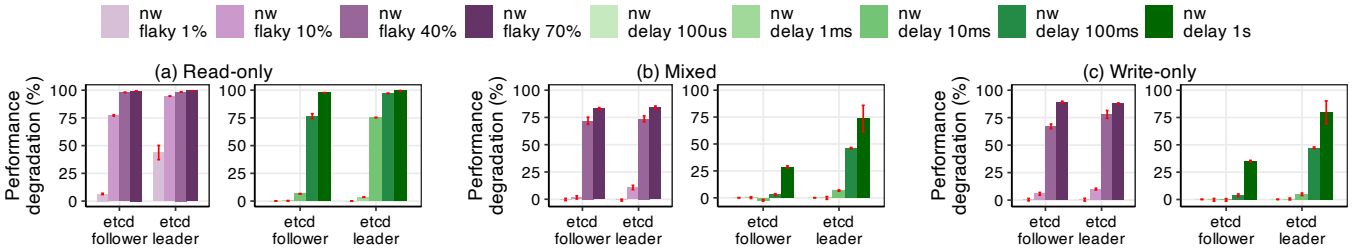

Figure 15: Performance degradation of 20-node etcd under different network packet loss and network delay. The darker the colors, the more severe the faults are. Each experiment was repeated 50 times for generalizability. Error bars refer to 95% confidence intervals.

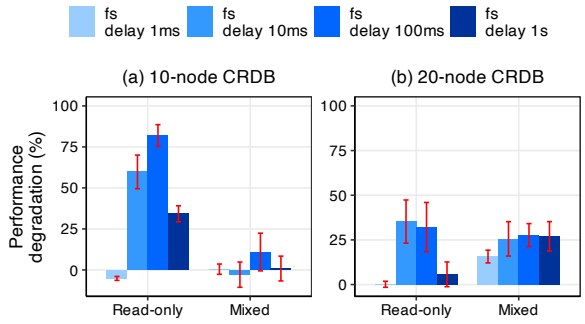

Figure 16: Performance degradation of 10-node and 20-node CRDB under different filesystem delays. The darker the colors, the more severe the faults are. Each experiment was repeated 50 times for generalizability. Error bars refer to 95% confidence intervals.

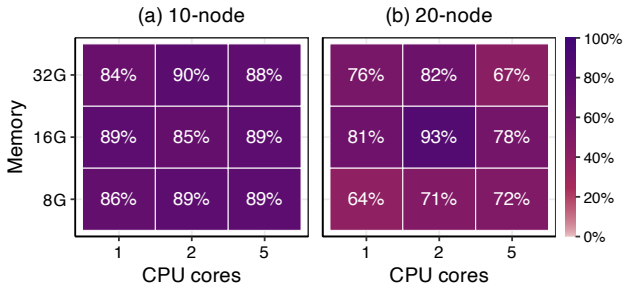

Figure 17: Performance degradation of etcd under different CPU and memory limits. Values in each cell correspond to the average degradation of the same set of experiments repeated 50 times. A 1 s network delay is injected to the etcd leader node. The darker the colors, the more severe the degradation is.

trend when the workload changes to mixed or the cluster size increases to 20 nodes.

To sum up, as the cluster size increases to 10 or even 20, our general observations and findings (Findings 1-4) regarding how systems are impacted by different fault types, fault severities, and fault locations are still consistent with those in Section 3.1.

B.2 Do Resource Limits Amplify Slow Faults?

Figure 17 presents the performance degradation when a 1 s network delay is injected to the etcd leader node. We set different resource limits on CPU cores (ranging from 1 to 5 cores) and memory sizes (ranging from 8G to 32G). As we can see, either under a 10-node or 20-node setup, the degradation of etcd is still sensitive to the amount of resources. For example, under the 20-node setup with a per-node memory of 32G, degradation ranges from 76%, 82%, to 67%, with a per-node CPU core limit of 1, 2, 5, respectively. This is consistent with our Finding 5 in Section 3.2.

B.3 How Workloads Affect Slow Tolerance

Figure 18 presents the performance degradation of etcd conditioned on different workload patterns (read-only, balanced mix, and write-only) and injected network delays (from 0 to 1 s, injected on the leader). Obviously, system degradation is sensitive to workload patterns. For example, for a 10-node etcd cluster under a 10 ms network delay (see Figure 18b), the performance degradation of etcd under read-only, balanced mix, and write-only workloads is 84%, 9%, and 4% (up to 21× differences). We also obtain similar results in a 20-node etcd cluster or when slow faults are injected to the follower node (see Figure 20). This is consistent with Finding 6 in Section 3.3.

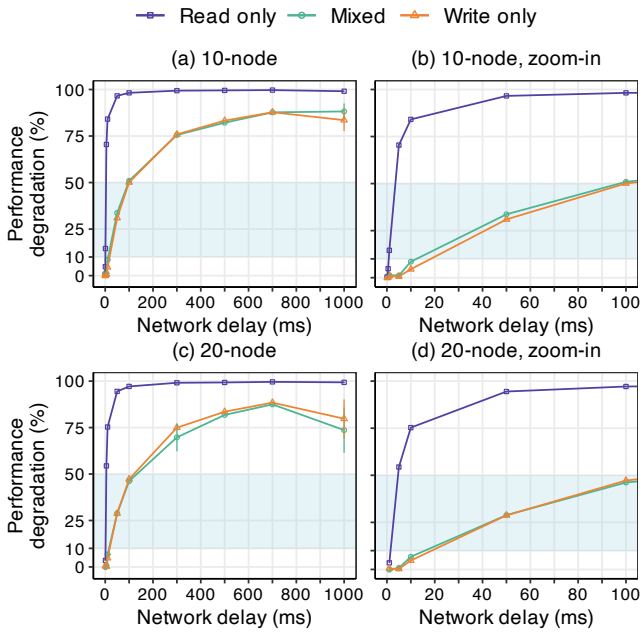

Figure 18: Performance degradation of etcd under different network delays (injected on the leader). Each set of experiment was repeated 50 times for generalizability. The shaded area highlights the "danger zone" where performance degradation escalates dramatically. Mixed: 50% reads and 50% writes.

Moreover, danger zone (between 10% and 50% degradation) still exists. For example, the danger zone for 10-node etcd under a read-only workload (injected on the follower) is from 10 ms to 50 ms (see Figure 20d). We also observe notable danger zones in the 20-node setup or when slow faults are injected to the leader node. This is consistent with our Finding 7 in Section 3.3.

C Leader Re-Election

Figure 19 shows the logic diagram of why severe slow faults on the leader can lead to better performance in etcd.

D Client-Side Reconnection in gRPC

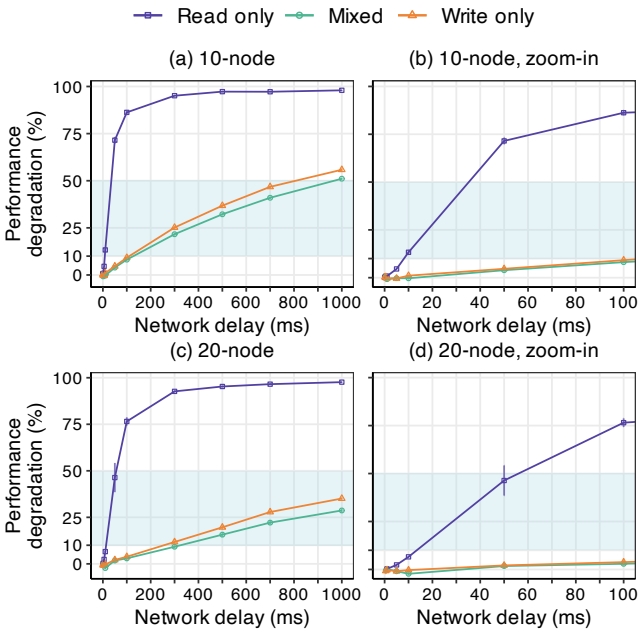

Figure 20: Performance degradation of etcd under different network delays (injected on the follower). Each set of experiment was repeated 50 times for generalizability. The shaded area highlights the "danger zone" where performance degradation escalates dramatically. Mixed: 50% reads and 50% writes.

cluster in etcd.

E Time to Recover

Metrics and notations. To determine when the system has recovered from slow faults, we calculate *recovery time* as the time it takes for the system to reach back a throughput that is higher than a *threshold*. The *threshold* is calculated as *avg_normal* – *sd_normal*, where *sd_normal* is the standard deviation of the series of throughput records before fault injection. Figure 22 presents the distribution of recovery time among all studied systems.

Recovery time in delayed filesystem and network. Systems can recover quickly from delayed filesystem and network. As shown in Figure 22, the average recovery time for all studied systems under a delayed network and filesystem is 0.8s and 1.0s respectively. We do not observe a notable jump

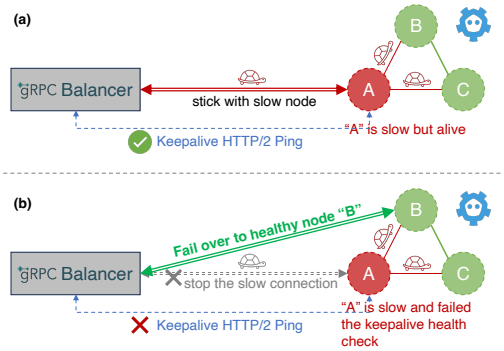

Figure 21: A slow follower can degrade cluster performance.

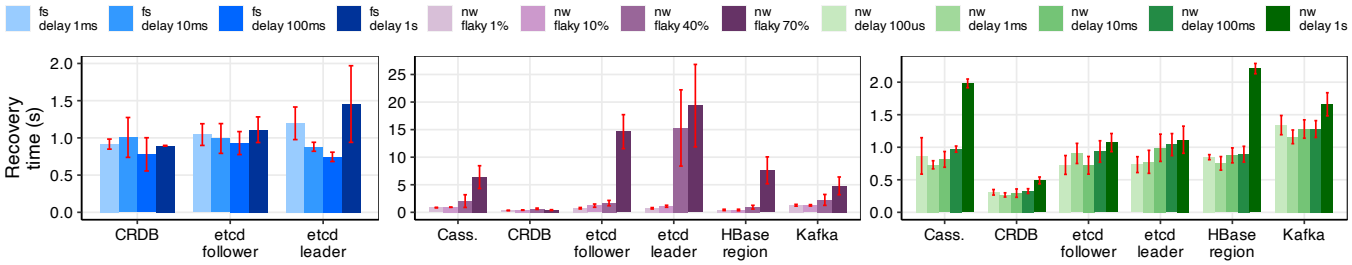

Figure 22: Time for performance to recover after filesystem delay (left), network packet loss (middle), and network delay (right). The darker the colors, the more severe the faults are. Each experiment was repeated 50 times for generalizability. Error bars refer to 95% confidence intervals.

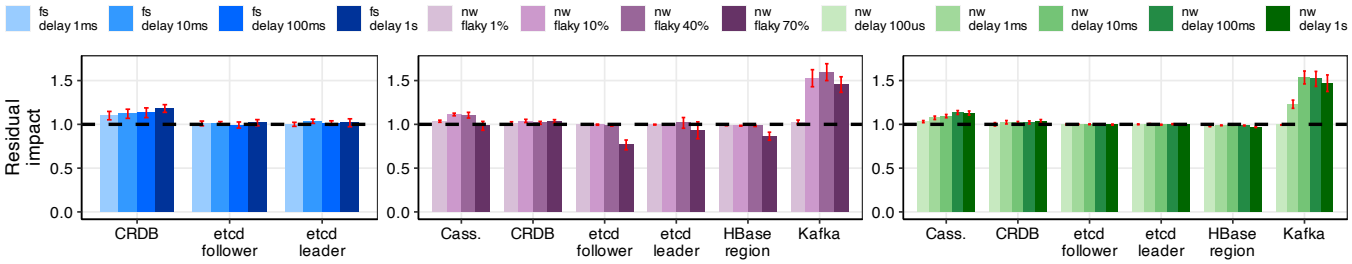

Figure 23: Residual performance after filesystem delay (left), network package loss (middle), and network delay (right). The darker the colors, the more severe the faults are. Each experiment was repeated 50 times for generalizability. Error bars refer to 95% confidence intervals.

in the recovery time as we iterate through higher delays. Kafka takes a slightly longer recovery time (an average of 1.3s). This is because of the distributed nature of Kafka (i.e., data streaming) which relies more heavily on network communication. Nevertheless, it is still acceptable as the recovery time is still within seconds. Also, CRDB generally needs more time to recover from filesystem delays (an average of 0.9s) than network delays (0.3s).

Recovery time in flaky network. However, in the face of network packet loss, the recovery time could be much longer. In general, the recovery time of all systems increases as their network becomes more flaky: the average time to recover under a 10%, 40%, and 70% packet loss is 0.8s, 3.6s, and 7.1s respectively.

We notice that the recovery time for a 70% packet loss is notably higher than in the other two cases. This is because the injected node sometimes fails to establish a connection with the cluster due to high packet loss and even experiences some downtimes. In this case, after faults are cleared, systems will schedule a considerable amount of background tasks to help the injected node catch up with the cluster (e.g., hinted handoff in Cassandra). In this case, system performance cannot recover until background tasks are mostly finished and no longer serve as bottlenecks. However, etcd may intentionally shut down faulty nodes, thus no longer recovered.

