(iii) Path at core switch. The switch ID of the core switch the packet will pass by is $\{0, edgePortID[6:0], 0, aggPortID[6:0]\}$. The upper 8 bits are the position of the aggregation switch it connected to and the lower 8 bits are the position of the aggregation switch port it connected to. The egress port ID at the core switch is the destination pod ID, which is available in the IP-tuple.

(iv) Path at destination aggregation switch. The switch ID of the destination aggregation switch the packet will pass by is $\{dstIP.pod, 0, edgePortID[6:0]\}$. The switch position (*i.e.*, the lower 8 bits) is the same as that of the source aggregation switch, eliminating the need for calculation. The port ID at the destination aggregation switch can be obtained from the *switch* field of the destination IP address.

(v) Path at destination edge switch. The switch ID and port ID can be directly obtained from the destination IP address.

Resource usage. Table 2 shows the resource usage of path calculation with regular addressing on the edge switch. Pyrrha use only a slight amount (0.18%) of SRAM to store hash seeds and only two hash function calls. The hash function is built-in in Tofino2, thus do not occupy any extra resource. Among those resources, the most utilized resource is the TableID, which only occupies 2.5% of the total TableID resources available in the Tofino2.

E.2 Hierarchical Congestion Root Table

We store the downstream congestion snapshot in a hierarchical congestion root table. The k^{th} table records ports that

are k hop away from the switch, whose keys are <switch-id, port-id>, and the value is a bit, denoting its congestion status. As shown in Figure 31(b), the storage usage of the congestion status snapshot is of the order $O(p)$ where p is the number of ports in the network (*i.e.*, $O(n)$ where n is the number of hosts for most topology). When the number of hosts is small, the usage of SRAM does not increase with the number of hosts. This is because Tofino2 allocates SRAM in blocks, and when the number of hosts is low, the size of each data structure fits within a single block. In our prototype, the hierarchical congestion root table occupies 176 KB in a fat tree with a host number of 11,664 (k=36) and 0.44 MB for 524,288 host (k=128).

E.3 Queue Assignment Module

The queue assignment employs a lazy update design to conserve queue resources. The components of the dynamic queue assignment module and the procedure of queue assignment are shown in Figure 32. The queue allocation module introduced in this section is applicable to both single-layer IQs and HIQs. For HIQs, the queue allocation module is also hierarchical, with each layer of queues being allocated by a corresponding layer of the queue allocation module.

Before entering queue assignment module, a packet is first processed by a congestion root matching module to determine whether it will pass through congestion roots (Appendix D.1). If it will, the packet will carry the IDs of all the congestion roots it will pass and proceed to the queue assignment module.

The packet first passes through *IsAssigned Table*, which has two dimensions: port ID and congestion root ID. This table stores bits to indicate whether a queue has been assigned to a congestion root on a port. Note that in our Tofino2 prototype, we use single-tier IQs to emulate two-level HIQs (§ C). Therefore, the congestion root ID is a concatenation of the IDs of the two potential congestion roots in two layers. If the corresponding bit in the table is 0, it indicates that the corresponding IQ has not been assigned. The packet then modifies this bit to 1 and enters the Multi-segment QueueID Stack to attempt to obtain a queue ID.

The *Multi-segment QueueID Stack* utilizes only two tables, *Stack Pointer Table* and *Stack Content Table*, yet it can independently assign queues in each port. The Stack Pointer Table is indexed by port ID and stores the top pointer of the queue ID stack corresponding to each port. The Stack Content Table holds the remaining available queue IDs for each port. When queue assignment is required, the packet first accesses the Stack Pointer Table to obtain the stack top pointer and then increments the top pointer in the table by 1. Subsequently, it reads the available queue ID from the top of the Stack Content Table. Finally, this queue ID is written into the *QueueID Record Table*, which has the same indexing as the IsAssigned table and stores the queue IDs that have already been assigned.

The pipeline architecture of Tofino2 ensures a strict order in table access among packets. After queue assignment is completed, subsequent packets that pass through the same port and congestion roots will find the corresponding bit in the IsAssigned table set to 1. Then, they will not perform any operations when passing through the Multi-segment QueueID stack. Instead, they will directly read the queue ID from the QueueID Record Table.

When unassigning a queue, the operations are basically the reverse of queue assignment. When an IQ is clear and the IQ is the leaf of the congestion tree, a signal packet is created, which carries the IQ ID to be unassigned as well as the port ID and congestion root ID. It sets the corresponding bit in the IsAssigned table to 0. Then, it increments the stack top pointer in the Stack Pointer Table by 1 and writes the unassigned IQ ID into the new stack top in the Stack Content table. Finally, it clears the corresponding record in the QueueID Record Table.

The SRAM usage of the queue assignment module is shown in Figure 31(c). The resource usage of the queue assignment module mainly stems from the IsAssigned table and the QueueId Record table. When using single-tier IQs, the congestion root ID is a concatenation of the IDs of two layers of congestion roots, which results in a space complexity of $O(n^{5/3})$ for these two tables where n is the

number of hosts in the topology. The SRAM usage of the queue assignment module is shown in Figure 31(c). Queue assignment module for single-tier IQs will occupy 8.64 MB in the fat tree with a host number of 11,664 (k=36), which is adequate to support the scale of typical modern topology.

Leveraging the rapidly maturating HIQ technology [94], on Pyrrha switch that support HIQ, the IsAssigned table and QueueId Record table can be decomposed hierarchically as in Appendix E.2, thereby reducing the space complexity to $O(n)$. We also implement a queue assignment module suitable for HIQ on Tofino2 to investigat the largest scale of topology that Pyrrha can support theoretically, the result shows only 2.2MB of SRAM is required to support up to 524,288 hosts.

E.4 Resource Usage of Processing Logic

In addition to the above three data structures, whose resource usage varies with the network scale, our prototype also includes some processing logic with fixed resource usage. This includes queue length detection, signal packet creating, constructing, handling, as well as queue pausing and resuming (Appendix D). The resource overhead of this processing logic is shown in Table 3. The results indicate that in our prototype, Pyrrha's resource usage is moderate and acceptable for Tofino2.

Table 6: Resource usage of Pyrrha with HIQs under 221,184 hosts topologies with irregular addressing.

E.5 Overall Resource Usage

In this subsection, we analyze the complexity of the overall resource utilization of Pyrrha on the Tofino2 prototype. Subsequently, we present Pyrrha's detailed resource usage across several representative network conditions. According to the statistics reported in megascale [49], the scale of current data centers can reach up to 10,000 nodes. Therefore, we use a fat-tree topology with 11,664 hosts as a representative case for our analysis. In addition, we investigated the largest scale of topology (*i.e.*, a k = 128 fat-tree with 524,288 hosts) that Pyrrha can support theoretically.

Complexity analysis. The computational resources utilized by Pyrrha are predominantly determined by the on the maximum number of network hops, with a minor correlation to the network's scale. Regarding storage resources, the overhead of Pyrrha's data structures is moderate. Denote the number of hosts in the topology as n. With irregular addressing, the storage overhead can be reduced to an order of $O(n)$ through two optimizations. With regular addressing, the storage cost for path calculation is negligible. The storage overhead of a hierarchical congestion root table is also on the order of $O(n)$. In our prototype, the storage cost for the queue assignment module is $O(n^{5/3})$. On switches that support HIQs, the storage cost for the queue allocation module is $O(n)$.

Resource		Usage	Percentage
Comp.	Exact Match Input xbar	297	11.60%
	Ternary Match Input xbar	76	5.76%
	VLIW Instructions	108	16.87%
	Hash Bits	1799	21.62%
	Hash Calls	33	27.50%
	Stateful ALU	44	55.00%
	Logical TableID	112	35.00%
Stor.	SRAM	845	52.81%
	TCAM	31	6.46%

Table 7: Resource usage of Pyrrha with HIQs under 524,288 hosts topologies with irregular addressing.

Overall, the computational resource overhead of Pyrrha remains constant across most network topologies. In our prototype, the storage overhead for Pyrrha is $O(n^{5/3})$. On switches that support HIQ, the storage overhead is $O(n)$.

Detailed usage. We present detailed reports of resource usage for Pyrrha on the Tofino2 prototype across several typical network environments. We first report the resource usage of Tofino2 prototype under the scale of a typical modern data center [49], which is shown in Table 4. In a network with 11,664 hosts (*i.e.*, fat-tree with k=36), the Stateful ALU and Logical TableID are the most utilized computational resources, accounting for 76.25% and 38.75% of the capacity, respectively. And SRAM is the most utilized storage resource, occupying 44.5% of the availale capacity.

In addition, we investigated the largest scale of topology that Pyrrha can support theoretically. Table 5 illustrates the resource usage of Pyrrha on a switch supporting HIQ within a 524k hosts network (*i.e.*, fat-tree with k=128) with regular addressing. The Stateful ALU and Logical TableID are the most utilized computational resources, accounting for 55% and 32.5% of the capacity, respectively. The storage usage is merely 18.38%. Table 6 and 7 shows Pyrrha 's resource usage on a switch supporting HIQ and the topology has 221k and 524k irregular addressed hosts (*i.e.*, fat-tree with k=96 and 128), respectively. In the case of irregular addressing, the computational overhead remains nearly identical, while the SRAM usage increases. In a network with 221k hosts, the SRAM overhead is 28.13%, and in a network with 524k hosts, the SRAM overhead rises to 52.81%, demonstrating that the storage overhead is linear.

eTran: Extensible Kernel Transport with eBPF

Zhongjie Chen[†] Qingkai Meng[‡] ChonLam Lao[¶] Yifan Liu[†]

Abstract

Evolving datacenters with diverse application demands are driving network transport designs. However, few have successfully landed in the widely-used kernel networking stack to benefit broader users, and they take multiple years. We present eTran, a system that makes kernel transport extensible to implement and customize diverse transport designs agilely. To achieve this, eTran leverages and extends eBPF-based techniques to customize the kernel to support complex transport functionalities safely. Meanwhile, eTran carefully absorbs user-space transport techniques for performance gain without sacrificing robust protection. We implement TCP (with DCTCP congestion control) and Homa under eTran, and achieve up to 4.8×/1.8× higher throughput with 3.7×/7.5× lower latency compared to existing kernel implementation.

1 Introduction

Datacenter applications are always evolving and becoming increasingly diverse. For example, recent microservice applications heavily rely on Remote Procedure Calls (RPCs) to communicate among loosely-connected components; storage applications require bulk data transfer and replications for fault tolerance; popular ML applications employ collective communication primitives such as AllReduce to exchange large volumes of model weights and gradients.

To better support these diverse applications, datacenter researchers have proposed many network transport designs. For example, the Homa transport [50, 55] with SRPT (Shortest Remaining Processing Time) and receiver-driven designs target low-latency RPCs; The DCTCP congestion control (CC) protocol [2] enhances the TCP transport for various datacenter workloads, including bulk transfers; The MLT transport [74] is designed specifically for distributed DNN training. There are many more transport designs for emerging datacenter workloads [14, 26, 30, 44, 45, 49, 51, 82].

However, very few transport designs have landed in the widely-used Linux networking stack to benefit broader users. For example, DCTCP took 4 years to land [18], while MPTCP took nearly a decade [51]; Homa (2018) [50] has been an author-maintained kernel module since 2021 but remains unmerged in mainline. To the best of our knowledge, no transport protocol has landed on the kernel since DCTCP. The key reason for the above status quo is that kernel transports take extremely heavy efforts to develop and maintain, and often give unsatisfactory performance. As a result, it cannot keep up with the fast evolvement and high performance requirements of datacenter transports.

People nowadays mainly resort to kernel-bypass techniques by implementing transport directly in the user space or in hardware. However, this approach largely sacrifices kernel-provided protection and manageability [4, 57, 61, 80, 81], not friendly to public cloud users. For instance, integrating transport within the application process [38, 78] risks malicious manipulation or unintended interference with transport events (e.g., acknowledgments, timeout). Alternatively, running transport in a separate process [41, 47] or on hardware [3, 82] introduces new infrastructure and tools, incurring high management burdens such as telemetry and debugging.

Instead, this paper takes the kernel approach and tries to tackle the following challenging problem: *how to make the kernel transport extensible to enable agile customization, while achieving kernel safety, strong protection, and high performance?* This is challenging because 1) customizability might expose new attack surfaces in the kernel, creating safety challenges; and 2) strong protection requires putting the entire transport states inside the kernel (e.g., the kernel TCP stack), which is usually contrary to high performance due to high kernel overhead (e.g., user-kernel crossing), and makes customization hard due to fixed kernel implementation.

Fortunately, we find that the growing trend of safe kernel extensions via the increasingly mature eBPF technique provides promising opportunities. This technique allows applications to inject statically-verified code into kernel eBPF hooks to change how the kernel reacts to certain events, e.g., incoming packets. Note that this is different from writing unsafe kernel modules that might crash the whole kernel. A bunch of recent eBPF verification work [8, 46, 69, 73, 76] has largely strengthened the safety of eBPF programs running inside the kernel. Recent advances in eBPF functionalities like XDP programmable network data path [58], dynamic memory allocation [20], exception handling [40], and exposing more kernel functions [42] make eBPF more and more capable.

We introduce eTran (**e**xtensible kernel **Tran**sport), a system for agilely customizing kernel transports. eTran achieves agile customizability and kernel safety by 1) leveraging existing eBPF infrastructure such as built-in data structures (eBPF maps), BPF timer, and XDP for fast packet IO, and 2) extending it with new eBPF hooks and maps to support complex transport functionalities while conforming to the strict eBPF verifier for safety. eTran allows safely offloading full trans-

port states and performance-critical operations into the kernel, achieving strong protection. For example, it supports packet acknowledging, flow pacing, fast retransmission, and more in eBPF. In terms of performance, eTran shows similarities with user-space transports for the following design choices: direct packet delivery to user-space without kernel-to-user copies; lightweight packet buffer management and syscall-free IO batching; streamlined transport implementation but preserving genericity. However, transport processing under eTran remains in the kernel, fully isolated from applications. Crucially, transport states are safeguarded by kernel eBPF, preventing direct access from untrusted libraries.

Under eTran, we implemented two representative and vastly different transports, the sender-driven TCP (with DCTCP congestion control) and the receiver-driven Homa, and show great performance gains. For TCP, eTran version achieves 2.4-4.8× higher throughput and 3.2-3.7× lower latency than kernel-native TCP, while being only 1.6-1.8× slower than a state-of-the-art microkernel-inspired kernel-bypass solution with comparable latency. For Homa, eTran version outperforms the kernel module implementation by 1.7-1.8× higher throughput and 3.9-7.5× lower latency for RPCs. We further showcase that eTran supports multi-tenancy, coexisting transport protocols and flexible traffic management.

2 Background and Motivation

2.1 Network Transports

Diverse transports for applications. Modern datacenters have developed various transports to better meet their workloads with two main categories as follows:

- *Sender-driven transports*, such as DCTCP [2], Swift [44], and more [1,45,49,72,75,82], heuristically control the sending rate on the sender side. These protocols are generally beneficial for elephant flows [32] or traffic patterns with low entropy. They are commonly used in machine learning training and storage applications [25,48,60].
- *Receiver-driven transports*, such as NDP [30], Homa [50, 55], and more [14, 26], assume last-hop congestion and proactively control the sending rate by allocating credits from receivers to senders [14,26,30,50]. These protocols prevent queuing and improve tail performance, especially for small flows that dominate RPC applications [15,50].

While datacenter transports differ in how to control the sending rate (e.g., different congestion signals), their implementation share the following common components:

- *Segmentation and reassembly* involve chunking data into packets for sending and reassembling them upon receiving.
- *Congestion control* explores the right sending rate to utilize the available network bandwidth while avoiding congestion. To adjust the rate, transports maintain various congestion states, such as RTT. To enforce rate control, both sender-driven and receiver-driven transports require pacing engines based on target rate, credit availability, or window size.
- *Loss recovery* detects packet loss and triggers retransmission. Transports usually leverage multiple ACK responses to infer packet loss and trigger fast retransmission. When this mechanism is insufficient, timeout-based retransmission serves as the last line of defense for reliable transfer.

Protection for transports. Transport implementation requires protection or isolation from the user-space applications, typically through kernel-based networking stacks. Here, we assume the following threat model that is common in public clouds: applications using transports might be malicious; the eBPF programs written by applications might be malicious but can be detected and prevented by the existing kernel verifier, recent advanced runtime verifier [40], or others (see §8); the kernel and eBPF subsystems are trusted, e.g., through verification techniques like [69]. Without protection, application bugs, crashes, or malicious behaviors could corrupt the transport states and impact other colocating applications [5]. Kernel-based protection has its additional benefit where the networking stacks can firewall malicious applications, enforce access control, and implement various rate-limiting policies [4,57]. On the other hand, eBPF, as a kernel-native mechanism, naturally provides kernel-based protection against user-space applications, which motivates us to explore the possibility of running transports inside eBPF.

2.2 eBPF Basics

eBPF (extended Berkeley Packet Filter) is a promising technique that allows users to run customized, verified programs at specific kernel hooks. It uses eBPF maps and eBPF helper functions to store and exchange various data types between kernel and user space. Overall, eBPF enables safe and efficient extensions of kernel capabilities without modifying kernel code or loading unverified (thus unsafe) kernel modules.

Increasingly capable eBPF. The Linux kernel community is advancing the eBPF subsystem to handle more complex logic. For instance, `kfunc` complements eBPF helper functions by exposing kernel functions and data structures with restrictions; `dynptr`, added in v5.19, allows pointing to dynamically-sized memory; a dynamic memory allocator was added in v6.1; and advanced structures like rbtree (Red-Black Tree) were added in v6.3. Although eBPF still has limitations (e.g., no floating-point arithmetic to avoid non-determinism [53]), its growing capabilities enable safe kernel transport customization.

Fast packet processing with eBPF. XDP (eXpress Data Path) [58] is an eBPF hook in the Linux kernel for fast packet processing; AF_XDP is a specialized socket family built on XDP for fast packet processing in the user space. Packets processed by XDP can be dropped, forwarded back, passed to kernel networking stacks, or redirected to AF_XDP sockets based on the return code specified by the eBPF program.

AF_XDP uses four rings for packet IO: TX/RX rings per socket and Fill/Comp rings per NIC queue. The application provides buffers via the Fill ring for the kernel to receive packets, which are then placed in the RX ring by the kernel.

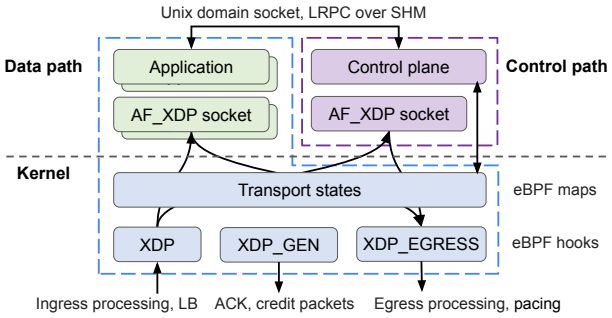

Figure 1: Overall architecture of eTran.

It submits buffers to the TX ring for transmission, and the kernel returns transmitted buffers to the Comp ring for reuse. All operations are asynchronous and optimized for syscall-free. Kernel operations of AF_XDP run in the NAPI context, which is Linux's event-driven packet processing mechanism. AF_XDP uses UMEM, a pre-allocated memory pool of fixed-size chunks, as the packet buffer pool. Currently, an AF_XDP socket can only bind to one NIC queue and UMEM while a NIC queue or UMEM can bind to multiple AF_XDP sockets.

3 eTran Design

eTran has the following four design goals:

- **Agile customizability**: eTran should allow agilely customizing diverse transports and their full functionalities.
- **Kernel safety**: eTran should prevent eBPF programs from tampering with or even crashing the kernel.
- **Strong protection**: eTran aims to maintain *all* transport states inside the kernel with corresponding state operations in eBPF, protecting against untrusted applications.
- **High performance**: eTran aims to achieve much higher performance than existing kernel transports and comparable performance to kernel-bypass ones.

Figure 1 shows the high-level architecture of eTran, which separates any transport into a control path and a data path. The control path handles non-performance-critical eBPF programs attaching/detaching, AF_XDP socket and UMEM creation/destroying, connection setup/teardown, and complex tasks that are unsuitable for eBPF (§3.1). It runs inside a root-privilege daemon, and multiple control paths from different transports can share the same daemon. Through this control path separation, eTran allows non-privilege applications to attach eBPF programs to the kernel through the control path daemon.

The data path handles performance-critical transport operations (e.g., packet reassembly, ACK/credit response, flow pacing) with streamlined implementation for high performance; it maintains all transport states (with state operations) inside the kernel for strong protection (§3.2). The data path runs across the kernel and user space: the kernel part runs in eBPF for kernel safety with direct access to transport states; the user-space part runs through untrusted libraries that cannot directly access transport states. Both parts can be agilely customized.

The data path and control path communicate through Unix domain socket and efficient LRPC [6, 24, 54] over shared memory. Additionally, eTran features flexible user-space IO by layering atop of the AF_XDP sockets (§3.3), multi-tenancy support, and flexible traffic management (§3.4).

3.1 eTran Control Path

Managing eBPF program. Applications submit transport-specific eBPF programs to our control path daemon to attach to the kernel, as such attaching requires root privilege. The daemon will first do a series of checks to make sure these programs submitted by different applications won't conflict with each other, e.g., overlapping ports or eBPF maps. Then, it will try to attach the eBPF programs to the hooks and create entries in `BPF_TYPE_PROG_ARRAY` for them, which will go through the kernel verification for liveness and safety.

Managing AF_XDP socket and UMEM. The control path daemon creates all AF_XDP sockets on behalf of applications and then transfers the file descriptors to applications through the Unix domain socket. This allows applications to use AF_XDP without privileges (e.g., `sudo`). Similarly, the daemon is also responsible for creating an individual UMEM for each application, mapping it into its address space. All sockets for a single application share the same UMEM.

Managing transport connections. The control path daemon handles connection management for connection-oriented transports such as TCP. Applications post control operations (i.e., `open/connect/listen/accept/close`) via LRPC channels; then the daemon intercepts the connection-related packets through its own AF_XDP socket and handles connection setup/teardown, then returns results to applications. eTran decides to put connection management into the control path due to the complexity of handshaking and timeouts, which are challenging for eBPF while being non-critical to transport performance. A similar design is adopted by TAS [41].

Managing CC and loss recovery. eTran decides to put few challenging-to-offload functionalities to the control path, including running advanced CC algorithms (e.g., involving floating-point arithmetic that is prohibited in eBPF) and handling severe loss recovery triggered by timeouts (not TCP fast retransmission). We will elaborate on this in §4.

3.2 eTran Data Path: Kernel Offloading

Running transport protocols and maintaining transport states inside the constrained eBPF environments requires enhancing the existing eBPF subsystem. We use the following three example issues to motivate the necessity of such enhancement:

① Many transports update states when packets get sent out, e.g., Homa decreasing the remaining bytes, but the XDP hook only works on ingress packets.

② Transports usually generate ACK and credit packets to coordinate senders and receivers, but the XDP hook does not support packet generation inside the kernel.

③ Almost all transports require a pacing mechanism to regulate when to send packets, but the XDP hook does not

support any buffering mechanism to defer packet sending.

The challenge is how to efficiently enhance the eBPF subsystem while not incurring destructive chances to eBPF, e.g., keeping similar semantics on the introduced changes, and reusing the existing kernel verifier and data structures. To address this challenge, eTran provides two new eBPF hooks, `XDP_EGRESS` and `XDP_GEN` (§3.2.1), and one new eBPF map, `BPF_MAP_TYPE_PKT_QUEUE` (§3.2.2).

3.2.1 New eBPF Hooks for Egress and Pktgen

XDP_EGRESS is a new eBPF hook that eTran designs to allow eBPF to efficiently customize egress packet processing, addressing the issue ①. eBPF programs attached to this hook accept an egress packet context as the input parameter and specify a return code to determine how this packet gets transmitted. We make the hook transparent to the NIC driver layer to avoid per-vendor code modifications. To achieve this, we place the hook in the vendor-agnostic AF_XDP kernel code, specifically, the `xsk_tx_peek_desc` function. This function fetches packet descriptors from AF_XDP TX rings and delivers them to the NIC drivers, finishing packet transmissions.

We also aim to reuse as many existing eBPF infrastructure as possible. First, `XDP_EGRESS` hook uses the same packet context (i.e., `struct xdp_md`) as XDP, facilitating the use of eBPF helpers designed for XDP. We add a new `umem_id` field at the end of the struct to indicate the UMEM of each packet, preventing unauthorized access to resources like connections and ports. For XDP programs, this field is invalid and inaccessible (see §4.1 for more detail). Second, the `XDP_EGRESS` hook shares the same return codes and actions as XDP:

- XDP_TX: Transmit the packet immediately.
- XDP_REDIRECT: Redirect the packet to a special map for buffering or another AF_XDP socket.
- XDP_DROP: Drop the packet.

XDP_GEN is another new eBPF hook that eTran designs to allow eBPF to efficiently generate packets. These packets can be customized based on the transport, e.g., ACK and credit packets, addressing the issue ②. eBPF programs attached to this hook also use the same packet context as XDP, and make packet-generating decisions based on the states from eBPF maps. Figure 2 shows how this hook works : first, the eBPF program at the XDP hook pushes necessary metadata (e.g., `seq` and `ack` in TCP) into a per-CPU eBPF queue, if it needs to generate an ACK packet; then the eBPF program at the `XDP_GEN` hook will pop any such metadata from the queue, fill it into a new packet frame, and send the packet out. eTran places the `XDP_GEN` hook in the `xdp_do_flush` function that is called at the end of a NAPI poll to generate packets.

A strawman approach dynamically allocates packet frames on-demand but incurs high overhead due to complicated and slow kernel memory management. Instead, we leverage batching to amortize the overhead: we pre-allocate enough frames and call the `XDP_GEN`-attached eBPF program in a finite loop whose budget is the same as NAPI; in each iteration, the eBPF

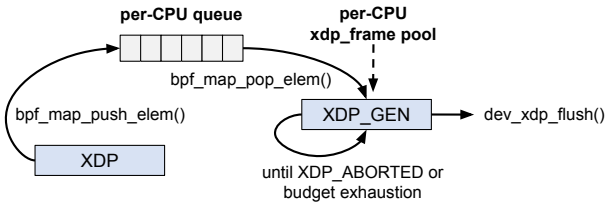

Figure 2: Coordination between XDP and XDP_GEN.

program may use a pre-allocated packet frame to generate a packet. We further leverage the *page_pool* allocator, an efficient memory allocator optimized for XDP, to do the frame pre-allocations. Doing batched packet generations essentially coalesces ACK or credit packets and sends them in batches for high performance; a similar coalescing mechanism has been leveraged in the transport implementations from Google Falcon [28], TAS [41], Caladan [24], and eRPC [38].

Our `XDP_GEN` hook supports three actions:

- XDP_TX: Transmit the ACK/credit packet immediately.
- XDP_DROP: Drop the ACK/credit packet.
- XDP_ABORTED: No more ACK/credit packets are generated, and the finite loop will be terminated.

3.2.2 New eBPF Map for Pacing

To address the issue ③, eTran designs a new eBPF map `PKT_QUEUE` (i.e., `BPF_MAP_TYPE_PKT_QUEUE`), serving as the backbone data structure for various pacing mechanisms. A `PKT_QUEUE` contains multiple buckets, each with slots storing pointers to `xdp_frames`, which describe packet metadata (e.g., packet address). We leverage the eBPF `dynptr` feature (§2.2) to allow eBPF programs to safely access these `xdp_frames` by the pointers stored in `PKT_QUEUE` buckets (i.e., by functions `bpf_dynptr_from_xdp_frame` and `bpf_dynptr_slice_rd/rdwr`).

eTran's `PKT_QUEUE` supports enqueueing and dequeueing `xdp_frame` to/from a specified bucket. Depending on the pacing mechanism, the bucket index is determined based on the packet transmission timestamp (i.e., `tx_timestamp`) or explicitly specified; we will cover more detail at the end of this subsection. We further wrap a series of eBPF kfuncs (§2.2) to help eBPF programs manipulate `xdp_frame` pointers. For example, an existing kernel function `dev_xdp_enqueue` is wrapped into a kfunc to transmit packets through NIC queues.

In a quick summary, our `PKT_QUEUE` allows safely tracking packets deferred for transmission, and its associated kfuncs allow transmitting packets from eBPF programs. Now, the next question is: *how to asynchronously execute an eBPF program (that transmits packets)?*

BPF timers as triggers. To answer this question, eTran's approach is leveraging the mature "callback" infrastructure of BPF timers [67]. The original BPF timer works as follows: eBPF programs call `bpf_timer_init` to register an eBPF callback function, then use `bpf_timer_start` to start the timer with input parameters of the desired timeout value and some flags; when the timeout is reached, the eBPF callback

function will be executed asynchronously. Instead of using the timeout functionality of BPF timers, eTran leverages their callback registration and asynchronous execution abilities. Concretely, we extend BPF timers with two new modes by adding new flags to the `bpf_timer_start` function:

- In the first mode, this function will enqueue the callback function registered with this timer into a per-CPU backlog queue and schedule `NETTX_SOFTIRQ`. The softirq context at the same CPU would dequeue and execute callback functions based on the transport-specific pacing mechanism.
- In the second mode, the function enqueues the callback into the backlog queue of a dedicated kthread created at kernel boot, and wakes it up. The thread will dequeue and execute callbacks based on the specific pacing mechanism.

The first mode triggers per-CPU callback executionn (common for most protocols), while the second mode suits transport protocols that require global scheduling such as Homa. Both modes can be used together if callbacks properly synchronize shared states. In our implementation, TCP uses the first mode, while Homa uses both modes.

The remaining question is: *how to support various pacing mechanisms used in different transports?* We classify pacing mechanisms into several categories and discuss individually.

Rate-based pacing. This is the most widely-used pacing mechanism as it effectively prevents bursts and reduces congestion spikes [28, 44]. eTran leverages `PKT_QUEUE` to implement a scalable and CPU-efficient timing wheel, following the state-of-the-art design Carousel [62]. Specifically, each `PKT_QUEUE` bucket serves as a timing wheel slot, indicating when stored packets should be transmitted. For details on eTran's `tx_timestamp` mapping to buckets and timing wheel operation, see the Carousel paper [62]. Note that eTran also supports complementing rate-based pacing with window boundaries. Our TCP implementation adopts this pacing.

Credit-based pacing. This is widely used in receiver-driven transport protocols such as Homa. Take Homa as an example: when an RPC cannot send packets because of insufficient credits, Homa puts the RPC packets into a pacing engine and waits for the credits to replenish. To support credit-based pacing, eTran lets each `PKT_QUEUE` bucket store packets belonging to a Homa RPC; when the credit of a RPC is replenished, eTran will transmit packets in the corresponding bucket.

Out-of-order completion for AF_XDP. For the existing AF_XDP, packets are always completed (i.e., transmitted) in the order of being pushed into the TX ring, and its buffer recycling mechanism only supports in-order completion. However, with pacing introduced in `XDP_EGRESS`, the transmission of some packets will be delayed, causing out-of-order completion. To address this, we enhance the AF_XDP packet buffer management with minor code changes. See §5 for more detail.

3.3 eTran Data Path: User-Space IOs

eTran carefully made design choices inspired by user-space transports for IOs, which are critical for performance gain over

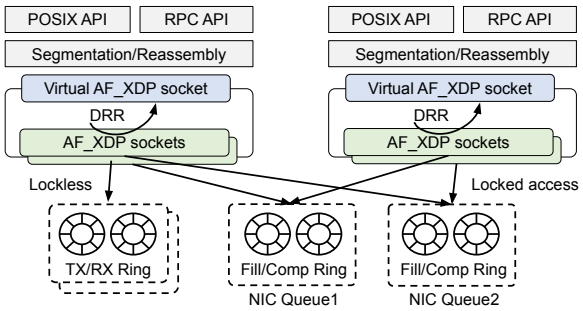

Figure 3: User-space packet IOs in eTran.

kernel-native transports. It offloads core transport operations to the kernel via eBPF and delivers data packets to the user space via AF_XDP sockets. A thin and untrusted user-space library reassembles raw data packets into transport-specific abstractions such as TCP flows or Homa RPCs and versa visa. However, we note that the untrusted library cannot directly access any transport state in the kernel, as it is within the non-privilege applications. Additionally, the library cannot access another application's UMEM (§3.1). This prevents untrusted libraries from corrupting kernel states or disrupting other applications, ensuring the transport stack remains protected.

Virtual AF_XDP socket. Figure 3 shows how our user-space library transforms AF_XDP packets into application-facing flows or RPCs. eTran utilizes multiple NIC queues, allowing different application threads to do packet IOs independently for high performance. Ideally, each application thread owns an AF_XDP socket accessing multiple NIC queues for higher parallelism and lower head-of-line blocking [13,37]; however, AF_XDP has an inherent constraint that one AF_XDP socket can only be bound to one NIC queue. To address this constraint, eTran proposes a *virtual AF_XDP socket* managing multiple real sockets (each bound to a NIC queue) via `epoll`.

Atop the virtual AF_XDP socket, eTran provides two types of APIs to fulfill the needs of different applications: 1) POSIX APIs with standard socket operations like `read` and `write`, and 2) event-driven RPC APIs with continuation callbacks like eRPC [38]. Applications using standard socket APIs can switch to eTran by LD_PRELOAD without any code change.

However, using virtual AF_XDP sockets also introduces new challenges on scheduling and thread synchronization.

Scheduling challenge. Packet arrival at a virtual AF_XDP socket indicates that packets have arrived at one or more real AF_XDP sockets. eTran must take care of how to pull packets from these real sockets in a load-balanced manner, especially to avoid starvation. To this end, eTran employs Deficit Round Robin (DRR) [66] scheduling to achieve efficient and fair packet processing among multiple sockets. When sending packets to real AF_XDP sockets, eTran operates similarly by enhancing the kernel `xsk_tx_peek_desc` function.

Synchronization challenge. All AF_XDP rings (i.e., TX/RX and Fill/Comp rings) are SPSC (single-producer, single-consumer) lockless rings designed for high-performance, run-to-completion packet processing. The TX/RX rings are per-

AF_XDP socket, therefore application and NAPI operations on them are still lockless. The Fill/Comp rings, however, are per-NIC queue. Multiple application threads can access them concurrently. A user-space spinlock is used to protect each Fill/Comp ring pair for correct concurrent access among application threads. No locking is needed for NAPI operations, as each NIC queue is handled by a single NAPI context.