Relationship between degradation and recovery time. A higher performance degradation does not necessarily yield a much longer recovery time. For example, CRDB degrades by 22% under a 1ms filesystem delay and then recovers in 0.92s, while it degrades much more by 72% under a 1s filesystem delay but then recovers faster in 0.78s. Similar observations can be obtained in most fault setups (except for those with high packet loss of 40% and 70%). This phenomenon can be attributed to the fact that most slow faults we introduced, while significantly impeding a distributed system, do not crash nodes. Thus, systems can quickly recover to normal once the faults are cleared.

F Residual Impact

Metrics and notations. We calculate the average throughput after slow faults are cleared (denoted as *avg_residual*), and compare it with the average throughput before fault injection (denoted as *avg_normal*). We quantify the residual impact as $\frac{avg_residual}{avg_normal}$ where a value higher than 1 indicates that the system is fully recovered and even outperforms the normal state. On the other hand, a value smaller than 1 indicates that the system's overall performance is still affected by the residual impacts of slow faults. Figure 23 presents the distribution of residual impacts among all studied systems.

Performance drop. Severe slow faults could incur notable residual impacts on system performance. For example, soon after the 70% packet loss is cleared, etcd follower still suffers from severe slowdowns for a while, while its performance gradually increases over time. As a result, it can only achieve an average performance that is only 77% of the normal state. Similar observations can also be obtained in HBase.

Performance gain. We observed that some systems issue bursty requests after slow faults finish. For example, the performance gains in CRDB (after filesystem delays) and Cassandra (after network delays) are all above 1, with an average of 1.13×

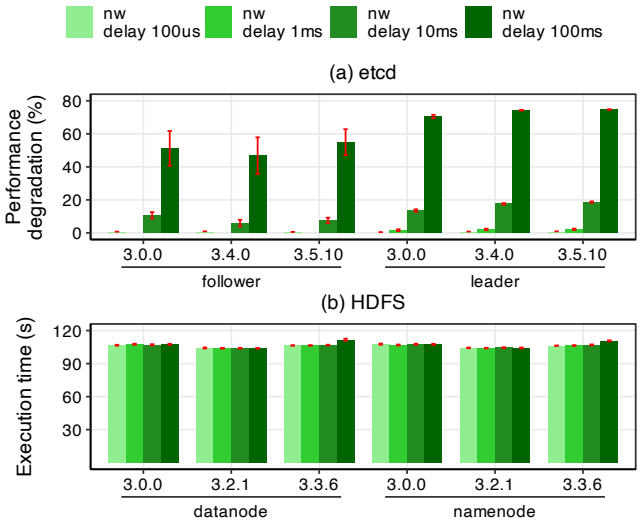

Figure 24: Cross-version analysis of HDFS and etcd under network slow faults. The x-axis shows different fault injection locations and system versions. The y-axis shows the performance degradation in etcd or the execution time of the TeraSort benchmark in HDFS.

and 1.08× respectively. Moreover, the more severe prior faults are, the more performance gain we can observe. This is due to systems' internal recovery mechanisms, such as backlog in CRDB and hinted handoff in Cassandra.

Kafka demonstrates the most performance gains among all systems, with an average of 1.4× after network faults are cleared. Also, we notice that its cumulated performance gain resembles its cumulated performance degradation during slow faults (see Figure 2). This is due to the delayed flush of messages. Producers in Kafka by default will buffer unsent messages (due to a slow network in our case) in the memory and then flush them all once the network faults are cleared. In this case, the performance gain we observe is similar to the performance degradation caused by slow faults. To validate this, we configured Kafka to force flushing every message, which eliminated such notable performance gains.

G Cross-Version Analysis

Distributed systems are constantly evolving, integrating bug fixes and new features that also influence their fault tolerance capabilities (e.g., HBase's log roll mechanism discussed in Section 4.2.3). In this section, we evaluate and compare the nuances of slow-fault tolerance across different versions (see Table 5) of two representative systems, HDFS and etcd. HDFS is a relatively mature system while etcd represents newer generations of distributed systems. Our goal is to understand the evolving trajectory of these systems in terms of their tolerance to slow faults.

System	Version	Year
HDFS	3.3.6	2023
	3.2.1	2019
	3.0.0	2017
etcd	3.5.10	2023
	3.4.0	2019
	3.0.0	2016

Table 5: Versions of HDFS and etcd used in the cross-version analysis.

Figure 24 presents the evaluation of etcd and HDFS under network slow faults. In both HDFS and etcd, the performance degradation does not vary much across different versions. As we increase the degrees of severity, the performance degradation in etcd leader or follower also increases accordingly. We also check other fault types (e.g., filesystem delays), showing similar results. In conclusion, there is no significant improvement in the slow-fault tolerance of these systems over time. Their version updates highlight a lack of focus on this field. Yet, the evident performance and awareness discrepancies across these systems show the feasibility and improvement we can obtain through moderate efforts.

Pyrrha: Congestion-Root-Based Flow Control to Eliminate Head-of-Line Blocking in Datacenter

Abstract

In modern datacenters, the effectiveness of end-to-end congestion control (CC) is quickly diminishing with the rapid bandwidth evolution. Per-hop flow control (FC) can react to congestion more promptly. However, a coarse-grained FC can result in Head-Of-Line (HOL) blocking. A fine-grained, per-flow FC can eliminate HOL blocking caused by flow control, however, it does not scale well.

This paper presents Pyrrha, a scalable flow control approach that provably eliminates HOL blocking while using a minimum number of queues. In Pyrrha, flow control first takes effect on the root of the congestion, i.e., the port where congestion occurs. And then flows are controlled according to their contributed congestion roots. A prototype of Pyrrha is implemented on Tofino2 switches. Compared with state-of-the-art approaches, the average FCT of uncongested flows is reduced by 42%-98%, and 99th-tail latency can be 1.6×-215× lower, without compromising the performance of congested flows.

1 Introduction

Given the increasingly stringent performance requirements on datacenter networks, avoiding congestion and the resulting delays has become critical for many applications. Indeed, measurement studies show that congestion events are frequent in today's datacenters, *e.g.*, bursty key-value stores [18, 30], web search services with massive queries [11], and data-parallel/machine-learning systems with partition/aggregation traffic patterns [29, 90, 92, 13, 26, 91, 4, 70, 33]. Generally, congestion occurs at an output port when the arrival rate of traffic exceeds its link bandwidth. Queues build up at congested ports. With an inflated buffer, flows could endure a long queuing delay or even face packet loss, hence flows' completion times (FCT) can be prolonged [11, 56].

State-of-the-art approaches to handle congestion is end-to-end congestion control (CC) [11, 95, 65, 56, 19, 55, 61, 15, 35, 6, 14, 86, 58]. Congestion can be detected by senders when congestion signals are sent back or feedback delay is observed. Usually, it costs senders at least one Round-Trip Time (RTT) to be aware of the congestion, and then senders may take several RTTs to converge to an appropriate transmission rate. In modern datacenters, the effectiveness of end-to-end CC is quickly diminishing with the rapid bandwidth evolution [36, 43, 74, 22](§ 2.1).

With the increasing link speed and performance requirements of datacenter networks, an intriguing and emerging alternative is per-hop flow control (FC), which can react to congestion much more promptly. It suppresses the transmission of the upstream entity before overwhelming the downstream queue, which avoids a large buffer occupancy. Generally, traffic in the same queue is controlled as a whole. Once the queue length exceeds a given threshold, a pause frame can be sent to pause the upstream entity [16, 17], avoiding further buffer build-up where congestion occurs. However, a coarse-grained flow control might spread the congestion to the whole network, inducing Head-Of-Line (HOL) blocking, and hurting the performance of victim flows [40, 54, 62, 57]. Here HOL blocking refers to flows being paused innocently (§ 2.2). A naïve approach to eliminate HOL blocking could be to isolate each flow into different queues and control each of them separately. However, such a per-flow granularity flow control is not scalable since the hardware resources of switches are limited. State-of-the-art flow control approaches hence aim at reducing the number of queues required by compromising the granularity of isolation [36]. Thus, the HOL blocking can not be eliminated entirely (§ 2.3).

This paper explores how to eliminate HOL blocking in a scalable manner, *i.e.*, minimizing the required number of queues. We observe that when congestion occurs, flow control first takes effect on the root of the congestion, *i.e.*, the port where congestion occurs. Then several congestion hotspots (*i.e.*, output port with buffer build-up) can appear along the back pressure path of flow control. These involved hotspots form a congestion tree, where the root of the

*First author and second author contribute equally to this work.

tree is the root of the congestion. Simply controlling the transmission of flows based on hotspots could induce HOL blocking. Instead, if we separately control the transmission of flows according to the congestion root they participate in, flows will not be paused innocently. As the number of concurrent congestion roots observed on each port is moderate, only a reasonably small number of queues on each port are required for traffic isolation in each switch [20].

Based on these insights, this paper presents Pyrrha, a congestion-root-based per-hop flow control protocol (§ 3). A framework is constructed for analyzing egress-based flow control algorithms. We analytically prove that Pyrrha is a HOL-blocking-free per-hop flow control protocol with the minimum queue requirements.

In Pyrrha, each switch maintains a snapshot of the congestion status of the downstream network. Flows that would pass through the same congestion root in their downstream paths could be pushed into a dedicated congestion queue locally in each upstream switch. Then, flows passing through different congestion roots can be controlled separately as soon as possible. Pyrrha solves a set of challenges.

- ***How to identify a hotspot's role?*** When congestion occurs, multiple congestion roots may be claimed in succession. This could occur when an upstream congestion hotspot claims itself root while its downstream hotspot disagrees, and vice versa. With a local view, it is hard to tell which root is the exact root in the upcoming congestion. Intuitively, given the behavior of flow control, congestion roots always locate on the most downstream ports that flows pass through. Inspired by the root-selection procedure of classic spanning tree algorithms [7, 32], Pyrrha employs a distributed self-stabilizing *merge* mechanism. A port can claim itself a *self-nominated* congestion root independently when it detects its queue buildup for the first time. It then abdicates its claim in favor of a *self-nominated* downstream root if (part of) its flows pass through the downstream claimer. Quickly, participating hotspots can converge to a congestion tree. Naturally, the congestion root is detected. (§ 4.1).
- ***How to identify a congested flow upon its arrival?*** For each arriving flow to a switch, its entire following path should be deterministic to the switch to identify a congested flow. Inspired by recent industrial path control practice [73, 52], Pyrrha proposes a hash-function-aware design for switches. Every switch can determine the path that a flow will take. With that information, the switch could match the path against the congestion status snapshot of the downstream network to determine whether it is a congested flow (§ 4.2).
- ***How to handle events-tangling scenarios?*** Congestion trees could overlap with each other which could result in a congested flow traversing several congestion roots. Besides, the congestion root in networks may vary with transient bursty traffic. Without careful scheduling among congestion queues, such flows could be mistakenly paused/resumed or delivered out-of-order. Pyrrha proposes a resource-efficient hierarchical queue structure corresponding to the physical topology. The design ensures both correct flow control semantic and in-order delivery even in highly dynamic scenarios (§ 4.3).

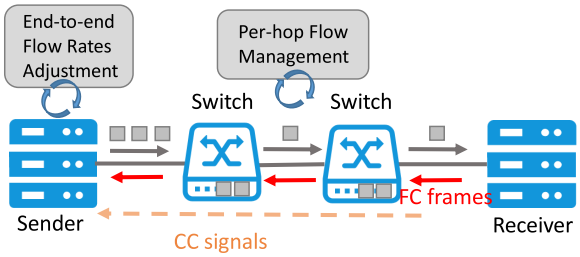

Figure 1: Our vision of labor division between CC/FC.

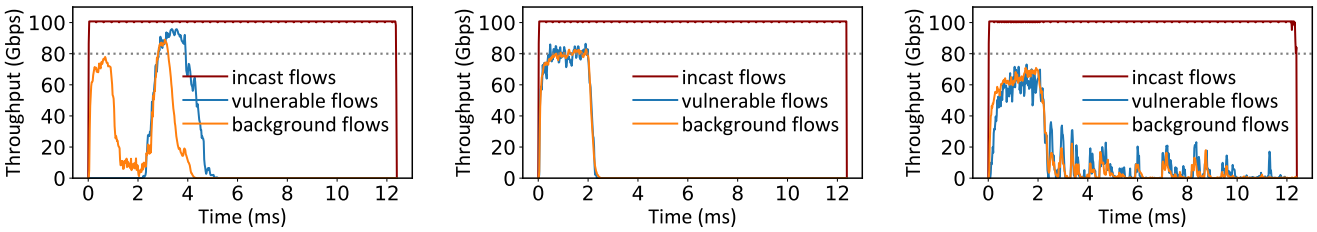
A prototype of Pyrrha is implemented on Tofino2 [48]. Testbed evaluations and large-scale NS-3 simulations have been performed. We compare Pyrrha with existing flow control protocols (*e.g.*, Priority Flow Control (PFC) [46], and BFC [36]). And we also incorporate Pyrrha with existing congestion control protocols (*e.g.*, DCQCN [95], TIMELY [65], and HPCC [56]). We find that the average FCT of uncongested flows is reduced by 42.8%-98.2%, and 99th-tail latency can be 1.6×-215× lower, without compromising the performance of congested flows. In addition, Pyrrha reduces the maximum buffer occupancy by up to 1.8×-6.2× (§ 6). As a contribution to the research community and to ensure reproducibility, our artefacts is made publicly available online [59]. *This work does not raise any ethical issues.*

2 Background and Motivation

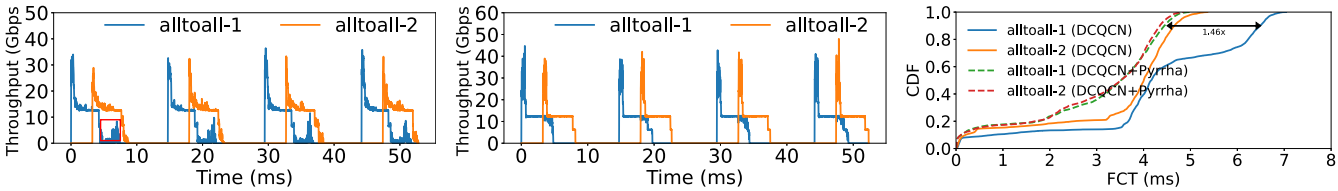
2.1 CC is Falling and FC is Rising

A variety of datacenter applications produce bursty traffic, which can result in different types of congestion, *e.g.*, incast, and load imbalance. To handle congestion, existing efforts focus on developing end-to-end congestion control (CC). CC can be classified into *reactive* and *proactive*. With reactive CC, congestion can be detected by switches (*e.g.*, ECN in DCTCP [11] and DCQCN [95], INT measurements in HPCC [56], PINT [19], PowerTCP [6] and Poseidon [86]) or end-hosts (*e.g.*, Timely [65], Swift [55], and On-Ramp [61]). After receiving congestion signals or if packet delays are observed, senders adjust the transmission rate. It may cost a flow several RTTs to converge to an appropriate rate even in a stable network condition. With proactive CC, bandwidth is allocated before the transmission (*e.g.*, ExpressPass [25, 58], Homa [67], NDP [41], Aeolus [43], and pHost [31]). However, whether to transmit in the first RTT is a dilemma, and proactive CC either wastes the first RTT or risks reintroducing congestion. Recently there are CCs [14, 69] which detect congestion at sub-RTT by



(a) PFC. (b) per-flow queue flow control. (c) BFC.

Figure 2: Performance when incast flows are mixed with non-incast flows.



(a) Throughput (DCQCN). (b) Throughput (DCQCN+Pyrrha). (c) FCT comparison.

Figure 3: Performance comparison under MoE workloads (collided phase).

leveraging switches to send back control frames directly. However, they can not quickly react to congestion especially when congestion occurs at the last hop (*e.g.*, incast).

Several trends. The control loop of CC is too long to handle transient congestion, given the fast evolution of datacenter networks: (i) The high port bandwidth allows to send out more flows within the first RTT, even before congestion control could step in [36, 43]. Transient bursty traffic results in a large buffer occupancy and at the same time mislead the rate adjustment of CC. (ii) The buffer size cannot catch up with the increased speed of its high bandwidth per port [36, 22]. It becomes harder for switches to buffer transient congestion and wait for end-to-end CC's intervention. (iii) The growing scale of datacenter networks and the emerging workloads (*e.g.*, distributed training) lead to more bursty traffic (*e.g.*, a larger scale incast) [74, 42, 75].

Our vision. To handle bursty traffic, per-hop FC protocols should step in. As shown in Figure 1, we propose a labor division between CC and FC:

- **(i) Per-hop FC handles transient congestion.** A switch can control the traffic transmission quickly by per-hop flow control frames. It is in a unique position to quickly manage flows that have already been injected into the network to avoid performance downgrades.
- **(ii) CC takes its part to handle persistent congestion.** CC can adjust the flow rates to increase/decrease the forthcoming traffic injection into the network when congestion occurs and to handle fairness issues.

2.2 HOL Blocking Problem of Simple FC

In RoCEv2 [16], PFC [46] ensures that the buffer does not overflow. PFC pauses the upstream entity at a per-port or per-priority-class queue granularity when the ingress queue length exceeds a given threshold. Further, when the upstream ingress queue exceeds the threshold, a pause frame will be sent to its upstream entities.

However, the intervention of PFC could spread congestion. When PFC is applied, flows that do not contribute to downstream congestion could be paused when they share the same queue with congested flows. The congestion scope can spread from congested ports to piles of innocent ports. Hence, it could downgrade the performance of uncongested flows. We define the above congestion spreading phenomenon as the **HOL blocking caused by flow control**, *i.e.*, a flow is paused innocently by the congested port that it does not pass through. HOL blocking could cause a throughput downgrade. More severely, PFC is vulnerable to deadlock with routing loops [40, 54, 62, 57].

Typical incast workloads. To demonstrate the HOL blocking problem, we conduct a simulation where incast flows are mixed with non-incast flows. 720-to-1 incast flows are generated with an average size of four Bandwidth-Delay Product (BDP) and non-incast flows are generated with a load of 0.8 following the Poisson arrival process (setting details in § 6). Figure 2(a) depicts the real-time throughput. To make it more clear, we use ***vulnerable flows*** to denote uncongested flows sharing paths with congested flows in the remainder of the paper since they are more likely to be hurt by congested flows. Other uncongested flows are denoted as ***background flows***. Hence, the throughput of vulnerable flows is severely hurt since they are paused by downstream switches with congested flows as a whole, leading to a large queuing delay. Besides, since a PFC pause frame storm occurs, congestion is spread to the whole network. Consequently, background flows suffer a throughput downgrade from 1ms to 4ms.

MoE workloads. We investigate the performance of Pyrrha under the traffic of a popular type of pre-trained large language model called Mixture-of-Expert (MoE). According

to [42], the traffic pattern can be characterized by an imbalanced alltoall where a significant portion of the traffic is sent to a few 'hot' experts. Owning to the synchronization nature of the training process, the traffic exhibits a periodic on-off pattern [75, 76]. Following [75], two groups of periodic traffic are generated.

Figure 3 shows the performance of flows with collided phase, *i.e.*, where their phase overlaps (the results of the interleaved phase are detailed in Appendix B). In the case of DCQCN+PFC, two groups of alltoall suffer from HOL-blocking as they compete for bandwidth, which in turn triggers PFC. The peak bandwidth lasts for approximately 1 ms during which non-hot experts complete their traffic reception, followed by hot experts continue receiving their traffic. The throughput of the alltoall-1 group is notably suppressed, even dropping to zero upon the arrival of the alltoall-2 group. Once a portion of the alltoall-2 flows finishes, alltoall-1 begins to grasp some of the bandwidth, as indicated by the red rectangle in the figure. While for DCQCN+Pyrrha, benefiting from the rapid reaction to the congestion, two groups of flows do not disturb each other, accelerating the tail latency by a factor of 1.46×.

2.3 State-of-the-art Flow Control is Flawed

To overcome the HOL blocking problem caused by coarse-grained control on queues, a naïve scheme is per-flow queue FC scheme. Figure 2(b) demonstrates the simulation results under the same settings as in Figure 2(a) when the switch assigns a dedicated queue to each flow passing through it. Vulnerable and background flows fully utilize the link, at the same time the throughput of incast flows does not downgrade (see [59] for theoretical analysis). However, tens of thousands of flows can be observed on ports [84]. Hence a per-flow granularity scheme is non-scalable.

Existing flow control approaches try to reduce the number of queues by compromising the isolation granularity.

Destination-based flow control. This line of work tries to isolate congestion by separating flows transmitting to different destinations. Revisiting super-computing literature decades ago, per-destination Virtual Output Queues (VOQs) [23, 27, 51] are assigned to separate flows with different destination addresses [85, 68]. However, per-destination VOQs are not scalable since the number of VOQs required scales with the number of hosts in networks. Floodgate [60] is a per-hop flow control leveraging per-destination windows to identify incast traffic in datacenter networks. Then, incast traffic can be isolated from non-incast traffic. However, it should maintain a per-destination state of the remaining sending window which demands much memory resources on switches. In summary, they only aim at eliminating HOL blocking caused by the last-hop incast and cannot handle other types of congestion such as load imbalance. In addition, they require per-destination resources which build barriers to deployment at scale.

Queue-based flow control. A second line of work targets at assigning flows into a limited number of queues to alleviate HOL blocking. Since it cannot isolate congested flows from uncongested flows entirely, HOL blocking cannot be avoided. In BFC [36], flows are assigned to a number of queues (*i.e.*, 32-128 queues per port) according to their *flow-id*s and hash functions. A flow is assigned to an empty queue if possible and could share it with other flows when all queues are occupied. As shown in Figure 2(c), with relatively large incast flows, both vulnerable and background flows maintain a very low throughput from 2ms to 12ms. The tail latency of flows is prolonged by 6× compared with the per-flow queue scheme. This is because incast flows can occupy queues for a long time. Vulnerable and background flows sharing the same queue with incast flows are severely hurt, and their transmission rate is mistakenly controlled by the network bottleneck (*i.e.*, the destination ToR of incast).

To sum up, existing solutions cannot totally avoid HOL-blocking, and some of them are impractical.

3 Pyrrha Overview

Our target is to eliminate HOL blocking caused by flow control in the most cost-effective way. In this section, we first illustrate why congestion root is the appropriate granularity of flow control along with the basic idea of Pyrrha, followed by a list of challenges.

3.1 Basic Idea

Before illustrating our basic idea, we introduce several concepts in flow control when congestion occurs. Figure 4 shows a typical congestion tree rooted at P5.

- **Congestion Hotspot.** When the congestion occurs, a flow control scheme starts to pause upstream, inducing several hotspots along its back-pressuring path. A congestion hotspot is an output port whose input rate exceeds its output rate and its queue accumulates.
- **Congestion Root.** As its name implies, a congestion root is the root cause of the congestion, where congested flows finally aggregate. Meanwhile, it is the root of the corresponding congestion tree.
- **Congestion Tree.** A congestion tree can be made up of a root (*e.g.*, P5), non-root hotspots (*e.g.*, P1-P3) and leaf ports (already controlled by the root but have not paused its upstream yet). In our paper, a congestion tree is named after its root (*e.g.*, T5 denotes the tree whose root is P5).

Why congestion-root-based FC? A non-differentiating treatment of flows passing through congestion roots and hotspots could result in HOL-blocking since flows passing through hotspots might not contribute to the congestion. To avoid involving innocent flows, flow control should decide the right scope of flows to control. Intuitions are that if a flow control only applies pause to flows contributing to the congestion root, HOL-blocking can be eliminated.

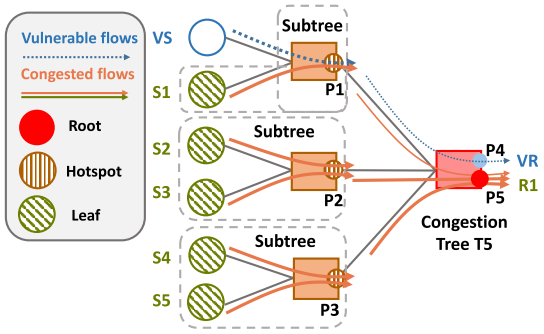


Figure 4: Congestion tree illustration.

Meanwhile, flows passing through different congestion roots should be handled separately to avoid interfering with others.

Quick reaction to congestion: identify congested flows upon arrival. Once a congestion root is detected, the congestion root information is propagated to its upstream switches when it is detected. Then each switch maintains a congestion status snapshot of its downstream networks. A congested flow can be detected upon its arrival in networks by checking whether its path matches existing congestion roots. Hence, its transmission can be controlled several hops earlier before it arrives at congestion roots. It reduces the occurrence of severe congestion and relieves the buffer pressure on following hops, especially on congestion roots.

Fine-grained isolation: manage traffic according to its contributed congestion roots. By default, flows are pushed into a physical output queue (OQ). For separate control, congested flows passing through the same congestion root should be pushed into a dedicated isolation queue (IQ) assigned to the corresponding congestion root. Different categories of flows, *e.g.*, congested flows contributing to different congestion roots, and uncongested flows are isolated respectively. Then, the transmission of congested flows can be controlled precisely by pausing the exact queue assigned to the congestion root, which avoids congestion spreading.

Based on the above ideas, we propose Pyrrha, a practical fine-grained flow control scheme based on congestion roots. Pyrrha achieves good properties, as shown next.

Theorem 3.1. *Pyrrha is a HOL-blocking free per-hop flow control protocol requiring the minimal number of queues.*

Proof. Inspired by the gradient graph [78, 77], we represent flows and queues as vertices, and their traversing relationship as edges. Congested flows contributing to the congested queue's congestion can be represented as its immediate neighbors. Based on this representation, congested flows can be identified as the neighbors of a congested queue. Similarly, potentially paused flows by a congested queue can be identified in our graph representation. In order to prove that Pyrrha is HOL-blocking-free, we formally prove that the set of congested flows and the set of potentially paused flows are identical for any congested queue. Futhermore, we prove that any flow control using fewer queues than Pyrrha cannot avoid HOL blocking. We use Dirichlet's box principle and proof by contradiction to establish this impossibility result. Our formal proof appears in [59]. □

3.2 Design Challenges

Identify congestion roots. Correctly identifying the congestion root is the prerequisite of proper flow control. In tree T5 of Figure 4, P1-P3, and P5 should agree that P5 is the root of incast. Otherwise, if P1 incorrectly identifies itself as an independent root, vulnerable flow VS→VR becomes a victim.

Identify congested flows. To control the transmission of flows separately, congested flows should be identified precisely. When an uncongested flow is mistakenly identified (*e.g.*, VS→VR) as a congested flow, it can be paused innocently. To recognize a congested flow quickly, a switch should obtain the flow's path to be traversed in its downstream network so that it can check the path against its downstream network snapshot.