Performance advantages of eTran. Compared to existing kernel transports such as Linux TCP and Homa kernel module, eTran has the following performance advantages: 1) efficient buffer management and syscall-free IO batching, 2) streamlined implementation without complicated kernel socket and (thus) file system, and 3) decoupled kernel transport processing[1], which reduces context switch [81] and improves instruction execution with better cache efficiency [41].

3.4 Multi-Tenancy and Traffic Management

eTran also offers software-based multi-tenancy and traffic management as a complement to hardware mechanisms (e.g., SR-IOV [17]). For different applications using eTran, the control path daemon isolates kernel resources (e.g., eBPF maps) by using different namespaces and assigns different NIC queues to different applications. This design prevents malicious applications from accessing others' IO buffers and enables operators to schedule problematic NAPIs on other CPUs to mitigate interruptions. Allocating at least one NIC queue per application is feasible, as modern NICs support hundreds to thousands of queues [68]. For applications not using eTran, XDP/AF_XDP naturally co-exists with other kernel built-in transports. We will demonstrate that eTran can operate seamlessly with kernel built-in transports in §6.3.

eTran uniquely excels in flexible traffic management as all packets traverse eBPF hooks. It natively supports traffic management such as traffic monitoring, access control, and rate limiting. eTran abstracts these tasks into *modular* eBPF programs, linked via `bpf_tail_call` that allows chaining multiple programs on a single hook. Operators can flexibly manage eBPF programs through the control path daemon.

4 Case Studies

This section takes two representative transports as examples to demonstrate how eTran enables implementing and customizing transport protocols in eBPF with high performance. The first transport is the widely-used TCP with DCTCP congestion control, which is a sender-driven and connection-orient protocol (§4.1). The second transport is Homa, which is a receiver-driven and connection-less protocol for datacenter RPCs (§4.2). These two transports represent a wide range of transport designs in literature [14, 26, 30, 44, 45, 49, 82]. We discuss more transport implementations in Appendix A. While eTran currently targets datacenter protocols pursuing performance, we believe it can be extended to non-datacenter scenarios such as wide-area networks. This would require more designs to handle more complex packet reordering and security mechanisms such as TLS [34] in eBPF.

[1]For Linux, the sender-side transport processing is coupled to the application context in kernel space when calling `write` or `send`.

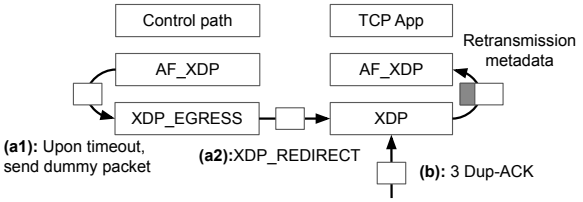

Figure 4: TCP retransmission in eTran. **(a)** is the retransmission triggered by the control path after a timeout, and **(b)** is the fast retransmission triggered by three duplicated ACKs.

4.1 TCP under eTran

TCP control path. As briefed in §3.1, the control path daemon manages TCP connections, congestion control (CC), and severe loss recovery when timeout happens. The daemon uses its own AF_XDP sockets to communicate with remote peers for the three-way handshake to establish TCP connections. It then installs TCP connection states and CC states into eBPF maps. Separating CC states into the control path is inspired by the CCP architecture [52] with two motivations: 1) eBPF does not have mature support for floating point computation that commonly appears in TCP CC algorithms, and 2) CCP has shown that separating CC from the datapath still gives similar CC behaviors and accuracy as in datapath. We defer the description of loss recovery to the end of this subsection, as it interacts closely with the data path.

eTran maintains the connection states in an eBPF hashmap while CC states are in an eBPF array. Storing CC states in an array allows eTran to `mmap` it into the daemon's address space through the `BPF_F_MMAPABLE` feature; this avoids the syscall overhead when the daemon updates CC states. To help eBPF programs locate the CC state, each connection state contains the index of the corresponding CC state in the array.

TCP data path. The eBPF program at the XDP hook receives both TCP control packets and data packets: it redirects control packets such as `SYN` and `SYN-ACK` to the control path AF_XDP; for data packets, it uses four-tuple as the key to look up TCP connection state in the aforementioned eBPF hashmap. The eBPF program then verifies the `ack` and `seq` values of data packets and updates TCP windows if valid. For common cases where `seq` is in order, packets are delivered to the virtual AF_XDP sockets in the user-space transport library (see §3.3). For out-of-order `seq`, eTran implements an out-of-order receiving mechanism similar to TAS [41].

Figure 4 shows eTran's workflow for loss recovery, including fast retransmission and timeout-triggered retransmission. To handle fast retransmission, once the eBPF program at the XDP hook detects three duplicate ACKs, it will rollback the transport state, piggyback the retransmission information (i.e., the rollback pointer) in the ACK packet, and deliver the ACK packet to user-space transport library. The library

will retransmit packets accordingly. The piggybacked retransmission information is stored in the headroom of the packet frame, enabling efficient coordination between the eBPF program and the user-space transport library. To handle timeout-triggered retransmission, once the control path daemon detects such timeout, it will send a dummy packet going through the `XDP_EGRESS` hook to trigger the fast retransmission logic of the eBPF program and then get dropped. This avoids locking operations between the data path and the control path.

The eBPF program at the `XDP_EGRESS` hook processes every packet transmitted by the AF_XDP sockets. It fills packets with the right TCP header and IP header based on the connection state maintained in eBPF maps and the right Ethernet header by looking up the kernel FIB table with `bpf_fib_lookup`. To reduce the cost of looking up the FIB table for every packet, eTran uses an eBPF array to cache results. When the flow control window and the CC window both permit, the `XDP_EGRESS` eBPF program will transmit the packet directly with the action of `XDP_TX`; otherwise, it will enqueue the packet into our `PKT_QUEUE` with the action of `XDP_REDIRECT`. Later, when both windows permit, the queued packets will be transmitted asynchronously (see §3.2.2). As briefed in §3.2.1, this eBPF program also prevents misbehaved applications from modifying connection states that do not belong to them. For example, it will check if the `umem_id` in the packet context matches the one maintained in the connection state and drop the packets if not matched.

4.2 Homa under eTran

Homa control path. Similar to TCP, Homa under eTran lets the control path daemon manage its socket creation, binding, and closing. Different from TCP, Homa runs CC in the data path via eBPF (rather than in the control path) with CC states maintained in eBPF hashmaps. There are two reasons for such a difference: 1) Homa CC or its receiver-driven credit generation is in the critical path of data packet transmission (in contract to TCP sender-driven CC that regulates rate), thus having huge performance penalty if running on a separate control path; and 2) Homa CC is relatively simple in terms of compute operations (e.g., no floating points), friendly to eBPF offloads. Since Homa is connection-less via short-lived RPCs, eTran also maintains its RPC states in the data path for efficient creation/destruction (with eBPF hashmaps).

The Homa control path detects RPC timeout and handles it by sending `RESEND` packets for retransmission. The daemon's timer thread periodically wakes up and scans RPC states in the kernel eBPF hashmap for detecting timeouts; it uses `bpf_map_lookup_batch` to reduce syscall overhead. Once the peer receives the `RESEND` in the XDP hook, XDP will piggyback the lost range and RPC buffer address (maintained in the kernel RPC state) on the packet and redirect it to the user-space library through AF_XDP for retransmission.

Other control-path events include maintaining infrequently changing priority cutoff values [55], freeing states in remote RPC servers when RPC clients do not explicitly confirm RPC completions, and aborting RPCs caused by machine crushes or long timeout by forcibly removing corresponding states.

Homa data path. Homa uses receiver-driven credit scheduling to achieve SRPT (Shortest Remaining Processing Time); eTran implements the credit scheduling at the XDP hook, while also enforcing sender-side SRPT at the `XDP_EGRESS` hook. When the XDP eBPF program receives the first *unscheduled packet* [50] of an RPC message, it creates a new CC state object, including the RPC ID and remaining bytes through `bpf_obj_new`, and enqueues it into a `bpf_rbtree` map, i.e., *credit list*. For subsequent packet arrivals, the eBPF program traverses the credit list, dequeues the corresponding state object, updates the state object with new remaining bytes, and re-enqueues it into the credit list.

The eBPF program at the `XDP_GEN` hook is responsible for selecting RPCs and sending credit packets. Conceptually, it has the following four steps: 1) selecting candidate RPCs from the credit list; 2) looking up the RPC state hashmap to find corresponding RPC states, then allocating credits; 3) removing finished RPCs from the credit list; 4) sending credits for the selected RPCs. However, we face two challenges due to eBPF constraints: lack of searching functionality in `bpf_rbtree` to implement RPC selections; instruction limit posed by the eBPF verifier disallows offloading complex logic.

eTran addresses these challenges by innovatively utilizing existing eBPF features. For the first challenge, we wrap a new eBPF kfunc called `bpf_rbtree_lower_bound` that returns the first node whose value is not less than the provided one; we then leverage this kfunc to select candidate RPCs ranked by their priorities while guaranteeing not selecting more than one RPC for each peer (required by Homa [55]). A common way to implement such RPC selections is through a 2-level rbtree as Homa does, but requires holding multiple locks simultaneously, which eBPF prohibits. Instead, we use `bpf_rbtree_lower_bound` to emulate such 2-level rbtree with a single rbtree; see Appendix B for more detail. For the second challenge, we use `bpf_tail_call` to break complex eBPF logic into multiple programs that go through the verifier separately. To pass states across different tail-called eBPF programs, we exploit per-CPU variables in the `bss` section.

On the sender side, the `XDP_EGRESS` eBPF program queues packets into the pacing engine (see §3.2.2) when no credit is available for this RPC. Upon credit replenishment, the callback enforces SRPT across RPCs using a `bpf_rbtree` of queued RPCs, sorted by the remaining bytes to send.

Due to space limitation, we elaborate on how eTran enables a flexible development model covering transport developers, application developers, and more in Appendix C.

5 eTran Implementation

Our eTran prototype contains 24K lines of C/C++, spreading across the Linux kernel, control path daemon, eBPF programs, and user-space transport library, as shown in Table 1. The

Category	Kernel	Control path daemon	eBPF programs: TCP/Homa	Transport libs: TCP/Homa
LoC	2597	8224	2173/5349	3661/2024

Table 1: eTran codebase breakdown with 24028 LoC in total.

current prototype runs on Linux kernel v6.6.0 and targets Mellanox mlx5 driver. Our Linux kernel change includes the two new hooks, the new eBPF map with associated kfuncs (for packet manipulation), `bpf_rbtree`'s new API as a kfunc, and AF_XDP's out-of-order completion with mlx5 driver support. We only make ~20 LoC change for the mlx5 driver, so that the driver can maintain the addresses of packet frames that get queued in the pacing engine, and only place them in the completion ring when they are eventually transmitted.

eBPF verifier. eTran does not change the verifier but just registers new eBPF hooks and kfuncs with the verifier for safety and security. In general, there are three types of checks done by the eBPF verifier: (a) eBPF program behaviors (e.g., bounded loops, NULL pointers, deadlock, etc.), (b) how eBPF programs access input contexts, and (c) how eBPF programs use eBPF helpers and kfuncs. Naturally, the eBPF verifier checks (a) for all eTran eBPF programs. It also checks (b) for `XDP_GEN` and `XDP_EGRESS` similarly to the existing XDP.

For (c), the principle is that eBPF programs must call these helpers and kfuncs safely and securely. For safety, we ensure the used kfuncs (either wrapped from the existing kernel functions or written by us) are non-preemptible and have finite execution steps. For example, our `XDP_EGRESS` hook uses the kfunc wrapped from the kernel `dev_xdp_enqueue()` function, which meets the safety requirement as it was designed to run in the softirq context. Our added kfunc for `bpf_rbtree` follows the implementation practice of existing eBPF helpers with extensive testing; nevertheless, we plan to verify it formally in the future. For security, we expose only necessary eBPF helpers to our new hooks and carefully reason through its security implications. The eBPF helpers exposed to the new hooks are only a `subset` of the ones exposed to XDP by kernel developers. For example, we exclude all socket-related helpers (e.g., `bpf_sk_lookup_tcp`) as the new hooks don't access these sockets; we exclude `bpf_redirect_map` for `XDP_GEN` to prevent redirecting packets arbitrarily.

6 Evaluation

This section aims to answer the following questions:

1. What are the latency and throughput of TCP and Homa under eTran compared to existing kernel ones and kernel-bypass ones (§6.1 and §6.2)?
2. How well does eTran support multi-tenancy and traffic management (through our new eBPF map) (§6.3)?
3. What is the performance of our new eBPF hooks (§6.4.1) and retransmission design (§6.4.3)?

Experiment setup. We use 10 `xl170` physical machines from CloudLab [19], each equipped with two 10-core Intel E5-2640v4 CPUs (2.4GHz), 64GB memory, and a Mellanox ConnectX–4 25 Gbps NIC. All machines are connected via a Mellanox 2410 switch under the same rack. For eTran (Homa/TCP) and Linux (Homa/TCP), all machines run Linux kernel v6.6.0. For TAS, we are unable to run it on Linux kernel v6.6.0 due to Mellanox driver issues, but we manage to run it on Linux kernel v5.15.0. Since TAS is built atop DPDK, we expect no performance differences between the two kernel versions. We only enable TCP Segmentation Offload (TSO) for Linux (Homa/TCP) as AF_XDP does not currently support it (see §7). There is no zero-copy optimization for eTran for a fair comparison (i.e., keep API semantics the same). Following prior work [80, 81], we disabled the NIC interrupt coalescing feature. All experiments use the default maximum packet size (MTU) of 1500 bytes. For DCTCP, we set the ECN marking threshold to 70KB, as done in prior work [55].

Comparison baselines. We compare eTran (Homa) to Linux/Homa (commit `8321cde`), a kernel module implementation of Homa that is highly optimized by the Homa authors. We refer to it as Linux (Homa) throughout this paper. We compare eTran (TCP) to TAS (commit `d3926ba`), a microkernel-style user-space TCP stack built on DPDK, and Linux (TCP) with DCTCP congestion control. By default, for eTran and TAS, we separate CPU cores for applications and interrupt processing/busy polling, and provision a dedicated core for control path/slow path. Linux (Homa) and Linux (TCP) use all provisioned cores to handle network load and applications.

6.1 Comparision with Linux (Homa)

Microbenchmarks. We first compare the basic latency and throughput between eTran (Homa) and Linux (Homa). We use a similar configuration described in the Homa paper [55]. The median latency of short messages and the throughput of large messages are measured by using a single client thread to send back-to-back requests (32B/1MB) to a single-threaded server, which responds with a 32-byte response. Next, we measure the throughput of a multi-threaded server receiving concurrent RPCs (500KB) from 7 clients, as well as the throughput of a multi-threaded client sending concurrent RPCs to 7 servers. Finally, we measure the RPC rate for small messages (32B), maintaining the same client-to-server ratio.

Table 2 summarizes the result. eTran (Homa) achieves lower median latency than Linux (Homa), i.e., 11.8μs vs. 15.6μs. eTran (Homa) outperforms Linux (Homa) in large message throughput, even with Linux (Homa) using TSO batching. In terms of RPC rate, eTran (Homa) achieves approximately 1.7-1.8$\times$ the message throughput of Linux (Homa). This gap is because eTran (Homa) uses AF_XDP for efficient packet IO while Linux (Homa) has a larger code path and uses costly structures like `sk_buff`.

Cluster benchmark. All the following experiments utilize the same cluster benchmark application from Linux (Homa) [55], conducted with 10 machines. In this experiment, each node serves as both a multi-thread client and a multi-thread server simultaneously. Clients randomly select servers to issue a batch of RPCs. Given that the data of modern RPCs primarily

	eTran (Homa)	Linux (Homa)
32B median latency (μs)	11.8	15.6
1MB throughput (Gbps)	17.7	14.5
Server throughput (Gbps)	23.0	23.1
Client throughput (Gbps)	22.7	22.9
Client RPC rate (Mops)	2.9	1.7
Server RPC rate (Mops)	3.3	1.8

Table 2: Comparison of basic latency and throughput between eTran (Homa) and Linux (Homa).

flows in one direction [64], we vary the request size up to 1MB while keeping the response size fixed as a small message. We use workloads W2-W5 in Homa paper [55] where W2 and W3 are dominated by short messages and W4 and W5 are dominated by large messages. Slowdown is the client-observed RTT divided by the ideal RTT for the same-length RPCs using eTran (Homa). For fairness, eTran (Homa) is configured with the same parameters as Linux (Homa).

Figure 5 shows the latency slowdown for workloads W2-W5. eTran (Homa) outperforms Linux (Homa) across all workloads. For the short message dominated workloads W2 and W3, eTran (Homa) achieves 3.9-7.5× lower P99 tail latency and 1.4-3.6× lower P50 latency compared to Linux (Homa). This is because: for W2 and W3 where the bottleneck is software overhead, eTran (Homa) leverages AF_XDP to achieve more efficient packet processing. For W4 and W5, which mainly consist of large messages, eTran (Homa) also slightly outperforms Linux (Homa). eTran (Homa) occasionally experiences higher tail latency than Linux (Homa) for large messages. This is because less optimized thread scheduling in eTran (Homa) causes interference between the pacing thread and applications; Linux (Homa) also faced this issue but mitigated it by carefully scheduling both threads to ensure pacing neither falls behind nor dominates CPUs. We plan to incorporate such transport-specific scheduling policies in the future, possibly through eBPF as well [63].

Figure 6 shows the RTT distributions for the shortest messages (10%) in W4 and W5, where eTran (Homa) achieves lower latencies across almost all percentiles. For example, eTran (Homa) achieves 4.1× lower P50 latency than Linux (Homa) in W4 and 3.9× lower in W5. The P99 latency is reduced by 4.3× in W4 and 2.9× in W5.

6.2 Comparision with Linux (TCP) and TAS

We built two POSIX API-based applications: a simple echo server and a key-value store derived from the TAS codebase (modeled after Memcached). The server handles requests using `epoll()`, and the client generates requests in a closed loop. All systems use the same binary but link to different POSIX implementations (e.g., Linux, TAS, and eTran).

Message throughput. Figure 7a shows the throughput of transferring a single back-to-back large message. eTran (TCP) performs comparably to Linux (TCP) but slightly lags behind TAS; for messages under 64KB, eTran (TCP) surpasses Linux (TCP). Figure 7b shows the throughput for small messages

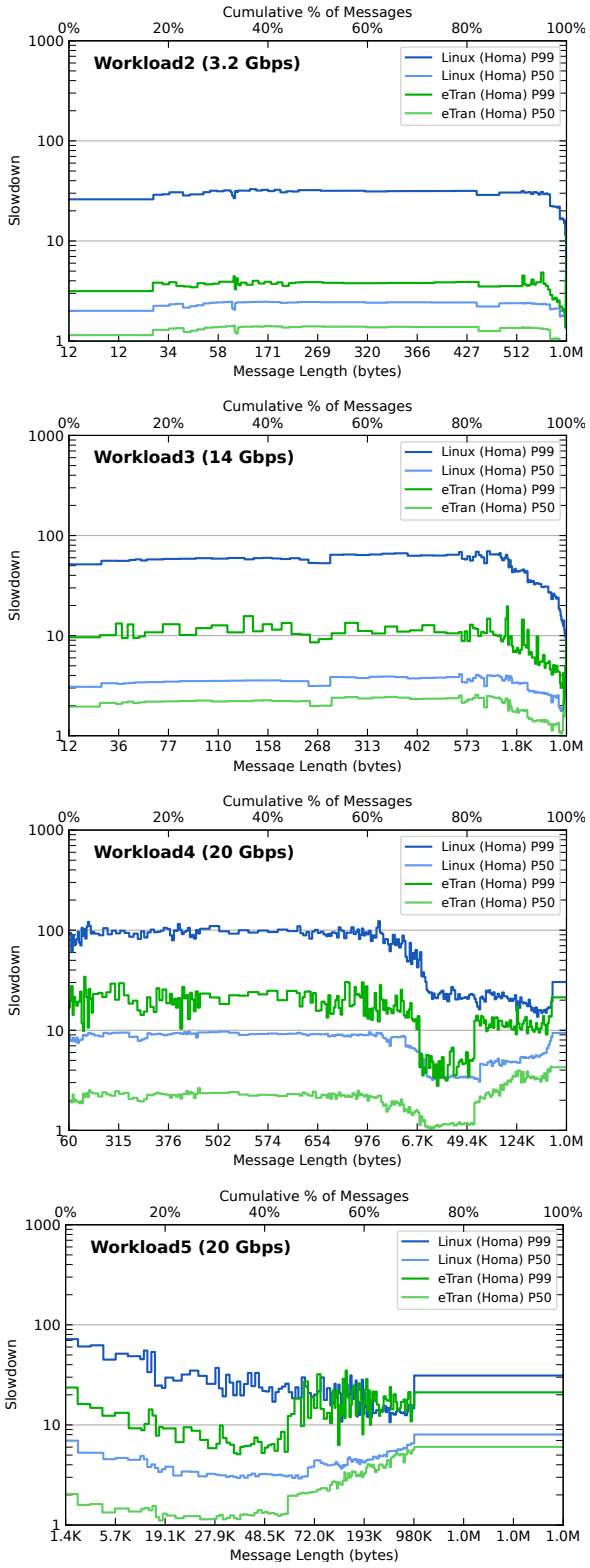

Figure 5: Median and 99th-percentile latency slowdown vs. message size for workloads W2–W5. The x-axis is scaled linearly to represent the number of RPCs, reflecting each workload's CDF of message lengths. W2 and W3 are dominated by short messages, while W4 and W5 feature larger messages.

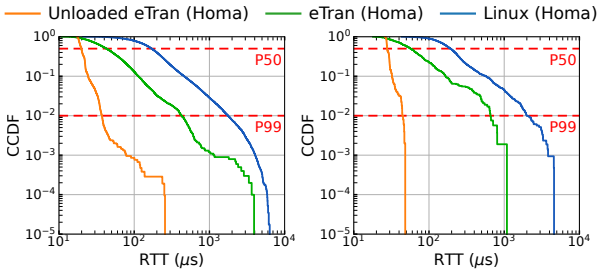

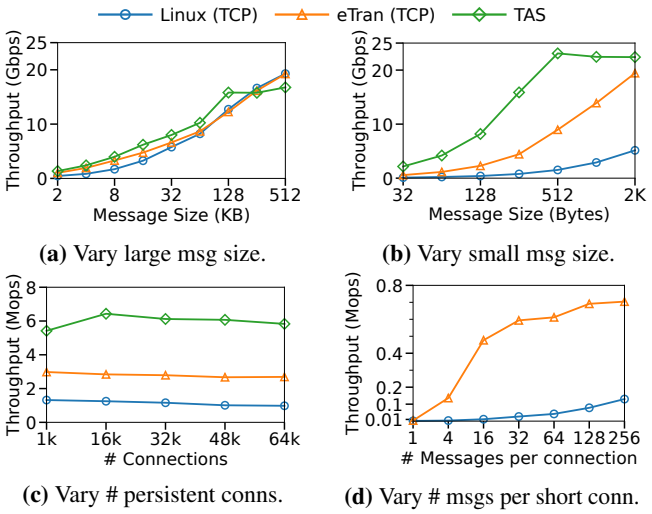

Figure 6: Complementary CDF of round-trip latency for the shortest 10% of RPCs in W4 (left) and W5 (right).

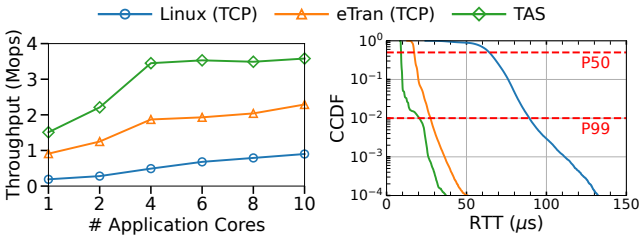
(a) Vary large msg size. **(b)** Vary small msg size.



(c) Vary # persistent conns. **(d)** Vary # msgs per short conn.

Figure 7: Comparison of message throughput for the TCP echo. Figure (a) has a single outstanding message, while Figure (b) has 64. TAS fails to achieve stable throughput for Figure (d), thus omitted.

with 64 outstanding messages per connection. This is measured using a single-threaded server handling 100 connections, partitioned across five clients each with five threads. For example, with 1KB messages, eTran (TCP) and TAS achieve 4.8× and 7.7× higher throughput than Linux (TCP), respectively. The gap between eTran (TCP) and TAS stems from TAS's use of dedicated cores for DPDK-based busy polling, while eTran (TCP) is interrupt-driven. Nevertheless, eTran (TCP) consistently outperforms Linux (TCP) across all message sizes and achieves 87% of TAS throughput for 2KB messages.

Connection scalability. We use as many clients as possible to generate the load with persistent connections. Clients send a single 64B request per connection and wait for a response in a closed loop. Figure 7c shows the result. The throughput of eTran (TCP) falls between Linux (TCP) and TAS: e.g., with 1K connections, eTran (TCP) achieves 2.26× the throughput of Linux (TCP), while TAS achieves 4.1× the throughput of Linux (TCP). Linux suffers high syscall overhead with limited TSO/GRO benefits with many connections. eTran (TCP) batches processing but is still less efficient than TAS due to the performance gap between AF_XDP and DPDK [39].

Short-lived connections. In this experiment, the client uses four threads to establish a total of 1K short-lived concurrent flows with a single-threaded server. Upon receiving the server's response for each connection, the client immediately closes the connection and establishes a new one. The result for TAS is omitted as it fails to achieve stable throughput due to its implementation bugs. As shown in Figure 7d, with one message per connection, the throughput of eTran (TCP) and Linux (TCP) is similar. With four or more messages per connection, eTran (TCP) significantly outperforms Linux (TCP). For example, eTran (TCP) achieves 42.7× and 5.4× the throughput of Linux (TCP) with 16 and 256 messages per connection, respectively. This is because the eTran (TCP) control path uses AF_XDP to perform efficient packet IOs for connection handshake and teardown, while the data path utilizes efficient LRPC to communicate with the control path.

(a) KV tpt vs. #app cores. **(b)** CCDF of KV RTT.

Figure 8: Performance comparison of the TCP key-value store.

Key-Value Store. We use a workload that has 100K key-value pairs (32B keys, 64B values) following a Zipf (s=0.9) distribution, with a 9:1 GET to SET ratio. Each of the five client machines establishes 6K persistent connections, leaving 32 outstanding requests per connection. Figure 8a shows that eTran (TCP) achieves 2.4-4.8× the throughput of Linux (TCP), with lower performance than TAS (which achieves 3.9-7.9× of Linux). Figure 8b provides more detailed insights into the latency when the server is under-loaded: eTran (TCP) has slightly higher latency than TAS but is significantly lower than Linux (TCP). More specifically, eTran (TCP) achieves 3.7× (17.2 µs vs. 64.2 µs) lower P50 latency and 3.2× (27.5 µs vs. 89.3 µs) lower P99 latency compared to Linux (TCP).

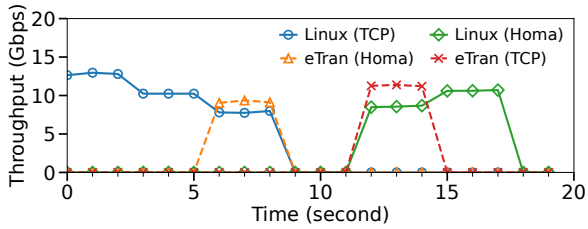
6.3 More Features

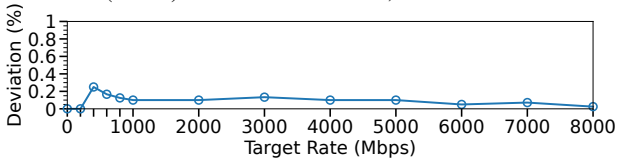
6.3.1 Multi-Tenancy and Coexistence

eTran (TCP/Homa) supports multi-tenancy and can coexist with Linux (TCP/Homa), thanks to XDP/AF_XDP not taking over the entire NIC. Figure 9 shows the throughput timeline when using different protocols. Launching our control path slightly reduces Linux throughput due to the extra XDP processing. This overhead can be removed by loading XDP on isolated queues from Linux (TCP/Homa) [71] and using hardware mechanisms (e.g., Flow Director [16]) for isolation.

6.3.2 Traffic Management

As an example, we show that eTran enforces accurate rate limiting with low overhead using `PKT_QUEUE` and pacing engine (§3.2.2). eTran tail-calls a simple eBPF program after `XDP_EGRESS` to retrieve the target rate from a policy table and





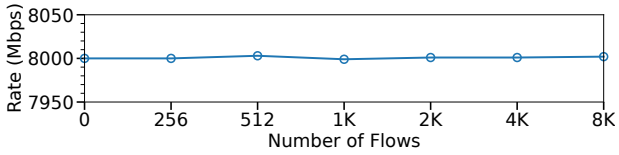


Figure 9: At 0 sec, APP1 starts TCP flows. At 3 sec, eTran launches the control path and loads eBPF. At 5 sec, APP2 sends RPCs with eTran (Homa). At 9 sec, both apps exit, and the control path switches protocols. At 12 sec, APP3 runs eTran (TCP), and APP4 sends RPCs with Linux (Homa). APP3 exits at 15 sec, and APP4 at 18 sec.

(a) The deviation from the target rate of eTran for a single flow.

(b) The actual rate achieved by eTran with a target rate of 8Gbps.

Figure 10: Rate conformance of eTran.

calculate the timestamp; it then uses this timestamp in the pacing engine to regulate the traffic rate. Figures 10a and 10b show rate conformance for single and multiple flows, with deviations under 0.4% as the rate and flow count increase.

6.4 Design Drill-Down

6.4.1 eBPF Hook Performance

We show that our new hooks offer powerful functionalities with minimal overhead. We employ three benchmarks from `bpf-examples` [9]: `tx-only` for small packet transmission, `l2fwd` for layer 2 forwarding, and `rx-drop` for packet discarding. 64B packets are used to stress test the performance.

XDP_EGRESS overhead. Table 3 shows that an empty hook reduces throughput by 6.6%. Out-of-order completion further lowers it to 86.1%. The primary overhead in `XDP_EGRESS` comes from constructing new packet buffers, which is mitigated by pre-allocations (§3.2.1). The overhead of out-of-order completion comes from higher cache miss rate incurred by increased memory footprint. As a reference, the table also notes the cost of map lookup operations in `XDP_EGRESS`.

XDP_GEN performance. We run `rx-drop`+XDP_GEN on two cores: one core generates ACK/credit packets using XDP_GEN, and another uses AF_XDP to drop received packets. We compare it to `l2fwd` on two cores: one core in the kernel redirects packets to AF_XDP, and another uses AF_XDP to forward packets back as ACK/credit packets. Table 4 shows that our overall throughput is slightly lower than `l2fwd` but with higher per-core throughput. This is because we avoid cross-core communication for ACK/credit packet transmission, as it is done inside the kernel. We conclude that `XDP_GEN` is efficient enough in transmitting ACK/credit packets.

Action	Tpt (Mpps)	Tpt loss (%)
AF_XDP `tx-only`	11.55	-
+ Empty XDP_EGRESS	10.79	6.6
+ OOO comp	9.95	13.9
+ ARRAY lookup	9.71	15.9
+ HASHMAP lookup	9.10	21.2

Table 3: Performance of XDP_EGRESS (single core).

	Tpt (Mpps)	# cores	Per-core tpt (Mpps)
`l2fwd`	6.73	1.74	3.87
`rx-drop` + XDP_GEN	6.03	1.35	4.47

Table 4: `l2fwd` vs. `rx-drop` + XDP_GEN on receiving data packets and responding with ACK/credit packets.

6.4.2 CPU Overhead Breakdown

Table 5 presents the CPU overhead across the networking stack for a multi-threaded server. We stress-test transport processing with a single NAPI, isolating it from applications explicitly for all systems. We made great efforts to tune the Linux stacks to be even better than the one reported in [55] under the same hardware. Note that this configuration is not general for all applications. Per-function cycles are obtained using Perf [29] and categorized with tools extended from [12]. Homa incurs higher overheads than TCP in both implementations due to frequent allocation/destruction for small RPCs. eTran significantly reduces primary overhead (*Socket/RPC*, *TCP/Homa+IP*) through streamlined implementation, with optimizations to *Sk_buff*, *Memory Mgmt* via lightweight xdpbuff and pre-allocated UMEM. *Scheduling* is optimized through batched IO and decoupled kernel transport processing. For Linux, per-request context switching incurs higher instruction counts, pipeline stalls, memory footprint, and poor cache locality [41]. *Other* overheads (e.g., security checks, kernel/user mode switching) are reduced due to file system bypassing and AF_XDP's syscall-free asynchronous IO.

6.4.3 Impact of Retransmission Design

We show that retransmission handling in the control path matches Linux (Homa) and Linux (TCP) performance. By launching 100 flows between two machines and measuring throughput under varying loss rates, Figure 11 shows the throughput penalty of different protocols. eTran (TCP) incurs a larger throughput penalty than TCP due to limited out-of-order optimization. Homa's retransmission is simple as packet loss is rare; both eTran (Homa) and Linux (Homa) show similar throughput decline. Due to space constraints, we show additional experiments on control path CPU usage, multi-queue impact, and interrupt interference in Appendix D.

7 Discussion and Future Work

Emerging kernel techniques. Many emerging kernel techniques inspire eTran design or might help improve eTran per-

Component	eTran (T)	Linux (T)	eTran (H)	Linux (H)
Application	0.48	0.53	0.95	1.04
Socket/RPC	0.63	**3.5**	0.98	**3.38**
Data copy	0.19	0.57	0.32	1.30
Sk_buff	0.15	0.47	0.08	0.39
TCP/Homa+IP	1.06)	**2.12**	1.47	**3.36**
Lock/Unlock	0.18	0.45	0.24	2.68
NIC Driver	1.17	1.54	0.83	1.81

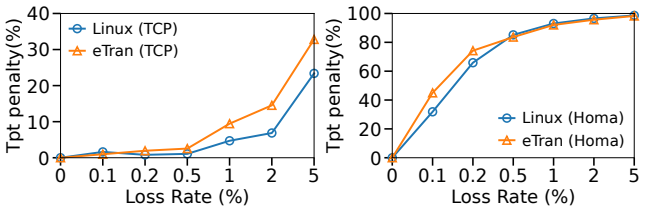
Scheduling	0.25	1.19	0.18	1.02
Other	0.21	1.82	0.38	1.41
Total (kcycles)	**4.37**	**12.51**	**5.48**	**17.43**

Table 5: Breakdown of CPU Cycles per Request. **T**: TCP; **H**: Homa.



formance. For example, the Linux kernel community made efforts to introduce queueing for XDP when redirecting among different network interfaces [33]; instead, our pacing engine is to provide a general queueing mechanism for packet transmission. We also note that the existing Linux qdisc (queueing discipline) cannot sustain the high packet rate as our pacing engine [62]. From Linux kernel v6.6, some NIC drivers support AF_XDP multi-buffer [22], enabling features like TSO and scatter/gather. Unfortunately, the mlx5 driver we are using does not support them yet; we expect it could help improve eTran's performance for large messages/long flows.