Handle tree-tangling scenarios. Several concurrent congestion trees can be intertwined among themselves. If non-root ports of trees are overlapped, these ports can play different roles in different congestion trees. These ports should not entangle transmission control received from different trees. When a tree is covered by another one, it results in a flow contributing to several congestion roots, which appear frequently in real systems. One may wonder why congestion still occurs at a port after part of its passing flows is controlled by its downstream congestion roots. This is because the congestion at the port is caused by itself other than its downstream ports. Figure 5(b) depicts an example that the path of a flow can first match a congestion root (P6) and then match another congestion root (P5). The transmission of the congested flow should be controlled by both congestion roots, *i.e.*, only when both congestion roots send a RESUME frame can the flow be transmitted. Besides, the transmission control of the flow should not interfere other flows sharing one of the congestion roots.

In addition, when the competing traffic changes, the congestion tree can shrink or expand, leading to congestion roots varying over time. For P3 in Figure 4, initially, packets of flows {S4-S5}→R1 are controlled in the IQ_{P5}. If flows {S1-S3}→R1 finish, P3 is likely to become the new congestion root later. Flows {S4-S5}→R1 are no longer the congested flows of P5, instead, they are congested flows of P3. Later-arrived packets of these flows should be carefully scheduled in case they are transmitted before packets previously queued into the IQ_{P5}, which results in out-of-order delivery.

4 Pyrrha Design

Figure 5 demonstrates the architecture of Pyrrha. The bottom part of the figure denotes the packet propagation among Pyrrha switches. And the upper part depicts the three major components of a Pyrrha switch. Congestion

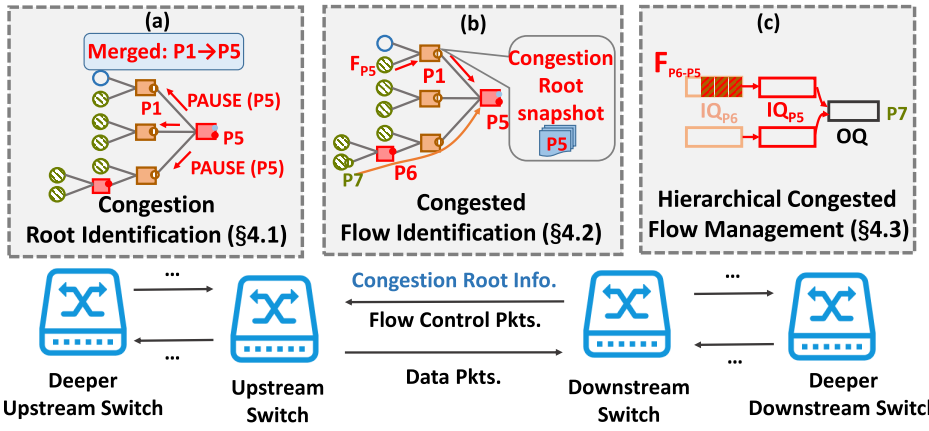

Figure 5: Pyrrha architecture.

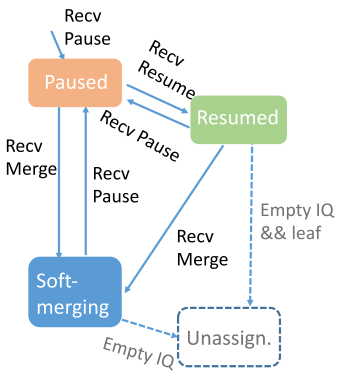

Figure 6: IQ state transitions.

Root Identification (§ 4.1) responds to downstream switches to detect congestion and identify the corresponding root. The congestion information is carried in flow control frames (*e.g.*, PAUSE) and propagated to upstream switches in a hop-by-hop manner. Congested Flow Identification (§ 4.2) maintains the snapshot of downstream network congestion states to help quickly recognize congested flows through path matching. Isolation queues (IQs) are structured in a hierarchy corresponding to the topology by Congested Flow Management (§ 4.3). Besides, details and discussions are put in § 4.4 and § 4.5.

4.1 Congestion Root Identification

Initial detection. Inspired by the root-election process of spanning tree protocols, a congested port can claim itself a *self-nominated* congestion root candidate independently. Initially, each port is attached with a OQ and flows are pushed into the OQ by default. Hence the queue length increase on the OQ can be regarded as an indication of congestion. When a data packet arrives at the OQ, a switch checks whether the queue length exceeds a given threshold K_{pause} (*e.g.*, several per-hop BDPs). If so, a hotspot is detected and the hotspot regards itself as a congestion root. Subsequent packets that arrive at the hotspot trigger a PAUSE frame to the corresponding upstream port from which the packet arrived.

Congestion root identification. According to behavior of flow control, a root is always the most downstream hotspot in a tree. Hence, we can identify the real congestion roots by merging upstream congestion tree into a more downstream one. As shown in Figure 5(a), when a congestion-root-candidate hotspot (P1) receives a PAUSE frame from a downstream root (P5), it indicates that part of its passing-through flows also traverses this downstream hotspot. Hence it recognizes itself as a false-positive congestion root. A new IQ for this new congestion root (P5) is assigned. All following packets matching the new root will enter the corresponding IQ. Then, the old congestion tree is canceled and merged into the new congestion tree. Note that this process can be iterative when there exist multiple layers of hotspots in a congestion tree. The false-positive congestion roots are eventually merged and the root of the new congestion tree is the real congestion root.

Merging process. To start merging, the false-positive congestion root notifies all its child nodes by sending a control message MERGE. MERGE is sent to all its upstream entities belonging to the (old) false-positive congestion root, carrying the ID of both old and new congestion roots. As shown in Figure 6, switches receiving the MERGE frame change the state of the corresponding IQ to soft-merging and propagate the notification to its upstream further. Soft-merging means that the old IQ now belongs to no congestion tree and can be unassigned once empty. The packets queuing in the old IQ are not controlled by the false-positive congestion root. Instead, only packets passing through the real congestion root are controlled (§ 4.3). The merging process finishes within a one-way delay, hence false-positive congestion roots have a negligible impact on performance.

4.2 Congested Flow Identification

Intuitions are that a congested flow passes through at least one congestion root.

Determining a flow's exact path. To determine whether a data packet belongs to a congested flow, the entire onward-path of each arriving packet at a switch should be deterministic. Pyrrha is compatible with traffic load balancing protocols that can locally get deterministic onward paths for flows [1, 44, 79, 64, 52]. Among those load balancing protocols, hash-based protocols (*e.g.*, per-flow ECMP and PLB [73]) are most widely deployed given its no-reordering properties [87]. Pyrrha proposes a hash-function-aware design. Pyrrha's switch calculates a packet's onward-path by using its IP tuples, routing hash functions, and seeds of its downstream switches, together with flow labels carried in its header if necessary as input. Besides, source routing is compatible with Pyrrha naturally since Pyrrha's switch can derive the onward-path of a packet by parsing its header.

The memory and computation resource to get a flow's path

is moderate, and following optimizations are facilitated by leveraging the industry-standard practices in datacenters. (i) Given that switches in datacenter only support limited types of hash functions (*e.g.*, CRC or XOR) to conduct efficient calculation [87, 93, 72], Pyrrha switch only needs to store the type of the hash function of other switches along with their hash seeds. (ii) In many widely deployed topologies [8, 37, 62, 82], the multiple equal path property and the up-down routing strategy can be leveraged to optimize the overhead. In those topologies, the forwarding tables of all core switches are identical. Hence, Pyrrha switch only needs to store one replica for redundant forwarding tables. Furthermore, for fat-tree, the path from a core switch to a given destination is unique, hence Pyrrha switch only conducts hash function calculation for the first two hops.

For other adaptive load balancing approaches, *e.g.*, per-packet spraying and DRILL [67, 34], which determine the path of flows through dynamic states, Pyrrha is a complementary solution to handle the hotspots caused by destination collision (*i.e.*, incast), where load balancing falls short. Experiments in Appendix 6.3 show that Pyrrha is compatible with DRILL and further improves the tail latency by 18.3% compared to pure Pyrrha. Pyrrha also handles corner cases where flows are re-routed to different paths due to link failures (Appendix § A).

Matching and maintaining snapshot. Pyrrha's switch maintains the *congestion-root table* of the downstream networks. As shown in Figure 5(b), the table maintains a snapshot of the congestion states of its downstream networks. When a PAUSE frame indicating a new congestion root is received, the congestion root is recorded in the table. When a packet arrives at the switch, its path can be obtained via above mentioned methods. The switch checks whether its path matches any entry in the congestion-root table. For port P1 in Figure 5(b), packets that will traverse P5 in its downstream path are identified as belonging to a congested flow. Hence, it's enqueued to a separate IQ, which is paused/resumed based on the state of the corresponding root. Otherwise, the packet belongs to an uncongested flow and is put in the OQ.

4.3 Congested Flow Management

To handle tangled scenarios where congestion trees are intertwined among each other or congestion roots vary over time, Pyrrha leverages a hierarchical methodology to manage congested flows corresponding to that of the topology. It can be supported by a Hierarchical Isolation Queue (HIQ) architecture, which manages congested flows in a hierarchy. Pyrrha installs HIQ during compilation according to its location in networks and manages the usage of queues dynamically during runtime through a mapping table. We also provide single-tier IQs prototype to fully support the function of HIQ.

Handling congested flow in hierarchy. Congestion trees are intertwined when non-root ports of trees are overlapped or a tree is covered by another one. For the first scenario, IQs on ports can naturally isolate control from different congestion roots on non-root ports. For the latter one, a congested flow could pass through multiple congestion roots. To ensure precise control isolation, a congested flow should match all corresponding IQs before it is forwarded. A hierarchical organization of IQs based on the location of their corresponding congestion roots in the topology enables a congested flow to match appropriate IQs *sequentially*. Especially, when per-flow load balancing is used, a flow at most encounters one congestion root among switches at the same level. It ensures in-order delivery when a congested flow alters its matched IQs.

Hierarchical Isolation Queue (HIQ) architecture. HIQ consists of several levels of IQs. Each IQ is positioned in a hierarchy according to its distance to the corresponding congestion root in the physical topology. Hence, the number of layers of the HIQ is determined by its location in the network. As shown in Figure 5(c), in a two-tier network, an uplink port of a ToR switch maintains two levels of IQs, since the farthest potential congestion root is two hops from it. Figure 5(c) depicts the HIQ architecture on P7, *i.e.*, the leaf port in Figure 5(b). P7 fully utilizes the two-level architecture of the HIQ, since the farthest congestion root P5 is two hops from it. Especially, the OQ is connected to the last level of the HIQ architecture. A dedicated scheduler is equipped for each level of queues to schedule the traffic transmission. Only when an IQ is in a resumed or soft-merging state can its packet be dequeued and pushed into the next-level IQs/OQ. From the perspective of a packet, this process is performed iteratively until it reaches the OQ. In the scenario depicted in Figure 5, when a flow that will traverse congestion root P6 and P5 arrives at the upstream switch of port P6, it matches the HIQ *from-near-to-far*. After a packet is dequeued from IQ_{P6}, it is pushed into a next-level IQ_{P5}.When there is no more matched IQ, it is pushed into the OQ. Hence, the packet can be forwarded to the next hop only after all matched congested roots are resumed. In this way, congested flows are controlled locally precisely.

IQs in HIQ are arranged by levels, supporting in-order delivery naturally. Considering the merging procedure in Figure 5(a), the congestion root is changed from P1 to P5. IQ_{P1} is in the soft-merging state and packets in it can be mixed with congested and uncongested traffic. Pyrrha should handle them separately to avoid HOL blocking. Congested flows of root P5 are dequeued from IQ_{P1} and then pushed into the next level IQ_{P5}. Uncongested flows are forwarded to OQ. In this way, precise isolation is achieved without inducing re-ordering.

Handling secession of the congestion root. Once the OQ length of the congestion root decreases below the resume threshold, it sends back RESUME to its upstream. Likewise, upstream switches could resume their upstream when their own IQ decreases below the resume threshold. It is an

iterative process that the congestion tree eliminates starting from the leaf switches to the root. A congestion port becomes a leaf when it has not sent PAUSE yet, or when the status of all its upstream entities is set to *unassigned*. The IQ of the leaf switch is unassigned when it becomes empty. When all the upstream IQs of a congestion root are marked unassigned and the queue length of OQ of the congestion root is below the resume threshold, the congestion root disappears naturally. Figure 6 depicts the state transition of the IQ usage. Only when an empty IQ is in a resumed or soft-merging state can it be marked as unassigned.

4.4 Miscellaneous Detailed Design

Congestion information propagation. There are three types of flow control frames in Pyrrha, *e.g.*, PAUSE, RESUME, and MERGE. These control frames carry the congestion information and control the transmission of congested flows accurately in a hop-by-hop manner. Correspondingly, there are three states for an IQ, *i.e.*, paused, resumed, or soft-merging. The state transitions of an IQ are shown in Figure 6.

When a congestion root is detected, a PAUSE frame is sent back to the upstream port through the ingress port of which the data packet is just received. Once a data packet is pushed into the OQ which is attached to the congestion root, Pyrrha switch checks the packet's ingress port and sends back the PAUSE frame. A PAUSE frame carries the ID of the congestion root (*i.e.*, identified as *switch-id:port-id*). Likewise, when the queue length of IQ exceeds the threshold K_{pause}, a PAUSE frame carrying the root ID is sent back to its upstream switch.

Cooperation on end-hosts. To handle persistent congestion, end-hosts should control the upcoming traffic into networks. Pyrrha can cooperate with congestion control protocols. And Pyrrha can perform better if end-hosts can respond to PAUSE (or RESUME and MERGE) frames. To pause and resume at a per-flow granularity, end-hosts could leverage a pull-based transmission model, which can be implemented by programmable smart NICs in RDMA networks. Especially, Pyrrha can also handle end-host congestion (*e.g.*, PCIe congestion) by backpressuring the traffic it receives.

Handling rare packet loss. Pyrrha reduces queuing length significantly. Hence, buffer overflow rarely occurs. However, Pyrrha does not guarantee lossless for rare cases where every port of a switch becomes the victim port of a k-1:1 incast lasting for one-hop RTT in turn, where k denotes the number of ports on switches. In this certain case, Pyrrha can start to drop packet and leverage IRN [66] for fast retransmission.

4.5 Scalability Discussions

Queue consumption. In the most extreme scenario, the number of congestion roots can be the number of ToRs in the network. However, the concurrent amount of congestion in networks is usually moderate. It is reported that only 3% of the links in edge and aggregation layers appear as a hotspot

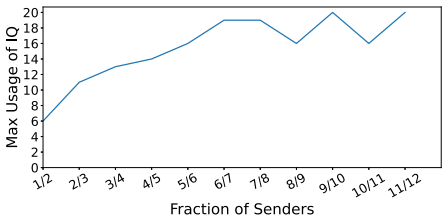

Figure 7: Queue usage analysis.

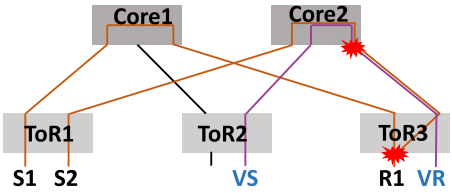

Figure 8: Testbed topology.

for more than 0.1% of time intervals [20, 21]. Moreover, the concurrent roots can be much less than that of hotspots.

To investigate the IQ usage, evaluations under stressful workloads where $(m-1)$ out of m ToRs send traffic simultaneously to the left 1/m of the ToRs are conducted. A k=12 fat-tree topology is employed and each host sends 40 one-BDP flows continuously to create a substantial network burst. Figure 7 illustrates the IQ usage of Pyrrha as the fraction of senders varies. The IQ utilization ranges from 6-20, approximately proportional to the number of pods k, which considered to be relatively moderate. Since commodity switches can support thousands of VOQs [23, 27, 51], assigning a dedicated queue to each downstream root is feasible. To handle corner cases where IQs are not enough, similar to BFC, Pyrrha leverages hash functions [39, 71] to choose an IQ according to the congestion root ID, at a cost of sacrificing precise isolation.

Deadlock prevention. Pyrrha is deadlock robust since OQs never get paused. To prevent cyclic buffer dependencies (CBD) caused by routing loops, Pyrrha switch checks whether the congestion root carried in the PAUSE frame is identical to its own identifier. If so, it ignores the PAUSE frame directly. (see detailed discussions in [59].)

5 Implementation and Testbed Experiments

We implement a Pyrrha prototype on Tofino2, a state-of-the-art programmable switch ASIC [48] with Reconfigurable Match Table (RMT) architecture. In this section, we briefly describe the key modules of the prototype, followed by the overhead analysis. Testbed evaluations show that Pyrrha can achieve good performance (§ 5.2). More implementation details are deferred to Appendix D and E.

5.1 Prototype of Pyrrha

We implement a Pyrrha prototype on Tofino2 with 2.5k lines of P4 code and 2k lines of Python code. The operations of Pyrrha is implemented entirely in the data plane at line rate.

Key modules and the pipeline. The Pyrrha prototype is

mainly composed of several modules, *i.e.*, (i) congestion root matcher, (ii) queue manager, (iii) queue state detector, and (iv) signal packet module.

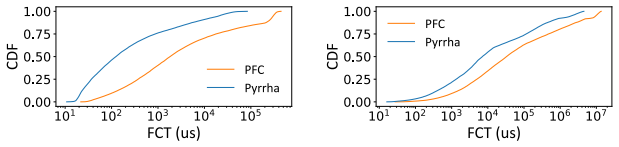
(i) Upon arrival, the data packet first undergoes a standard processing procedure, including forwarding and admission control. Subsequently, the data packet is forwarded to the congestion root matcher, an integral component of the path calculation unit and a congestion root table, facilitating the congested flow identification. Specifically, the path calculation unit calculates the packet's egress ports of its onward path. The congestion root table records the status of ports, indicating whether the port is congested or not. (ii) Then packets enter the queue manager for queue assignment. The queue manager assigns queues to traffic based on the congestion roots it would pass through. Central to its design is a multi-segment stack, wherein each segment manages the available queues for a specific egress port.

(iii) The queue state detector checks whether the length of the assigned queue exceeds the pause threshold or decreases below the resume threshold, and then triggers appropriate signal packets. The queue length is retrieved by utilizing *ghost threads* in Tofino2.

(iv) When it is necessary to send a signal packet, the signal packet module leverages the packet trigger functionality to construct signal packets, such as PAUSE and RESUME. Upon receiving a PAUSE or RESUME, the module engages Tofino2's *AFC (Advanced Flow Control)* mechanism to pause (or resume) the queue.

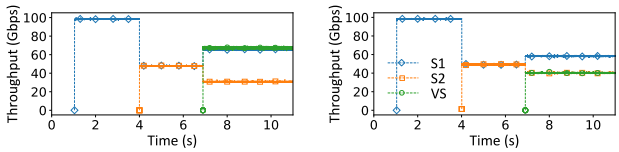
Feasibility of HIQ The architecture of HIQ is supported in current Metro Ethernet (MetroE) service routers [3, 2]. And a recent work of implementing multi-level scheduler on ASIC [94] also verifies its feasibility. According to private talks with chip vendors, they consider it possible to implement HIQ in their next-generation switching chips. For instance, the two-layer HIQ can be obtained by connecting two traffic manager models in series and specifying the next-level IQ to be pushed in when a packet is dequeued. Although HIQ is not supported by the architecture of Tofino2 currently, the features of HIQ can be fully supported via single-tier queues (Appendix C).

Complexity and overhead. Tofino2 adopts pipeline architecture, wherein the resource allocation is determined at compile time. It enables us to ascertain Pyrrha's resource requirements without running it in a large-scale cluster. According to the statistics reported in megascale [49], the scale of current data centers can reach up to 10,000 hosts. Therefore, we use a k=36 fat-tree topology with 11,664 hosts as a representative case. Pyrrha prototype can easily scale to it, with around 11 MB (*i.e.*, 44.5% of Tofino2) of the memory resource consumption. Specifically, the memory usage of Pyrrha prototype is mainly composed of three units, *i.e.*, path calculation unit, congestion root table, and queue manager, overall consuming 9.25 MB. And the processing logic consumes around 1.88 MB. (i) As analyzed in § 4.2,



(a) Vulnerable flows (Web Server). (b) Vulnerable flows (Web Search).

Figure 9: FCT of testbed experiments.



(a) Pyrrha (b) PFC

Figure 10: Throughput of testbed experiments.

the memory consumption of the path calculation can be optimized by leveraging the industry standard, occupying 0.44MB SRAM. (ii) The congestion root table is organized hierarchically, where the n^{th} table records ports that are n hop away from the switch, and the port is identified as <switch-id, port-id>. Hence, the storage usage of the congestion root table is proportional to the number of ports in networks, occupying 176 KB SRAM. (iii) The queue manager firstly checks whether the congested flow is assigned with a queue through a *IsAssigned Table* and assigns a queue if necessary by looking up a multi-segment *QueueId stack* which records the available queue. Then it updates the *QueueId record table* to record the queue assignment status. This module overall consumes 8.64MB SRAM. Furthermore, leveraging the rapidly maturating HIQ technology [94], Pyrrha can scale to topologies that is an order of magnitude larger. (detailed analysis are deferred to Appendix E).

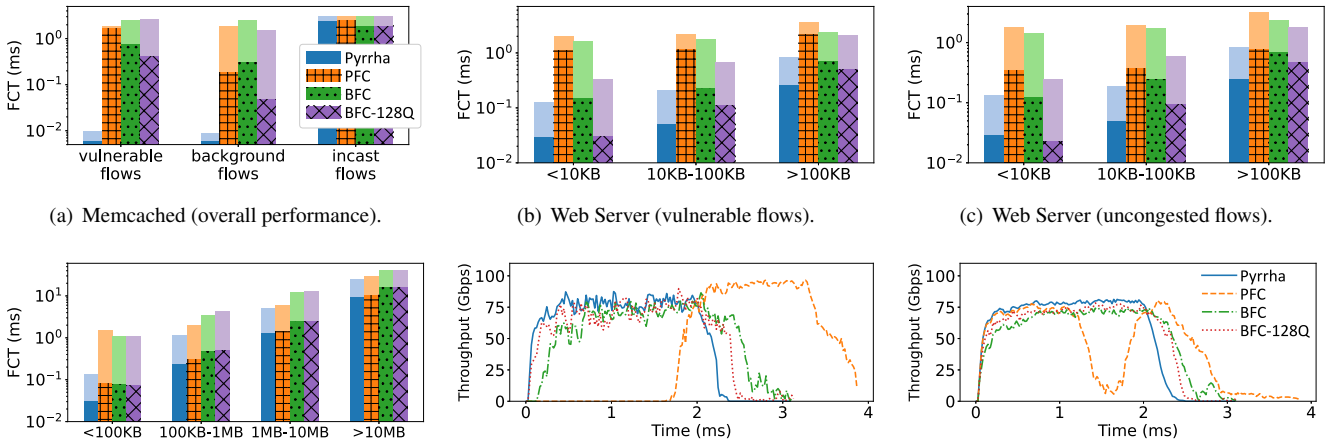
5.2 Testbed Evaluation

Topology. We use a 2-level leaf-spine topology as shown in Figure 8, consisting of three ToR, two core switches, and two hosts per rack, all connected via 100 Gbps links.

Workloads. We evaluate Pyrrha under incast-mix scenarios. Incast flows are generated by letting hosts S1 and S2 transmit flows to host R1 simultaneously. Vulnerable flows are generated by letting host VS send flows to host VR. Flows S2→R1 and VS→VR share the same port on the core switch. Web Server and Web Search flows are generated following a Poisson arrival process (§ 6).

Pyrrha reduces the FCT of vulnerable flows. Figure 9 demonstrates the FCT performance of vulnerable flows. For PFC, vulnerable flows are HOL blocked by incast flows, suffering a large queuing delay. Pyrrha quickly detects the congestion on the destination ToR switch and isolates incast flows into a dedicated queue. Thus, the FCT of vulnerable flows is greatly reduced.

Pyrrha improves the throughput. Figure 10(a) shows the throughput when flows on three hosts S1, S2, and VS start



(a) Memcached (overall performance). (b) Web Server (vulnerable flows). (c) Web Server (uncongested flows).

(d) Web Search (uncongested flows). (e) Web Server (vulnerable flows). (f) Web Server (background flows).

Figure 11: Performance of FC. The deep/light color in the figures represents the average/99th-tail value for each bar.

to arrive at 1s, 4s, and 7s, respectively. Pyrrha improves the throughput of vulnerable flows to 66.7 Gbps without compromising the overall throughput of incast flows (100 Gbps). The network throughput is improved by 26.7 Gbps.

6 Simulation Evaluation

Topology. A non-blocking clos-network is used. It contains 4 core switches, 10 ToRs, and 160 hosts, similar to the topology used in [67]). Each ToR is connected to its hosts and cores via 100/400 Gbps links, respectively. The per-hop propagation delay is 600ns. The base RTT is 5.1μs, and the base BDP is 64KB. A 3-tier fat-tree topology with 1024 hosts is also leveraged to investigate the scalability of Pyrrha.

Workloads. Under incastmix scenarios, flows following a Poisson arrival process with a load of 0.8 and periodic incast flows each composed of 30-40 MTUs with a load of 0.5 are generated. An incast destination does not receive Poisson arrival flows hence the traffic load does not exceed link bandwidth. The incast degree is 720-to-1. For Poisson arrival flows, three workloads are used [67, 80, 11], where Memcached is composed of small flows, where most of the flows are smaller than 1KB, and Web Server and Web Search are large flows mixed with small flows where a small ratio of large flows dominate the average flow size.

Parameters. There are two parameters of Pyrrha, *i.e.*, the threshold to pause (*i.e.*, K_{pause} times one-hop BDP) and the threshold to resume (*i.e.*, K_{resume} times one-hop BDP). In our evaluations, K_{pause} is set to 2, and K_{resume} is set to 1. Besides, the maximum number of IQs can be used is set to 100, but Pyrrha only uses a dozen of IQs in most cases. A dedicated subsection discusses why these values are used (§B.1). The switch buffer capacity is 20MB. Pyrrha uses shared buffer mode. PFC uses dynamic threshold and $\alpha = 2$.

Metrics. Average/99th-tail FCTs are evaluated. We monitor maximum buffer on each hop to investigate the composition of buffer reallocation that Pyrrha brings.