Improving eBPF programming. eTran suffers from limited synchronization support in eBPF programming. For example, eBPF prohibits holding two locks simultaneously, posing significant challenges for implementing Homa's credit list (§4.2). Another example is that eBPF lacks blocking synchronization primitives like Mutex, necessitating careful spinlock use. We understand this limitation is rooted in the fact that the eBPF execution is non-sleepable and non-preemptable to simplify safety verification, but any relaxation of it would hugely simplify eBPF programming for complex applications.

eTran limitations. eTran relies on the eBPF subsystem to customize transports, suffering from similar limitations as eBPF. For example, eBPF does not support floating point arithmetic, motivating eTran to adopt the CCP architecture to separate CC into the control path daemon for sender-driven transports. Currently, eTran depends on the kernel for CPU scheduling, which can lead to tail latency issues, as noted in prior works [24, 54]. In addition, since AF_XDP bypasses kernel layers, eTran lacks the integration of other kernel subsystems such as file system. We leave them for future work.

8 Related Work

High-performance network transports. There has been a line of work on high-performance transports, e.g., mTCP [36], IX [4], Arrakis [57], TAS [41], eRPC [38], Snap [47], Demikernel [78] and Junction [23]. Most rely on kernel-bypass, busy polling to achieve high performance and co-locate with applications in the same process context (*library OS*). In contrast, eTran transports operate within the kernel interrupt-driven NAPI context, with protection ensured by eBPF. This trades performance for CPU efficiency and prevents applications

(a) Comparison of TCP. **(b)** Comparison of Homa.

Figure 11: Throughput penalty at varying packet loss rates.

from interfering with transport processing and states. Both IX and Arrakis provide transport protection for *library OS*. However, IX repurposes virtualization hardware non-standardly, while Arrakis relies on NIC virtualization, which is more limited and inflexible than software-based approaches. TAS and Snap separate the kernel-bypass transport on isolated cores from applications (*Microkernel*). Although retaining flexibility, it must reimplement many functionalities from scratch. Conversely, eTran still uses some kernel networking infrastructures, and new transports can co-exist with existing kernel ones. eTran also differs from *kernel* transports: eTran transports are split to the control path (user-space) and the data path (kernel eBPF); the untrusted library uses AF_XDP socket for efficient IO and metadata exchange (rather than relying on syscalls), while being restricted from directly accessing kernel transport states maintained in eBPF. This design enables safely customizing high-performance kernel transports.

eBPF verification. eTran relies on verification techniques to guarantee the safety of running application-supplied eBPF programs inside the kernel. Therefore, a bunch of eBPF verification work in this space such as [8, 40, 46, 69, 73, 76] would benefit eTran and enhance our kernel safety and security.

Kernel offloads. Offloading application functions to the kernel via eBPF has recently emerged to avoid kernel overheads and improve performance [11, 27, 37, 56, 59, 79–81]. Different from offloading applications via eBPF, eTran targets making kernel transport extensible by extending eBPF subsystems.

Extensible kernels. eTran adopts a similar approach that is reminiscent of the extensible kernel research in the 1990s such as SPIN [7], Exokernel [21], and VINO [65]. The key difference is that eTran relies on existing kernel eBPF subsystem for safety and targets performance-hungry network transports in modern datacenters. There is a line of recent work on making kernel TCP more extensive via eBPF [10, 31, 35, 70, 77]. However, they only focus on the TCP transport and allow customizing a small portion of TCP behaviors such as initial congestion window, CC schemes, and path management.

9 Conclusion

eTran is an extensible kernel transport system, achieving agile customization, kernel safety, strong protection, and high performance simultaneously. It achieves these goals by extending the kernel-safe eBPF, hiding transport states inside the kernel, and absorbing techniques from user-space transports. eTran code is available at https://github.com/eTran-NSDI25/eTran.

APPENDIX

A Implementing More Transports

In this section, we extend our case studies beyond Homa and TCP, exploring the implementation of other transport protocols (specifically, their host logic) under eTran. We focus on congestion control (CC) while loss recovery and segmentation/reassembly are omitted as they are less important.

Swift [44] is a representative RTT-based transport protocol. It adjusts the congestion window using RTT measurements and distinguishes fabric congestion from host congestion. Swift's CC algorithm can be implemented entirely in XDP. Swift typically uses window control and switches to rate-based pacing when the congestion window falls below 1. This can be implemented with two maps of `BPF_MAP_TYPE_PKT_QUEUE`. Swift requires NIC hardware timestamp, which can be provided via XDP RX metadata [43].

HPCC [45] is a transport protocol that utilizes in-network telemetry (INT) to gather precise load information for CC. The CC algorithm on the sender side of HPCC can be implemented using XDP. Additionally, HPCC employs rate-based pacing with window boundaries, which can be implemented similarly. Specifically, HPCC incorporates a flow scheduler that scans all flows to assign credits. Only flows that have accumulated sufficient credits and are within the window limit can be transmitted. This flow scheduler can be implemented using the dedicated kthread of the BPF timer.

DCQCN [82] is another ECN-based transport protocol that integrates with QCN. On the sender side, DCQCN controls the sending rate using a per-flow timer and a byte counter. The byte counter is updated in XDP, while the per-flow timer can be implemented using an array of BPF timers. Each connection tracks the index of its corresponding BPF timer, similar to how the CC state index is managed in DCTCP. DCQCN enforces rate control entirely based on the rate, which can be implemented similarly to DCTCP.

NDP [30] is a receiver-driven transport protocol that incorporates packet trimming. The receiver-driven logic and credit-based pacing can be implemented similarly to Homa. The main difference is that NDP does not prioritize short messages like Homa. Instead, it lets all flows share bandwidth fairly by default.

B RBtree Operations

The fundamental approach involves utilizing a single red-black tree to manage two distinct trees. We assume each machine is assigned a unique *peerid*, and each RPC is identified by a unique *rpcid*, which consists of a five-tuple. The first tree, termed the *RPC Tree*, maintains the states of all RPCs. The second tree, referred to as the *Peer Tree*, tracks the highest priority RPC from each peer. In the *RPC Tree*, the key for lookups is defined as (treeid = 0, peerid, bytes_remaining, rpcid). In the *Peer Tree*, the key for lookups is defined as (treeid = 1, bytes_remaining, peerid). Keys are compared from left to right. All operations are performed using three APIs: `bpf_rbtree_add()`, `bpf_rbtree_remove()`, and `bpf_rbtree_lower_bound()`, which have the time complexity of $O(\log N)$.

Operations in XDP. When XDP receives a new RPC that needs to be scheduled, it creates an object and inserts it into the *RPC Tree* and takes a snapshot of the value of bytes_remaining in the RPC state for future search. Subsequently, XDP tries to adjust the *Peer Tree*. It starts by searching the *RPC Tree* using the key (treeid = 0, peerid = our_peerid, bytes_remaining = 0, rpcid = 0).

1. If the search results in (treeid $\neq$ 0 or peerid $\neq$ our_peer or rpcid $\neq$ our_rpcid), it indicates that we are not the highest priority RPC for this peer, and no further action is taken.
2. If the search results in (treeid = 0 and peerid = our_peer and rpcid = our_rpcid), it indicates that we are the highest priority RPC for this peer. In this case, we search the *RPC Tree* with the key (treeid = 0, peerid = our_peer, bytes_remaining = our_remaining, rpcid = our_rpcid + 1) to determine if a previous highest priority RPC exists. If such an RPC is found, it is removed from the *Peer Tree*. The new RPC is then inserted into the *Peer Tree*, and its status is marked as present in the *RPC Tree*.

When a new batch of packets arrives for this RPC, a search is performed in the *RPC Tree* using the key (treeid = 0, peerid = our_peer, bytes_remaining = snapshot_bytes_remaining, rpcid = our_rpcid). If no matching object is found, it indicates that the RPC has fully used granted, and no action is needed. Otherwise, it is removed from the *RPC Tree*, its bytes_remaining value is updated, and it is reinserted into the *RPC Tree*. Then, we adjust the *Peer Tree*:

1. If the RPC is already present in the *Peer Tree*, indicating it is still the highest priority RPC from this peer, the key (treeid = 1, peerid = our_peer, bytes_remaining = snapshot_bytes_remaining, rpcid = our_rpcid) is used to search for it in the *Peer Tree*. Then, the object in the *Peer Tree* is removed and reinserted.
2. If the RPC is not present in the *Peer Tree*, the case is treated as a new RPC state.