6.1 Comparing with Flow Control

In this section, we use large-scale NS3 simulations to compare Pyrrha [59] with existing flow control protocols (*e.g.*, PFC and BFC). For BFC, two versions with 32 and 128 queues per port are used, as in its paper (*e.g.*, BFC is used to denote BFC-32). Figure 11 shows the FCT and throughput.

6.1.1 PFC

PFC hurts the performance of uncongested flows since they can be paused innocently by their downstream ports when incast occurs. This especially hurts the performance of workloads that are composed of small flows (*e.g.*, Memcached). For Web Server workload, PFC even spreads the congestion to the whole network thus background flows that do not share the same destination pods of incast flows also get hurt. The throughput performance depicted in Figure 11(f) is a side note to this issue. For background flows, it achieves stable high throughput until PFC pause frame storm occurs at 1.5ms. Then background flows endure a significant throughput loss that lasts for about milliseconds.

6.1.2 BFC

BFC assigns flows to multiple queues according to flow identifiers (FID) and hash functions. It can partially alleviate HOL blocking caused by congested flows and improve the performance of uncongested flows to an extent compared to PFC. However, HOL blocking occurs when congested flows and uncongested flows share the same queue, or flows are hashed into the same flow FIDs. Hence, BFC can not obtain extremely low latency as Pyrrha does. Along with the number of queues used by BFC increases, *i.e.*, from 32 to 128, the performance of BFC is improved. For Web Search workload, the tail latency of BFC is not good because BFC sets a relatively smaller threshold to detect congestion compared to PFC. It can risk spreading congestion.

The third group of bars in Figure 11(a) shows the performance of incast (congested) flows. More results of incast flows are deferred to Appendix B. Pyrrha does not

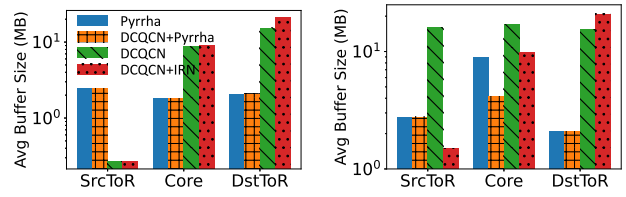
Figure 13: FCT performance.



(a) Memcached. (b) Web Server.

Figure 14: Buffer occupancy (DCQCN) is split into three parts, *i.e.*, queue length on SrcToR, core and DstToR.

compromise the performance of incast flows compared to PFC. BFC reduces the average FCT of incast flows because BFC splits different flows into different queues and incast flows may use several queues simultaneously. Incast flows can use more bandwidth during the resume phase via the round-robin scheduling mechanism among queues.

6.2 Cooperating with Congestion Control

In this section, we incorporate Pyrrha with state-of-the-art CC (*e.g.*, DCQCN and HPCC). Experiment results of TIMELY is left in Appendix B. The authors' contributed simulation codes, if available, are used in our evaluations [10, 53]. Following [56, 61], a per-flow sending window on hosts is added to all approaches, limiting the in-flight packets of a flow. PFC is used to provide a lossless network for CC by default. Besides, to fully understand the performance of CC, we also evaluate pure CC and use IRN [66] to handle packet loss. IRN leverages selective retransmission to perform an efficient loss recovery.

6.2.1 DCQCN

Since Pyrrha reduces the buffer occupancy by a large extent, we set $K_{min} = 50KB$ and $K_{max} = 200KB$ to cooperate with DCQCN. Figure 12 depicts the average and 99th-tail FCT across different workloads. DCQCN alone can not handle incast flows quickly thus PFC is triggered. Particularly, under Web Server, a PFC pause frame storm occurs. PFC is triggered from the destination ToR of incast and finally reaches the hosts that the source ToR switches connected to, which affects background flows.

Given that PFC has some side effects, one may wonder how DCQCN performs when leveraging IRN for retransmission instead of relying on PFC. However, IRN is not a cure for DCQCN. As shown in Figure 26(b), although DCQCN with IRN reduces the FCTs of small flows compared to DCQCN with PFC, FCTs of larger flows are prolonged. Packet loss hurts the goodput of networks. Besides, when all inflight packets are lost, loss recovery can only get triggered via timeouts. Timeout retransmission hurts the performance of small flows and the tail latency of large flows.

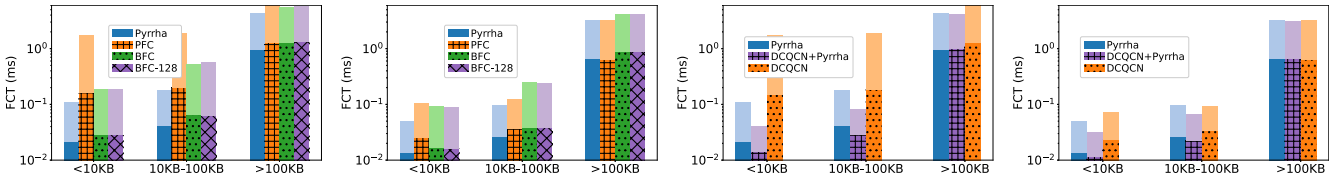
When adding Pyrrha to DCQCN, Pyrrha can significantly benefit uncongested flows (*e.g.*, vulnerable and background flows) by quickly recognizing and isolating incast flows. Pyrrha reacts quickly on in-network congestion by handling it locally, which is especially beneficial to small flows. Therefore, Pyrrha's performance improvement on small flows is the most significant. When the flow size increases, the improvement becomes relatively less obvious. Because large flows give more time for DCQCN to take effect.

Figure 14 shows the maximum buffer occupancy among different hops. Instead of letting congested flows overflow the congestion root, Pyrrha can quickly control their transmission locally. Then the buffer occupancy on the congestion root, *i.e.*, the destination ToR switch, can be greatly reduced. Since Pyrrha pushes back congested flows, the buffer occupancy on the source ToR switch is increased.

From another perspective, when adding DCQCN to Pyrrha, the FCT of small flows can be improved further compared to pure Pyrrha. This is because DCQCN can control the transmission of flows based on a finer granularity than a pause-resume manner. For flows sharing the same path, DCQCN can adjust the rate of each flow individually while Pyrrha controls them as a whole. And congestion control favors small flows since large flows are more likely to be marked and convey the congestion signals back to senders. In addition, the buffer occupancy on the core switch can be further reduced, as shown in Figure 14(b).

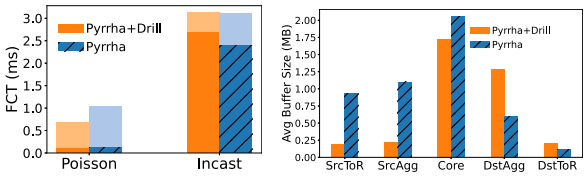
6.2.2 HPCC

When adding Pyrrha to HPCC, uncongested flows carry the queue length of the OQ to avoid unnecessary rate reduction on them. And congested flows carry the queue length of



(a) Web Server (vulnerable flows). (b) Web Server (uncongested flows). (c) Web Server (vulnerable flows). (d) Web Server (uncongested flows).

Figure 15: FCT performance under k=16 fat-tree.



(a) FCT performance. (b) Buffer occcupancy.

Figure 16: Cooperating Pyrrha with DRILL.

IQs. For clarity, Figure 13 shows the FCT distribution of HPCC. Pyrrha helps improve the performance of HPCC. While HPCC achieves good performance on a portion of small flows, as shown in Figure 26(g), this is because HPCC leverages INT to get the in-network information to reduce the queue length aggressively, which benefits small flows. As a cost, its tail latency is prolonged since the transient small flows could interfere with the rate adjustment process and influence the network throughput.

6.3 Additional evaluations and Discussions

Performance under Large-scale Topology. To investigate the scalability of Pyrrha, evaluations under k=16 fat-tree topology (*i.e.*, 1024 hosts) is conducted. Figure 15 shows the performance of different protocols under Web Server. The trend of performance differences between different algorithms is very similar to that of the results in § 6. We analyze the results from two perspectives: (i) When comparing FC with CC protocols, especially for flows smaller than 100KB, fine-grained FC protocols such as BFC and Pyrrha outperform PFC as well as CC protocols. This advantage is attributed to the rapid response of fine-grained FC to network congestion, which provides a degree of mitigation against HOL blocking. (ii) In terms of cooperation between FC and CC, as depicted in Figure 15(c), when Pyrrha is integrated with CC, small flows can achieve the lowest latency. This is because Pyrrha rapidly reacts to the network congestion, preventing HOL blocking for traffic that has already been injected into the network. Concurrently, CC address the persistent congestion associated with larger flows.

Cooperating with adaptive load balancing scheme. Load balancing schemes handle congestion by re-arranging the traffic to avoid path collision. However, they can not handle congestion caused by destination collision (*i.e.*, incast), and Pyrrha acts as a complementary solution to handle it. Pyrrha works together with adaptive routing by only recognizing and handling the congestion of incast.

We investigate the performance when Pyrrha works with DRILL, an adaptive load scheme that chooses the forwarding port according to the queue length dynamically. Similar to § 6, incast-mix traffic is generated and a k=8 fat-tree topology is used. Results in Figure 16 show that Pyrrha works well with DRILL. The integration of DRILL with Pyrrha further reduces the latency of Poisson flows compared to pure Pyrrha. The performance gain is attributed to DRILL's ability to distribute traffic effectively, thereby preventing queue buildup at the upstream (*e.g.*, SrcToR, SrcAgg, and Core), as shown in Figure 16(b). However, this optimization comes with a trade-off in the latency of incast flows, which is higher compared to the pure Pyrrha.

Additional evaluations. In Appendix B, we further explore the performance of Pyrrha under several scenarios, (i) when the size of incast flows varies, (ii) when facing multiple congestion roots, (iii) MoE traffic with interleaved phase, and (iv) when the congestion roots vary. We also compare Pyrrha with per-flow queue scheme and CC without sending window. Besides, the parameter selection and merging mechanism of Pyrrha is evaluated. A variant of Pyrrha using single-tier queues is investigated (§ C.2).

Discussions. Discussions regarding how Pyrrha handles link failures, as well as a review of related works, are put in the Appendix A.

7 Conclusion

This paper was motivated for a labor division between congestion control and flow control. It is time to embrace per-hop flow control in datacenter networks to react to congestion promptly. We presented Pyrrha, a congestion-root-based per-hop flow control. It controls the transmission of flows at a fine granularity without congestion spreading, requiring a minimum number of queues. The performance of flows can be significantly improved. We are currently discussing with a major vendor the implementation of Pyrrha in its products.

Acknowledgments

We sincerely thank our shepherd Gianni Antichi and the anonymous reviewers for their valuable feedback on this paper. Figure 17: When the size of incast flows varies.

A Discussions

Dealing with link failures. For link failure that exactly occurs at the port of congestion roots, Pyrrha sends RESUME frames to its upstream switches to avoid unnecessary further control. For link failure on other ports, the failure is transparent to Pyrrha when source routing is used. When hash calculation is used to get flows' path, the calculation can be dynamically adjusted by introducing a rerouting table when route changes by leveraging existing rerouting protocols to propagate the rerouting information.

Related works. The IEEE standard group advocates Congestion Isolation (CI) [47], supporting the isolation of congested data flows within datacenter. An egress port can identify flows causing congestion and isolate them locally. The progress of the IEEE standard proved the necessity of Pyrrha from the side. However, CI can only control congested flows that already arrived at the congested port. Besides, CI uses only one dedicated queue for all congested flows, resulting in HOL blocking among congested flows passing through different congested ports.

In addition, there are several existing lines of work that go beyond flow control and congestion control. dcPIM [24] takes several RTTs to match senders and receivers before starting transmission to avoid congestion. TCD targets solving the problem that traditional flow control (*e.g.*, PFC and CBFC [17]) interferes with the congestion detection of congestion control protocols. It proposes an undetermined state by leveraging the ON-OFF pattern caused by flow control, and only the flow identified as congested reduces its rate according to congestion control. It can give more penalty to congested flows afterward but does not handle congestion that already occurs. ABM [5] is an efficient buffer-sharing scheme that leverages both spatial and temporal features of the buffer. Queue scheduling approaches target at providing approximate fair queuing [81, 89] or strict priority [12, 38, 9, 83]. Scheduling approaches do not differentiate congested flows from those uncongested thus they can not eliminate HOL blocking. CASSINI [76, 75] adjusts the communication phases of ML jobs to share the bandwidth. These works are orthogonal to Pyrrha.

B Supplemental Results

When the size of incast flows varies. Now we investigate the performance of uncongested flows when the size of incast flows varies. As shown in Figure 17, Pyrrha achieves a stable performance when the size of incast flows increases. This is expected since Pyrrha can already control the transmission of incast flows when the size of incast is smaller than one BDP (§ 6.2). The performance of BFC downgrades to a large extent with long incast flows. Because long incast flows occupy the queues continuously, HOL blocking uncongested flows sharing the same queue with them. For CC protocols, the FCT of uncongested flows becomes stable after the incast size increases to three BDPs since congestion control begins taking effect.

When facing multiple congestion roots. We investigate the scenario where multiple congestion roots exist. An uneven hash function is used to conduct load imbalance. ToR switches can choose among four core switches to forward, the possibility to route to the first core switch is 50%, and the other three paths share the left 50% uniformly. This is called hash polarization, which can occur in datacenter networks. Flows are generated as the incastmix scenario (§ 6.2). Hence, there are multiple congestion roots in networks, *e.g.*, load imbalance on the upstream ports of ToR switches and incast on their downstream ports.