Operations in XDP_GEN. In XDP_GEN, the key (treeid = 1, bytes_remaining = last_min, peerid = last_peerid + 1) is used to search the *Peer Tree*, where *last_min* and *last_peerid* represent the last minimum bytes_remaining and the last peerid used, respectively. They both start from zero. If the RPC has completed its grant, it is removed from the *Peer Tree*, and the resulting information is then used to search and remove the RPC from the *RPC Tree*.

```

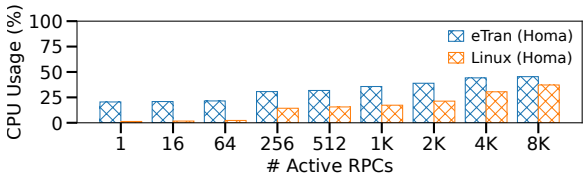
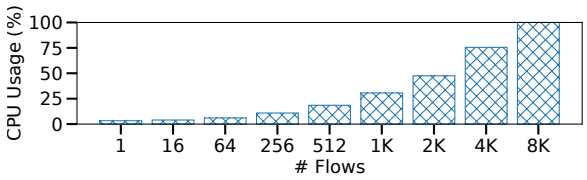
Listing 1: Transport component hooks and corresponding APIs.

C Development Model



eTran envisions a flexible development model targeting different levels of developers. For transport developers familiar with eBPF programming and transport implementation such as timers and loss recovery, eTran provides a set of low-level APIs for them, as shown in Listing 1. The transport developers can quickly prototype customized transports by directly leveraging these APIs or based on our implementation of Homa and TCP (§4) and then safely deploy them in the Linux kernel. For application developers who focus on user-space application development, they can specify which transport (among eTran-supported ones) to use for their applications. For site reliability engineers and networking administrators, eTran further enables them to conveniently fine-tune the parameters or implementation (thus the performance) of these transports.

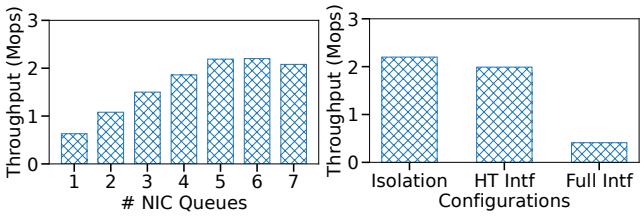
We note that our development model is conditioned on the new eBPF hooks and maps in eTran being upstreamed into the Linux kernel. Although this is partially out of the scope of our eTran research, we have tried to minimize changes to the existing kernel eBPF subsystems, thus being friendly to existing eBPF applications as far as we know. Another important factor that determines whether eTran can be upstreamed into the kernel is security, which we elaborate on in §5.



D Additional Design Drill-Down

D.1 CPU utilization of Control Path

We now examine the control path CPU utilization for Homa and TCP. In eTran (Homa), the control path uses a timer thread to check RPC states from the kernel. In eTran (TCP), it runs the CC algorithm and timeout detection. In this experiment, eTran (Homa) performs lookups with a batch size of 16, and eTran (TCP) employs a CC interval of 200μs. We vary the number of RPCs/flows and measure the CPU usage of the control path, the result is shown in Figure 12a and Figure 12b. Both eTran (Homa) and eTran (TCP) exhibit increased CPU usage as the number of RPCs/flows grows. Compared with Linux (Homa), eTran (Homa) incurs higher CPU overhead because it relies on system calls to look up transport states. For eTran (TCP), 8K connections can saturate one CPU core. The control path of eTran (TCP) can be scaled out by partitioning connections across multiple threads.



(a) eTran (Homa) vs. Linux (Homa)

(b) eTran (TCP)

Figure 12: CPU usage of eTran (Homa), Linux (Homa), and eTran (TCP), under different numbers of RPCs/flows.

(a) Impact of multi-queues. **(b)** Interrupt interference.

Figure 13: Throughput comparison under different configurations.

D.2 Impact of Multiple Queues and Interrupt Interference

We now examine whether eTran can scale with the NIC queues. We take TCP as an example, as Homa doesn't work well with RSS. We replicate the connection scalability experiment described in §6.2, fixing the number of CPU cores for the application while varying the number of NIC queues. 32K connections are separated across five clients. Figure 13a shows that eTran scales with NIC queues from 1 to 5, but beyond that, throughput slightly declines. This is due to multiple application threads requiring locked access to the Fill ring and Comp ring.

We are also interested in the performance of eTran when the application cores are collocated with the NAPI cores. We conduct the same experiment above with three configurations: 1) separate to different physical CPU cores, 2) separate to different logical CPU cores, and 3) combine on same logical CPU cores. Figure 13b shows the result. The performance of the second configuration is lower than the first mode due to Hyper-Threading (HT) interference. The third configuration exhibits poor performance due to the serve interference between application threads and NAPI [81]. Considering eTran offloads all transport states in eBPF, how to utilize eBPF for CPU scheduling [63] to optimize eTran is an interesting direction. We leave it as future work.

White-Boxing RDMA with Packet-Granular Software Control

Chenxingyu Zhao[1], Jaehong Min[1], Ming Liu[2], Arvind Krishnamurthy[1]
[1]University of Washington, [2]University of Wisconsin-Madison

Abstract

Driven by diverse workloads and deployments, numerous innovations emerge to customize RDMA transport, spanning congestion control, multi-tenant isolation, routing, and more. However, RDMA's hardware-offloading nature poses significant rigidity when landing these innovations. Prior workflows to deliver customizations have either waited for lengthy hardware iterations, developed bespoke hardware, or applied coarse-grained control over the black-box RDMA NIC. Despite considerable efforts, current customization workflows still lack flexibility, raw performance, and broad availability.

In this work, we advocate for *White-Boxing* RDMA, which provides control of the hardware transport to general-purpose software while preserving raw data path performance. To facilitate the white-boxing methodology, we design and implement *Software-Controlled RDMA (SCR)*, a framework enabling packet-granular software control over the hardware transport. To address challenges stemming from granular control over high-speed line rates, SCR employs effective control models, boosts the efficiency of subsystems within the framework, and leverages emerging hardware capabilities. We implement SCR on the latest Nvidia BlueField-3 equipped with Datapath Accelerators, delivering a spectrum of new customizations not present in legacy RDMA transport, such as Multi-Tenant Fair Scheduler, User-Defined Congestion Control, Receiver-Driven Flow Control, and Multi-Path Routing Selection. Furthermore, we demonstrate SCR's applicability for GPU-Direct and NVMe-oF RDMA with zero modifications to machine learning or storage code.

1 Introduction

Remote Direct Memory Access (RDMA) empowers data center workloads with high-performance networking thanks to hardware-offloaded transport. However, as deployments shift from single-tenant lossless fabric to multi-tenant lossy Ethernet and applications expand from HPC to storage and GPU communication, a one-size-fits-all approach to RDMA hardware transport is inadequate. Consequently, extensive innovations have emerged to customize RDMA transport. From the industry, Microsoft Hyperscale Deployment [1–3], Google Falcon [4], AWS SRD [5], Meta [6], Alibaba HPN [7], and the Ultra Ethernet Consortium (UEC) [8], among others, are driving RDMA transport customizations at scale. This is supplemented by academic contributions spanning topics such as congestion control [9–16], multi-tenant isolation [17–19], routing [20, 21], reliability [22–24], and more.

Although the innovations are in full swing, RDMA's hardware nature imposes significant rigidity on integrating these customizations. Fundamentally, ASIC hardware iterations are expensive both in terms of time and monetary cost. For instance, DCQCN congestion control [2] baked into ASICs by Microsoft and vendors of RDMA NIC (or RNIC) has persisted for nearly a decade. Despite subsequent congestion control innovations, the hardware rigidity has hindered the integration of new ideas. Some cloud providers have explored bespoke hardware or FPGA RNICs [25, 26], but these solutions still require substantial efforts and lack widespread availability compared to commercial RNICs. Alternatively, software-based approaches [18, 24, 27, 28] treat RNIC hardware transport as a black box, enforcing customizations through upper-layer mediators. However, these software overlay mediators are coarse-grained at the message/verb granularity (up to GB in size) instead of the transport-layer packet granularity (typically 1024B) and introduce additional processing overhead, leading to latency penalties and security concerns [17].

Inspired by the successful practice of white-boxing switches [29–34], we propose *white-boxing* RDMA, a new methodology to customize RDMA hardware transport. Historically, switch vendors tightly integrated control logic with hardware data planes, limiting flexibility for user-defined control. With white-box switches, control planes run in customizable software while preserving the data plane in high-performance hardware, sparking a series of SDN innovations over the last decades. Similarly, we advocate the same methodology for the current RNIC; we expect to take transport control from the hardware into software for flexible customization while keeping the data path in performant hardware.

Besides the need for customization, another key enabler for white-boxing RDMA is the advancements of SmartNICs [35–40]. SmartNICs provide two building blocks for white-boxing RDMA: computational power and control interfaces. Taking the latest Nvidia BlueField-3 (BF3) as one example, it interposes general-purpose Datapath Accerlators (DPA) in line with the data path, potentially supporting flexible control logic without incurring host-side CPU overhead. Moreover, DPA features heavy multi-threading capabilities to keep pace with line-rate processing. DPA also leverages low-profile RISC-V designs to achieve energy and cost efficiency. These advancements pave the way for white-boxing RDMA.

Realizing the vision of white-boxing RDMA poses two main challenges: flexibility and efficiency. In terms of flexibility, we aim to accommodate diverse control functionalities that rely on various control signals, versatile control laws, and control actions. As for efficiency, fine-grained control over RDMA transport encounters challenges in keeping pace with high-speed line rates. For instance, at 100 GbE with a

1500B MTU, achieving 8.3 Mpps generates packet-granular signals (such as ACK and TX) at the sub-μs level (120 ns!). Processing signals at this granularity demands high efficiency, as even single access to DDR memory (hundreds of ns) entails a relatively significant time cost. Therefore, boosting processing efficiency is essential.

In this work, we introduce a control framework called *Software-Controlled RDMA (SCR)*. Drawing from classical control theory [41–43], SCR centers on two fundamental questions: *What to Control* and *How to Control*. Addressing the first question, we propose the *Dequeue Rate* control model, which regulates the rate at which the RNIC fetches messages from memory regions associated with queue pairs. This control knob serves diverse purposes across local-host, fabric, and peer-receiver domains (detailed in §4.2). As for *How to Control*, the SCR framework comprises three subsystems: signal/event collector, event queues, and event processor. These subsystems are carefully designed to tackle the challenges of flexibility and efficiency. The event collector aims to gather comprehensive signals from various domains, while event queues enhance efficiency through coalescing signals. For event processors, we build a Deterministic Multi-Threading (DMT) system to achieve high-efficiency and general-purpose processing (detailed in §4.3).

We prototype SCR on the latest Nvidia BlueField-3 SmartNIC. Specifically, we leverage BF3 DPA's *central* architecture position: DPA can interact with RNIC hardware, communicate with the host CPU, and inject traffic into the fabric. Moreover, implementing SCR using the DPA minimizes the host CPU's computational burden and operates in a *non-intrusive* manner for host-side applications and libraries. We successfully deliver a spectrum of new functionalities not present in legacy RDMA transport: 1) Achieving fair multi-tenant QP scheduling (up to 1.78x improvement in fairness index compared to the default scheduler; up to 52.8% latency reduction); 2) Enabling user-defined congestion control (Swift [10]); 3) Enabling multi-path routing selection (MP-RDMA [20]; PLB [44]); 4) Enabling receiver-driven control (Homa [15]). Importantly, we demonstrate that storage scenarios using NVMe-oF RDMA and machine learning using GPU-Direct RDMA can benefit from these customizations without any code changes to applications and libraries.

2 Background and Motivation

2.1 Why Customize RDMA

We first comprehensively summarize prior efforts in customizing RDMA transport and then identify the implications (*I*) for an RDMA customization framework.

• Better Congestion Control: To achieve lossless fabric, RoCEv2 employs PFC, which, despite its effectiveness, faces issues like PFC storms, HoL blocking, and deadlocks [3,45,46]. Mitigating these drawbacks, numerous congestion control algorithms have been developed, including Microsoft's ECN-based DCQCN [2], Alibaba's INT-based HPCC [9], Google's RTT-based Timely [47] and Swift [10], and ACK-Based ACC [11], showcasing how to customize RDMA congestion control, especially for hyper-scale lossy Ethernet. *I1: New types of signals from the transport layer enable improved forms of congestion control laws.*

• Stronger Multi-Tenancy Performance Isolation: RDMA transport bypasses in-kernel multi-tenant isolation mechanisms, resulting in inadequate multi-tenancy isolation within cloud environments. Studies such as Husky [19,48], and Harmonic [17] have demonstrated a pressing need for improved performance isolation among multi-tenants sharing RNIC. Solutions like Flor [24], X-RDMA [49], and Justitia [18] introduce a software mediation layer between the tenant and the RNIC driver, aiming to improve multi-tenant isolation. *I2: New measurements reveal the need to control new domains like RNIC micro-architecture and multi-tenant host.*

• Receiver-driven Flow Control: The many-to-one traffic pattern, common in GPU collective communications [50] and storage IO [1], often leads to incast congestion at the responder. This challenge is intensified by RDMA's one-sided operations, which are agnostic to responder-side controls. RCC [51] proposes receiver-driven congestion control for RDMA, with EQDS [16], Homa [15], NDP [52], and pHost [53] advocating for a receiver-driven control loop. *I3: Emerging workload patterns motivate new types of flow controls, such as receiver-driven flow control.*

• Per-Packet Multi-Path Routing: RoCEv2's default single-path routing ensures in-order packet delivery but fails to utilize the fabric's multiple paths. MP-RDMA [20] introduces mechanisms for multi-path routing. AWS SRD [5] emphasizes multi-path routing benefits for RDMA in the production environment. And switches such as Nvidia Spectrum [54] and Broadcom Tomahawk [55] support adaptive routing (per-packet ECMP). *I4: New types of routing controls like multi-pathing are beneficial for RDMA transport.*

RDMA transport customization is vast in the literature, and we present additional studies in Appendix Table 6.

2.2 How Prior Works Deliver Customization

RNIC offloads control functions onto rigid ASIC hardware, making reprogramming most customizations difficult. We compare prior efforts to deliver customizations as follows:

1) One approach is collaborating with RNIC vendors to integrate customizations into next-gen ASICs, such as Microsoft/Mellanox incorporating DCQCN into ConnectX. However, this method relies on hardware generation cycles, which typically span years.

2) Developing a bespoke RNIC from scratch using FPGA or ASIC. FPGA-based solution [17, 20, 26, 56, 57], despite significant engineering efforts, still generally exhibit discrepancies compared to native commercial RNIC ASICs, which have evolved over almost a decade to become a commodity. Cloud providers like AWS SRD [5], Google 1RMA [25], and

Falcon [4] can tape out custom ASICs, yet requiring substantial costs and expertise, and they are primarily utilized for internal operations rather than as broad commodities.

3) Software overlay solutions [16, 18, 24, 28, 58] provide userspace libraries over RNIC drivers. However, host software is limited to operating at Verb-level (*i.e.,* message level) and still treats the hardware transport as a black box to work around. Userspace libraries are not transparent to the host software stack because they customize drivers or insert mediators between the RNIC and applications. This added software mediator inevitably incurs a latency penalty [18, 24, 28], consuming host CPU cycles, and could raise security concerns for cloud tenants [17].

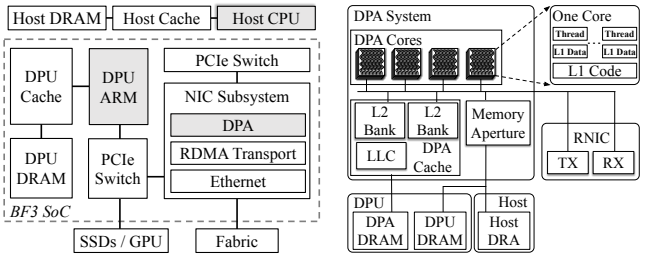
4) Fully software emulation like SoftRoCE [59] lacks the crucial property of hardware-accelerated data paths.

2.3 Our Goals

Flexible and Packet-Granular Control: In delivering RDMA customization, software agility surpasses hardware rigidity. Thus, we aim to leverage flexible software to enable diverse control functionalities. We aim to enforce packet-granular control at the hardware transport, a lower layer than userspace message-granular coarse-grained control.

Raw High-Performance Data Plane: High performance is crucial for RDMA; otherwise, people could opt for fully programmable transport like in-kernel TCP/IP. Thus, we adhere to the principle of *Zero-Intrusion* (or *Zero-Touch*) for the hardware data plane to maintain its original high performance.

Deployment Ready: We utilize commodity hardware to provide ready-to-deploy solutions and adhere to the principle of *smart-edge-dumb-core*, placing complex functionalities on end-host devices while keeping in-network switches simple. Next, we explore the capabilities of commodity hardware.



3 Characterizing Commodity Hardware

3.1 Requirements of Control System

Before characterizing existing hardware, we first examine the capabilities required for an ideal control system. Drawing from classic control theory's signal-driven feedback-loop [41–43], we identify three key components for an ideal control system: *signal collectors*, *processors*, and *action executor*. To achieve our design goals, these three components necessitate specific hardware capabilities. These requirements drive our following characterization.

3.2 Existing Hardware Model

As shown in Figure 1a, with the advancement of SmartNICs [35, 37, 38, 62], several processors within one server can be potentially utilized to implement the control system. Taking the latest BlueField-3 as an example, we have three options: Host CPU, DPU-embedded ARM CPU (off-path cores), or Datapath Accelerators (on-path cores). Next, we explore their potential capabilities and identify a suitable candidate.

(a) System Model (b) DPA Architecture

Figure 1: **System Model and DPA Architecture. Referring to Public Information Provided by the Vendor [60, 61].**

	Host CPU	DPU ARM	DPA
ISA	x86 Xeon	Arm v8.2+	RISC-V

Table 1: **Comparing Heterogeneous Processors.**

Testbed: Our testbed (used throughout the paper) consists of two servers connected to a 100GbE switch. Each server has dual Intel Xeon Gold 6346 processors, 384GB DDR4, PCIe Gen4, and an Nvidia BlueField-3 DPU with 100GbE cables. Each server is equipped with one Nvidia A30 GPU (24GB HBM2, 933GB/s memory bandwidth) with driver-550 and CUDA v12.4. The host machines run Ubuntu 22.04 with kernel 6.5.0, DOCA SDK v2.6, and SPDK v24.05. We configure SR-IOV VFs for multi-tenant support.

3.3 Characterizing Datapath Accelerators and Others

As Table 1 shows, we characterize the Datapath Accelerator (DPA) and compare it with Host CPUs and DPU ARM cores. We focus on micro-benchmarking the DPA because extensive research has already been conducted on x86/ARM cores [39, 63–66]. Chen et al. [63] characterizes the DPA from the architectural perspective. We investigate DPA functionalities relevant to the control requirements mentioned, for example, the fine-grained interaction between RNIC and DPA (*e.g.,* Programmable Congestion Control), not covered in [63].

DPA Overview: DPA is a general-purpose on-datapath co-processor. Figure 1a illustrates the conceptual position of the DPA within the BF3 overall architecture, and Figure 1b provides a detailed view of the DPA's micro-architecture. As Table 1 lists, DPA comprises 256 hardware threads and possesses its own cache and memory system. DPA can access the host memory and DPU on-SoC memory with load/store

(a) Multi-Thread Execution (b) PCC Events (WRITE Verb) (c) L2 Send/Receive (d) Memory Access Latency

Figure 2: **Characterizing Hardware Capabilities of Datapath Accelerators (DPA).**

instructions (*i.e.,* via memory aperture [60]). DPA can operate the RNIC, which is co-packaged on the same PCIe card.

For R1, Multi-threading Performance: DPA features heavily multi-threaded computation with 256 hardware threads (even more than the host's beefy x86 CPU). In Figure 2a, we conduct General Matrix Multiplications (GEMM) to assess scalability while increasing the number of threads (Each thread computes the tiled outer product of GEMM [67]). Each operation represents one multiplication. The scalability trend closely approaches a linear relationship.

Notably, DPA cores in low-profile and low-cost RISC-V are much less powerful than x86/ARM cores. As shown in Figure 2a, it may require up to 16 DPA threads to achieve equivalent processing capability as one ARM thread. Therefore, tailoring the functionality over a single DPA thread, which involves a low amount of code and lightweight operations, becomes necessary. Although DPA offers 256 threads, given these low-code constraints, we believe that the wimpy cores partially satisfy the R1 requirement.

For R2, Interaction with RNIC: The RNIC offers the Programmable Congestion Control module [68] for the DPA, facilitating fine-grained interactions between the RNIC and DPA. These include the DPA receiving per-packet signals (TX/ACK/NACK/CNP, detailed definitions in §4.3.1), measuring RTT by injecting the RTT request packet into the RNIC, and the RNIC providing APIs for the DPA to set per-flow rates. In Figure 2b, we measure the event rates while varying the link load. It is evident that the DPA can receive packet-granular events. Note that NACK (packet loss) and CNP (congestion) events are rare; hence, the bars representing them are small.

For R3, Raw Ethernet Capability: Since we need to send and receive small-sized control signals over fabric, we test DPA's communication APIs for transmitting data. These APIs operate at the raw L2 Ethernet level, allowing for flexible customization of L3/L4 protocols such as TCP/IP or UDP/IP. Figure 2c illustrates the performance of L2 sending and receiving. For a single thread, it achieves packet rates of about 1.8 Mpps, meeting the requirements for μs-scale communication. As the number of threads increases, single-thread performance degrades due to contention, but the total Mpps increases. Since control signal packets are generally small, we focus on Mpps for small packets, such as 100B.

For R4, Memory Access Latency: Signal collectors interact with the host ideally via memory access. In Figure 2d, we measure the latency for DPA accessing the local cache, local memory, DPU on-SoC DRAM, and host-side DRAM. On workloads, we use the memory bandwidth test from *lmbench* [69], a classical micro-benchmark suite. We highlight several takeaways: DPA accessing L1 is significantly faster than accessing the DDR memory; DPA accessing local memory is faster than accessing the DPU memory and host memory; DPA L1 and L2 are precious and limited resources shared by multiple threads. Thus, during the design and implementation, we should keep the stateful memory (*e.g.,* per-flow states) compact and reduce memory access times.

We discuss the host CPU's and DPU ARM's limitations in meeting the above four requirements in Appendix §A.1. Compared to DPA, the host CPU and DPU ARM lack a control interface for requirement R2 and face performance issues for the other requirements.

Overall, we conclude that DPA is a suitable but not perfect candidate among three. We must address challenges like wimpy core constraints on low-code execution and limit states maintained to improve cache locality. Importantly, for generality, we loosely couple our design with any specific hardware. If DPA's APIs are exposed to host CPU and ARM cores, we can adapt our design to be compatible with them.

4 Software Control RDMA Framework Design

4.1 Overview

The key questions for Software-Controlled RDMA (SCR) are *What to Control* and *How to Control*. Firstly, we introduce a control model that forms the foundation of SCR to address the first question (§4.2). Next, addressing the second question relies on the event-driven rate computation framework (§4.3).

4.2 Dequeue Rate Control Model

QP Scheduler Model: We first examine RNIC's QP scheduler, which serves as the infrastructure for controlling network traffic at the sender side. Figure 3 illustrates the behavior of the RNIC QP scheduler, also functioning as the rate limiter: When tenants post WQEs to the SQ, the host driver notifies the RNIC via doorbell to update QP context (QPC), and the RNIC fetches several WQEs to aid in scheduling decisions. The scheduler leverages per-QP metadata, such as QPC and WQE, along with per-QP rates, to determine the execution order of WQEs. Typically, these per-QP rates are allocated by the congestion control module, such as DCQCN. For simplic-

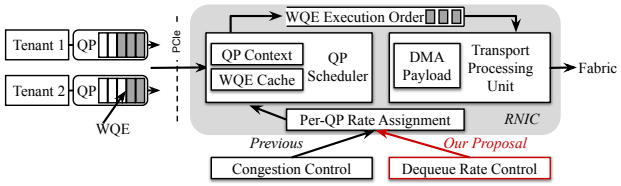

Figure 3: **RDMA NIC Queue Pair Scheduling Model.**

ity, we focus solely on the scheduler's input (metadata and rate assignment) and output (WQE execution order), while the internal structures of schedulers fall outside the scope of our work. Rich literature investigates the design of schedulers and rate limiters [70–72] (Tassel [70] specifically for RNIC). After the scheduler generates the WQE execution orders, the Processing Units of the Transport Logic (*e.g.,* RoCEv2) dequeue the WQE, DMA the payload from host memory, and complete packetization before sending it out over the wire.

	Standalone Metric	Competing with BW-Hungry	BW-Hungry QP (64KB Msg.)
Th.-Sensitive (4KB Msg.)	88.30 Gbps	33.25 Gbps	57.64 Gbps
Lat-Sensitive (256B Msg.)	2.44 us	5.31 us	90.57 Gbps

Table 2: **Limitations of DCQCN-Only Rate Assignment.**

Although the current RNIC QP scheduler delegates the per-QP rate assignment to fabric congestion control like DCQCN, unfortunately, relying solely on fabric congestion to control the sending rate has limitations. For instance, as shown in Table 2, consider a scenario where tenants compete with a bandwidth-hungry QP. We observe that the throughput-sensitive tenant experiences significant degradation and unfairness in throughput while the latency-sensitive QP suffers from increased latency. A desired behavior is that the throughput-sensitive QP can fairly share bandwidth with the bandwidth-hungry QP, while the latency-sensitive QP experiences no latency increase when competing with the bandwidth-hungry QP. It is worth noting that their aggregate bandwidth is at line rate, indicating no congestion in the fabric, so DCQCN does not react accordingly. Many prior works also report similar inadequacies in RDMA congestion control for multi-tenant scenarios [17, 18, 24, 28, 73].

Dequeue Rate: We observe that the input of the QP scheduler is a powerful control knob that can go beyond the congestion control's sending rate. As Figure 3 shows, we leverage this input knob as the per-QP *Dequeue Rate*, reflecting the rate at which the RNIC retrieves messages from memory regions. For instance, in WRITE verbs, the WQEs dequeued from the SQ indicate the message size per request, and then the dequeue rate is determined by the total message sizes over a given time period. The choice of the dequeue rate originates from its beneficial *multiplicity* as follows.

Multiplicity of Dequeue Rate: As Figure 4 shows, the dequeue rate influences multiple aspects of RDMA transport: 1) Primarily, it impacts the sending rate, as messages can only

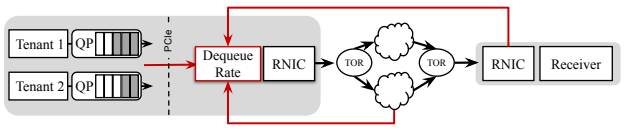

Figure 4: **Dequeue Rate Affects Multiple Domains.**

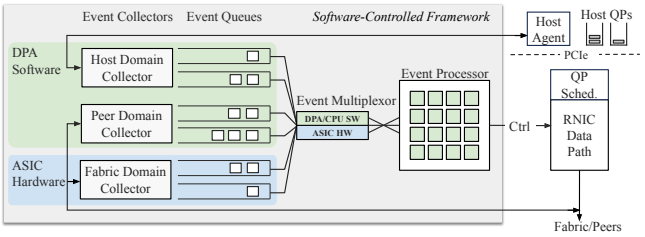

Figure 5: **Event-Driven Rate Computation Framework.**

be sent out by the RNIC hardware once dequeued from the host; 2) It affects PCIe utilization because a higher dequeue rate leads to increased PCIe utilization for DMA transfers; 3) The dequeue rate determines resource allocation within RNIC hardware, such as ASIC Processing Units, since dequeue operations initiate subsequent hardware processes like packetization; 4) The dequeue rate can respond to back pressure from the receiver side, as slowing down the sender's dequeue rate can alleviate pressure on the receiver side. In Appendix §A.2, we empirically evaluate how the dequeue rate influences various aspects mentioned above. Overall, the dequeue rate offers a comprehensive control, making it a suitable control knob for SCR.

4.3 Event-Driven Rate Computation Framework

With the dequeue rate control model, we next design an event-driven framework to collect multi-domain signals, compute the rate, and output the control actions. As Figure 5 shows the workflow, we next describe the subsystems of the framework.

4.3.1 Event Collectors Subsystem

Design Goals: As prior literature shows, the key enabler for flexible control is collecting accurate and diverse signals from multiple domains (*i.e.,* signal sources). Therefore, the primary objective of event collector systems is to be *all inclusive*, capable of providing a wide range of events. Furthermore, while we strive to collect more signal types, we prioritize *deployment-friendly* solutions that utilize existing features of NICs and switches rather than requiring specialized devices. Next, we outline how to achieve these design goals:

Multiple Domains: To control the dequeue rate, we gather signals from three primary domains: *Fabric Domain*, *Host Domain*, and *Peer Domain*. Table 3 lists the specific signals collected from each domain. These domains employ distinct mechanisms to gather events as follows:

Fabric Domain: We employ two types of collecting mechanisms: 1) In-Band Mechanisms: In-band packets carry signals such as CNP/ACK/NACK. Additionally, the TX/RX pipe of the RNIC can generate TX/RX events during network trans-

Domain	Signal	Definition
Fabric Domain	TX	Completion of transmitting a burst of packets, including timestamp and total byte count
	RX	Completion of receiving a burst of packets, including timestamp and total byte count
	CNP	Congestion Notification Packet (*e.g.,* ECN)
	ACK	Acknowledgements
	NACK	Negative Acknowledgements
	RTT	Measurements of Round Trip Time
Host Domain	App-Hints	Application-specific policies (*e.g.,* Fair bandwidth sharing among tenants)
	PCIe Util.	PCIe real-time bandwidth and latency
	RNIC Util.	RNIC hardware resource utilization
Peer Domain	Receiver Credits	Rate at which peer can handle incoming traffic
	Peer PCIe Util.	Peer node's PCIe bandwidth and latency
	Peer RNIC Util.	Peer RNIC's resource utilization

Table 3: **Signals From Multiple Domains. This list includes typical signals but can be expanded as needed.**

fer. RTT can also be obtained by timestamping the in-band packets. Some commodity RNICs, such as the BF3 used in this project, already support the collection of in-band signals such as CNP/ACK/NACK/TX/RTT. To our knowledge, the current BF3 does not support RX signal collection. As an alternative, we enable RX signal collection through host domain collectors, which will be discussed later. 2) Out-of-Band Mechanisms: Out-of-band packets probe network status in a telemetry manner. For probing packets, we implement the sender and receiver using the BF3 DPA, which supports communication over the fabric as shown in §3.3. We design a UDP-based protocol for transferring out-of-band messages over raw Ethernet APIs. Several reasons support the choice of UDP-based protocols: RoCEv2 is based on UDP, allowing one to track the header field of the RDMA in-band connection and reuse the meta info for associated out-of-band transfers. Additionally, UDP alleviates the burden of maintaining connections and handling reliability. An example of out-of-band probing is RTT measurements. The sender initiates out-of-band RTT request packets that are IP-routable. Upon the receiver NIC's ping-pong response to the RTT request packets, the sender can calculate the RTT. Unlike in-band RTT measurements with static per-ACK granularity, out-of-band RTT offers flexibility in the frequency of sending out RTT request packets. Also, out-of-band RTT carried as payloads is more flexible than in-band RTT, avoiding packet header format modifications.

Host Domain: We design several methods to collect host-domain signals: 1) For application hints, the event collector provides a shareable memory region that applications can access using load/store instructions, allowing them to write signals with sub-μs latency. Specifically, we implement the collector using two components: a lightweight agent on the host CPU and a process on the DPA. The host agent collects application hints and writes them to a shared memory region, from which the DPA process reads the signals. 2) For PCIe utilization measurement, we employ two methods: The first method involves the host-side agent utilizing tools like Intel PCM [74] to query real-time stats, followed by writing these stats to the event collector via the shared memory region. The second method entails implementing a proactive approach using PCIe endpoints like NIC to detect PCIe utilization. Specifically, the DPA process initiates a ping, to which the host agent responds with a pong, allowing the DPA to analyze PCIe latency. Importantly, both the host agent and the DPA process are configured per node rather than per flow, ensuring there are no scalability issues. This implementation is efficient because all flows within the same server typically share the same RNIC, host, and PCIe interconnect. 3) For RNIC utilization, we can utilize the RNIC hardware's query API to obtain real-time status. Also, we analyze the fabric domain signals to infer current RNIC utilization, such as the number of active connections.

Peer Domain: Signals of this domain must traverse the network fabric between the requester/responder. Similar to the fabric domain's out-of-band mechanism, we operate raw Ethernet packets to send/receive signals between local/peer nodes. We employ a UDP-based protocol to ensure the signal is routable while eliminating unnecessary heavy-weight mechanisms like connection setup and reliability. This approach achieves low latency and low processing overhead. Peers initially gather node information, including application hints, PCIe, and RNIC utilization, using the method outlined above for the host domain. These signals can serve as credits from the receiver to throttle the sender's dequeue rate. Once peers have gathered their information, they can transfer it using the lightweight UDP-based protocol. In our practice, using raw UDP with 128 Bytes payloads is sufficient to encapsulate essential information like flow ID and credits. We implement the sender and receiver using the BF3 DPA on both local and peer nodes. The sender injects packets into the network in several modes: periodically, sampling, and based on anomaly triggers. In the periodic approach, we set the packet interval to one RTT, balancing timely information delivery with moderate network usage. Considering that one DPA thread can handle 1.8+ Mpps, as detailed in §3.3, we can consolidate senders for multiple QPs into a single thread. With a typical RTT setting of 20 μs [75], a single thread can support up to 36 flows. In the sampling approach, the sender transmits out-of-band packets only after a specified number of in-band bytes have been sent. The anomaly-triggered method conserves network bandwidth by activating only when significant changes are detected, such as changes in the PCIe or port utilization.

4.3.2 Event Queues and Multiplexer Subsystem

Motivating Queuing and Coalescing: Event queues temporally store events[1] from the collectors before the multiplexer dequeues events and invokes the processor to handle them. The event queue subsystem is to facilitate *event coalescing*, a crucial mechanism for managing high-speed packet-granular signals. In Figure 6, we motivate the coalescing mechanism using the TX events example. Three factors contribute to

[1]Events encapsulate signals and their associated metadata such as flowID. We use the terms of events and signals interchangeably in the paper.

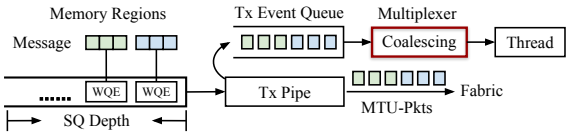

Figure 6: **Coalescing Mechanism (TX Events Example).**

the rapid accumulation of per-packet TX events: Firstly, in RDMA operations such as WRITE, each WQE can indicate a large message size (up to GB), while the wire has a typically small and fixed MTU size (*e.g.,* 1024B). Therefore, a message associated with a single WQE could be segmented into a large number of MTU-sized packets. Secondly, for SQ, users often configure a large queue depth to enhance utilization through batching, further speeding up the accumulation of per-packet signals. Thirdly, depending on the complexity of control laws, the processor may operate slowly. This speed may be outpaced by the event arrival rate, resulting in event queue buildup. If we process each per-packet event sequentially, the event queue will quickly fill up. Thus, coalescing multiple consecutive events into one event is a promising solution to improve processing efficiency. We micro-benchmark the effectiveness of coalescing in Appendix §A.3. Importantly, in addition to the TX signals from the fabric domain, signals from other domains can also benefit from coalescing, driven by similar motivations.

Design Goals: According to the above observations, the queuing system aims at 1) Supporting efficient and flexible coalescing strategies; 2) Applying to various types of signals. To achieve these two goals, we not only utilize existing functionalities in ASIC hardware but also introduce new functionalities in DPA software, as detailed below.

Hardware Coalescing/Multiplexing: As described in §4.3.1, event collectors for in-band signals, such as TX, ACK, and CNP events, are ASIC hardware modules positioned with the RNIC TX/RX pipelines. In addition to the event collectors, the current BF3 ASIC hardware also supports coalescing these in-band signals and subsequently invoking DPA threads for processing. However, to our knowledge, the current hardware coalescing and multiplexing approach has two main limitations: 1) Applicability: It is limited to in-band signals from the fabric domain, excluding other signal types from domains such as Host or Peer Domains, which cannot leverage these hardware circuits; 2) Flexibility: The hardware supports only fixed strategies for coalescing and multiplexing. Specifically, for coalescing, it only supports an *Accumulation* strategy, which accumulates values indicated by each event and outputs a single summary event. For multiplexing, it periodically invokes a thread based on hashing results of the flow ID associated with the events. Critically, it does not provide a programming interface for users to define more versatile coalescing and scheduling strategies. To address these shortcomings, we enhance the applicability and flexibility of the queuing system with software implementations using DPA.

Software Coalescing: As we previously described in §4.3.1, for out-of-band signals and host domain signals, we employ software-based collectors over the DPA cores (Figure 5 denoting DPA Software). These types of signals can not benefit from hardware coalescing. Consequently, the event coalescing and multiplexing for these out-of-band signals are software-based implementations over DPA. Specifically, we first allocate a queue for each type of event for each flow, simplifying the logic without considering cross-flow and cross-type dependencies. We adopt the single-producer and single-consumer model for these queues to ensure lock-free operation. These queues are allocated using the memory resources accessible to the DPA process. Unlike hardware coalescing, which is limited to the *Accumulation* strategy, software coalescing offers the flexibility to implement additional strategies through software modifications. In addition to basic strategies such as *Accumulation*, *Keep-Latest-Event*, and *Keep-Oldest-Event*, we support more complex strategies. For instance, when flow rates stabilize (*e.g.,* converge after a slow start), continuing to process certain fabric events like TX could be wasteful for processor cycles. Instead, we coalesce multiple TX events into one processing event, saving unnecessary processing cycles. Specifically, when the hardware multiplexer hands over TX events to the DPA software processing thread, we early terminate processing and enqueue events. Full processing executes only if we accumulate enough signals in the event queue. Such complex strategies are not supported by current hardware coalescing.

Software Multiplexing: The multiplexer is responsible for dequeuing events and invoking the DPA thread to process. Ideally, we aim to consolidate all functions—such as enqueuing, coalescing, dequeuing, and invoking—onto the DPA cores to free processing cycles of the host CPU or DPU ARM. However, to our knowledge, DPA operates a specialized real-time OS (RTOS) with limited capabilities for thread and process management, leading to two main issues:

1) The DPA process cannot create threads during runtime (*e.g.,* utilizing POSIX thread system calls). Consequently, we rely on the host CPU or DPU ARM to pre-launch a process with a pool of threads (we discuss the pool size parameter in §4.3.3). Within this pool, specific threads are dedicated for collecting events (*e.g.,* sending/receiving out-of-band packets), while others are dedicated to processing. Event queues are stored in process-global memory accessible to both collectors for enqueuing and processor threads for dequeuing.

2) DPA's inter-process communication (IPC) capabilities are limited. The current BF3 DPA allows only a specialized process (*i.e.,* doca_pcc) to set flow rates. Therefore, other processes handling host-domain and peer-domain events need to communicate with the doca_pcc process to adjust flow rates. However, the DPA lacks typical IPC mechanisms like Linux pipes or domain sockets. Instead, we use the host CPU or DPU ARM as an agent, facilitating memory sharing with processes handling host-domain and peer-domain events. Furthermore, the host CPU (or DPU ARM) utilizes a Mailbox Mechanism

[68] to activate doca_pcc for setting the flow rate. Importantly, most functionalities still operate on the DPA, with the host CPU merely handling lightweight operations to compensate for the current limitations of the DPA RTOS.

4.3.3 Event Processor Subsystem

Design Goals: The event processor subsystem is to execute user-defined control laws. The primary goal for the event processor is computational efficiency, given that the per-packet signal interval could be as short as a sub-μs. Inspired by classical OS and architecture techniques [76–78], we aim at building a *Deterministic Multi-Threading* (DMT) model. Next, we propose several mechanisms to realize such a model on a multi-core processor of the BF3 DPA.

Run-to-Completion and Shared-Nothing: To ensure deterministic execution, computation adheres to the run-to-completion manner without context switching or preemptive scheduling. Given the packet-granular signals at the sub-μs level, context switching becomes prohibitively expensive. By default, we handle event processing fairly for all event types without prioritization. Thus, when the multiplexer schedules an event, it waits until the target thread is idle before invoking it rather than preempting. Furthermore, processors operate based on the shared-nothing principle, avoiding inter-thread locking or synchronization. Specifically, the multiplexer maps each event to only one thread and assigns the same type of event from the same flow to the same thread. Each thread holds its partition of global stateful records, ensuring the thread remains independent of others.

Scalable Thread Pool: We allocate hardware threads into separate pools corresponding to different purposes, such as handling fabric events or peer-domain events. Under the run-to-completion model , where threads are not dynamically created during runtime, the pre-determined size of the thread pool is a critical parameter. Considering scalability, we carefully determine the appropriate thread pool sizes for two primary types of event processing:

1) For per-node processing, the number of processing threads does not need to scale with the number of QPs (flows). Some types of signals, such as those from host domains, can be processed per node without the need for per-flow processing. As described in §4.3.1, host domain signals like PCIe utilization are shareable to all QPs over the same RNIC, as they share the same PCIe interconnect. Consequently, there is no need to establish per-QP threads to process these signals. Instead, we configure a limited number of threads (generally fewer than 10) dedicated to each host signal such as PCIe Utilization, Application Hint, and RNIC utilization;

2) For per-flow processing, it intuitively seems that the number of processing threads should scale with the number of flows. However, we introduce an observation indicating that such scaling is *not* always necessary for our thread steering policy as follows:

Steering Policy: For signals requiring per-flow processing such as in-band fabric signals TX/ACK, out-of-band fabric signals RTT, and peer signals, we pre-determine the thread pool size before launching the DPA process. For a small number of QPs (*e.g.,* fewer than thread pool size), the subscription ratio of threads to QPs is fixed (*e.g.,* 1:1). For a large number of QPs exceeding the thread pool size, signal processing for multiple QPs is consolidated into a single thread.

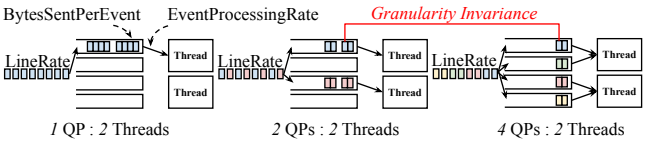

Figure 7: **Example of the Granularity Invariance Principle. While fixing two threads, the coalescence granularity remains invariant while increasing the number of flows from two to four.**

Processing Fidelity: Surprisingly, consolidating signal processing for multiple QPs does not affect processing fidelity. To measure fidelity, we introduce the metric *coalescing granularity*, defined as the number of bytes sent out per event. Recalling §4.3.2, when the event queue builds up, multiple per-packet signals are coalesced into a single event. Consequently, a single event representing more bytes indicates more events awaiting processing. Coalescing granularity, therefore, serves as an effective metric for assessing the waiting time due to contention faced by the processing thread. A smaller granularity indicates finer control and improved fidelity. Next, we introduce a theoretical principle suggesting that consolidating the processing of multiple QPs into a single thread will not compromise fidelity:

Granularity Invariance Principle: For N flows saturating a fixed line rate ($LineRate$), when N exceeds the number of processing threads T, the coalescing granularity for each flow remains *invariant* even though increasing the number of flows (Figure 7 illustrates an example).

Proof: The principle holds because the line rate is invariant to the number of flows. Consider a processing system capable of handling packet-granular events without dropping events for any sent bytes. Let $BytesSentPerEvent_i$ be the number of bytes each flow i sends per event, and $EventRate_i$ the rate at which events are processed. Assuming a fixed number of processing threads T, uniform coalescing strategy for all flows ($BytesSentPerEvent_i = Bspe$ for all i), and equal sharing of processing capability among the flows:

$$LineRate = \sum_{i=1}^{N} BytesSentPerEvent_i \times EventRate_i$$
$$= Bspe \times \sum_{i=1}^{N} EventRate_i$$

Since $\sum_{i=1}^{N} EventRate_i$ is a constant C (total event processing capacity shared among flows), we have: $LineRate = Bspe \times C$. Given C and $LineRate$ are invariant with respect to N (fixed T), $Bspe$ remains constant even as N increases. Hence, the coalescing granularity for each flow does not change.

The *Granularity Invariance Principle* provides scalability guarantees for per-flow processing utilizing the fixed number of threads, which applies to in-band fabric signals, out-of-band fabric signals, and peer signals. To achieve a reasonable coalescing granularity (*Bspe*), we typically launch 64 threads for processing in-band fabric signals. We empirically demonstrate its effectiveness and scalability in §6.1. For out-of-band fabric signals and peer signals, each flow's sender and receiver transmit out-of-band signals periodically (*e.g.,* per RTT), by sampling (*e.g.,* per BDP), or respond to anomaly triggers as discussed in §4.3.1. Compared with per-packet in-band signals, out-of-band signals are relatively coarse-grained, indicating more bytes sent per event. Thus, a smaller thread pool (16 in our setting) is sufficient for processing.

Strike Time-Space Trade-off: Improving both time/space efficiency is essential for DPA, which features a low-profile design with relatively wimpy cores and memory subsystems. Facing the fundamental time-space tradeoff, we employ distinct strategies for memory-intensive stateful operations and computation-intensive stateless operations. Details follow:

For stateful operations, we prioritize space efficiency by improving cache locality. Transport control algorithms often rely on stateful operations like membership queries, key-value queries, and counting. Stateful memory typically scales with the number of flows or the value range of flow information (*e.g.,* flow ID), but DPA memory resources are limited. To optimize stateful memory usage, we offer a computation library powered by compact data structures and algorithms. For membership queries, such as identifying the first packet of a flow, we utilize BloomFilter [79]. For key-value queries, such as recording flow statistics, we provide a HashMap. For counting tasks, we employ HyperLogLog [80] to estimate the cardinality and use Count-Min sketch [81] to estimate cumulative values.

For stateless operations, we prioritize time efficiency by lowering the instruction count. In addition to memory access costs, the instruction count directly translates into the execution time. For example, to improve time efficiency, we opt for fixed-point numbers (FXP-16) instead of floating-point numbers for arithmetic operations. Additionally, we employ bitwise operations for multiplication, square root calculations, and other arithmetic computations.

5 Spectrum of New Customizations

In this section, we demonstrate how to enable new functionality over SCR. To comprehensively cover a wide range of innovations, we categorize them into various system domains, as illustrated in Figure 8. For each domain, we explore candidate policies. Considering the rich customizations (Appendix Table 6), one policy never fits all, even for a single domain like congestion control. Thus, these policies showcase SCR's expressiveness (without claiming to be the best) and stimulate other innovations for diverse workloads and deployments.

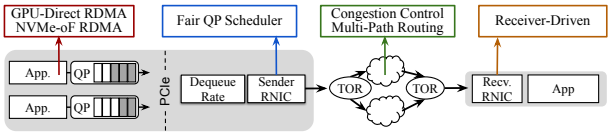

Figure 8: **New Customizations from Various Domains.**

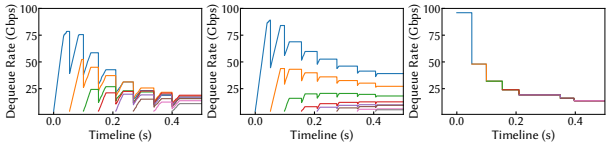
5.1 Host Domain: Fair QP Scheduler

In this domain, we investigate the case of customizing the RNIC QP Scheduler to improve fairness and performance isolation across multiple tenants. Several prior works [17, 18, 24, 28, 73] investigate the importance of addressing multi-tenancy issues of QP schedulers.

Customized Policy: We specify one simple yet practical policy: Achieve fair bandwidth allocation for QPs with varying message sizes. SCR can support other policies, such as different performance metrics and different definitions of fairness. Here, we take a typical bandwidth fairness example. Before delving into the mechanisms, we first explain why the legacy RNIC is not fair for some scenarios. As described in §4.2, the QP scheduler dequeues WQEs from tenants' QPs, prompting RNIC to initiate DMA transfers to fetch messages across the PCIe. Consequently, the QP scheduler's decisions can significantly impact host-to-RNIC PCIe resources and RNIC hardware utilization. By default, RNIC adopts a greedy approach, prioritizing large message sizes to achieve high utilization, a phenomenon widely observed [18,24,56]. However, this greedy strategy may result in unfair resource allocation in multi-tenant environments with varying message sizes, potentially violating cloud providers' bandwidth commitments.



Control Laws: Firstly, we need to measure the real-time bandwidth for each flow, which is a metric to evaluate fairness. We utilize the TX events from SCR event colletor, which provide per-QP flow ID, event timestamps, and the amount of bytes sent out. For each flow, SCR event processors record the timestamp of the last observed TX event, calculate the time duration since then until the current event, and derive the real-time bandwidth utilization as the bytes sent out divided by the time duration. Note that such bandwidth calculation applies to events coalesced using the accumulation strategy. We utilize Exponentially Weighted Moving Average (EWMA) to smooth the real-time bandwidth. To enhance efficiency, BloomFilter performs the new flow identification, flow records are stored using HashMap, and floating-point calculations are approximated using fixed-point arithmetic.

Next, we present three algorithms to achieve fairness. Note that it is desirable to maintain high utilization while achieving fairness. SCR event processors support user-customized algorithms, here demonstrating three typical cases: 1) Default RNIC QP scheduler mechanism; 2) Static Allocation Algorithm: We statically control the dequeue rate for each flow as $\frac{Link_Capacity}{Num_Of_Flow}$. 3) Water Filling (Progressive-Filling) Algorithm: Water Filling is a classical strategy to achieve max-min fairness in bandwidth allocation problems [82, 83]. Specifically, in our dequeue rate control model, we initially set the dequeue rates at starting values (discussed later) and

Case Studies	Packet-Granular Signals/Events	Benefits and Performance Gains
Fair QP Scheduler	TX Events	Improving Fairness with Varying Message Sizes; Isolating Performance between Lat./BW. Tenants
Congestion Control (§A.6)	Fabric RTT Events; Host/Peer Endpoint Latency	Enable RTT-based CC in addition to ECN-based CC
Multipath Routing (§A.7)	Fabric-Domain RTT Probing	Enable Sender-Side Multi-Path Monitoring and Selection
Receiver-Drivern Control (§A.8)	Peer Credits; Peer Congestion Notifications	Handle Incast; Enable NIC-Initiated ECN-like Backpressure
ML and Storage (§A.9)	The above signals are applicable.	Enhancing Fairness with Zero-Intrusion for GPU-Direct RDMA and NVMe-oF RDMA Applications and Libraries

Table 4: **Summary of Case Studies on Utilized Packet-Granular Signals and Achieved Benefits.**

then progressively increase rates. If a tenant QP can saturate the dequeue rate (*i.e., BW_EWMA* $\approx$ *DequeueRate*) and the link capacity permits, we continue increasing it. However, if the tenant QP does not fully utilize the dequeue rate (*e.g.,* for non-bandwidth-hungry QPs), we stop further increases. Additionally, if a tenant's bandwidth degrades (*i.e., BW_EWMA* $\ll$ *DequeueRate*), we decrease the dequeue rate and reclaim the credits. Event processors based on the DMT model ensure the rapid completion of the filling process and simultaneous progress among multiple flows.

(a) Scale down to half; Start from 0 (b) Scale down to $\frac{n-1}{n}$; Start from 0 (c) Scale down to $\frac{n-1}{n}$; Start from $\frac{1}{n}$

Figure 9: **Various Water Filling Strategies for Handling Flows Dynamicity (8 Bandwidth-Hungry QPs).**

To handle the dynamics of flows coming and going, we adjust the bandwidth allocations as follows: when a new flow joins, we scale the allocations for each existing flow i down to $\frac{n-1}{n} \times DequeueRate_i$ and start the new flow at $\frac{1}{n} \times LineRate$ (where n is the number of flows); when a flow terminates, we reclaim its allocated *DequeueRate*, making it available for other flows. In Figure 9, we visualize three Water Filling strategies with time-series dequeue rates for 8 flows, initiated one by one at 50 ms intervals (More experiment setup in §A.4). Our strategy (Figure 9c) demonstrates efficiency in both fairness and convergence time. Water Filling offers a broad design space, including strategies for handling the flows dynamicity and several tunable parameters, such as step size. In Appendix §A.4, we present more traces with varying parameters. In this work, we focus on the expressiveness of SCR (without claiming algorithms to be the best) and defer the algorithm optimality to future research.

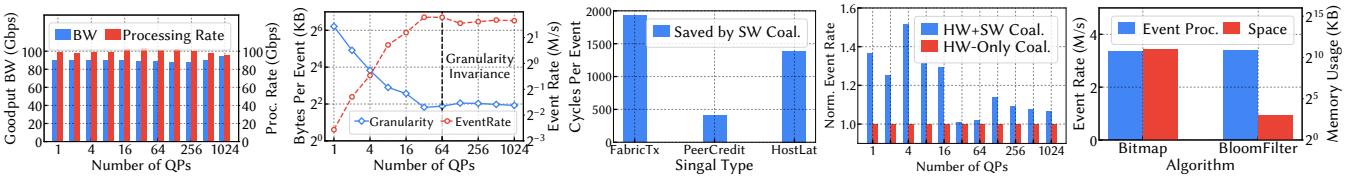
5.2 More Case Studies

Table 4 summarizes key enablers and performance gains for more case studies. Due to space constraints, we provide their descriptions and experiments in the appendix (§A.6, §A.7, §A.8, and §A.9). Given the rich literature on RDMA, we provide a feasibility analysis for other works in §A.13.

6 Evaluation

Implementation: We implement SCR over the DPA in over 7.8K lines of C/C++ code. We describe specific SDK dependencies in A.10. We describe our testbed in §3.2.

6.1 Micro-Benchmarking SCR



Setup: In Figure 10, we micro-benchmark the SCR framework using Perftest *ib_write_bw* [84] to generate traffic. We vary the number of QPs (flows) up to 1024 per node. The message size is set to 64KB with a queue depth of 4, allowing full 100Gbps line rate utilization. We launch up to 64 DPA threads. We primarily use the following metrics:

- *Event Rate:* Number of events handled (millions/second);
- *Coalescing Granularity:* Bytes sent per event;
- *Processing Rate:* Event Rate $\times$ Coalescing Granularity.

Processing Capacity: In Figure 10a, we demonstrate that the processing rate of the SCR can match the line rate traffic. In this experiment, SCR's processing task is to enforce fairness across multiple tenants. We utilize up to 1024 concurrent QPs and dump out the processing rate for the fabric TX signal, which is the most frequent signal among all signal types from all domains. The figure illustrates that SCR can handle these signals even during line-rate traffic. The processing rate exceeds the application goodput, as the bytes indicated by the TX event include both transport headers and payloads.

Scalability: In Figure 10b, we investigate the scalability using the same setup as the previous test. As we increase the number of QPs from 1 to 64, each flow exclusively utilizes one thread for event processing as designed in §4.3.3. With varying the number of flows and corresponding threads from 1 to 64, the line rate remains saturated and unchanged, reducing the processing load on individual threads. Thus, as the number of QPs increases to 64, we observe that the SCR can process events with the finest granularity and peak event rate. Beyond 64 QPs, we do not increase the thread count; instead, multiple flows are consolidated into a single thread. Excitingly, as analyzed by the *Granularity Invariance Principle* in §4.3.3, the granularity remains invariant even with up to 1024 QPs. This indicates that the SCR can handle more flows without additional threads, maintaining the same processing fidelity.

Software Coalescing Applicability: In Figure 10c, we show the applicability of software coalescing. Unlike hardware coalescing, which is limited to in-band signals from the fabric domain, software coalescing in SCR extends to signals across all domains. In this test, we apply software coalescing to fabric TX signals, peer credit signals, and host PCIe latency signals, showing the reduction in processing cycles per event. We use cycles as the metric—rather than execution times—because the DPA lacks a sub-μs timer (for reference, the DPA system clock runs at 505 MHz). Also, the figure highlights the flexibility of user-defined coalescing strategies. For TX events, we implement coalescing based on the cover-

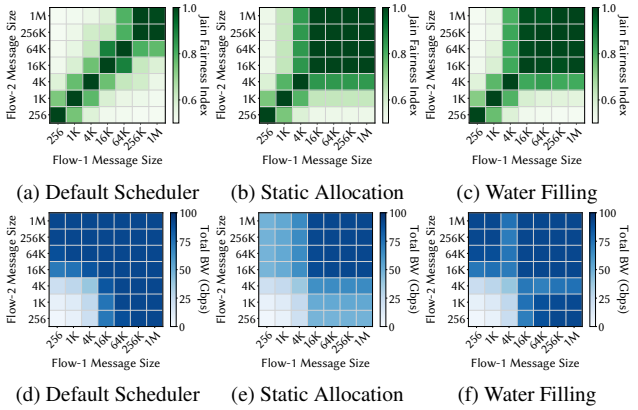
Figure 10: **Micro-Benchmarking Key Properties of the SCR Framework.**



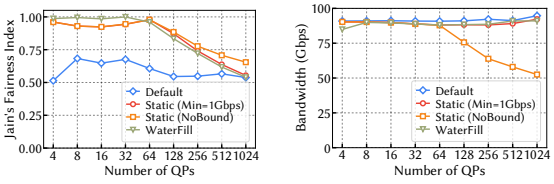
age status of flow rates (detailed in §4.3.2). For peer and host signals, we employ the *Keep-Latest-Event* strategy.

Software Coalescing Efficiency: In Figure 10d, we present the enhanced efficiency of software coalescing over typical hardware-only coalescing. As in previous experiments, we report the event rate for TX events with multi-tenant isolation processing task. To demonstrate enhanced efficiency, we normalized the combined hardware and software (HW+SW) coalescing against hardware-only (HW-Only) coalescing. The results show that software coalescing improves efficiency, particularly when the number of threads is limited, thereby increasing the load per thread. For instance, with only four threads, the HW+SW coalescing achieves a 51.3% higher event rate compared to the HW-Only coalescing.

Space Efficiency: In Figure 10e, we show the space efficiency for stateful operations, using the example of identifying the first signal of new flows—an essential operation for initiating processing. The Precise Bitmap Algorithm pre-allocates one bit for each potential flow ID. Upon signal arrival, it indexes the bit according to the flow ID to verify existence. With Flow IDs generated by BF3 hardware being 24 bits long, the Bitmap requires about 2 MB of memory (2^{24} bits). The Bloom Filter is an approximate algorithm for membership queries, with memory usage scaling only with the number of flows, not the value range. To achieve a false positive rate of 0.03 with three hash functions for up to 8192 flows, BloomFilter requires just 8 bits per flow (totaling 8KB). The Bloom Filter's space requirement is smaller than that of the Bitmap algorithm. Additionally, both methods can achieve similar event processing rates as they execute O(1) operations.

6.2 Achieving Fairness with the QP Scheduler

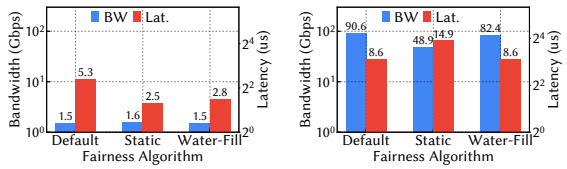
In Figure 11, we report the bandwidth as the utilization metric and Jain's Fairness Index [85] as the fairness metric. We present the evaluation results for the three aforementioned algorithms (§5.1). We set up two competing tenants using Perftest [84] WRITE verbs and vary the message size. The total link capacity is 100 Gbps. Figure 11a and 11d depict the performance of the default scheduler. It can only ensure fair allocation when both tenants use the same message size, as indicated by the diagonal line in Figure 11a. With the default scheduler, large messages can achieve high utilization, as shown in Figure 11d. Notably, for small messages (*e.g.,* 256 B), which are not bandwidth-hungry, they cannot saturate the link capacity. Figure 11b illustrates the fairness results when using the static allocation algorithm, which is the fairest



(a) Default Scheduler (b) Static Allocation (c) Water Filling

(d) Default Scheduler (e) Static Allocation (f) Water Filling

Figure 11: **Enhancing Fairness and Utilization in QP Scheduling. Deeper Color is Better for Both Metrics.**



as it allocates exactly $\frac{1}{n}$ bandwidth to each tenant. However, static allocation can lead to bandwidth over-provisioning for smaller messages and starvation for larger messages. For instance, while bandwidth-hungry tenants with large message sizes (*e.g.,* 1 MB) can starve due to the 50 Gbps budget, small messages like 256B fail to fully utilize 50 Gbps. As a result, overall utilization suffers. The Water Filling algorithm strikes a balance between fairness and utilization by progressively filling the bandwidth demands for all tenants. As depicted in Figures 11c and 11f, the Water Filling algorithm can achieve comparable fairness to static allocation while enhancing utilization. Unlike static allocation, the Water Filling prevents over-provisioning for small messages and starvation for large messages. In Figure 11, the Water Filling algorithm improves the fairness index of up to 1.78x compared to the default scheduler (*e.g.,* 4KB-msg. QP *vs.* 1MB-msg. QP).

In Figure 12, we scale the number of QPs to evaluate fairness algorithms. Each server manages up to 1024 QPs, with each QP's message size uniformly sampled from the range [4KB, 1MB], resulting in varied message sizes across QPs. In this experiment, we use WRITE operations, while experiments for READ are in Appendix §A.5. The queue depth is 4 for all QPs. In Figure 12a, the Static and Water Filling allocations can improve fairness by up to 1.88x than the default scheduler (for #QPs=4, increasing from 0.51 to 0.96). Figure 12b shows that all three algorithms can almost saturate the line rate. Notably, when the number of flows exceeds 100, each flow is allocated less than 1 Gbps. Achieving accurate hardware rate limiting at the granularity of Mbps for RNICs is still challenging [86, 87]. In Figure 12b (Static-NoBound),

(a) Fairness Index (b) Bandwidth Utilization

Figure 12: **Fairness Across Multiple Tenants (WRITE).**

(a) Latency-Sensitive QP (b) Bandwidth-Hungry QP

Figure 13: **Performance Isolation (Lat QP *vs.* BW QP).**

setting the flow rate below 1 Gbps reduces total utilization and the inability to saturate the line rate, likely due to excessive arbitration within the rate limiter. Thus, to avoid low utilization, we set a minimum bandwidth bound of 1 Gbps per flow for both Static and Water Filling approaches. Setting the bandwidth roughly at 1 Gbps rather than a more precise Mbps level explains the decline in the fairness metric when the number of flows exceeds 100. Beyond 100 flows, the significance of achieving fairness becomes minimal since each flow is allocated only a small amount of bandwidth, which is fairly similar across flows.

6.3 Enhancing Tenants Isolation with the QP Scheduler

In Figure 13, we illustrate enhancing fairness and isolation can decrease latency for latency-sensitive tenants when competing with bandwidth-hungry tenants. We use Perftest WRITE [84] to set up two competing tenants: one bandwidth-hungry, utilizing large-message sizes (64 KB) and large batch sizes (128), and the other latency-sensitive, using small-message sizes (256B) and small batch sizes (4). Figure 13a displays the latency results for the latency-sensitive QP, while Figure 13b shows the bandwidth for the bandwidth-hungry QP. Under the default scheduler, the latency-sensitive tenant experiences significant latency spikes. With static allocation, where the bandwidth-hungry QP is limited to half the line rate, interference with the latency-sensitive tenant is reduced, but throughput suffers. Water Filling algorithms maintain high utilization while simultaneously reducing latency. In Figure 13, the Water Filling algorithm reduces latency by up to 52.8% compared to the default one while achieving high utilization. For the latency-sensitive tenant, all three algorithms deliver the same bandwidth. For the bandwidth-sensitive tenant, Water-Filling matches the default scheduler's latency. However, the Static algorithm increases latency due to restricting the bandwidth-hungry QP to only half the line rate.

Moreover, as depicted in Figure 13, we can draw a straightforward yet significant observation: SCR enables customization without compromising (even improving!) RDMA data plane performance, particularly critical latency metrics. This observation holds true across all case studies.

6.4 Discussion

More Cases and Guidelines: As referenced in Table 4, more cases are detailed in the appendix. We report some developer guidelines in A.11 and suggestions for vendors in A.12.

Relationship to DOCA PCC: We reference PCC [68] for APIs of setting rates for QPs and obtaining fabric-domain signals. In SCR, we propose the Dequeue Rate Control Model (§4.2 and §4.3.1), Software Coalescing and Multiplexing to address DPA RTOS limitations (§4.3.2), and strategies to efficiently utilize DPA (§4.3.3). We anticipate that these contributions will also benefit PCC.

Limitations of SCR: In §4.3.1, we describe the lack of RX signals. In §4.3.2, we discuss the inability to create threads during runtime and the IPC limitation. In Figure 12, achieving precise rate limiting at the Mbps granularity remains a challenge. In §A.7, we describe the limitation on how to specify routing paths. In Appendix A.11 and A.12, we report some latency issues such as setting rates. We expect future software and hardware advancements to address these issues.

Generality: Besides the BF3 DPA, we explore generalizing the SCR design to other platforms such as hardware devices for Google Falcon [4] and Broadcom's Inband Flow Analyzer (IFA) [88, 89]. Google Falcon, according to the spec [4], features a Rate Update Engine (RUE), which occupies a similar architectural position as the BF3 DPA. Thus, our dequeue rate control and coalescing/multiplexing strategies could be adapted for use with the RUE. Similarly, according to Broadcom IFA's draft, the Initiating Function Node can potentially fulfill a role akin to the BF3 DPA in SCR.

Resource Costs: We discuss computational and network resources costs of SCR. In practice with BF3, we use minimal computational resources from the host CPU or DPU ARM, typically for lightweight tasks such as launching DPA threads or responding to host probes; a single CPU core suffices in our experiments. Moreover, DPA, based on RISC-V, is designed for efficiency in power usage, chip area, and monetary cost [60, 90]. Besides BF3 DPU, even the low-power version of the BF3 (SuperNIC [91]) incorporates DPA. In terms of network resources, both out-of-band probing and in-band telemetry consume bandwidth. It is a common challenge [9, 92, 93].

7 Conclusion

In this work, we introduce Software-Controlled RDMA (SCR) to realize the vision of white-boxing RDMA. SCR applies the dequeue rate control model and facilitates an event-driven rate computation framework. We enable a spectrum of new functionalities not present in legacy transport. We envision SCR to help land past and future RDMA transport innovations.

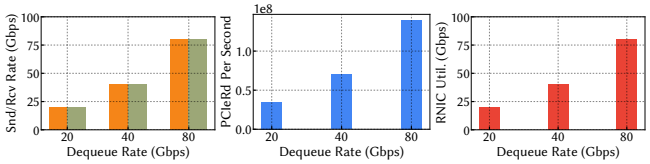
A Appendix

A.1 Limitations of CPU/DPU-ARM in Meeting Control System Requirements



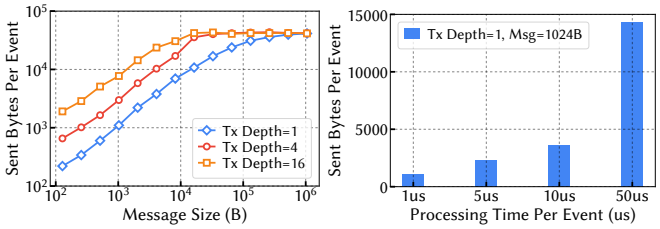
R1 Multi-threading Performance: For CPU and DPU ARM, while the host CPU has many cores, these cores should primarily be allocated to tenants for revenue-generating workloads. In contrast, the ARM CPU possesses only 16 cores without hyper-threading, partially satisfying the R1 requirement.

R2 Interaction with RNIC: For CPU and DPU ARM, several issues arise. Firstly, they currently lack APIs to acquire packet-granular signals, particularly in-band per-packet signals like ACK/CNP. Also, as far as we know, these cores lack APIs to enforce control actions, such as changing the per-flow rate during runtime. While the lack of APIs can be addressed in the short term, another long-term concern remains. As Figure 1a shows, DPA is co-packaged with the RNIC, with Network-on-Chip direct access to RNIC TX/RX pipes, resulting in lower access latency. However, host CPUs or ARM cores must cross the host PCIe or on-SoC PCIe to interact with RNICs. Furthermore, the host CPU and ARM cores access RNIC signals with the Performance Monitoring Unit (PMU) counters, which work in a sampling manner instead of timely monitoring.

R3 Raw Ethernet Capability: CPU and DPU ARM satisfy the requirements of the general network, including the in-kernel TCP/IP stack and RDMA transport. However, DPA is more tightly integrated with RNIC than CPU and ARM cores.

R4 Memory Access Latency: Note that it is trivial for the host CPU to monitor host-domain resource usage and record it with host memory, but this is not the case for the ARM CPU. Although the ARM CPU can access host memory using RDMA (μs scale), this incurs longer latency than the load/store accessing capabilities of the DPA (sub-μs scale).

A.2 Evaluation of Dequeue Rate's Impact Across Multiple Domains



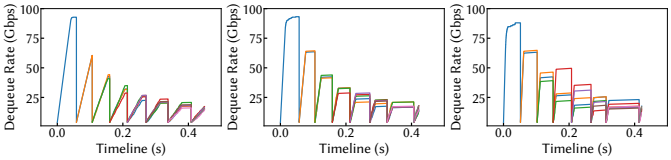
(a) Send/Receive BW (b) PCIe Utilization (c) RNIC Processing

Figure 14: **Dequeue Rate's Impact on RDMA Transport.**

In Figure 14, we explore the impact of dequeue rate on various domains: Fabric, Host, and Peer. Figure 14a illustrates how varying dequeue rates can regulate traffic sent into the fabric and received by peers. In Figure 14b, we monitor PCIe utilization using Intel PCM [74] tools across different dequeue rates. To understand how the dequeue rate influences RNIC

hardware utilization, we track DMA jobs initiated by the RNIC to fetch messages from host memory. Specifically, we use Intel PCM to monitor the IIO (Integrated Input/Output) controller for In-Bound read activity, representing the number of bytes requested by RNIC for reading from main memory via DMA. Figure 14c demonstrates the effect of the dequeue rate on RNIC DMA job execution.

A.3 Micro Benchmark of Coalescing TX Events



(a) Batching Triggers Coalescing (b) Slow-Proc. Triggers Coalescing

Figure 15: **Coalescing Experiments (TX Events Example).**

In Figure 15, we conduct a micro-benchmark on the coalescing of multiple TX events by accumulating the *sent_bytes* indicated by each TX event into a single sum value. Figure 15a demonstrates that larger message sizes per WQE and deeper SQ depths can trigger the coalescing of multiple TX events. It's worth noting the presence of a ceiling for *sent_bytes_per_event* due to the PCIe-related configuration on maximum batching size. Additionally, Figure 15b illustrates how slower event processing can also induce TX event coalescing. Overall, coalescing proves to be a promising mechanism for absorbing the high burstiness of packet-granular events.

A.4 Traces of Water Filling Procedure

(a) Step=0.02 GBps (b) Step=0.05 GBps (c) Step=0.1 GBps

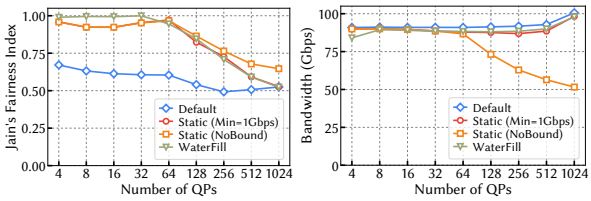


Figure 16: **Traces of Water Filling Procedure (#QPs=8). Scale down to 0; Start from 0.**

In Figure 16, we present time-series dequeue rates for eight flows during the Water Filling procedure. The minimum message QP utilizes 4KB, while subsequent QPs double this size successively, resulting in different message sizes per QP. All QPs have a queue depth of 4 and can saturate a 100 Gbps line rate individually. We initiate the dequeue rate at 0.5 Gbps, with step sizes varying from 0.03 Gbps, 0.05 Gbps to 0.1 Gbps. Flows are started one by one at 50 milliseconds intervals. To clearly demonstrate the impact of step size, we employ a strategy to handle flow dynamics: when a new flow joins, we simply reset all allocations and restart the Water Filling procedure. As indicated by the traces, smaller step sizes aid in converging to fairer rate allocations but require more time to achieve convergence. Table 5 shows the total time required for all flows to converge to a stable state when eight QPs begin filling concurrently. Note that to generate the trace for Figure 16, we need to output logs, which introduces some delay in the time series. For the measurements in Table 5, we disabled log printing to eliminate such delays.

Filling Step Size	Convergence Time
0.02 GBps	294 μs
0.05 GBps	122 μs
0.10 GBps	49 μs

Table 5: **Time Cost for All Flows to Converge to Stable Rates.**

A.5 Support RDMA READ Operation

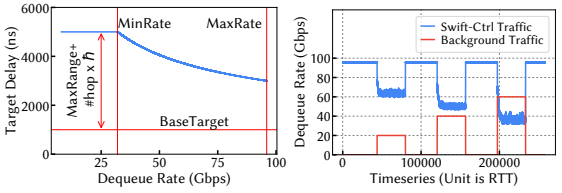
(a) Fairness Index (b) Bandwidth Utilization

Figure 17: **Achieving Fairness Across Multiple Tenants (RDMA READ).**

In Figure 17, we demonstrate that SCR is applicable to various RDMA operations, including READ and WRITE. The experimental setup is identical to that shown in Figure 12, except that this experiment uses RDMA READ operations instead of the RDMA WRITE operations used previously. The results are similar: Static and Water-Filling allocations enhance fairness while maintaining high utilization and scalability, as analyzed in §6.2. SCR supports multiple RDMA operations, differing primarily in whether the requester's or responder's BF3 DPA takes effect. For WRITE operations, the Fair QP scheduler takes effect at the requester's BF3 DPA, as the requester sends out data and collects TX signals. Conversely, for READ operations, the Fair QP scheduler takes effect at the responder's BF3 DPA, since the responder sends out data and collects TX signals.

A.6 Fabric Domain: Congestion Control

In the fabric domain, we investigate congestion control (CC), a classical and everlasting problem. Most RNIC vendors [36, 94,95] baked DCQCN into the ASIC. With the introduction of



SCR, there is a promising opportunity for commercial RNICs to reap the benefits of other innovative CC [10, 11, 13, 47, 96].

Customized Policy: With ECN-based algorithms already demonstrated by DCQCN, we now explore implementing RTT-based CC using SCR. Delay-based CC is desired for several large-scale RDMA deployments [5, 46].

Swift Control Laws: We investigate Swift, a typical delay-based CC algorithm proposed by Google [10]. Swift's core logic is as follows: Additively increase the congestion window when RTT is less than the target delay; multiplicatively decrease the congestion window when RTT exceeds the target delay. With SCR, we examine RTT measurement and target delay computation, two building blocks for Swift's control.

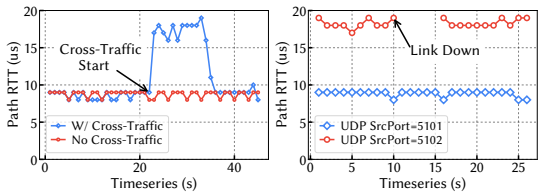
Measuring RTT Delays: Swift control loops decompose the end-to-end delay into three components: Fabric Delay, Local NIC TX/RX Delay, and Remote NIC RX/TX Delay. Swift measures fabric delay by utilizing ACK packets to convey in-band timestamp information. As described in §4.3.1, SCR supports out-of-band per-flow RTT measurements, offering greater flexibility compared to in-band RTT measurements. This method allows for control over the frequency of sending RTT requests and eliminates the need to customize the ACK packet format. Pingmesh [92] shows such proactive RTT measurement is feasible in large-scale environments. For local NIC TX/RX delay indicating local host congestion, Swift originally utilizes timestamps from the local host and NIC to calculate per-packet delays, necessitating precise time synchronization between the NIC and host. Alternatively, SCR utilizes the host-domain signal of PCIe latency to reflect host congestion. For the remote NIC TX/RX delay, SCR utilizes signals from the peer domain, such as peer PCIe latency, to represent this delay.

Computing Target Delay: Swift encodes most of the complexity into the computation of the target delay, enabling it to scale to multiple competing flows and multiple-hop network typologies. The target delay calculations require floating-point and complex arithmetic operations like square root. To enhance efficiency, SCR employs fixed-point and bitwise operations. Given that Swift is a window-based algorithm and the current BF3 RNIC employs a rate-based mechanism, we utilize the Bandwidth-Delay Product (BDP) approach to translate the per-flow rate into the per-flow window.

(a) Target Delay Curve (b) Swift-Control Traffic

Figure 18: **Statistics Dump for Swift Congestion Control.**

Experiments of RTT-Based Congestion Control: As shown in Figure 18, we dump out the runtime statistics to verify the functionality of Swift. In Figure 18a, we present a trace demonstrating how the dequeue rate affects the target delay. According to our testbed, we configured Swift's parameters as follows: base target as 1 μs, #hop as 1, per-hop scaling factor as 2 μs, max scaling range as 2 μs, Min Rate as 32 Gbps, and Max Rate as 96 Gbps. We observe that our implementation accurately follows Swift's control law and reproduces the curve behavior as in the original design [10]. In Figure 18b, we generate background traffic varying from 20 Gbps, 40 Gbps to 60 Gbps and monitor the Swift-Controlled traffic. We can observe that SCR-enabled Swift can converge to the appropriate bandwidth to avoid fabric congestion.



A.7 Fabric Domain: Multi-Path Routing Selection

We investigate the second case of the fabric domain, Multi-Path Routing, which is advocated by several industrial-level RDMA customizations such as Google PLB [44] in Falcon, AWS SRD [5], and UEC Transport [8].

Customized Policy: We monitor multi-path status and repath according to congestion status and link failure at the sender side. We revisit one prior policy, MP-RDMA [20], which repurposes the *Src Port* field of the RoCEv2 transport to indicate the *Virtual Path ID*, enabling switch ECMP to execute multipathing accordingly. MP-RDMA relies on the in-band ACK clocking to detect congestion status for each *Virtual Path*. The end-host logic of MP-RDMA is prototyped via FPGAs, not commercial RNICs. Next, we examine the feasibility of multi-path routing using SCR.

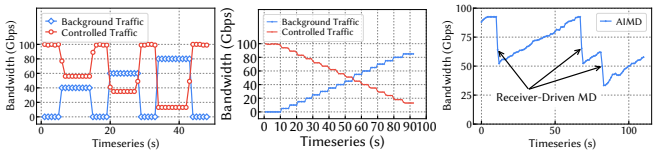