Figure 19 shows the performance of different approaches. Pyrrha reduces the average and tail FCT of non-incast flows. Pyrrha detects the congestion on source ToR switches and sends congestion notifications to the connected source hosts. Then, senders can send other flows that do not pass the imbalanced ports to utilize the network. For congested flows passing through both load imbalance and incast ports, their transmission is well controlled. Hence, the queuing delay

of Poisson flows is quite small. For CC approaches, they can not alleviate the throughput downgrade caused by load imbalance, hence FCTs of Poisson flows are prolonged.

Supplemental results under k=16 fat-tree. Figure 20 shows the additional evaluations of Pyrrha, TIMELY, and HPCC under the k=16 fat-tree. The results are consistent with Figure 6.3 where Pyrrha is compared with DCQCN.

Per-flow queue scheme. Figure 22 shows the performance of flow control protocols in incastmix scenarios, including the per-flow queue scheme. For Memcached, the per-flow queue scheme can achieve as low latency as Pyrrha for background flows. While for vulnerable flows, the per-flow queue scheme can not reduce their tail latencies. Due to the fact that the per-flow queue scheme does not start to control a newly arrived congested flow until it is transmitted to the congested port. It induces a large buffer occupancy at the network bottleneck. Moreover, vulnerable flows and congested flows share the same bottleneck at core switches. When there are a large number of congested flows, vulnerable flows can only get a small fraction of bandwidth share. As a by-product, the per-flow queue scheme reduces the average FCTs of incast flows, as shown in Figure 18.

CC with no window. Figure 26 shows the performance of Pyrrha, DCQCN, and HPCC when no sending window is applied. In comparison to protocols with sending window, the same traffic pattern as Figure 12 is generated. Without the sending window, the queuing delay on source ToR is increased across all protocols, as shown in Figure 26(e). The rationale is the absence of initial transmission control allows for a greater volume of traffic to be injected into the network, leading to longer queue length and increased queuing delays at the source ToRs before CC or FC steps into. DCQCN experiences a larger degree of congestion as each flow can concurrently inject a larger volume of traffic into the network. Likewise, DCQCN+IRN suffers from a larger loss rate which results in performance degradation. In the absence of the sending window, HPCC endures a more severe performance degradation since HPCC is designed to be a window-based protocol. Benefiting from the fast reaction to network congestion, the latency of Pyrrha is slightly increased compared to that with sending window.

Performance under MoE workloads (interleaved phase). Figure 21 depicts the performance of two groups of alltoall flows with interleaved phase, *i.e.*, the two groups of traffic do not overlap with each other. With the interleaved phase, two groups of flows are slightly affected by each other. By adding Pyrrha to DCQCN, there is still performance improvement of the latency of flows, as depicted in Figure 21(c). This is because the traffic of alltoall-1/alltoall-2 itself can induce transient congestion and Pyrrha can handle it better.

Comparing with TIMELY. We use the parameters recommended by the TIMELY authors in their paper. As shown in Figure 25, when adding Pyrrha on TIMELY, the performance improvement of TIMELY is similar to that for DCQCN.

Deep dive of the per-hop queuing delay. To fully understand how Pyrrha works, we investigate the flows' queuing time among different hops, where the experiments settings is the same as in § 6.2. Figure 23 shows the result. Queuing time is split into three parts, where SrcToR denotes the uplink ports of ToR, *i.e.*, the first hop of packets. Likewise, DstToR denotes the downlink ports of ToR, *i.e.*, the last hop of packets. The average queuing time reflects the extent of HOL blocking that uncongested flows encounter. For DCQCN, vulnerable flows are HOL blocked by incast flows at the core switches. When adding Pyrrha to DCQCN, it eliminates the queuing time for vulnerable flows significantly. For Web Server, Pyrrha also helps reduce the queuing delay of background flows since it does not cause congestion

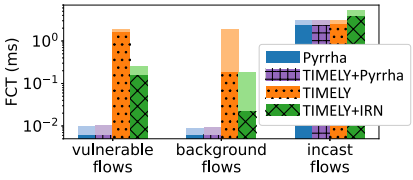

Figure 25: TIMELY: Memcached (overall flows).

spreading, and only flows causing congestion are paused. Pyrrha reacts quickly on congestion at the last hop, hence the queuing time of incast flows is mainly composed of the time spent on the srcToR and core switches.

Pyrrha is robust when congestion roots vary. We provide additional testbed results when congestion roots vary. The testbed setting is the same as in § 5.2. When flows on three hosts S2, VS, and S1 start to arrive at 1s, 4s, and 7s, respectively, the congestion root changes from the core switch to the destination ToR. Pyrrha can also converge quickly and achieve good throughput.

B.1 Parameter and Mechanism Validation

Parameter Selection. In this section, the performance of Pyrrha under different parameters is evaluated. We scan parameters under incastmix scenarios of Memcached. Figure 27 depicts the 99th-tail FCT of the vulnerable flows. K_{resume} is set to 1 when sweeping K_{pause}, and K_{pause} is set to 10 when sweeping K_{resume}. Pyrrha is relatively insensitive to different K_{pause} and K_{resume} value, which is preferred in the industry.

As shown in Figure 27(a), Pyrrha achieves the smallest tail latency when K_{pause} ranges from 2 to 35. When the value of K_{pause} is larger than 35, the tail latency increases. This is because Pyrrha reacts slowly on congestion with a large pause threshold.

As shown in Figure 27(b), the tail latency of Pyrrha remains unchanged when sweeping K_{resume}. For that, with a fixed value of K_{pause}, the timing and correctness of congestion root identification are the same, and K_{resume} only affects the queuing delay arrangement of congested flows on different hops.

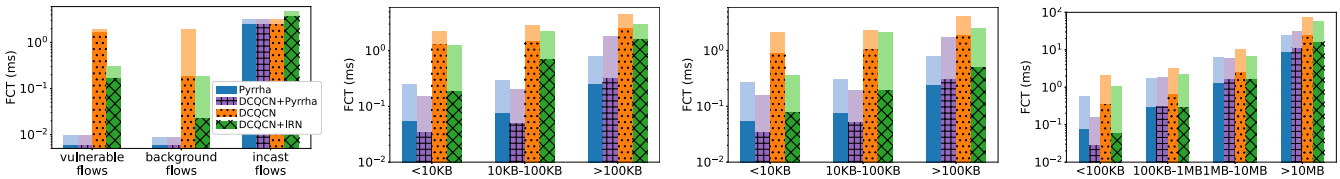
Mechanism validation. With merging, Pyrrha is insensitive to K_{pause} and K_{resume}. As shown in Figure 27(a), without merging, when K_{pause} varies (*e.g.*, 2-35), the inaccurate root detection induces queuing of vulnerable flows. While with merging, those false-positive congestion roots caused by inappropriate parameters could be corrected. The queuing delay shown in Figure 28(a) and 28(b) validates it.

Figure 27(b) demonstrates the performance when K_{resume} varies. Notice that K_{pause} here is set to 10, and the incorrect congestion detection exists. Figure 28(c) shows that the queuing delay increases when K_{resume} is set to a smaller value. This is due to a small resume threshold could be strict to resume and vulnerable flows in the IQ of the false-positive root can be blocked for a long time. With merging, different values of K_{resume} does not influence the queuing delay, as shown in Figure28(d).

C IQ Management

C.1 Methodology

The function of HIQs (*e.g.*, hierarchical congestion matching and in-order delivery) can be achieved by leveraging single-tier IQs. Considering a two-tier HIQ matches congestion roots belonging to two different levels. We denote the single-tier IQ matching two-level congestion roots as IQ_{A_i} and IQ_{B_j}



(a) Memcached (overall flows). (b) Web Server (vulnerable flows). (c) Web Server (uncongested flows). (d) Web Search (uncongested flows).

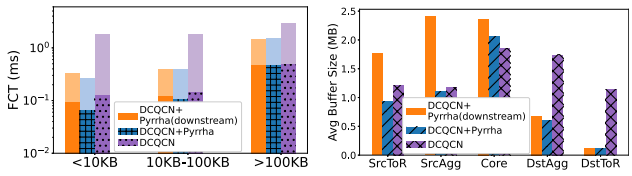
respectively and use lower case letters a_i and b_j to denote the corresponding congestion roots. For a network with two congestion roots a_1 and b_1, there can be flows matching congestion roots a_1, b_1, and $a_1 \wedge b_1$. To handle these three types of congestion flows, for HIQs, IQ_{A_1} and IQ_{B_1} can be arranged into two levels. For single-tier IQs, three dedicated IQs (*i.e.*, IQ_{A_1}, IQ_{B_2} and $IQ_{A_1 \wedge B_2}$) are needed. Generally, to isolate different congested flows as in two-tier IQs (*e.g.*, n first level IQs $IQ_{A_1}, \ldots, IQ_{A_n}$ and m second level IQs $IQ_{B_1}, \ldots, IQ_{B_m}$), the single-tier IQs need additional $n * m$ IQs (*i.e.*, $IQ_{A_1 \wedge B_1}, \ldots IQ_{A_n \wedge B_m}$).

For single-tier IQs, to ensure in-order delivery, it should be careful when a congested flow alters its chosen queue. Scenarios where a flow changes the queue it uses only occur when (i) a congestion root vanishes , or (ii) a new congestion root is detected. For the first scenario, since the IQ to be unassigned must be empty, packets of the flow are not in different queues hence in-order delivery is satisfied naturally. The second scenario is described in § 4.3, where a new congestion root b_1 is detected after a_1. Then IQ_{B_1} and $IQ_{A_1 \wedge B_1}$ are assigned to traffic passing b_1 and traffic passing both congestion roots. Following arrival packets passing through both congestion roots a_1 and b_1 alters from IQ_{A_1} to $IQ_{A_1 \wedge B_1}$. A order mark is inserted into the IQ_{A_1}, and $IQ_{A_1 \wedge B_1}$ can not be resumed until the order mark is dequeued from IQ_{A_1}. Note that IQ_{A_1} can be paused by congestion root b_1 before the order mark is dequeued due to that flows passing through both port a_1 and b_1 can be pushed into IQ_{A_1} before congestion root b_1 is detected. Given that Pyrrha detects congestion roots rapidly, packets in IQ_{A_1} can be moderate hence the order mark can be dequeued in a short time.

C.2 Experimental Verification

To reduce the complexity, we can analog two-tier HIQs which is enough for two-tier Clos-networks. For three-tier



(a) FCTs. (b) Buffer Occupancy.

Figure 29: Performance when using single-tier congestion queue to perform a two-tier HIQ.

Clos or fat-tree networks, it only matches congestion roots that two hops away from the destination host. And we leverage CC protocols to handle the congestion close to the source host.

We evaluate the performance of Pyrrha when single-tier congestion queues are used to analog the behavior of a two-tier HIQ in a three-tier topology. Figure 29 shows the performance of Pyrrha and Pyrrha handling downstream congestion roots by leveraging single-tier IQs. Results show that when comparing Pyrrha (downstream)+DCQCN with Pyrrha+DCQCN, the latency of flows smaller than 100KB is increased. But Pyrrha (downstream)+DCQCN reduces the latency of flows significantly compared to pure DCQCN.

D Pyrrha Prototype and Discussion

In this section, we present our Tofino2 prototype, with Figure 30 depicting its pipeline. We divide the pipeline into three parts, each detailed in a separate subsection (Appendix D.1 - D.3). Finally, we summarize the Tofino2 features leveraged in our prototype and examine the practicality of implementing Pyrrha on the RTC (Run-To-Completion) architecture, *e.g.*, Juniper Trio [88].

D.1 Ingress Pipeline

Packet Classifier. The packet classifier is located at the front of the ingress pipeline. The module determines the packet type according to the Ethertype field in the Ethernet header. (We use Ethertypes that are not used by the IEEE standard to mark different types of packets.) There are three types of packets: data packet, signal packet, and generated packet. Different types of packets then go through different modules.

Forward Engine. Only data packets go through the forwarding engine. The forwarding engine looks up the table deployed in advance and determines the egress port of the data packet. This module is similar to that of most commercial switches.

Congestion Root Matcher. This module contains two submodule: route calculation unit and hierarchical congestion root table. The methodology of route calculating is described in § 4.2, and the optimization to reduce the resource usage is detailed in Appendix E.3. And as described in § 5.1, the hierarchical congestion root table records the congestion roots and their states in a hierarchical manner. When a data packet passes, the module first calculates its route, then matches its route against the congestion root table hierarchically. If the packet matches one or more congestion roots in PAUSE state, the matched congested root id(s) is (are) carried in its metadata, which is stored in PHV and will be used in the following modules. When a signal packet passes, the module first calculates the location of the congestion root it indicates, then modifies the state of the corresponding congestion root in the hierarchical congestion root table.

Queue Manager. This module manages the mapping between the congestion root id and queue id. When a packet passes, the module tries to match the congestion root id it carried in metadata against mapping table. If there is no matched entry, the module assigns a new queue to this congestion root. When a queue is unassigned, the module deletes the corresponding entry.

Queue State Detector. *Ghost* is used in this module to detect the change in queue state. When Ghost is triggered by predefined thresholds (K_{pause} or K_{resume}), a Ghost packet is generated to the ingress pipeline and writes the queue length into a register in this module. When passing through this module, the data packet tries to read the value in the register corresponding to the queue in which it will be queued. Then the data packet compares the queue length it read with the previous queue length stored in another register. If the queue length exceeding K_{pause} or falling below K_{resume} for the first time, a PAUSE/RESUME packet is needed to be sent. In such case, the module marks the packet.