Control Laws: SCR offers two key functionalities: Multipath Monitoring and Path Selection. To monitor the status of multiple paths, we employ out-of-band telemetry to probe status proactively. In SCR, the local collector pings the peer, which responds with a pong, allowing the local collector to obtain the RTT. By varying the header field of the request, we can enforce RTT requests through different paths in the fabric. For header field assignments, we adopt a random generation approach, similar to the practice used in MP-RDMA [20] and PLB [44]. After detecting the RTTs of multiple paths, we select the path with the lowest latency. For path selection enforcement, we use the source port field of RoCEv2 to indicate the path, as MP-RDMA advocates. Currently, it is feasible to specify the source port field of RoCEv2 for each QP using APIs like *mlx5dv_modify_qp_udp_sport()* [97]. However, this cannot be done at the granularity of individual packets. Thus, we rely on the BF3 hardware flow engines within the NIC-embedded switch to rewrite the packet header [60].

Experiments of Monitoring Multi-Path Status: As Figure 19 shows, we demonstrate two scenarios for monitoring multi-path RTT. In Figure 19a, we present the measurements that reveal the congestion status of network paths effectively. We introduce 100 Gbps background cross-traffic between the sender and receiver, observing an increase in RTT when cross-traffic begins and a decrease when it ceases. In Figure 19b, we

(a) Path RTT with Cross-Traffic (b) Multi-Path RTT

Figure 19: **Latency Monitoring Across Multiple Paths.**

present another scenario monitoring multiple path statuses by varying the source port to control routing paths. By manually adding a 10 μs latency for traffic with UDP SrcPort 5102, we compare it with traffic on UDP SrcPort 5101, revealing accurate latency representation for different paths. We also simulate a link failure scenario for the path of UDP SrcPort 5102. We configured a timeout value (100 μs) to detect the link failure, causing the loss of RTT probing packets. Figure 19b illustrates RTT probing's ability to detect link failures and recovery. This information aids in SCR selecting the optimal path for RDMA traffic, even at the per-packet level, via RoCEv2 header manipulation.



A.8 Peer Domain: Receiver-Driven Control Loop

In this domain, we investigate the receiver-driven control loop, which is not present for legacy RDMA transport. RDMA operations, especially one-sided READ/WRITE, are designed to be sender-driven, allowing transfers to bypass the involvement of the peer entirely. However, sender-side controls may struggle to handle traffic patterns that cause congestion at the receiver side, such as many-to-one incast. The receiver-driven paradigm can help handle the incast [15, 16, 52, 53].

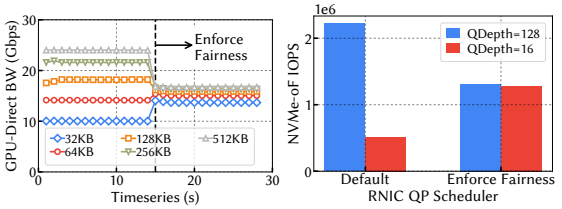
Customized Policy: We refer to one typical receiver-driven protocol, Homa [15]. In Homa's control loop, the sender is only allowed to send bytes after receiving a *grant* from the receiver, enabling efficient handling of incast scenarios by allowing a few senders to transmit simultaneously. Next, we leverage SCR to transfer such receiver-initiated signals to benefit RDMA one-sided operations WRITE/READ.

Control Laws: SCR provides the peer-domain signals as described in §4.3.1. Peer-domain signals, transmitted out-of-band as packet payloads, offer flexibility for carrying information, distinct from modifying in-band packet headers. The in-band manner requires addressing size limitations and ensuring packet routability across the fabric and middlebox. To support Homa-like grant mechanisms, we utilize peer domain signals to convey the grant information. Originally, Homa utilized a window-based control mechanism where credits indicated the allowable byte counts. Given that the current BF3 supports only rate-based control, we have made two modifications: First, we use credits to represent the available bandwidth (in Gbps) for the sender. Second, the senders operate *optimistically*, continuing to transmit at the current rate unless new credits are received to adjust the traffic.

In addition to grant mechanisms, we also support a second receiver-driven mechanism where the receiver issues ECN-like backpressure notifications to the sender. Commodity RNICs currently lack mechanisms to mark ECN bits at the receiver NIC. This functionality is beneficial for related work [17, 98] because receivers can mark the ECN bits to backpressure the senders. While SCR doesn't directly mark ECN bits on in-band packets, we utilize out-of-band peer-domain signal packets to convey ECN-like information to backpressure senders.

(a) Recv.-Granted Credit (b) 16-to-1 Incast (c) Recv.-Init. ECN

Figure 20: **Receiver-Driven Control Mechanisms.**



Experiments of Receiver-Driven Control: In Figure 20a, we illustrate the mechanism of receiver-granting credits to handle the 2-to-1 incast scenario. We use Perftest to configure two clients (one BF2 and one BF3) sending data to the same destination server (one BF3), with BF2-to-BF3 traffic acting as the background cross-traffic. The BF3-to-BF3 connection demonstrates the receiver-granting credits mechanism. Specifically, the receiver-side SCR monitors the real-time bandwidth utilization of the given port and calculates the credit as the remaining bandwidth headroom. These credits are then transferred to the sender as peer-domain signals, allowing the sender-side SCR to set the dequeue rate accordingly. From Figure 20a, we observe that the sender appropriately utilizes the remaining bandwidth. In Figure 20b, we dynamically scale the number of background senders up to 16, adding one sender every 5 seconds, with each sender generating traffic at 5 Gbps, achieving an incast ratio of up to 16-to-1. The figure shows that the BF3-to-BF3 connection, equipped with the receiver-granting credits mechanism, effectively captures the remaining bandwidth across all settings.

In Figure 20c, we demonstrate a scenario of receiver-initiated ECN-like backpressure flow control. We utilize Perftest [84] to establish a QP connection between the sender and receiver, generating WRITE traffic at the line rate (100 Gbps). The receiver can trigger receiver-driven backpressure signals while congestion is happening at its side. Upon receiving peer-domain signals, the sender multiplicatively decreases (MD) the dequeue rate and then performs additive increases (AI) without further backpressure signals. To ensure visibility, we use a small AI factor to extend the AI process. As shown in this experiment, while WRITE is inherently sender-driven, it currently can benefit from the receiver-driven control loop.

A.9 Application Domain: ML and Storage

We highlight the feasibility of harnessing SCR framework to NVMe-oF RDMA and GPU-Direct RDMA because storage [1, 99] and machine learning workloads [46, 100] take the significant portion of current data center traffic. They can seamlessly leverage our framework with minimal overhead, as SCR operates at the hardware transport level without changing the host software stack. Specifically, it leaves essential data path functionalities like peer-to-peer DMA transfer unchanged (*i.e.,* GPU-to-NIC and SSD-to-NIC). Also, SCR requires no alterations to the application code, host drivers like CUDA, and libraries like SPDK [101] and NCCL [102]. Moreover, SCR ensures optimal raw RDMA performance.

Customized Policy: We ensure application-driven bandwidth allocation for multi-tenant storage or ML workloads without changing any application code. Specifically, multiple NVMe-oF initiators on the same host share NVMe-oF RDMA bandwidth according to the policy, regardless of their individual IO depth settings. Similarly, multiple tenants on the same GPU share GPU-Direct bandwidth according to the policy, even though the size of messages sent from HBM varies among them. The control law is the same as in §5.1, but the policy in §5.1 manages traffic from main memory to PCIe endpoint (EP); this policy controls EP-to-EP traffic.

(a) GPU-Direct RDMA (b) NVMe-oF RDMA

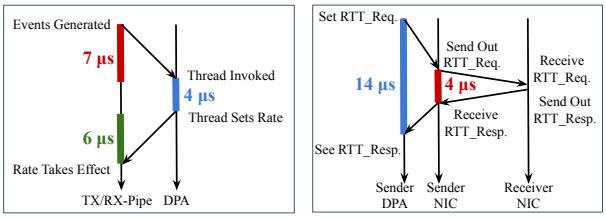
Figure 21: **Ensuring Fairness in GPU-Direct and NVMe-oF RDMA Traffic.**

Experiments of Achieving Fairness for ML/Storage Workloads: In Figure 21a, we demonstrate how SCR effectively manages GPU-to-GPU RDMA communication. Using Perftest, we set up five concurrent RDMA connections between two GPUs, utilizing GPUDirect RDMA to directly transfer messages between HBMs without involving the host DDR as an intermediary. Here, we demonstrate the impact of an application-driven QP scheduler. Initially, with five connections having different message sizes and using the default scheduler, bandwidth allocation favors large message tenants. When SCR is used to ensure even sharing, all tenants benefit from an equitable share of the bandwidth. Importantly, no modifications were made to any of the host software stack.

In Figure 21b, we showcase the efficacy of SCR for storage workloads utilizing NVMe-oF RDMA. At the NVMe-oF target side, we employ SPDK to configure one *nvmf_tgt* with NULL devices, rather than read SSDs, to maximize network traffic without encountering bottlenecks on the storage medium. On the initiator side, we set up two tenants. Both tenants issue 4KB write requests, while varying the IO queue depth for different tenants. It is evident that with the default QP scheduler, smaller IO depths struggle to obtain the bandwidth. However, when we employ SCR to enforce an application-specific policy of even sharing, these tenants can equitably share the bandwidth without compromising utilization. Importantly, no modifications were required for the SPDK NVMe-oF implementation and the applications.

A.10 SDK Dependency and Implementation

We implement SCR over the DPA in over 7.8K lines of C/C++ code, covering both DPA and host management functionalities. Fabric-domain signal collection and dequeue rate updates are facilitated using the DOCA PCC SDK [68]. For host-domain signal collection, we utilize the RPC and Command Queue mechanisms in the DOCA DPA SDK [60]. Peer-domain signals are managed using the FlexIO SDK [103] for out-of-band communications. Additionally, all analytic, approximation, and arithmetic libraries are implemented in C code, compatible with the DPA RISC-V toolchain.



We operate most SCR functionalities on the DPA, only managing very lightweight tasks on the host x86 CPU and none on the DPU ARM cores. By default, we set up 25 DPA threads to handle signals from the fabric domain, including TX, ACK, CNP, NACK, and RTT. One DPA thread establishes communication with the host, and two manage telemetry tasks: one for ping and another for pong. Additionally, two threads exchange signals between peer domains—one for receiving and another for sending. The host CPU is required only to initialize the DPA process and relay the host domain signals to the DPA, for which a single x86 CPU core is sufficient.

A.11 Guidelines for Implementing Other Functionalities

In addition to the aforementioned functionalities, SCR has the potential to support various other customizations. Here, we provide general implementation guidelines based on our analysis and experience.

Timescale of Control Feedback Matters. While SCR can produce per-packet signals at data plane speed, event processing might lag behind such high data rates. We identify three main components contributing to the overall latency of making control decisions: 1) Event triggering, 2) The computation procedure itself, and 3) The time it takes for control feedback to take effect.

We conducted a microbenchmark to quantify the delay breakdown, as shown in Figure 22. For in-band events like TX/ACK events (Figure 22a), event triggering, from the hardware TX/RX pipe generating the events to the DPA invoking the thread to process, could take up to 7 μs. This latency is due to event queuing, event multiplexer operation, and loading the program onto the DPA thread. To accelerate event triggering, we can keep the DPA thread busy waiting rather than relying

(a) In-Band Events (b) Out-of-Band RTT Events

Figure 22: **Event Processing Latency Breakdown.**

on interrupt-like triggering, which can hide the latency. The second component of latency is the processing itself, which is heavily influenced by the complexity of the control laws. Here, we measure the Swift control law with some additional bookkeeping tasks, like maintaining per-flow dequeue rate, which takes about 4 μs. After making the decision for the new rate, the DPA thread writes new values to hardware registers. We measure how long it takes for the changes to take effect, which may require up to 6 μs to start affecting the data planes. This is longer than expected, and we anticipate that next-gen DPA hardware can optimize this rate-installing procedure. For out-of-band events like RTT (Figure 22b), besides the fabric delay, there are two components: 1) The latency between the DPA setting the request bit and the RNIC actually sending out the RTT request. 2) The delay between the RNIC receiving the RTT response and invoking the DPA thread to process. These two delays can take up to 10 μs, which can be optimized by the DPA thread busy waiting for the RTT response and vendors optimizing the delay between the request set and the request sent out. Overall, we observe that event processing could lag behind the data plane by a few microseconds even after optimization. Control lagging behind data is widely observed for high-speed line rates, not unique to our setting but also in traditional in-kernel congestion control for TCP/IP [104–106]. We propose two guidelines to address the lagging issues: 1) Congestion control algorithms would be better designed to work at the RTT granularity, as more fine-grained control could lead to inaccuracies. 2) If algorithms still aim for sub-RTT control, they should be designed to tolerate signaling coalescing, that is, folding consecutive signals into one event. This approach can help hide latency by combining multiple processing steps into one. Control laws should consider coalesced signals, similar to how Swift considers coalesced ACKs.

Keep Simple yet Effective Control Law. We evaluate simplicity from several aspects: 1) the computation of the control logic, 2) the memory access for per-flow states, and 3) the types of required signals. As we measured above, the latency for computing is positively proportional to the instruction counts of the control logic. Although SCR provides general-purpose computation to implement diverse logic, we still need to accelerate the control logic with approximation techniques to ensure faster reactions. Besides the instruction count, memory access is also expensive in terms of time cost. Reducing the memory footprint, such as fitting into the L1 cache, can reduce the time overhead associated with memory access. On the type of signals, we propose leveraging the signals supported by SCR, such as in-band and out-of-band signals. Although some complex signals like switch-aided in-network telemetry can enhance precision, they come with the cost of end-host processing cycles and switch customizations.

A.12 Suggestions for Next-Gen Datapath Accelerator

Based on our experience implementing SCR over DPA, we suggest improvements for the next-gen hardware in the following areas:

- Decrease event-triggering and rate-installing latency: As we described in the §A.11, the latency of event invocation and rate update is crucial for the timely response of the control loop. Next-gen DPA should optimize program loading time and reduce latency for user-invoked DPA threads via RPC mechanisms (*e.g.,* Mailbox RPC [68]).
- Expand the set of signals/events accessible from the RNIC. Diverse signals are essential to enable flexible control laws. For instance, at present, only in-band TX events are accessible. Rx events indicating the timestamp and bytes received would provide valuable additional signals. Currently, the RX pipe does not provide the API for the DPA to access INT fields. Also, expanding the set of NIC counters accessible for DPA would be beneficial. Currently, only TX/RX bytes counters are available. For instance, exposing utilization counters for RNIC micro-architecture resources accessible to DPA, as Neo-Host [107] enables, is promising.
- Expand the set of control actions. Currently, only the rate and RTT requests are considered control actions. As previously mentioned, incorporating additional control actions such as modifying the RoCEv2 header, like adjusting the source port or setting the ECN bits, would be beneficial.
- Streamline and improve the flexibility of DPA process management. The DOCA PCC process is currently the only one capable of adjusting the rate. However, at present, it cannot be easily extended to support other functionalities such as accessing host memory or operating raw Ethernet APIs. As a result, we must set up other DPA processes to access host memory and operate raw Ethernet APIs, which introduces some overhead in inter-process communication (IPC).

A.13 Extended Analysis for Prior Work

Table 6 is an extended list of related works, and we analyze the feasibility of supporting these customizations using SCR.

Prior Work	Why Customization	Prior Customization	Feasibility and Limitations using SCR
Microsoft: DCQCN [2]; Large-Scale Deployment [3]; Storage [1]	CC / FC	ASIC/ Tuning	DCQCN and PFC are SCR default strategies.
AWS: SRD [5]	CC / Re. / MP	Bespoke HW	SCR explores delay-based CC and multi-path routing similar to SRD.

Ryan Kosta
UCSD *

Edouard Bugnion
EPFL

Marios Kogias
Imperial College London

Abstract

Datacenter congestion control protocols are challenged to navigate the throughput-buffering trade-off while relative packet buffer capacity is trending lower year-over-year. In this context, receiver-driven protocols — which schedule packet transmissions instead of reacting to congestion — excel when the bottleneck lies at the ToR-to-receiver link. However, when multiple receivers must use a shared link (*e.g.,* ToR to Spine), their independent schedules can conflict.

We present SIRD, a receiver-driven congestion control protocol designed around the simple insight that single-owner links should be scheduled, while shared links should be managed with reactive control algorithms. The approach allows receivers to both precisely schedule their downlinks *and* to coordinate over shared bottlenecks. Critically, SIRD also treats sender uplinks as shared links, enabling the flow of congestion feedback from senders to receivers, which then adapt their scheduling to each sender's real-time capacity. This results in tight scheduling, enabling high bandwidth utilization with little contention, and thus minimal latency-inducing buffering in the fabric.

We implement SIRD on top of the Caladan stack and show that SIRD's asymmetric design can deliver 100Gbps in software while keeping network queuing minimal. We further compare SIRD to state-of-the-art receiver-driven protocols (Homa, dcPIM, and ExpressPass) and production-grade reactive protocols (Swift and DCTCP) and show that SIRD is uniquely able to simultaneously maximize link utilization, minimize queuing, and obtain near-optimal latency.

1 Introduction

Datacenter workloads like ML training [32, 62] and disaggregated resource management [30] increasingly demand high-throughput and low-latency networking. While datacenter hardware continues to offer higher link speeds, switch packet buffer capacity is failing to keep up, and SRAM density trends show that this is unlikely to change [17, 24]. The combination imposes a challenge for congestion control, which generally relies on buffering to deliver high throughput. The challenge is compounded by other important concerns such as hardware heterogeneity and cost of operations [23, 35].

The most established approach to managing congestion is by reactively slowing down sender transmission rates after detecting a problem. This is the approach of sender-driven (SD) protocols [4, 8, 9, 12, 44, 47, 50, 54, 67, 69, 73, 74] like DCTCP [8] and Swift [44] in which senders make decisions based on network feedback. The reactive nature of SD protocols often requires several roundtrips to address congestion; a limitation for workloads dominated by small flows [16, 33, 56]. Further, the flow abstraction makes it difficult to reduce latency through message-centric scheduling [10, 13].

To address these limitations, a recent line of work [16, 20, 31, 36, 39, 56, 61] proactively schedules packet transmissions instead of reacting to congestion buildup. Scheduling is typically implemented by having receivers send *credit* packets to senders, which the latter consume to send back data. This enables tight control over ToR-to-Host ports which are usually the most congested [33, 65, 72]. The receiver-driven (RD) approach enables high throughput with limited buffering in dcPIM [16] and near-optimal latency in Homa [56].

The fundamental tension in the design of receiver-driven schemes is how to schedule packets over shared links. Each receiver has exclusive control of its downlink but must share the bandwidth of the network's core and that of sender uplinks with other receivers. In a distributed protocol, this creates scheduling conflicts if receivers do not coordinate. Proposed solutions for this problem include explicit pre-matching of senders and receivers (dcPIM [16]), in-network credit throttling (ExpressPass [20]), and the overcommitment of receiver downlinks (Homa [56]). Despite impressive results, each of these approaches makes a sacrifice in either message latency, protocol complexity, or packet buffer utilization.

We propose SIRD, a receiver-driven design based on the following simple insight: exclusive links (receiver downlinks) should be managed proactively, and shared links (sender up-

*Work done while at EPFL.

links and switch-to-switch links) should be managed reactively. In practice, this means that receivers gather congestion feedback from shared links which gives them the means to coordinate, while still explicitly controlling their downlinks. By deducing the bandwidth availability of shared links, and especially that of senders, receivers can be more precise in their credit allocation. This allows them to drive high link utilization without inducing contention and the corresponding queuing in the network. Low queuing, in turn, enables fast message delivery as the network does not introduce head-of-line blocking.

SIRD implements receiver-driven scheduling that reacts to shared-link congestion feedback using 1) end-host signals to detect congestion on sender uplinks, and 2) ECN [63] to detect congestion in the network's core. Congestion information flows via data packets to receivers and is fed into two independent control loops, with the most congested determining how much credit can be allocated to any given sender. SIRD's design is end-to-end and does not require the use of in-network priority queues or unconventional switch configuration.

We implement SIRD in 4300 SLOC within Caladan [29], a state-of-the-art dataplane operating system. We show that SIRD can efficiently allocate credit, minimize queuing, and implement round-robin and SRPT policies at 100Gbps.

We use network simulation to systematically compare SIRD to three state-of-the-art proactive protocols (Homa [56], dcPIM [16], and ExpressPass [20]) and two production-grade reactive protocols (DCTCP [8] and Swift [44]). Our evaluation shows that SIRD can simultaneously maximize link utilization, minimize queuing, and obtain near-optimal latency. Specifically: (1) SIRD causes 12× less peak top-of-rack (ToR) buffering than Homa yet achieves competitive latency and utilization. (2) Compared to dcPIM, SIRD has no message exchange rounds before sending and outperforms it in link utilization, peak ToR buffering, and tail latency by 9%, 43%, and 46%. (3) SIRD achieves 10× lower tail latency and 26% higher utilization than ExpressPass. (4) SIRD outperforms DCTCP and Swift across the board, especially in incast-heavy scenarios.

2 Background

The main goal of congestion control (CC) is to allocate network resources in a work-conserving manner while avoiding packet loss. There are also other, at times conflicting, CC goals, *e.g.,* fairness, flow completion time or deadlines, and multi-tenancy.

Existing datacenter CC schemes for Ethernet networks can be broadly split into two categories: reactive and proactive. In reactive (also sender-driven (SD)) schemes [8–10, 44, 47, 50, 54, 67, 74], senders control congestion by participating in a distributed coordination process to determine the appropriate transmission rates. Senders obtain congestion information through *congestion signals* like ECN [8, 63, 67], delay [44, 54], and in-network telemetry [47, 69].

In proactive schemes [5, 13, 16, 20, 31, 36, 46, 56, 61] bandwidth is allocated explicitly, either globally, or in a distributed manner. Global approaches [46, 61], use a centralized arbiter that controls all transmissions and hence face scalability challenges. Distributed proactive designs operate either end-to-end [13, 16, 31, 56] or with switch involvement in credit management [5, 20]. In end-to-end protocols, which are receiver-driven (RD), each receiver explicitly schedules its downlink by transmitting special-purpose credit tokens to senders. The credit rate can be explicitly controlled by a pacer [20, 36] or be self-clocked [16, 31, 56].

2.1 Exclusive and shared links

Packets flowing to a receiver host can experience congestion either at the ToR-host link, which is exclusive to the receiver, or at host-ToR uplinks and the network core, which are shared among multiple receiving hosts.

Exclusive links: In the context of RD protocols, ToR-to-Host links (downlinks) can be seen as exclusively controlled by a single entity, the receiver. By controlling the rate of credit transmission, a receiver can explicitly control the rate of data arrival - assuming the bottleneck is the downlink. In fact, downlinks are the most common point of congestion in datacenter networks [33, 44, 65, 72]. Congestion at the ToR downlink is the result of incast traffic from multiple senders to one receiver. In turn, incast is the result of the fan-out/fan-in patterns of datacenter applications [25].

RD schemes excel in managing incast traffic because each receiver explicitly controls the arrival rate of data [13, 16, 20, 31, 36, 56]. This level of control also allows RD schemes to precisely dictate which message should be prioritized at downlinks and can even factor-in application requirements [60]. Recent work has delivered significant message latency improvements by scheduling messages based on their remaining size (SRPT policy) [31, 39, 56]. In contrast, SD schemes [8–10, 44, 47, 50, 54] treat downlinks as any other link. Senders must first detect incast at a receiver's downlink and then independently adjust their rates/windows such that the level of congestion falls below an acceptable target.

Shared links: Unlike exclusive downlinks, core and sender-ToR link bottlenecks pose a challenge for RD schemes. Shared link bottlenecks can appear when multiple receivers concurrently pull data packets over the same link. Before discussing existing approaches to deal with this key challenge, we delve deeper into the specifics of shared-link congestion.

When congestion occurs in the network *core*, multiple flows from unrelated senders and receivers compete for bandwidth on core links. Note that although the core may comprise multiple tiers, it is fundamentally shared infrastructure. Congestion at the core of a fabric is less common than at down-

links [33, 56, 65] but can still occur due to core network oversubscription. Oversubscription can be permanent to reduce cost [65] or transient due to component failures. Congestion at the core can also occur because of static ECMP IP routing decisions that cause multiple flows to saturate one core switch and one core-Tor downlink, while other core switches have idle capacity [7, 35].

Uplink congestion occurs due to the fan-out of multiple flows to different receivers or due to bandwidth mismatch between the sender's uplink and the receiver's downlink. Because the resulting packet buffering is in hosts and not in the fabric, sender congestion is a less severe problem from the perspective of packet loss. For RD schemes, uplink congestion is known as the *unresponsive sender problem* [56] and leads to degraded throughput as independent scheduling decisions of receivers may conflict, wasting downlink bandwidth. For example, two receivers may both decide to schedule the same sender A at the same time, even if one of the receivers could be receiving data from sender B. Whereas the term *unresponsive* has been used in the context of SRPT scheduling, where messages are transmitted to completion, we will use *congested sender* as a general description of uplink congestion.

RD protocols have proposed various mechanisms for overcoming the tension between independent receiver scheduling and the fact that some links are shared. One of the earliest designs, pHost [31], employs a timeout mechanism at receivers to detect unresponsive senders and direct credit to other senders. NDP [36] employs very shallow buffer switches and eagerly drops packets, using packet trimming to recover quickly. NDP receivers handle uplink sharing by only crediting senders if they transmit data packets - whether dropped or not. pHost and NDP do not explicitly deal with core congestion and, further, analysis by Montazeri *et al.* [56] showed that neither of the two achieves high overall link utilization. Homa [56] introduced *controlled overcommitment* in which each receiver can send credit to up to k senders at a time. Homa achieves high utilization as it is statistically likely that at least one of the k senders will respond. However, it trades queuing for throughput by meaningfully increasing the amount of expected inbound traffic to each receiver. To let short messages bypass network queues, Homa leverages switch priority queues, which are typically used for application-level QoS guarantees [12, 37, 44]. dcPIM [16] employs a semi-synchronous round-based matching algorithm where senders and receivers exchange messages to achieve a bipartite matching. This coordinates the sharing of sender uplinks but congestion at the core is only implicitly addressed by the protocol's overall low link contention. The downside of this link-sharing approach is message latency. dcPIM delivers small messages quickly by excluding them from the matching process. However, messages larger than the bandwidth-delay-product (BDP) of the network must wait for several RTTs before starting transmission. ExpressPass [20] manages all links, exclusive and shared, via a hop-by-hop approach which configures switches to drop excess credit packets, which in turn rate limits data packets in the opposite direction. To reduce credit drops, ExpressPass uses recent credit drop rates as feedback to adjust the future sending rate, and in this way also improves utilization and fairness across multiple bottlenecks. Out of the designs discussed so far, ExpressPass is the only one that explicitly manages core congestion and can operate with highly oversubscribed topologies. ExpressPass's hop-by-hop design helps it achieve near-zero queuing [20] but is more complex to deploy and maintain due to its switch configuration and path symmetry requirements.

2.2 The impact of ASIC trends on buffering

Congestion control protocols depend on buffering to offset coordination and control loop delays and, as a result, face a throughput-buffering trade-off. Maximum bandwidth utilization can trivially be achieved with high levels of in-network buffering, but at the cost of queuing-induced latency and expensive dropped packet retransmissions. Conversely, low buffering can lead to throughput loss for protocols that are slow in capturing newly available bandwidth.

High-speed packet buffering is handled by small SRAM buffers in switch ASICs, the size of which is not increasing as fast as bisection bandwidth. For example, nVidia's top-end Spectrum 4 ASIC has a 160MB buffer, which corresponds to 3.13MB per Tbps of bisection bandwidth [58]. The previous 12.8Tbps and 6.4Tbps top-end Spectrum ASICs were equipped with 5MB and 6.6MB per Tbps respectively [52, 53] (full list in Appendix A). Unfortunately, future scaling of SRAM densities appears unlikely given CMOS process limitations [17, 24]. In parallel, datacenter round-trip times (RTT) are not falling as they are dominated by host software processing, PCIe latency, and ASIC serialization latencies. Consequently, as link speeds increase, CC protocols must handle higher BDPs with less switch buffer space at their disposal.

To better absorb instantaneous bursts of traffic, switch packet buffers are generally shared among egress ports. Some ASICs advertise fully shareable buffers while others implement separate pools or statically apportion some of the space to each port [33]. On top of the physical implementation, various buffer-sharing algorithms dynamically limit each port's maximum allocation to avoid unfairness [8]. However, if a large part of the overall buffer is occupied, the per-port cap becomes more equitable, limiting burst absorbability [33].

Figure 1 provides some context by comparing the buffer use of Homa, a state-of-the art RD protocol, with recent switch buffer capacities under the Websearch workload [10]. The dotted lines represent the per-port (left) and completely shared (right) buffer capacities of the hypothetical switches, adjusted on a per-unit basis to the port radix of our simulation methodology (§6.2). In practice, the buffer is neither partitioned nor fully shared; however, between the two extremes, hardware trends are constraining the throughput-buffering trade-off.

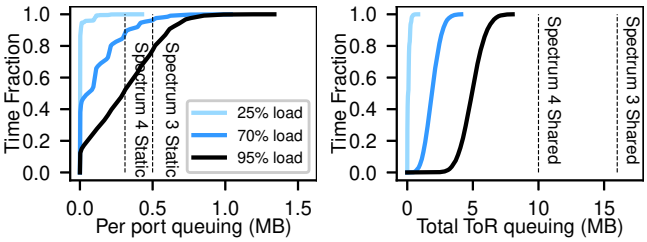

Figure 1: Homa queuing CDFs under various network loads for workload Websearch [10]. The dotted lines represent the switch buffer size adjusted to the actual radix of our simulated ToR; see §6.2.

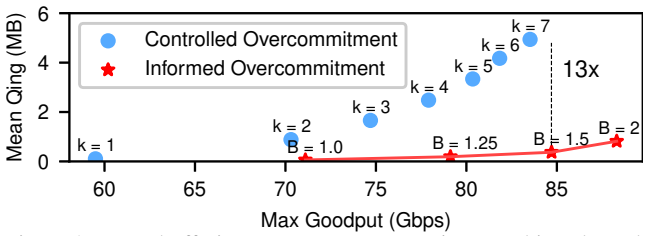

Figure 2: Mean buffering at ToRs versus maximum achieved goodput when sweeping the overcommitment parameter for SIRD (informed overcommitment) and Homa (controlled overcommitment). Results obtained in simulation by running the Websearch workload at 95Gbps on 100Gbps links across 144 servers; see §6.2.

3 SIRD Design Pillars

SIRD is an end-to-end receiver-driven scheme that manages exclusive links proactively and shared links reactively. In practice, this means that receivers perform precise credit-based scheduling when the bottleneck is their downlinks and use congestion feedback to coordinate over shared links. SIRD does not face the limitations of prior work as it:

- is end-to-end, with all decision-making happening at end hosts, and does not rely on advanced switch features or configuration.
- achieves high throughput by using sender and core link congestion feedback to allow receivers to direct credit to links with spare capacity.
- causes minimal buffering in the network by drastically reducing the need for downlink overcommitment.
- does not need switch priority queues to deliver messages with low latency, thanks to minimal buffering.
- can start message transmission immediately without a prior matching stage.
- explicitly tackles core congestion through its shared link management approach.

Efficient credit allocation: SIRD's design allows receivers to send the appropriate amount of credit depending on the real-time availability of the bottleneck link. For downlinks the task is trivial as the link's capacity is managed by one receiver. However, when the bottleneck is shared (sender uplink or core link), SIRD receivers detect competition for bandwidth and adjust the amount of issued credit dynamically. For example, if a sender is the bottleneck for two receivers, each will allocate the appropriate amount of credit for their share of the sender's bandwidth. This approach makes the distribution of credit efficient because it is given to hosts that can promptly use it rather than being accumulated by congested senders. As a result, SIRD can achieve high link utilization using a small amount of credit, *i.e.,* with little overcommitment.

SIRD combines efficient credit allocation and overcommitment in *informed overcommitment*. Each receiver is allotted a limited amount of available credit B. The minimum valid value of B is $1 \times BDP$ as this is the amount of credit required to pull $1 \times BDP$ of inbound traffic and fully utilize the downlink. Higher values of B lead to downlink overcommitment, which increases tolerance to congested shared links but also increases expected queuing.

Figure 2 highlights the benefit of efficient credit allocation in SIRD by comparing the throughput-buffering trade-off across equivalent overcommitment levels for Homa (k), which introduced and uses RD overcommitment, and SIRD (B) under maximum network load. Informed overcommitment yields the same overall goodput despite overcommitting downlinks $14\times$ less, which leads to $13\times$ lower queuing. The goodput-queuing trade-off benefit is maximum at high network load, under which congestion and loss are most likely, and naturally fades as load lessens.

SIRD implements informed overcommitment through a control loop at each receiver, which dynamically adjusts credit allocation across senders based on sender and network feedback. When a sender is concurrently credited by multiple receivers, the sender receives credit faster than it can consume it, causing it to accumulate. This is undesirable as receivers have a limited amount of credit to distribute. Equivalently, limiting accumulation makes credit available to other senders that can actually use it. SIRD's control loop rebalances credit by setting an accumulated credit threshold, $SThr$, that is similar in spirit to DCTCP's marking threshold [8], Swift's target delay [44], or HPCC's η [47]. At each sender, while the amount of accumulated credit from all receivers exceeds $SThr$, a bit is set in all outgoing data packets. Based on arriving bit values, each receiver adjusts the maximum amount of credit that can be allocated to the congested sender in an additive-increase/multiplicative-decrease (AIMD) manner. In this paper, we use DCTCP's [8] AIMD algorithm.

SIRD uses the same mechanisms to handle core congestion with ECN as the signal. Receivers read the CE bit of data packets and adjust per-sender credit limits using AIMD.

Each receiver runs two AIMD algorithms in parallel, one for senders and one for the core, each with its own input signal. The algorithm instance of the most congested area determines credit allocation. This separation of signals allows SIRD to use different signal/algorithm combinations to handle bot-

tlenecks at hosts and switches. Beyond ECN, SIRD can use signals such as end-to-end delay on infrastructures with timestamping support [44] or In-Band Telemetry [47, 69]. In this paper, we use the same proven and simple combination for both and leave the exploration of more complex algorithms and signals to future work.

Starting at line rate: Prior work [31, 36, 39, 56] has demonstrated the latency benefits of starting transmission at line rate, without a gradual ramp-up or preceding control handshakes that take at least one RTT. SIRD's credit allocation mechanism operates *while transmission progress is made*, and thus, senders immediately start at line rate, sending the first BDP bytes *unscheduled* (without waiting for credit).

We further optimize the design based on the following simple observation: small messages benefit the most from unscheduled transmission since their latency is primarily determined by the RTT while throughput-dominated messages see minimal gain. For example, in the absence of queuing, delaying transmission by one RTT increases the end-to-end latency of a message sized at $10 \times BDP$ by 9% compared to 200% for a single-packet message. Therefore, to reduce unnecessary bursty traffic and queuing, SIRD senders do not start transmitting messages larger than a configurable threshold (UnschT) before explicitly receiving credits from the receiver. For messages smaller than UnschT, senders send the first $min(BDP, msg_size)$ bytes without waiting for credit.

Switch priority queues not required: By efficiently allocating credit, SIRD achieves high link utilization with minimal fabric queuing, thereby largely eliminating its impact on latency. Thus, SIRD can be deployed without any in-network QoS support, though it can benefit in terms of tail latency from having a total of two priority levels.

4 SIRD Design

At a high level, SIRD is an RPC-oriented protocol, similar to other recently proposed datacenter transports [16, 31, 56]. SIRD may be used to implement one-way messages or remote procedure calls [42, 43, 56]. SIRD assumes that the length of each message is known or that data streams will be chunked into messages. SIRD further assumes that ECN is configured in all network switches, with the ECN threshold set according to DCTCP best practices [8]. SIRD is designed to be layered on top of UDP/IP for compatibility with all network deployments. The UDP source port is randomly selected for each packet for fine-grain load balancing, allowing an ECMP network to behave as effectively as random packet spraying [26]. We make no assumption of lossless delivery, in-network priority queues, or smart NICs and switches.