At the end of the ingress pipeline is the signal packet module, which contains three sub-modules corresponding to three types of packet.

Signal Packet Creator. Only data packets will pass through this module. Recalling that in the Queue State Detector module, the data packet is marked if a signal packet is needed to be sent. Then this module will check the marker and uses Pktgen to generate a new packet if the marker is valid. The *new programmable Pktgen trigger* of Tofino2 enables carrying some data plane metadata in the generated packet, which greatly expands programmability.

Signal Packet Constructor. The generated packets will pass through this module. This module will reorganize the metadata and construct the header of the signal packet.

Signal Packet Handler. This module will pause/resume the IQ based on the queue information carried in the signal packet. The dataplane pause/resume is achieved via *AFC*, a new feature of Tofino2. If the signal packet switches some flows from a working queue to another queue, the signal will be modified to a Order Mark and pushed into the origin queue. Otherwise, the signal packet is useless and dropped by the module.

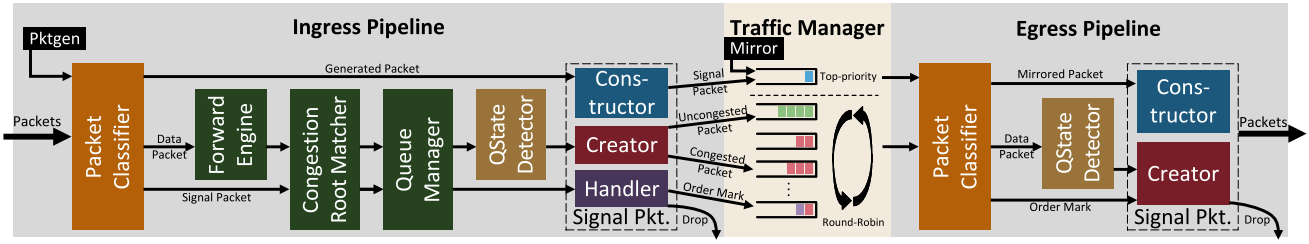


Figure 30: Pipeline of Pyrrha implementation on Tofino2

D.2 Traffic Manager

In the Traffic Manager, we configure a highest priority queue as the queue through which the signal packets pass. Other queues are configured as the same priority and scheduled in a Round-Robin manner. Among these queues, one is used as OQ, and the rest of the queues are used as IQ, which are managed by Queue Manager in Ingress Pipeline.

D.3 Egress Pipeline.

Packet Classifier. The functionality of this module is similar to the Packet Classifier in Ingress Pipeline. All packages are divided into three types: mirror packet, data packet, and Order Mark.

Queue State Detector. Unlike the Queue State Detector in Ingress Pipeline, this module uses the queue length carried by the egress packet to detect the change of queue state. This module mainly focuses on one kind of queue state: CLEAR. If an IQ is clear, it means we can unassign it when other conditions are met.

Signal Packet Creator. Because the programmable Pktgen trigger is not available in Egress Pipeline, this module uses *mirror*, another Tofino feature, to create signal packets. To deliver the signal packet to Ingress Pipeline, the module mirrors the packet to the top-priority queue of the loopback port. For the data packet with a CLEAR mark, this module just mirrors the header to create a small-size signal packet. For the Order Mark, this module mirrors the whole packet and then drops the origin packet.

Signal Packet Constructor. In this module, the mirrored packet is constructed as a signal packet. For the packet mirrored from the data packet's header, the module discards all the origin headers and reconstructs the signal header. For the packet mirrored from the Order Mark, the module only makes minor modifications.

D.4 Feasibility on RTC switches

In our Tofino2 prototype, we utilized the following features that may not be supported by all programmable switches: Ghost thread, packet trigger, and AFC (Advanced Flow Control). (i) Ghost thread is used to get queue lengths at the ingress pipeline. (ii) The packet trigger functionality can generate new packets at the end of both the ingress and egress pipelines. (iii) AFC enables the pausing and resuming of queues in the programmable data plane. We then discuss how to implement these features on other types of programmable switches that adopt RTC (Run-To-Completion) architecture, *e.g.*, Juniper Trio [88].

(i) In programmable switches, queue lengths are typically visible after packets pass through TM (Traffic Manager), *i.e.*, during the process of egress. For Tofino, the Ghost thread is required due to the hardware limitation that information can not be directly conveyed from to egress to ingress. However, in the RTC architecture, the memory is shared between ingress and egress, thus Ghost thread is naturally not required.

(ii) The packet trigger functionality is not directly supported by current RTC switches. Fortunately, through private discussion with a vendor of the RTC switch chips, we have learned that the feature can be easily implemented using background threads and will be integrated into its forthcoming RTC architecture switch chip. More precisely, the design involves dedicated background threads and associated data structures that are reserved for packet generation. These background threads are continuously active, polling the data structures for the notifications of packet generation. When a need arises to generate new packets, the necessary packet generation information is written into the corresponding data structure. Upon detection of this information, the background threads initiate the generation process accordingly.

(iii) Currently, AFC is not supported by existing RTC chips. The support for AFC in Tofino2 demonstrates the feasibility of exposing this functionality to the programmable data plane. Considering the necessity to support prevalent flow control protocols such as PFC, the capability to pause and resume queues should be a standard functionality in RTC. We are optimistic that future releases of RTC switch chips will support this essential functionality.

E Resource Usage on Tofino2

In this section, we detail the resource overhead of the Pyrrha prototype on Tofino2. Tofino2 adopts pipeline architecture, wherein the overhead of storage and computational resources is determined at compile time. It enables us to ascertain Pyrrha's resource requirements without running it in a large-

scale cluster. We separately compile three key data structures that are related to the size of the topology to report their overhead across different topological scales (Appendix E.1-E.3). Subsequently, we present the resource usage of processing logic, which remains constant irrespective of the scale of topology (Appendix E.4). Ultimately, we analyze the computational and storage resource complexities of Pyrrha and provided an exhaustive account of resource utilization under several typical network conditions. (Appendix E.5)

According to the statistics reported in megascale [49], the scale of current data centers can reach up to 10,000 nodes. Therefore, we use a fat-tree topology with 11,664 hosts as a representative case for our analysis. In addition, we investigated the largest scale of topology that Pyrrha can support theoretically, *i.e.*, approximately an order of magnitude larger than the state-of-the-art datacenter networks. The results demonstrate that Pyrrha is capable of scaling to large-scale networks. Our prototype of Pyrrha can support a typical modern data center with over 10,000 hosts. Leveraging the rapidly maturating HIQ technology [94], Pyrrha is capable of scaling up to support topology approximately an order of magnitude larger than the typical modern datacenter networks.

Our overhead analysis focuses on the ToR switches since they should track the most extensive status information for their downstream networks, thereby consuming the largest amount of resources. It is notable that the data plane storage and the forwarding plane buffers are segregated in the Tofino2. Thus Pyrrha's consumption of storage does not impact the forwarding performance.

E.1 Path Calculation

This section details how we implement hash-based path calculation for fat-tree topology in our Tofino2 prototype. The path calculation can be divided into two parts: determining available egress ports and selecting the forwarding port from available ports by hashing. Given the fact that switches in datacenter only support limited types of hash functions (*e.g.*, CRC or XOR) to conduct efficient calculation [87, 93] and use switch-specific hash seeds to avoid hash polarization. Hence, Pyrrha switch only needs to store a bitmap to indicate the type of the hash function of other switches along with their hash seeds (§ E.1.1).

In many widely deployed topologies [8, 37, 62, 82], the characteristics of up-down routing and equal paths can be leveraged to optimize the overhead of storing other switches' forwarding tables. We demonstrate that path calculation can be done within $O(n)$ resource usage where n is the number of hosts in the topology. For a fat-tree with 11,664 hosts, Pyrrha's path calculation occupies 0.44MB SRAM (*i.e.*, 1.8% of Tofino2) (§ E.1.2). If IP addresses are organized regularly as discussed in [8], the storage cost can be further reduced to 0.18% of Tofino2 (§ E.1.3). Otherwise, a Pyrrha switch needs to store forwarding tables on other switches to calculate the path, incurring extra storage overhead.

E.1.1 Hash functions used in the data center

Current switches only provide a limited number of hash functions to prevent complex hashing from impeding forwarding rates [87, 50]. To avoid traffic polarization caused by identical hash functions across different switches, it is a common practice to employ switch-specific seeds to derive switch-specific hash functions [28]. Before performing the hash function, the input data (*e.g.*, IP tuple) is XORed with the switch-specific seed, making the output of identical input data and hash function different among switches. Switches' hash seeds are not hardcoded but accessible through the control plane interface [28]. Therefore, a switch can calculate the hash outcomes of other switches by storing a limited number of hash functions and other switches' hash seeds.

E.1.2 Path Calculation without regular addressing.

To calculate the path, Pyrrha switch needs to store the forwarding tables of other switches. In this subsection, we mainly focus on the structure and the storage overhead of forwarding tables in fat-tree topology. As shown in Figure 31(a), under two topology-relevant optimization, Pyrrha switch can calculate path in $k = 36$ (*i.e.*, 11,664 hosts) fat-tree with 0.44 MB of SRAM. The SRAM usage is acceptable in Tofino2, which has 25 MB SRAM in total. These optimizations can also be applied to other clos-based topologies.

No optimization. Without optimization, a switch needs to store all forwarding tables on other switches. Take fat-tree topology as an example; the size of the forwarding table on a switch is of the order $O(n)$, where n is the number of hosts. The number of the switch is of the order $O(n^{2/3})$. Thus, the size of extra storage usage to calculate the path is of the order $O(n^{5/3})$. Storing all forwarding tables will occupy 12.6 MB in the fat tree with a host number of 3456 (k=24).

Up-down routing optimization. In many topologies, routing adheres to the up-down principle, where packets are first forwarded upward and then downward [45]. In such topologies, switches only need to store upstream routing entries for upward hops and downstream routing entries for downward hops. In a fat-tree, a switch must store entries for all switches in its source pod, all entries for core-layer switches, and only downstream entries for switches in other $(k-1)$ pods. Though it can not reduce the complexity of the resource usage, this optimization can save storage resources on the order of $O(n^{5/3})$ in the fat tree. Storing forwarding tables will occupy 14.1 MB in the fat tree with a host number of 5,488 (k=28) under up-down routing optimization.

Equal path optimization. In many topologies, there are

multiple equal paths between nodes. Take the source aggregation switch as an example. When a packet destined for another pod arrives, the switch only needs to forward it to any one of the upward links without differentiating between the various upward links. Therefore, the edge switch only needs to store the forwarding table entries of the hosts within their own pod to determine the forwarding decisions on aggregation switches within that pod. Similarly, edge switches only need to store one routing table that maps different IPs to different pods for all core switches, as core switches are only concerned with which pod the packet needs to be forwarded to. For the aggregate switches of the other $k-1$ pods, the edge switch only needs to store $k-1$ different forwarding tables. This optimization can reduce the storage resources usage to the order of $O(n^{4/3})$. Storing forwarding tables will occupy 2.56 MB in the fat tree with a host number of 11,664 (k=36) under equal path optimization.

Full optimization (used in our prototype). Combining the two optimizations mentioned above, we can further reduce the storage resource overhead to the order of $O(n)$. The storage usage of storing forwarding tables is reduced to 0.44 MB in the fat tree with a host number of 11,664 (k=36) under full optimization. In addition, we investigated the largest scale of topology that Pyrrha can support theoretically, *i.e.*, approximately an order of magnitude larger than the state-of-the-art datacenter networks. In our prototype, storing forwarding tables will occupy 8.7 MB in the fat tree with a host number of 524288 (k=128) under full optimization.

Next, we introduce the specific content of the forwarding tables to storage and then analyze the complexity. (i) A ToR switch is required to store $K/2$ downstream entries for itself. If the destination IP of a packet is missed in the downstream entries, the switch should select a port from upward ports by hash to forward the packet. The complexity is of $O(n^{1/3})$. (ii) The ToR should store store $k^2/4$ downstream entries, for all aggregation switches within the same pod. If the destination IP is not within the pod, the aggregation should select an upward port by hash to forward the packet. The complexity is of $O(n^{2/3})$. (iii) The ToR should store $k^3/4$ entries for all core switches, containing the mappings between destination IPs and their corresponding pods, with a complexity of $O(n)$. (iv) Additionally, for the aggregation switches in each of the other $k-1$ pods, $k-1$ tables need to be stored, each with a size of $k^2/4$, to store the mappings of different destination IPs within that pod to the appropriate edge switches, with a complexity of $O(n)$. (v) For all other edge switches, tables of size $k/2$ that record the mappings between destination IPs and hosts should be stored, also with a complexity of $O(n)$. Therefore, under full optimization, the storage overhead complexity for maintaining the forwarding tables is $O(n)$.

Apply optimizations on other topologies. The two optimizations mentioned above can be applied to most clos-based topologies [37, 63, 82].

E.1.3 Path Calculation with regular addressing

In this subsection, we discuss how to conserve storage overhead for forwarding tables based on the regularity of the topology's addressing. Our discussion is based on the fat-tree topology with addressing method presented in [8]. We believe that this approach can be applicable to the vast majority of topologies with regular addressing schemes.

IP address format. The address of a host is $10.pod.switch.host$, where *pod* is the pod number, *switch* is the edge switch's position in the pod (counting from left to right) the host connected to, and *host* is the host's position among hosts connected to the switch.