SIRD defines two main packet types: **(1)** `DATA`: a packet that contains part of the payload of a message. Data packets can be scheduled, requiring credit to be sent, or unscheduled. Messages with size $> UnschT$ are scheduled and make an initial credit request by sending a zero-length `DATA` packet; **(2)** `CREDIT`: a control packet sent by the receiver to the sender to schedule the transmission of scheduled `DATA`.

Generally, the flow of packets consists of credit flowing from receivers to senders and data flowing in the opposite direction. Credit leaves the receiver in a `CREDIT` packet, is used by the sender, and returns with a scheduled `DATA` packet.

4.1 Credit Management

Each SIRD receiver maintains two types of credit buckets that limit the amount of credit it can distribute: a global credit bucket and per-sender credit buckets.

The *global credit bucket B* controls overcommitment by capping the total number of outstanding credits that a receiver can issue. Configuring $B \geq BDP$ is necessary to enable link saturation. Further, B bounds the queuing length from scheduled packets to $B - BDP$ bytes at the ToR's downlink. Our analysis (§4.2) and evaluation (§6) show that setting B as low as $1.5 \times BDP$ is sufficient for high link utilization.

Each receiver also maintains a credit bucket per sender machine it communicates with. The *per-sender credit bucket* caps the number of outstanding credits the receiver can issue to a sender. Informed overcommitment is implemented by adjusting the size of the per-sender credit bucket according to the level of congestion at the core and the sender (max $1 \times BDP$). Reducing the bucket size means that less of the receiver's total credit can be allocated to a congested source or path, and thus, more is available for other senders.

4.2 Informed Overcommitment

Informed overcommitment uses two input signals that communicate the extent of congestion in the network and at senders. The signals are carried in `DATA` packets and are the ECN bit in the IP header set by the network and a bit in the SIRD header set by the sender. Each receiver runs two separate AIMD (additive-increase, multiplicative decrease) control loops and uses the most conservative of the two (similar to Swift [44]) to adjust per-sender credit bucket sizes. Each control loop is configured with its own marking threshold ($NThr$ and $SThr$). $NThr$ should be set according to DCTCP best practices [8] to limit queuing in the network core. Note that $NThr$ is much higher than the maximum allowed $B - BDP$ of persistent queueing at ToR switches. Thus, ToR switches never have to mark ECN.

$SThr$ should be set to limit the amount of credit a sender can accumulate, thus allowing receivers to efficiently distribute their limited aggregate credit. Intuitively, $SThr$ determines the level of accumulated credit the control loop is targeting when a sender is congested, *i.e.,* receiving credit faster than it can use it. Setting it too high means each sender can accumulate substantial amounts of credit, and consequently, B would

need to be configured higher to increase aggregate credit availability. Conversely, setting $SThr$ too low does not allow the control loop any slack when converging to a stable state and can cause throughput loss.

To understand the relationship between $SThr$ and B, we analytically examine a simple congested-sender scenario from the perspective of a receiver R to find: how much total credit (B) does R need when receiving from k congested senders, to still have enough credit available to saturate its downlink. Assuming each congested sender sends to f receivers in total, its available uplink bandwidth for R is BW/f. Assuming uniform link speeds, we are interested in the case where senders are the bottleneck and cannot saturate R, or:

$$BW_{supply_k} < BW_{demand_R} => \frac{BW}{f} < \frac{BW}{k} => f > k \quad (1)$$

In this case, each of the k senders accumulates up to $SThr$ credit in stable state, or $SThr/f$ from each receiver assuming an equal split (see §4.4). Therefore, to be able to saturate its downlink, R's B must be large enough to allow $1xBDP$ of credit to be in flight despite accumulation at congested senders, or:

$$B \geq BDP + \sum_{k} \frac{SThr}{f} \; ; \; f \geq 2, f > k \quad (2)$$

If k_{max} is the number of congested senders that maximizes the right side of the inequality, then $f_{max} = k_{max} + 1$ (f in denominator) and the maximum value of the term is:

$$\sum_{k}^{k_{max}} \frac{SThr}{k_{max}+1} = \frac{SThr}{k_{max}+1} \sum_{k}^{k_{max}} 1 = SThr \frac{k_{max}}{k_{max}+1} < SThr \quad (3)$$

It follows that, in steady state, R can account for any number of congested senders as long as $B \geq BDP + SThr$. Under dynamic traffic patterns (see §6.2.4) higher values of B can help increase the supply of credit in transient phases. Further, policies other than fair sharing can loosen this property. For example, if senders strictly prioritize some receivers, then, in the worst case where R is de-prioritized by all k senders, Equation 2 loses f from the denominator and B depends on the number of worst-case congested senders.

Table 1: Core configuration parameters.

UnschT	Messages that exceed UnschT in size ask for credit before transmitting.
B	Per-receiver global credit bucket size. Caps credited-but-not-received bytes.
NThr	ECN threshold, configured as for DCTCP.
SThr	Sender marking threshold (*sird.csn*).

Algorithm 1 Receiver Logic

Variables:
- $\boldsymbol{b}$: consumed credit from global receiver bucket of size B,
- $\boldsymbol{sb_i}$: consumed credit from the bucket of sender i,
- $\boldsymbol{senderBkt_i, netBkt_i}$: Sender and network credit bucket size,
- $\boldsymbol{rem_i}$: Requested but not granted credit for sender i.

8: $c_r \leftarrow c_r - dataPkt.size$
9: $send(r, dataPkt)$
10: **end procedure**

4.3 Congestion Control Algorithm

Algorithm 1 describes the behavior of a SIRD receiver. When credit is available in the global bucket and on the command of the credit pacer (§4.4), the receiver tries to allocate credit to an active sender (ln. 8). It first selects one of the senders with available credit in the per-sender bucket (ln.9) based on policy (ln.10). The receiver sends a `CREDIT` packet (ln. 12) and reduces the available credit in the global and per-sender buckets, and updates the remaining required credit for that message (ln. 13). Whenever a `DATA` packet arrives (ln. 1), if it is scheduled, the receiver replenishes credit in the global bucket (ln. 3) and the per-sender bucket (ln. 4). Then, it executes the two independent AIMD control loops to adapt to a congested sender (ln. 5) and a congested core network (ln. 6), respectively. The receiver sets the size of the per-sender bucket as the minimum of the two values (ln. 9).

Algorithm 2 describes the implementation of the sender-side algorithm for scheduled `DATA` packets. A host can send

data to a receiver only if it has credit from said receiver. Congested senders mark the *congested sender notification (sird.csn)* bit if the total amount of accumulated credit exceeds $SThr$ (ln. 7). The sender can send unscheduled `DATA` packets at any point in time. It is worth noting that SIRD senders naturally handle scenarios where a meaningful portion of uplink bandwidth is consumed by unscheduled packets. Since senders limit credit accumulation by informing receivers to allocate less credit, the transmission rate of scheduled packets converges to the leftover bandwidth.

4.4 Other Design Concerns

SIRD can be configured to schedule for fairness *e.g.,* by crediting messages in a round-robin manner, or for latency minimization, *e.g.,* by crediting smaller messages first (SRPT), or to accommodate different tenant classes. SIRD implements policies at the receiver (ln .10), which is the primary enforcer, and at the sender (ln. 6). By minimizing queuing in the fabric, SIRD does not need to enforce policies there, simplifying the design. Regardless of which policy is configured at senders, SIRD allocates part of the uplink bandwidth fairly across active receivers, as to ensure a regular flow of congestion information between sender-receiver pairs.

SIRD receivers pace credit transmission to match their downlink's capacity. Pacing improves message latency by reducing downlink queuing from scheduled packets even below the tight $B - BDP$ bound but is not needed for correctness.

If switch priority queues are available, `CREDIT` packets are sent over a higher priority lane to further reduce RTT jitter. The unscheduled prefixes of messages smaller than $UnschT$ also use this lane to bypass transient network queueing. SIRD does not require in-network priority queues to deliver high performance but sees tail latency benefits in some cases (§6.2.4).

Packet loss in SIRD will be very rare by design, but the protocol must still operate correctly in the presence of CRC errors or packet drops due to faults or restarts. SIRD employs Homa's [56] retransmission design in which receivers infer loss when no new packets are received for an incomplete message after a period of a few milliseconds. Upon detecting the loss of a scheduled segment, receivers also reclaim the credit allocated for said segment. SIRD's modest credit overcommitment (*e.g.,* 50%) ensures that receivers can continue fully utilizing their bandwidth even in the improbable event where a sizeable chunk of packets is lost. Finally, SIRD incurs no performance penalties from out-of-order packet deliveries as it does not rely on packet order for loss detection and only delivers completed messages to applications.

5 Caladan Implementation

SIRD, with its message-level API and simple credit management design, can be implemented in NIC hardware or in software. The former eliminates PCIe latencies from the RTT, reducing the *BDP*, and allows for nanosecond-scale pacing and delivery of packets on the wire. We demonstrate that the latter is also possible, at 100Gbps, by implementing SIRD in 4300 SLOC as a UDP-based transport protocol in Caladan [29], a state-of-the-art kernel-bypass dataplane operating system and CPU scheduler. We chose Caladan because of its mature network stack and its lightweight green thread abstraction, suitable for building latency-sensitive applications. SIRD is open source and available on GitHub [1].

The SIRD stack follows an asymmetric design where dedicated spinning threads perform specialized tasks. On the receiver-side, each SIRD node has one dedicated thread that runs the control loops and implements downlink scheduling policies, like round-robin or SRPT, by transmitting paced `CREDIT`s according to Algorithm 1. SIRD reduces network queuing by pacing credit at slightly less than the line rate, as proposed in Hull [9]. Dedicated receiver cores read from RX rings and adjust credits, ensuring the system can quickly replenish new credits for redistribution. Each dedicated receiver core has two RX rings, one for packets of scheduled messages and one for packets of unscheduled messages; this helps avoid drops of scheduled packets during high rates of unscheduled traffic. For efficiency, and to sustain 100Gbps line rates, memory allocation and data copying operations are removed from the credit replenishment path to a small set of dedicated threads which copy packets, reassemble messages from packets, which can be received out of order, and deliver messages to applications via inline callbacks.

The sender-side implementation also has a central thread, which accepts `CREDIT` packets and schedules the transmission of all `DATA` packets, whether these are unscheduled or scheduled. This thread implements Algorithm 2 which marks the *sird.csn* bit of `DATA` packets by comparing the amount of accumulated credit to $SThr$. Like the central receiver thread, this thread paces itself to ensure that packets are not given to the NIC faster than it can consume them. The thread accepts new message requests via asynchronous shared-memory queues, where the application API returns error codes if resource limits are exceeded.

6 Evaluation

We evaluate SIRD using our Caladan implementation and through simulation to answer the following questions: **(1)** Can a software implementation of SIRD deliver 100Gbps along with minimal queuing under incast (§6.1.1) and efficient credit management under outcast (§6.1.2)? **(2)** How well does SIRD navigate the throughput-buffering-latency trade-off in larger scale workloads compared to existing work (§6.2.1)? **(3)** Is SIRD's congestion response robust at high load pressure and can it handle core congestion (§6.2.2)? **(4)** Can SIRD deliver messages with low latency in large scale workloads (§6.2.3)? **(5)** How important is SIRD's sender-informed design in maximizing utilization with minimal buffering? How sensitive is

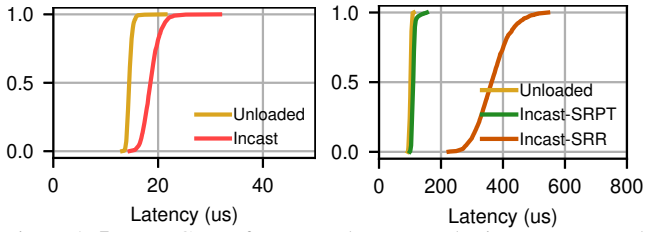

Figure 3: **Incast:** CDF of message latency under incast compared to an unloaded baseline for 8B requests (left) and 500KB requests (right). The incast is formed by six senders transmitting 10MB messages in an open loop.

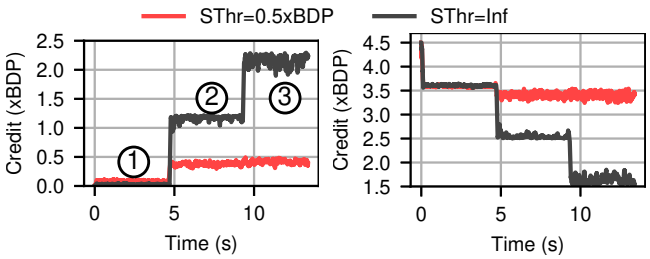

Figure 4: Left: credit accumulated at congested sender. Right: sum of credit available at the three receivers - initial total: $4 \times 1.5 = 4.5 \times BDP$. 100ms moving average. The circled numbers indicate the number of receivers at that stage of the experiment.

SIRD to its parameters (§6.2.4)?

6.1 System Evaluation

We evaluate SIRD at a small scale using Cloudlab's [27] sm110p machines equipped with 100Gbps ConnectX-6 DX NICs and Xeon 4314 CPUs, all located in the same rack. Our implementation uses 9KB jumbo frames and the unloaded RTT of the SIRD-Caladan stack is approximately 18 µs. Latency measurements are end-to-end, measured by the client, and include four request/reply copies to/from the application layer. We sample other system metrics every 2ms. While the size of requests may vary from experiment to experiment, replies are of minimal size.

We configure SIRD parameters as follows: $BDP = 216KB$ (24 jumbo frames), $B = 1.5 \times BDP$, $SThr = 0.5 \times BDP$, $UnschT = 1.0 \times BDP$. We do not use switch priority queues.

6.1.1 Receiver Congestion

SIRD's main objectives when handling incast are eliminating queuing-induced latency for small messages and being able to reduce latency for larger messages through credit-based scheduling. To evaluate this, we run an experiment where six senders saturate a receiver by sending 10MB requests at a rate of 17Gbps each. A seventh sender periodically transmits either 8B or 500KB requests and captures the latency distribution.

Figure 3 (left) plots the round-trip latency experienced by short requests, which are unscheduled. When the receiver is saturated, we observe only a few microseconds of additional latency compared to when the receiver is unloaded, which corresponds to a couple of packets of queuing, either at the ToR or at the host stack. For context, the median latency under load for the same experiment using kernel TCP Cubic was above 1ms. SIRD achieves this result because it limits the number of scheduled inbound bytes to B and thus the extent of downlink queuing to $B - BDP$. Further, since in this case senders respond to credit immediately, credit pacing effectively eliminates downlink queuing, while still achieving 96Gbps in this experiment.

Figure 3 (right) shows the latency of *scheduled* 500KB requests under two receiver scheduling policies. Under SRPT, the receiver allocates credit to the message with the fewest remaining bytes and thus quickly prioritizes 500KB over 10MB requests, leading to near-unloaded latency despite the saturated downlink. SIRD can also implement fairer policies like per-sender round robin ("SRR") as shown. Finally, as it causes minimal network queuing, SIRD can implement such policies without in-network QoS support.

6.1.2 Sender Information

When senders are the bottleneck (outcast), SIRD tackles the congested sender problem by providing congestion feedback to receivers and allowing them to adjust their credit allocation. To evaluate the mechanism's efficacy at 100Gbps, we run an outcast experiment where a single sender sends 10MB messages at full rate to three receivers in a time-staggered manner. Figure 4 (left) shows that, without informed overcommitment ("$SThr = Inf$"), the level of credit accumulated at the congested sender increases with every new receiver. This is because each receiver independently gives the sender $1 \times BDP$ worth of credit to achieve full rate. Through congestion feedback ("$SThr = 0.5 \times BDP$"), receivers coordinate and scale down their credit allocation until credit accumulation at the sender is less than $SThr = 0.5 \times BDP$, on average. Credit, instead, stays at receivers, and can be used to schedule other senders. Figure 4 (right) shows the sum of credit available at the three receivers, each receiving a max-min fair share of the sender's bandwidth. Without informed overcommitment, each receiver allocates $1 \times BDP$ worth of credit to the congested sender. With it, each allocates $(BDP + SThr)/num_rcvers$.

6.2 Simulations

We use network simulation to evaluate SIRD on large-scale workloads and compare it to other protocol designs.

We compare SIRD to 5 baselines: DCTCP [8], a widely deployed sender-driven scheme [33], Swift [44], a state-of-the-art production sender-driven scheme, Homa [56], because of its near-optimal latency and its use of overcommitment, ExpressPass [20], as it employs a hop-by-hop approach to managing credit, and dcPIM [16], as a unique point in the

design space as it explicitly matches senders and receivers. We do not extend Homa with Aeolus [39] for the reasons discussed in [40]. Note that the Homa and dcPIM papers [16,56] already include favorable comparisons to NDP [36], Aeolus [39], PIAS [13], pHost [31], and HPCC [47], thus we did not include them in our evaluation.

We implement SIRD on ns-2 [11], reuse the original ns-2 DCTCP implementation (using the same parameters as [10], scaled to 100Gbps) and the original ns-2 ExpressPass implementation [21], and port the published Homa simulator [55] to ns-2 using the same parameters as in [56] scaled to 100Gbps. The published Homa simulator does not implement the incast optimization [56], which further relies on two-way messages. We use a community Swift simulator, kindly made public [3], and configure its delay parameters to achieve similar throughput to DCTCP, respecting the guidelines [44]. Finally, we use the published dcPIM simulator [15]. SIRD's simulator is open source and available on GitHub [2].

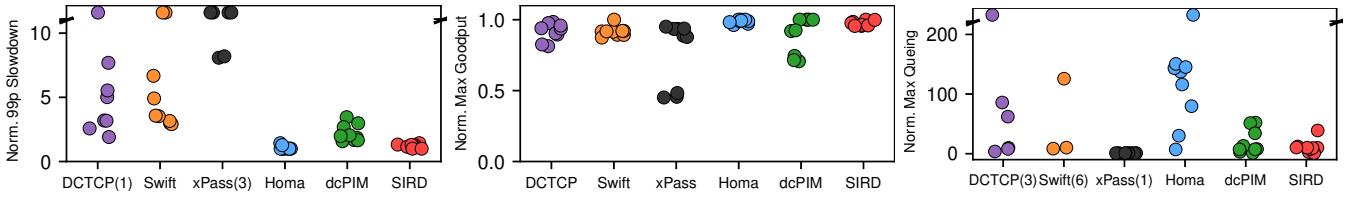
Table 2 lists protocol parameter values. DCTCP and Swift use pools of pre-established connections (40 for each host pair). SIRD approximates SRPT scheduling like Homa and dcPIM. SIRD, Homa, and dcPIM use packet spraying, DCTCP and Swift use ECMP. Homa uses 8 network priority levels, dcPIM 3, and SIRD 2 (§4.4). The initial window of DCTCP and Swift is configured at *BDP* like in [10]. The RTT latency is similar to prior work.

Topology: We simulate the two-tier leaf-spine topology used in previous work [8, 10, 16, 31, 56] with 144 hosts, connected to 9 top-of-rack switches (16 hosts each) via 4 spine switches, with link speeds of 100Gbps to hosts and 400Gbps to spines. We simulate switches with infinite buffers, *i.e.,* without packet drops (1) to avoid making methodologically complex assumptions as drop rates and thus latency and throughput are very sensitive to switch buffer sizes, organization, and configuration [33,40] (see §2.2); and (2) to study the intended mode of operation of the protocols that leverage buffering to achieve high link utilization and operate best without drops. The intentional dropping of credit packets to adjust sender rates by ExpressPass is maintained. SIRD never uses more than a small fraction of the theoretical capacity (§6.2.1) and is not affected by this setup.

Workload: Each host operates both as client and server, sending one-way messages according to an open-loop Poisson distribution to uniformly random receivers (all-to-all). We simulate 3 workloads: **(1) WKa**: an aggregate of RPC sizes at a Google datacenter [28]; **(2) WKb**: a Hadoop workload at Facebook [64]; **(3) WKc**: a web search application [10]. We select them to test over a wide range of mean message sizes of 3KB, 125KB, and 2.5MB respectively.

We simulate these 3 workloads on 3 traffic configurations, for a total of 9 points of comparison. The configurations are: **(1) Balanced:** The default configuration described above. We vary the applied load, which does not include protocol-dependent header overheads, from 25% to 95% of link capacity. **(2) Core:** Same as (1) but ToR-Spine links are 200Gbps (2-to-1 oversubscription). Due to uniform message target selection, $128/144 \approx 89\%$ of messages travel via spines, turning the core into the bottleneck. We consequently reduce the load applied by hosts by $\times 0.89 * 2$ to reflect the network's reduced capacity. This is not meant to reflect a permanent load distribution, but we hypothesize that it is possible transiently. **(3) Incast:** We use the methodology of [16,47] and combine background traffic with overlay incast traffic: 30 random senders periodically send a 500KB message to a random receiver. Incast traffic represents 7% of the total load.

We report goodput (rate of received application payload), total buffering in switches, and message slowdown, defined as the ratio between the measured and the minimum possible latency for each message. In the incast configuration, we exclude incast messages from slowdown results.



6.2.1 Performance Overview

Figure 5 shows how protocols navigate the trade-offs between throughput, buffering, and latency by plotting their relative performance across all 9 workload-configuration combinations. The best-performing protocol on each of the 9 scenarios gets a score of 1.0 (per metric) and the others are normalized to it, so that goodput is always ≤ 1.0 whereas queuing and slowdown are always ≥ 1.0. We report the highest achieved goodput and peak queuing over all the levels of applied load. We report 99^{th} percentile slowdown across all messages of each workload at 50% applied load which is a level most protocols can deliver in all scenarios. The following figures and calculations do not include cases where a protocol cannot satisfy a specific load level or cannot stop network buffers from growing infinitely.

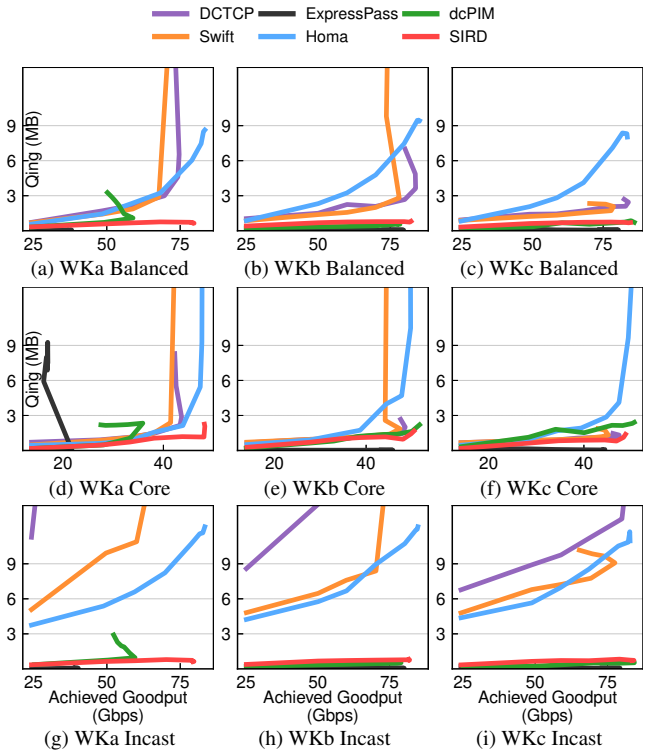
Overall, SIRD is the only protocol that consistently achieves near-ideal scores across all metrics. Specifically, SIRD causes 12× less peak network queuing than Homa and achieves competitive latency and goodput performance.

Table 2: Default simulation parameters for each protocol.

Prot.	Parameters
all	•RTT(MSS): 5.5µs intra-rack, 7.5µs inter-rack •$BDP = 100KB$; link@100Gbps
SIRD	•B : $1.5 \times BDP$, •$UnschT$: $1 \times BDP$ •$NThr = 1.25 \times BDP$, •$SThr = 0.5 \times BDP$
DCTCP	•Initial window: $1 \times BDP$, •g=0.08 •Marking ECN Threshold: $1.25 \times BDP$
Swift	•Initial window: $1 \times BDP$ •base_target: $2 \times RTT$, •fs_range: $5 \times RTT$ •$\hbar$: $1.25 \times BDP$, •fs_max: 100, •fs_min: 0.1
XPass	•$\alpha = 1/16$ •$w_{init} = 1/16$ •$loss_tgt = 1/8$
Homa	Same as [56] at 100Gbps (incl. priority split)
dcPIM	Same as [16]

(a) Slowdown (b) Goodput (c) Queuing

Figure 5: Normalized goodput, queuing, and slowdown across all 9 configurations. Each metric is normalized based on the best-performing protocol for the given metric and configuration. For queuing and slowdown, lower is better. For goodput, higher is better. Normalized slowdown and buffering are capped at 10× and 200×, respectively, and higher values are plotted in the overflow area. The numbers in parentheses show the number of unstable configurations for each protocol which are not plotted. X-axis jitter is added for visibility. Find the data in Table 4.



SIRD outperforms dcPIM in message slowdown, and peak goodput and queuing by 46%, 9%, and 43% respectively. ExpressPass causes practically zero queuing thanks to its hop-by-hop design, and 88% less than SIRD, but SIRD delivers 10× lower slowdown and 26% more goodput. Even under full fabric saturation, SIRD induces at most 0.8MB of ToR queuing in receiver-bottleneck scenarios and 2.3MB in core-bottleneck scenarios. Given a packet buffer capacity of 3.13MB/Tbps (see §2.2), these values correspond to a maximum buffer occupancy of 8% and 23%, respectively.

6.2.2 Congestion Response

We now zoom in on how each protocol manages congestion across various levels of applied stress. Figure 6 plots maximum buffering across ToR switches as a function of achieved goodput for balanced (top), core (middle), and incast (bottom) configurations. The reported goodput is the mean across all 144 hosts and reflects the rate of message delivery to applications. ToR queuing covers both downlinks and links to aggregation switches (core).

Overall, SIRD consistently achieves high goodput while causing minimal buffering across load levels, even under high levels of stress. Through informed overcommitment, SIRD makes effective use of a limited amount of credit and achieves high goodput while reducing the need for packet buffer space by up to 20× compared to Homa's controlled overcommitment. Further, SIRD displays a more predictable congestion response compared to dcPIM and ExpressPass. As expected, based on Figure 5a, DCTCP and Swift cause meaningful buffering without achieving exceptional goodput. Mean queuing is qualitatively similar (appendix Figure 13).

dcPIM and ExpressPass sometimes compare favorably to SIRD but only when the mean message size is not small. They both struggle in terms of achieved goodput and buffering in **WKa** for all three configurations (left column). In WKa, ≈ 99% of messages are smaller than $1 \times BDP$ and are responsible for ≈ 40% of the traffic. ExpressPass's behavior is known and discussed in [20]: more credit than needed may be sent for a small message which may then compete for bandwidth with productive credit of a large message. For dcPIM, the likely reason as discussed in [41] is that to send a small

(d) WKa Core (e) WKb Core (f) WKc Core
(g) WKa Incast (h) WKb Incast (i) WKc Incast

Figure 6: Maximum ToR queuing vs. achieved goodput. Configurations: Balanced (top), Core (middle), Incast (bottom).

message, a sender has to preempt the transmission of a larger message which can cause the receiver of the latter to remain partially idle. SIRD's behavior is consistent across workload message sizes thanks to slight downlink overcommitment which absorbs discontinuities in large message transmission.

In the core configuration (Figure 6 - middle row), where the core is the bottleneck, we observe that SIRD's reactive congestion management, despite sharing the same ECN-based mechanism as DCTCP, achieves steadier behavior because it limits the number of bytes in the network. Homa, though lacking an explicit mechanism to regulate queing at the core, does constrain peak queuing below 19MB (6MB/Tbps of switch BW) because it limits outstanding bytes to the aggregate overcommitment level of receivers. The same applies to dcPIM

(a) WKa Balanced (b) WKc Balanced

(c) WKa Core (d) WKc Core

(e) WKa Incast (f) WKc Incast

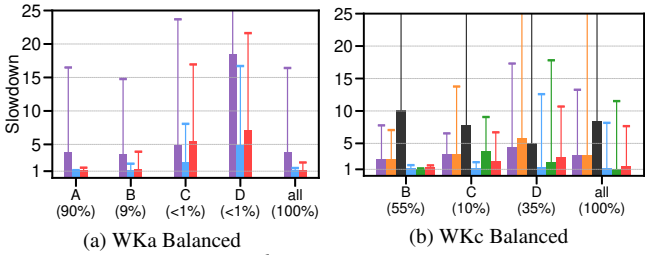

Figure 7: Median and 99^{th} percentile slowdown at 50% offered application load. Each bar group contains the messages in the following size ranges: $0 \leq A < MSS \leq B < 1 \times BDP \leq C < 8 \times BDP \leq D$. Also shown is the percentage of messages that belong to each group. WKc has no sub-MSS messages. Protocols that cannot deliver 50% load are not shown.

though queuing is much lower as it does not overcommit.

Last, the incast configuration (bottom row) illustrates the relative advantage of RD schemes over DCTCP and Swift. Homa's results would be different if the incast optimization described in [56] was implemented and the workload consisted of request-response pairs instead of one-way messages.

6.2.3 Message Latency

Figure 7 shows the median and 99^{th} percentile slowdown for different message size ranges across configurations at 50% applied load (except WKb results which fall between the other two and can be found in appendix Figure 12). Across each workload as a whole (rightmost bar cluster "all"), SIRD is generally on par with Homa, and generally outperforms dcPIM in terms of tail latency. For small, latency-sensitive messages $< BDP$ (100KB - groups A and B), SIRD, dcPIM, and Homa offer close to hardware latency. Both in aggregate and for small messages, DCTCP and Swift perform an order of magnitude worse at the tail because they cause meaningful buffering without having a bypass mechanism like Homa.

(a) WKa Balanced (b) WKc Balanced

Figure 8: Median and 99^{th} percentile slowdown at 70% offered application load. Protocols that cannot deliver 70% load are not shown. Legend same as in Figure 7.

For messages larger than $1 \times BDP$ (groups C and D), SIRD comes closest to near-optimal Homa and strongly outperforms the other protocols. SIRD achieves up to $4\times$ lower latency than dcPIM in this size range because it does not wait for multi-RTT handshakes before sending a message as discussed in §3. Note that Figure 7b is comparable to Figure 3d in [16]. Similarly, SIRD outperforms ExpressPass on latency because it does not take multiple RTTs to capture the full link bandwidth, and because it implements SRPT.

The differences in latency for protocols other than dcPIM and ExpressPass, which wait before ramping up transmission, can be explained through their *effective* scheduling policies. That is, assuming that a protocol manages to deliver enough messages to achieve 50% goodput, lowering latency is a matter of appropriately ordering the transmission of messages (assuming no conflicting application concerns). For example, DCTCP achieves equivalent or better latency than Swift in all but the incast scenarios. We argue that this is because Swift is better at fairly sharing bandwidth between messages thanks to its faster-converging control loop. Latency-wise, fair sharing is inferior to SRPT since it delays individual messages in favor of equitable progress. Along the same lines, SIRD cannot always match the latency of Homa because it approximates SRPT less faithfully: (1) unlike Homa, a portion of the sender uplink is fair-shared (50% in this case). (2) To avoid credit accumulation in congested senders, informed overcommitment adjusts per-sender credit bucket sizes equitably. This mostly impacts the latency of group C, as the bucket size may be small due to sender congestion and not grow during the lifetime of a message smaller than $8 \times BDP$. Consequently, compared to near-optimal Homa in the Balanced configuration, SIRD's 99^{th} percentile slowdown in group C is $1.85\times$ and $2.68\times$ higher at 50% and 70% application load respectively, while it outperforms the other protocols.

Figure 8 shows slowdown under a higher applied application load of 70% for the protocols that can deliver it. At this load level, message scheduling becomes more important and Homa's near-optimal SRPT implementation sees its relative performance improve in some cases.

In summary, SIRD delivers messages with low latency, outperforms dcPIM, ExpressPass, DCTCP, and Swift, and is competitive with Homa, which nearly optimally approximates

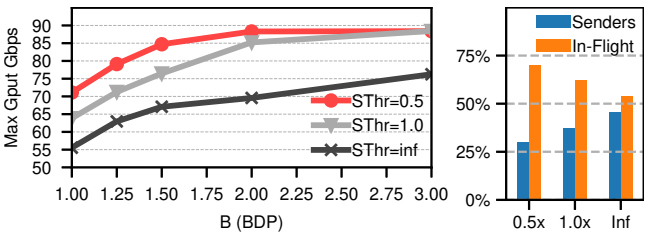

Figure 9: Left: Max goodput across values of B and $SThr$. Right: Credit location at max goodput as a function of $SThr$. $B = 1.5 \times BDP$. "In-flight" is CREDIT and DATA. Credit at receivers is low at this load.

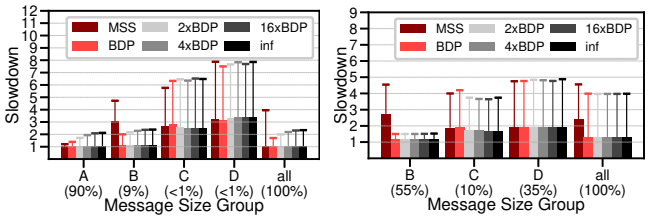

Figure 10: Slowdown as a function of UnschT for WKa (left) and WKc (right) at 50% application load in the balanced configuration;

SRPT [56].

6.2.4 Sensitivity Analysis

In this section, we explore SIRD's sensitivity to its key parameters: B, $SThr$, and $UnschT$, as well as to the availability of switch priority queues. SIRD's sensitivity to $NThr$ is the same as DCTCP's to K [8].

Informed overcommitment: Equation 2 introduced the linear steady-state relationship between B and $SThr$, the two key parameters of informed overcommitment. Figure 9 (left) shows the measured maximum achieved goodput in Balanced WKc as a function of B and $SThr$.

We observe that the presence of informed overcommitment increases achievable goodput by ∼25%, confirming that the introduced sender-informed mechanism is necessary to fully utilize the network with a limited amount of credit, and thus low queuing. When the mechanism is disabled ($SThr = \text{inf}$), there is stranded and unused credit at congested senders, which prevents receivers from achieving the full rate. Figure 9 (right) shows where in the topology credit is under max goodput. Lower $SThr$ values reduce the credit accumulation at senders, and improves throughput by increasing the number of in-flight CREDIT and DATA packets.

With the mechanism enabled, the curves asymptotically converge to the same maximum goodput of 90Gbps. Reaching the plateau with a lower value of B also demands lowering $SThr$ to reduce credit stranded at senders (Equation 2). Queuing increases with B as in Figure 2 and remains stable when varying $SThr$. We selected $B = 1.5 \times BDP$ rather than $B = 2.0 \times BDP$ for our experiments because it halves the maximum buffering caused by scheduled packets from $1\times$ to $0.5 \times BDP$ ($= B - BDP$). We do not configure $SThr$ lower than $0.5 \times BDP$ as we deem it unrealistic to implement in software, as it may cause unwanted marking due to batch credit arrivals. The minimum correct value for this topology is $0.15 \times BDP$, as per the guidelines [8].

Unscheduled transmissions: SIRD allows the unscheduled transmission of the BDP prefix of messages $\leq UnschT$. Figure 10 explores the sensitivity to this parameter using workloads WKa and WKc. Setting $UnschT = MSS$ meaningfully increases median and tail latency for messages with sizes in $[MSS, BDP]$ while higher values offer no appreciable net benefit. This also holds at 70% load. Increasing $UnschT >> BDP$ in WKc has little impact on max and mean ToR buffering, which range within [696,747]KB and [363,378]KB respectively. In contrast, because 99% of messages in WKa are unscheduled, max and mean ToR buffering scale from 501KB to 1016KB and 220KB to 435KB, respectively, as UnschT increases. It is worth noting that saturating the fabric's bandwidth, which is when queuing is maximized, is far less likely with high-request-rate workloads like WKa.

The default value of $UnschT = 1 \times BDP$ is a satisfying compromise as large values do not yield latency benefits yet can unnecessarily expose the fabric to coordinated traffic bursts (*e.g.,* incast). We confirm this by running WKc under the incast configuration which has a high concentration of $5 \times BDP$ message bursts. We observe the following performance degradation when comparing $UnschT = 4 \times BDP$ to $UnschT = 16 \times BDP$: Overall 99^{th} percentile slowdown increases by 34% while maximum and mean ToR queuing increases by 5.7× and 80% respectively. These results justify our decision to introduce a size threshold above which messages are entirely scheduled.

In deployments with severe incast consisting of messages smaller than BDP, UnschT can be configured to be smaller than MSS. If, for example, 100 hosts concurrently send a $0.5 \times BDP$ message to a single receiver, the latter will effectively receive 100 small packets requesting credit. The receiver will immediately start issuing credit based on its policy and ramp-up to full bandwidth utilization one RTT after the senders transmitted. In TCP terms, this specific scenario is roughly equivalent to each sender starting with a window of one MSS, and ramping to the correct window value just one RTT later.

Use of switch priority queues: SIRD may use a second 802.1p priority level for control packets and/or unscheduled DATA. Figure 11 shows how the use of priorities impacts message slowdown for WKa and WKc in terms of (i) possible degradation when switch priority queues are unavailable, and (ii) the benefit of prioritizing unscheduled DATA.

We observe that, across message sizes, median slowdown is largely unaffected and tail slowdown benefits from high priority transmission in some cases. Small messages benefit because they bypass the small queues SIRD forms ($\approx 1 \times BDP$ per link at the 99^{th} percentile and $\approx 0.1 \times BDP$ on average).

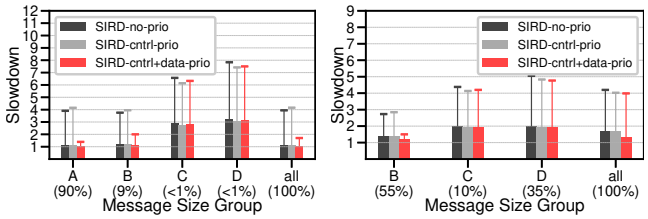

Figure 11: Slowdown as a function of priority use for WKa (left) and WKc (right) at 50% application load in the balanced configuration;

This is more evident in WKa where 99% of messages are unscheduled. Sensitivity to priorities is similar at 70% load (not shown), where, compared to 50% load, group A's tail slowdown benefits 5% more from `DATA` prioritization and group B's 6% less.

Maximum goodput increases by 1% and 2.4% with control packet prioritization for WKa and WKc respectively, as credit is delivered slightly more predictably. Queuing in the network is also insensitive to the use of priorities. Given SIRD's low sensitivity to the availability of switch priority queues, we argue that it can be deployed without this dependency with little sacrifice. This differentiates SIRD from Homa, which is designed around the use of priorities to bypass long in-network queues, and dcPIM, which strongly benefits from tight control packet delivery due to its semi-synchronous nature.

7 Related Work

The topic of datacenter congestion control has been extensively explored due to the increasing IO speeds, the µs-scale latencies, emerging programmable hardware, RPC workloads, and host-centric concerns [4–6, 8–10, 12, 13, 19, 20, 22, 31, 34, 36, 38, 42–48, 50, 51, 54, 56, 57, 61, 66–71, 74].

SD schemes like DCQCN [74], Timely [54], HPCC [47], Bolt [12], and PTT [67] use network signals in the form of ECN [8, 68, 74], delay [44, 54], in-band telemetry [47, 69, 73], and packet drops [10] to adjust sending windows [8, 44, 47, 66] or rates [38, 54, 70]. Some operate end-to-end with no or trivial switch support [8, 44, 54, 67] while others leverage novel but non-universal switch features to improve feedback quality [47, 69, 73] or to tighten reaction times [12, 19, 71].

RD protocols attempt to avoid congestion altogether by proactively scheduling packet transmissions [5, 16, 20, 31, 36, 39, 46, 49, 56, 61] and have already been discussed (§2). Orthogonally to the scope of this paper, FlexPass [49] enables fair bandwidth sharing among proactive and reactive protocols. EQDS [59] enables the coexistence of traditional protocols like DCTCP and RDMA by moving all queuing interactions to end-hosts and using an RD approach to admit packets into the network fabric.

Previous work has followed different approaches regarding the desired flow/message scheduling policy. The traditional approach is to aim for fair bandwidth allocation at the flow level [8, 44, 54, 74]. Alternatively, D^2TCP, D^3, and Karuna [18] prioritize flows based on deadlines communicated by higher-level services. A recent line of work [10, 13, 31, 39, 56], which includes both proactive and reactive protocols, attempts to approximate SRPT or SJF (shorted job first) scheduling in the fabric which minimizes average latency [10, 14]. SIRD can approximate a variety of policies at receivers and senders and avoids the need for fabric policies as it keeps in-network queuing minimal.

8 Conclusion

SIRD takes a holistic approach to datacenter congestion management by tackling the fundamental tension of receiver-driven designs, which is the management of shared links. SIRD applies proactive scheduling to exclusive receiver downlinks, which are statistically the most congested, and leverages sender and fabric congestion feedback to reactively allocate the bandwidth of shared links. Compared to existing designs, SIRD manages to simultaneously deliver high link utilization with hardly any network buffering, and low message latency. SIRD does so without assuming advanced switch ASIC features nor switch priority queues, which makes it compatible with existing and heterogeneous datacenter networks. We implemented a prototype of SIRD in software, on the Caladan stack, and showed that it can efficiently allocate credit while delivering 100Gbps.

Abstract

The rapid expansion of large language models (LLMs) requires the development of extensive GPU clusters, with companies deploying clusters with tens to hundreds of thousands of GPUs. This growth significantly expands the design space for LLM training systems, requiring thorough exploration of different parallelization strategies, communication parameters, congestion control, fabric topology, *etc.* Current methods require up to 10k simulation experiments to identify optimal configurations, with inadequate exploration leading to significant degradation of training performance.

In this paper, we tackle the overlooked problem of efficiently conducting parallel simulation experiments for design space exploration. Our analysis and experiments show that Single-process Multi-experiment (SPME) achieves superior performance by reducing scheduling overhead and optimizing resource utilization, yet remains insufficient for current AI cluster scales. To enhance SPME's efficacy, we introduce Multiverse, a novel GPU-based AI training simulator. Multiverse leverages the computing throughput of GPUs efficiently with optimizations such as a pull-based synchronization, high-fidelity intra-server communication, and a kernel-fusion technique. Extensive experiments validate the accuracy and efficiency of Multiverse, demonstrating less than 3.0% discrepancy with real-world LLM training on clusters of up to 54,000 GPUs, achieving $43.1-73.2\times$ speedup over state-of-the-art CPU-based simulators in various use cases.

1 Introduction

The growth of the scale of LLM models requires large training systems [4, 27]. Companies like Tesla and Meta are building clusters with more than 24 thousand GPUs [16, 30] with O(100k) GPU clusters on the horizon. As a consequence, the design space of the LLM training becomes wider and deeper [15, 28, 54], encompassing the parallelization strategy, parameters of collective communication primitives, congestion control algorithms and parameters, fabric topology

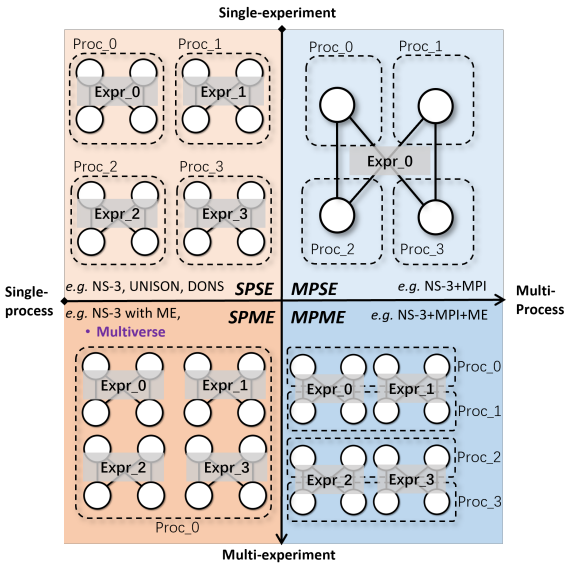

Figure 1: Four types of multi-experiment parallel strategies.

design, and others (see §2.1). As all of these options can interact in complex and unpredictable ways, discovering the optimal design point for a training system requires a massive number of simulation experiments with different option combinations, to fully search the design space. For example, exploring the optimal parallel group size requires ∼100 experiments, while identifying the optimal topology for connecting large-scale GPUs requires over 10k experiments. Insufficient exploration of the design space can lead to suboptimal operational regimes, for instance, employing a suboptimal topology could result in a $3.4\times$ longer training iteration time [58, 59].

Fortunately, we observe that the experimental runs for different points in the design space are generally embarrassingly parallel, which we can leverage to reduce the end-to-end exploration time. How do we best parallelize these experiments? The obvious answer — running n experiments on n CPU cores — falls short of current performance needs, especially when considering that competition for shared resources like memory capacity and low-level cache of CPUs mean that scaling is

sublinear. We believe that, by considering all the experiments at the same time, we can do better.

Our intuition is that batch processing a significant number of experiments aligns well with GPU architecture, which relies on a Single Instruction, Multiple Data (SIMD) execution model. We note that recent work has taken a similar approach to speed up single-experiment network simulation, using a technique called Data-Oriented Design (DOD) [18]. In a DOD-based simulator like DONS [21], users pack data, *e.g.*, packets, in a way where the simulation framework can process steps of the simulation procedure in unison (*e.g.*, running all of ingress pipelines of all switches at the same time) for parallelism and cache efficiency benefits.

We propose to extend the SIMD abstraction to multi-experiment simulation using a strategy in which users run multiple experiments *in a single simulation process*, a strategy we call SPME. Akin to the advantages of Deep Learning and DONS, the advantage of this approach is a substantial reduction in process-inherent overhead and duplicate cache/memory usage. A major additional benefit is that SPME is more amenable to deployment on actual GPUs, whose vastly superior core count and specialization for SIMD provide sizable performance benefits for this type of application.

In this paper, we present Multiverse, the first GPU-based AI training simulator. Multiverse is a DOD-based simulator, but the first to characterize an Entity-Component-System (ECS) model for AI training systems, the first to apply a SPME execution strategy, and the first to adapt all of the above to the constraints of GPU execution. For the latter in particular, Multiverse incorporates three novel techniques for GPU-based AI training simulation: a pull-based synchronization method for lock-free data transfer, a high-fidelity intra-server communication model, and a kernel-fusion technique to greatly improve GPU efficiency.

We perform extensive experiments to confirm the speed and accuracy of SPME and Multiverse. For SPME, our approach occupies a new point in the design space shown in Figure 1. On one axis, we have an existing, well-known criterion: whether to use a single process (SP)[1] or try to accelerate it with multiple processes (MP). On the other axis: running a single experiment in a single process (SE) or running multiple experiments in a single process (ME). We implement all four types of parallel strategies using state-of-the-art simulators (§2.2) and find that on both GPUs and CPUs, SPME achieves the best performance among the four (MP∗E suffers from synchronization overhead, while ∗PSE is inefficient in resource utilization).

For Multiverse as a whole, results show that it can achieve $43.1-73.2\times$ speedup over the state-of-the-art across various use cases (from 50 to 10k simulation experiments) and cluster scales (from 128 to 54k GPUs). Further, the simulation results, such as iteration time, align closely with actual LLM training in real clusters with 1,024 H100 GPUs, exhibiting a difference of less than 3.0%.

We summarize the contributions of this paper as follows:

- We identify the need for parallel experimentation in the design space exploration of large LLM training systems. We then conduct an in-depth analysis and testing of various strategies for parallelizing multiple experiments. The results indicate that the SPME approach outperforms others. We believe that the superior performance of SPME can be attributed to its reduction in process scheduling overhead and its cache-friendly nature.
- We further discover that the DOD principle and the GPU can maximize the potential of the SPME approach. The operational mode of DOD enables parallel execution of identical simulation logic across experiments and devices, such as the forwarding in switches and flow control at the hosts, closely resembling the Single Instruction, Multiple Data (SIMD) tasks that GPUs excel at. We design Multiverse, an AI training simulator, and propose three optimization techniques.
- We evaluate Multiverse on a real testbed, and Multiverse can achieve up to $73.2\times$ speedup over other methods, across various use cases and cluster scales. For simulation accuracy, the training performance metrics output by our simulator closely match the real-world results on a cluster with 1,024 H100 GPUs, showing a discrepancy of $<3.0\%$. Multiverse is open sourced at https://github.com/NASP-THU/multiverse.

2 Background and Motivation

2.1 Exploring the LLM Training Design Space

LLMs require specialized AI training infrastructure, leveraging dozens to 10s/100s of thousands of GPUs that work in concert to complete pre-training or fine-tuning tasks [15, 16, 30, 54]. Constructing large-scale infrastructure to support efficient training involves navigating a deep and broad design space, as illustrated in Figure 2. Mainstream training frameworks such as Megatron [54] and DeepSpeed [48] offer efficient implementations of various parallelization strategies, Data Parallelism (DP), Pipeline Parallelism (PP), and Tensor Parallelism (TP), to utilize large amounts of GPUs efficiently. Collective communication plays a pivotal role in facilitating result interactions among GPUs, utilizing operations like allreduce for gradient synchronization and allgather for full parameter access. The transport protocols and physical network topology underpin the operation of the aforementioned software layers, exerting a fundamental influence on the training performance of LLMs.

Navigating such a vast design space requires extensive exploratory experiments based on simulators, which serve as a crucial tool to validate system designs due to their lower

[1] SP can utilize multi-cores on a single server with multi-threading [8, 21].

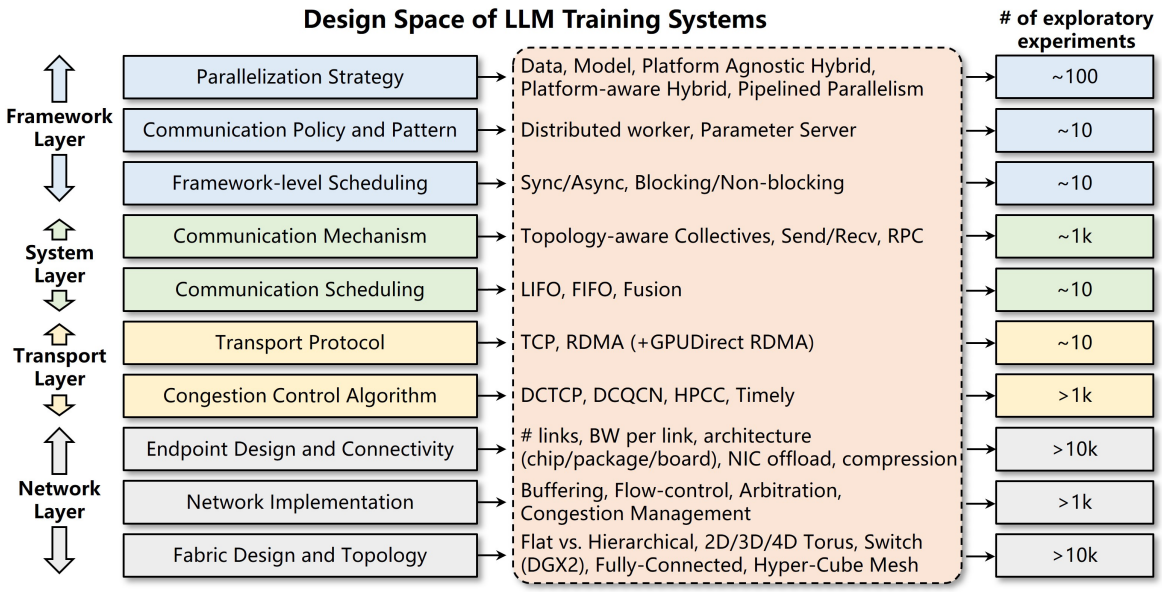

Figure 2: Design space and the number of explorations of LLM training systems.

cost compared to physical testbeds and their higher accuracy relative to analytical models [21, 34, 62]. We list two practical cases to demonstrate how simulation can be utilized to explore optimal design choices for LLM training.

Topology search: There are tons of ways to connect a large number of GPU servers, with classic topologies such as Rail-Optimized Fattree (ROFT) [43], Torus [29], BCube [22], Fat-tree [5], and Dragonfly [31]. However, these well-known topologies may fall short when faced with the evolution of model architectures and training techniques. For example, although ROFT can provide strong all-reduce performance, its all-to-all performance remains less than optimal. Researchers usually try to change parameters such as layers, port numbers, connection relationships, and more in the classic topologies, conduct >10k simulation experiments to compare them, and finally find the most suitable topology for LLM training. For instance, deploying a superior topology can yield a 3.4× increase in training speed [58, 59].

Parallel group size optimization: Allocating GPUs into TP/PP/DP group is also a crucial design decision [26, 42], because TP demands high bandwidth regions while PP needs the avoidance of bubbles. The comparison of group sizes typically requires almost one hundred simulation experiments, depending on the model size and the hardware topology [36].

Although the optimization process can be divided into two distinct phases—a long-term phase for GPU topology search and a short-term phase for other optimizations—to reduce the number of required experiments, a significant number of experiments are still needed in the short-term phase when considering parallel strategy search and collective communication algorithm search. Thus, enhancing simulation speed continues to be an essential objective.

2.2 Multi-experiment Parallelization

We taxonomize the parallelization strategy of multiple independent simulation experiments into four types along two axes: (1) using a single-process or multi-processes to execute one simulation program, and (2) running a single experiment or multiple experiments within one simulation program.

1. Single-Process Single-Experiment (SPSE): This is the most commonly used method during design space exploration, where multiple processes are initiated, each executing a single experiment. For a given experiment, NS-3 [49] and OMNeT++ [57] default to using a single process with a single thread, whereas DONS [21] and UNISON [8] utilize multi-threading (multi-core) to accelerate a single experiment.

2. Multi-Process Single-Experiment (MPSE): This approach uses multiple processes to run a single simulation experiment, like NS-3 or OMNeT++ with MPI [20].

3. Single-Process Multi-Experiment (SPME): Within one program, this strategy extends the single experiment in SPSE to multiple experiments to economize on the inherent overhead of processes.

4. Multi-Process Multi-Experiment (MPME): Similarly, this approach employs multiple processes to execute one program in SPME. For instance, NS-3 utilizes various processes to accelerate a single program, which encompasses several independent topologies running different experiments.

We implement these four parallel strategies based on state-of-the-art simulation technology, and conduct extensive ex-

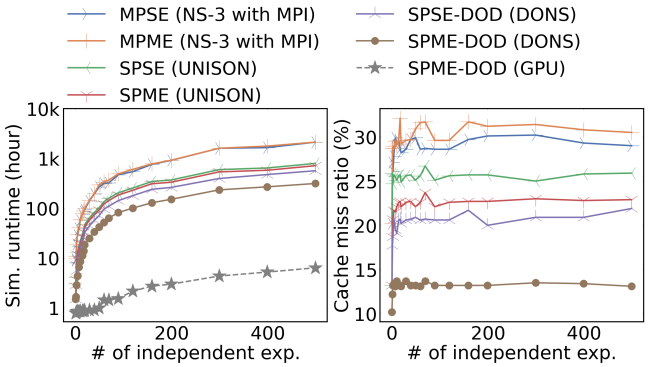

Figure 3: The performance comparison of four multi-experiment parallel strategies.

periments to verify their respective performance. The experimental scenario involves searching for the optimal collective communication algorithm for a cluster with 128 GPU servers, aimed at training a GPT-3 13B model. The simulated topology is Fattree with k=8 (Fattree8), which has 80 switches and 384 links with 100 Gbps. We test these strategies by measuring the time simulators required to complete 1 to 500 independent experiments on a machine, equipped with 80 CPU cores and one H100 GPU. The GPU cache configuration includes 1.3MB L1, 40MB L2, and 55MB L3. Experiments were implemented using C++. The experimental results are depicted in Figure 3, leading us to the following four conclusions.

1. High synchronization overhead in MP∗E: Both MPSE and MPME (the number of processes is set to the optimal value that maximizes CPU utilization) exhibited the poorest performance, necessitating 2k hours to complete 500 experiments. Process-based parallelization cannot share data without incurring context-switching overhead. Experimental results show that high synchronization overhead among multiple processes degrades simulation performance, this problem has been demonstrated in previous literature [21, 62].

2. High cache miss rate in SPSE: We use UNISON and DONS to assess the performance of SPSE. UNISON [8] introduces an efficient multi-threading parallelism technique for NS-3 and claims to achieve super-linear speedup as the number of CPU cores increases, making it the strongest variant to date. DONS [21], leveraging the Data-Oriented Design (DOD) concept, restructures the architecture of the network simulator, achieving improved performance on multi-core CPUs. In both methods, we set the optimal number of cores for each experiment (∼24 cores for Fattree8) to achieve the highest super-linear speedup ratio (∼30×). Consequently, both exhibit superior performance compared to the multi-process versions. However, under multiple experiments, this approach that naively parallelizes by running copies of the simulators will prolong the time of each experiment spent (*i.e.*, the scaling of this dimension is sublinear), due to frequent CPU context switches and severe cache misses.

3. SPME has better performance: We realize the SPME concept by configuring multiple topologies (∼16) within UNISON and DONS. The results show that the performance of both UNISON and DONS improves, benefiting from lower cache misses and process scheduling overhead across experiments. However, DONS with SPME still require significant time (∼370 hours) to complete this case; when used as an exploratory tool, this slow speed is not simply acceptable.

4. Unlocking the potential of SPME requires DOD and GPU: SPME offers a significant performance enhancement for DOD-based DONS. DOD disentangles logic from data, allowing logic to concurrently manipulate the same type of data across all entities. This enables SPME+DOD to identify cross-experiment batching and parallelization opportunities that existing methods ignore. Moreover, this pattern aligns seamlessly with the Single Instruction Multiple Data (SIMD) characteristics of GPUs. The extensive cores within GPUs can further accelerate parallelism across multiple experiments. As a comparison and a preview, Figure 3 illustrates the performance of SPME+DOD+GPU, which surpasses the best available solutions on CPUs by more than 70 times.

2.3 Realizing and Accelerating SPME+DOD for AI Training Systems

With the above observations, we believe that SPME+DOD represents a viable path towards realizing high-performance exploration tools. DOD can improve the execution efficiency of the SPME parallel strategy by separating simulation logic from data as mentioned earlier. Thus, this paper introduces Multiverse, a simulator that realizes SPME+DOD for simulating AI training systems, centered around three key ideas.

1. ECS modeling to enable SPME+DOD for AI training systems. Multiverse uses the Entity-Component-System (ECS) architecture [3, 17] to realize the DOD principle. ECS decomposes objects into separate logic (named *system*) and data (named *component*), and it is currently the default way to realize DOD. We choose ECS because it is easy to develop and prior work, namely DONS [21], has proven its performance benefits. We describe the ECS-based modeling for AI training systems in §3.2.

2. Realizing the SPME+DOD simulation in GPU. SPME+DOD allows multi-experiment simulators to exploit parallelism and coherence (both instruction and data) across experiments to achieve high efficiency on a high-throughput parallel processor like a GPU. To make Multiverse a practical tool for multi-experiment exploration, we delegate all aspects of the simulation to GPUs (§3.3). We centrally manage storage within the GPUs and compile all ECS logic into the GPU, which will adaptively utilize all cores to execute the same simulation logic across all experiments.

3. Optimizing the GPU-based LLM training simulator with three techniques. In the process of developing Multiverse, we see plenty of room to improve performance. Firstly,

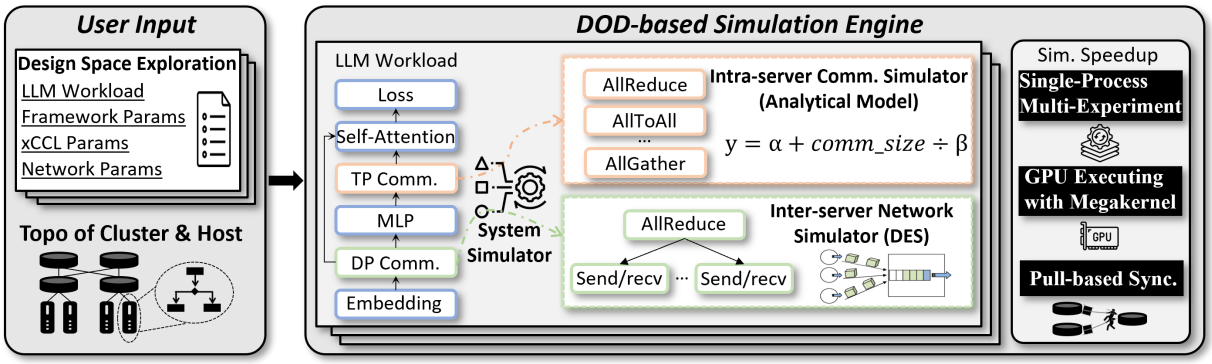

Figure 4: Multiverse's architecture.

executing network simulations with multithreading frequently led to many-to-one write conflicts. To reduce the overhead associated with locks, we implement a pull-based synchronization method. For example, one egress port actively pulls packets from the corresponding ingress ports. Secondly, the communication protocols between NVIDIA GPUs within a single server are not open source. Through extensive profiling experiments, we build an analytical model to estimate the time that GPUs take to execute various collective communication operations. Lastly, we propose a kernel-fusion technique to significantly improve GPU efficiency, compiling the simulation functions, along with wrapper code for component management, into a unified GPU megakernel [45].

3 Multiverse Design

We first overview the architecture of Multiverse and then describe its ECS-based modeling for the AI training system. Finally, we show how to map the ECS models to the GPU. We present the optimization techniques for Multiverse in §4.

3.1 Architecture

Figure 4 shows the key components in Multiverse. Users only need to write the application code, set up an AI training system, including workload, CCL parameters, topology, *etc.* , and specify multiple experiments to run; then Multiverse automatically perform multi-experiment simulations on GPUs.

System Simulator. The system simulator controls and schedules the process of AI training simulation. Its input is the model workload [2], similar to the input in ASTRA-sim [47], which characterizes the computation graph per GPU. Its node is computation operations (such as `Embedding`, `Attetion_linear`, and `MLP_linear`) or collective communication operations (such as `Allreduce`, `Allgather`). We assume that the computation operations are already annotated with the computation times, as the workload produced by Chakra [2]. Multiverse supports typical parallel strategies (*e.g.*, TP, PP, and DP).

For inter-server collective communication operations, the system simulator generates a series of point-to-point send and receive flows by implementing the collective communication algorithms (CCAs) of NCCL [23]. However, within a given CCA, the inherent overhead of the NCCL software stack influences the start time of each flow. To improve the simulation accuracy, we hijack the NCCL APIs to profile the start and end time of each communication in a CCA operation. Consequently, we calibrate the simulation of inter-server collective communications by introducing the measured overhead.

Intra-server Communication Simulator. For an intra-server collective communication operation among GPUs (*e.g.*, TP communications), Multiverse simulates it directly based on the proposed analytical model, which has different empirical parameters according to the operator type and GPU type. This model provides both fast and accurate intra-server communication simulation.

Inter-server Network Simulator. The system simulator registers many point-to-point cross-network communication demands in this network simulator, which would conduct a discrete-event simulation (DES) to rigorously enforce packet-level events and guarantee correctness, like NS-3 [49]. The system simulator is notified when the flow is completed.

GPU Memory Simulator. Since some experimental setups (*e.g.*, the parallel group sizes) may exceed the GPU memory space, Multiverse supports the simulation of GPU memory usage. Before the actual simulation, Multiverse checks whether the parallel strategy and other settings respect the memory size limits. If not, Multiverse generates an *OOM* error.

GPU Runtime. The runtime utilizes ECS abstractions to efficiently allocate multi-experiment simulation tasks to the GPU. Multiverse firstly compiles the ECS system functions, along with wrapper code for component management, into a unified GPU megakernel. Then, the execution graph of ECS systems is transferred to the GPU and processed by the megakernel in every simulation step. The system execution graph informs the runtime that identical systems are executed in each simulation step, and then the GPU adaptively uses all cores to process this system for the corresponding entities across all experiments.

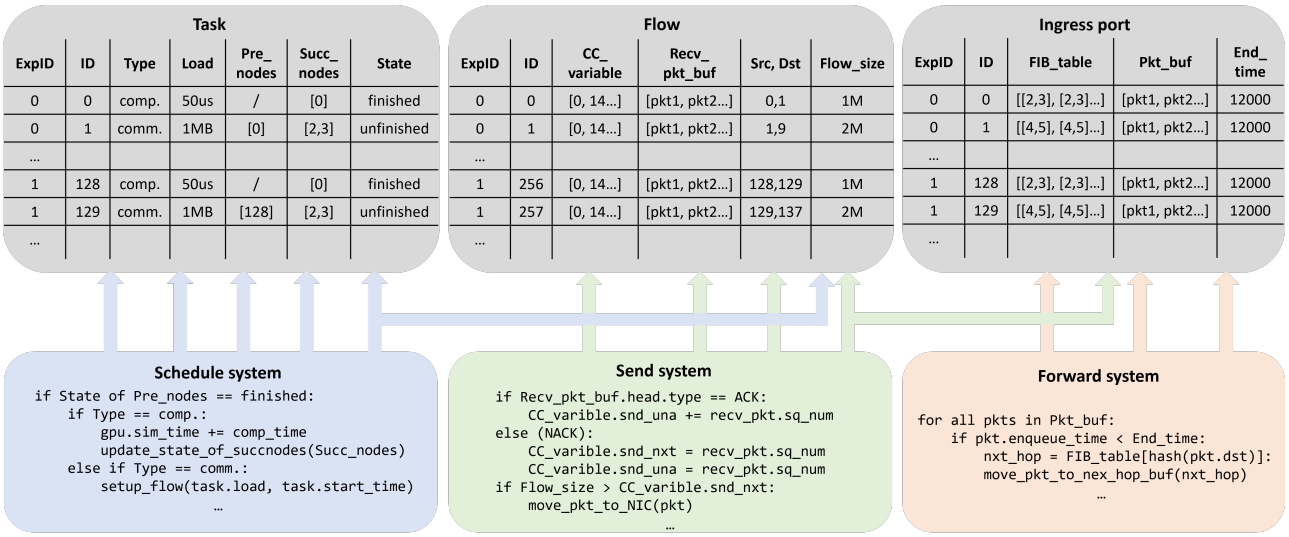

Figure 5: Archetypes and Systems (simplified) in LLM training systems.

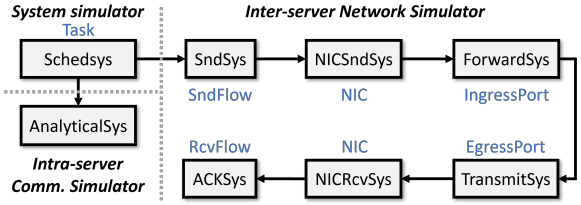

Figure 6: The system execution graph of Multiverse. The terms marked in blue refer to entities.

3.2 ECS Modeling for an AI Training System

Multiverse models the AI training process using Entity-Component-System (ECS) abstractions to realize a high-performance multi-experiment simulator.

Entities and Components. In the context of AI training, we retain the network entities in DONS, such as *Sender*, *IngressPort*, *EgressPort*, and *Receiver*, while introducing pivotal new entities like training *Task*, and *Flow*. The state of an entity is characterized by the values of its components. For instance, as shown in Figure 5, the components defining a *Task* entity encompass type (computation or communication), load (computation time or communication volume), predecessor nodes, and successor nodes. The *Flow* entity is distinguished by components that include its state, congestion control variables, and sending buffer. Entities of the same kind that have the same components are said to share an archetype. Figure 5 illustrates three archetypes of AI training system, as well as example component values for 4 entities of each archetype. Other entities and components are consistent with DONS.

Systems and Queries. Systems represent the data-parallel computations (*i.e.*, simulation logics) executed on collections of entities. A system is delineated by a query that specifies the component data included in the input and a function that is executed on these data. Queries are designed to select entities that possess a predetermined set of components.

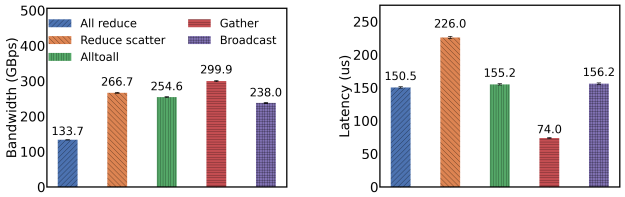
For instance, the `Schedule` system in Figure 5 is executed per *Task*. At each step, it checks the completion status of the predecessor nodes, and activates the successor task nodes. For computation tasks, it increases the simulation clock to advance the simulation process; For inter-server communication tasks, it inputs new flows in the packet-level *Network Simulator*; For intra-server communication tasks, the `AnalyticalSys` system executes the analytical model to estimate the communication time.

System execution graph. This graph defines the entire set of ECS systems needed to execute in a simulation step, as illustrated in Figure 6. Nodes in the graph represent systems, and edges represent the execution order.

In a simulation step, Multiverse executes eight systems: `Schedule`, `AnalyticalSys`, `SendSys`, `NICSndSys`, `ForwardSys`, `TransmitSys`, `NICRcvSys`, and `ACKSys`. After Task entities execute the `Schedule` system, the intra-server communication is simulated by `AnalyticalSys`, then new flows (new *SndFlow* entities are created) are injected into the network simulator, where *SndFlow* entities execute the `Send` system to send packets to the corresponding destinations. Then packets traverse *NIC* and a forwarding path comprised of consecutive *IngressPort* entities and *EgressPort* entities. Finally, the packets arrive at the *RcvFlow* entity, which sends back an acknowledgment (ACK) if needed. After the round, Multiverse starts the next simulation step until the simulation ends. As proved in DONS, this mode of execution ensures the simulation correctness if the length of one simulation step is set reasonably (§5).

3.3 Multi-experiment Simulation in GPUs

The system execution graph enables the runtime to recognize that all experiments will utilize the same systems during sim-



ulations. This understanding allows for safe and efficient parallel execution. By having clear knowledge of execution and data types, Multiverse gains significant control over how simulation logic is assigned to GPUs, leading to high-performance simulations. Multiverse compiles all ECS systems along with the necessary wrapper code for component access into a single GPU megakernel [45]. Then, this megakernel executes the system execution graph for each step of the simulation. Notably, archetypes and their components are set up as column stores in GPU memory.

Management of Component Storage across Experiments. In multi-experiment simulations, Multiverse centrally oversees the storage of all component data. It constructs a single in-memory table that holds component data for entities sharing the same archetype across all experiments, as illustrated in Figure 5. To facilitate efficient access to consecutive components, these tables are organized as column stores, with component data stored in contiguous memory, adhering to standard ECS practices [3]. To handle the per-experiment state when processing entities, Multiverse includes an implicit `ExpID` component in each table, which allows for quick retrieval of experiment-specific data for each entity.

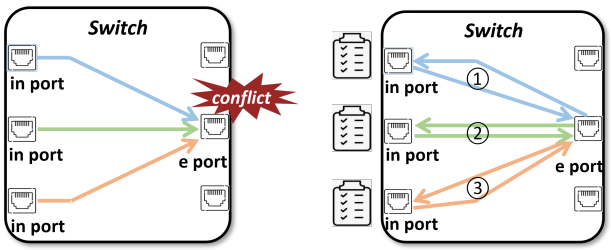
This cross-experiment storage approach improves the cache miss rate of Multiverse. During execution, neighboring GPU threads that process consecutive entities in a table can access component data coherently, even if those entities belong to different experiments. If separate tables were maintained for each experiment, data access would become incoherent when only a few entities per experiment matched an ECS query, as neighboring threads would access data from different tables.

Executing ECS Systems in GPUs. At a higher level of abstraction, Multiverse uses the NVIDIA CUDA C++ compiler to compile these systems for execution on the GPU. Each system invocation is mapped directly to a single GPU thread, utilizing the single instruction multiple threads (SIMT) programming model. To facilitate the parallelization of entity updates and data flow across the execution graph, ECS systems are structured as functions that take the components of individual entities as inputs. When an ECS system is integrated into the execution graph, Multiverse uses the provided ECS query to identify all matching archetypes and their corresponding column indices for each accessed component. This information enables Multiverse to generate the necessary code for managing component access and to invoke the ECS system function across multiple GPU threads for each entity that matches the criteria.

For example, in Figure 5, the `Send` system requires data from columns 3 and 4 in the `Flow` table. Using this information, Multiverse creates a system entry function that links GPU threads to table row indices and supplies the retrieved component data to the ECS system function. Given a table with N rows, Multiverse would call the system entry function N times, with each call resulting in a single GPU thread executing the ECS system function. In the case of the `Send` system, if the query identifies N rows in the `Flow` table, Multiverse would invoke the entry function N times, providing the first N invocations with column pointers for the `Flow` table.

(a) Bandwidth (β). (b) Latency (α).

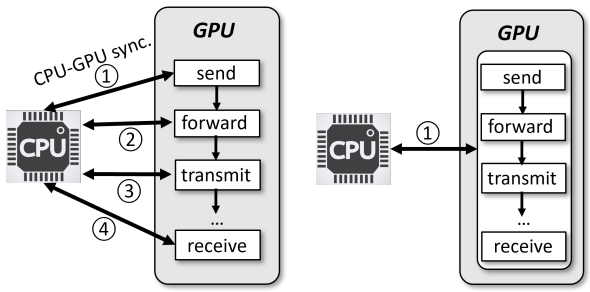
Figure 7: Calibrated bandwidth and latency parameters in the analytical model.



4 Multiverse Optimization

4.1 Intra-server Communication Simulation

In LLM training systems, TP traffic among intra-server GPUs constitutes a significant proportion of the aggregate network load, rendering the precise simulation of TP traffic necessary to accurately simulate LLM training. TP traffic predominantly transfers through high-bandwidth, intra-server conduits such as NVLink and PCIe. Existing simulation methodologies, however, grapple with accurately modeling TP traffic. Dedicated packet-level simulators (*e.g.*, NS-3 [49], DONS [21]) for inter-server networks face challenges in accurately simulating intra-server communication due to the fundamentally different communication protocols involved. Existing AI training simulators employ analytical models (*e.g.*, ASTRA-sim [47]) to estimate this communication: $y{=}\alpha{+}comm_size/\beta$, where α and β represent the communication latency and bandwidth, respectively. And *comm_size* denotes the total communication volume for a GPU during the collective communication operation. The advantage is the speed of simulation. However, a significant drawback is the inaccuracy of the model parameters, as they fail to capture the overhead introduced by the NCCL software stack.



Through extensive empirical testing, we discover that the parameters within analytical models cannot remain static. Deploying a server equipped with 8 A100 GPUs interconnected via 300GB/s NVLink, we use the analytical model from ASTRA-sim to estimate the completion time of TP yields an error margin ranging from 20% to 72%. We identify that the issue does not lie with the linear model itself, but rather with the need for its parameters to vary according to different scenarios. To encapsulate this pattern, we conduct tests to examine the relationship between the communication size and the completion time of various collective communication operators. By fitting a linear model to the results, we are able to derive revised parameters.

As shown in Figure 7, the analytical model we proposed

(a) Multiple-to-one write conflict. (b) Pull-based sync.

Figure 8: Resolute the multiple-to-one write conflict with pull-based synchronization.

(a) Kernel-based. (b) Megakernel-based.

Figure 9: The execution of the ECS systems in GPU.

meticulously adjusts specific parameters (α and β) for each collective communication operation, contingent upon the number and type of GPU (*e.g.*, A100/H100) within a server. The bandwidth values deviated from officially documented metrics, and the latency can be 70*us* to 200*us*. This calibrated approach facilitates the accurate simulation of intra-server communication; evaluation results reveal that the error is merely $0.7\%-1\%$. Crucially, this modeling approach enables a significant enhancement in speed without compromising accuracy. This attribute is beneficial for augmenting the compute throughput of ECS architectures within GPUs, affording a substantial uplift in the simulation performance.

Simulating the overlap of communication and computation. Furthermore, the computation time can be significantly influenced by the degree of overlap with communication due to resource contention, such as streaming multiprocessors (SM) and high-bandwidth memory (HBM) bandwidth. To address that, Multiverse adjusts the computation time based on the overlap between computation and communication. Initially, Multiverse specifies the duration of each computation operator without overlap in the input file. During the simulation, this duration is modified according to the overlap ratio between computation and communication operators and the extent to which the computation duration is extended due to this overlap. To determine the overlap ratio, the duration of the communication operator is obtained using either a scale-out package-level network simulator or a scale-up analytical model. By comparing the durations of the communication and computation operators, the overlap ratio is calculated. Additionally, an empirical modeling approach is used to evaluate the extent to which computation time is extended when the computation operator overlaps with the communication operator. This model considers various factors, including the model type, the computational operator, and the GPU type.

4.2 Pull-based Data Synchronization

In Multiverse, the `nic_forward` and `forward` systems extensively perform multiple-to-one write operations, a scenario where current ECS frameworks (like Unity ECS [56]) exhibit significant limitations due to the lack of atomic operations. As a workaround, these frameworks are compelled to accumulate all send events in a global buffer, subsequently processing them sequentially in the main thread. This methodology severely compromises parallel efficiency. The key challenge is managing concurrent writes without resorting to the conventional lock-based synchronization techniques.

We adopt a pull-based data synchronization strategy to enhance parallel efficiency. This approach bifurcates the multi-to-one writing process within the system into two distinct phases: `set_write_plan` and `write`. In the `set_write_plan` phase, packets slated for dispatch are preliminarily listed in a to-do queue. Then, in the `write` phase, each destination actively retrieves the packets intended for it from the source. For example, we divide the `forward` system into two subsystems: `set_forward_plan`, and the `forward`. In the former, a to-do list (realized as a bitmap) is maintained for each ingress port within the current switch, earmarking impending forward events. Subsequently, in the `forward`, each egress port independently pulls the packet from the ingress ports based on its to-do list one by one, as illustrated in Figure 8b. This method allows all ports to execute the `forward` system in a lock-free manner, improving parallel efficiency.

4.3 Execution with Megakernel

A crucial aspect of Multiverse setup is the execution of the entire system execution graph. The straightforward method would be to run each system as an individual CUDA kernel. However, this strategy has a significant problem. In GPU, initiating a kernel is a time-consuming process because it needs to be initialized by the CPU. As shown in Figure 9a, Multiverse consists of numerous ECS systems, leading to a high amount of CPU-GPU synchronization overhead, which notably decreases GPU efficiency.

As shown in Figure 9b, Multiverse uses a GPU-driven method with a large-scale kernel design [45]. Multiverse compiles all systems in the execution graph into a single CUDA kernel, *i.e.*, megakernel. This kernel is initiated by the CPU once per batch simulation and completes the entire execution graph before returning to the CPU. To manage both the execution of systems defined by the application and necessary engine-level operations, such as evaluating ECS queries and sorting tables, Multiverse creates a task graph. This graph

outlines the full execution of each batch simulation step. Multiverse uses a simple task graph scheduling policy in which all GPU threads work on the same node together before moving to the next node in the task graph. While this approach could lead to low GPU utilization if there is not enough work per node, large-batch simulations of multi-experiment typically provide a significant amount of work per node. So we can easily fully utilize all the GPU cores with a megakernel.

5 Implementation

We base Multiverse on the Madrona framework [52]. Multiverse 's current core code base has $\sim 13k$ lines of C++ code, which we release for the networking community. Currently, Multiverse supports both TP (Tensor Parallelism) and DP (Data Parallelism) parallelization strategies, along with collective communication algorithms including Ring Allreduce, Allgather, and Reducescatter. Additionally, Multiverse integrates multiple congestion control algorithms such as DCQCN, HPCC, and DCTCP, as well as load balancing algorithms like ECMP and packet spraying. Here we briefly describe the length of a step in Multiverse, and how it use multiple GPUs.

The length of one simulation step. Multiverse traverses the execution graph in one simulation step, advancing the simulation clock incrementally. Given that the execution of distinct systems within the execution graph is sequential, prolonged step length can lead to temporal errors. This step length effectively corresponds to the notion of *lookahead* concept in parallel DES [20]. Taking inspiration from DONS [21], we set $min\{link_delay\}$ as the lookahead. Because event propagation between servers and switches inherently involves at least one link delay.

Using multiple GPUs. Given the finite resources within a single GPU, evaluation reveals that the number of experiments that one GPU can simultaneously run is limited, when each experiment is of substantial scale. Multiverse can leverage multiple GPUs for parallel exploration experiments. Upon user configuration of available GPUs, Multiverse will assess the necessity of reallocating certain independent experiments across different GPUs. If necessary, Multiverse will automatically balance the workload among multiple GPUs to maximize simulation speed. The execution across GPUs are independent.

6 Evaluation

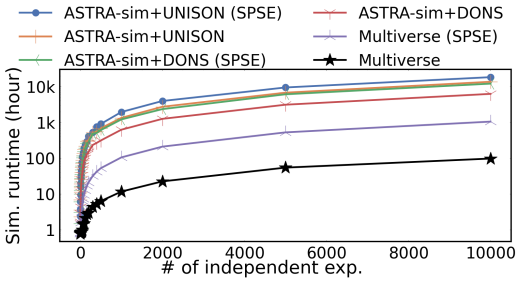
We evaluate Multiverse's simulation speed, accuracy, and scalability. We summarize our results as follows:

Key Results.

- **Simulation speed:** Multiverse can achieve a 57.4-73.2× speedup over the state-of-the-art across various use cases, ranging from 50 to 10,000 simulation experiments, and cluster sizes, from 128 to 8,192 GPUs.
- **Scalability:** Using only one GPU, Multiverse can run one simulation experiment for a cluster of up to 54,000 GPUs and achieve up to 43.1× speedup over other methods. And Multiverse can parallel run 52 simulation experiments for a cluster of 1,024 GPUs and 13 simulation experiments for a cluster of 8,192 GPUs.
- **Fidelity:** Multiverse's simulation results, such as iteration time, align closely with real-world LLM training on testbeds, with a difference of $<3.0\%$, even at 1,024 GPUs.

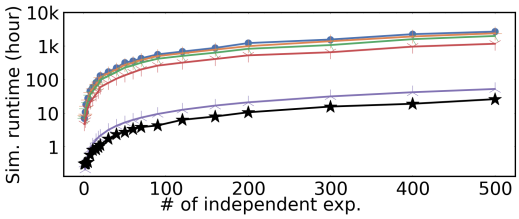
Alternatives. We select existing state-of-the-art simulators for AI training systems as our comparisons.

- **ASTRA-sim+UNISON:** ASTRA-sim [47, 60] is a comprehensive AI training simulator. To enhance its simulation speed, we improve the network simulator using UNISON [8], a recently proposed multi-threading simulation kernel. This approach can utilize the SPSE and SPME manners, denoted as *ASTRA-sim+UNISON (SPSE)* and *ASTRA-sim+UNISON*, respectively.
- **ASTRA-sim+DONS:** We incorporate ASTRA-sim with another state-of-the-art network simulator, DONS, to implement an accelerated ASTRA-sim. This method can utilize the SPSE and SPME manners, denoted as *ASTRA-sim+DONS (SPSE)* and *ASTRA-sim+DONS*, respectively.
- **Multiverse (SPSE)**: This approach takes Multiverse to follow the SPSE manner. And it employs all the optimization technologies we proposed.



Setup. We conduct experiments with these alternatives on a Linux server configured with one NVIDIA H100 GPU, an 80-core Intel CPU@2.10GHz, and 256GB of memory.

To verify Multiverse's accuracy, we run real LLM training jobs (with LLaMA 65B and GPT-3 175B model) on a cluster, which is based on the Fattree, inter-host RoCEv2 network. The cluster consists of 128 servers, each equipped with eight NVIDIA H100 GPUs and eight Mellanox ConnectX-7 NICs (2×200Gbps). Intra-server GPUs are interconnected via NVLink, providing 900GBps bandwidth. The clusters include two kinds of scale: 128 GPUs and 1,024 GPUs.



We take four real use cases of design space exploration to test the performance of Multiverse, as shown in Table 1. These use cases span a comprehensive spectrum, including topology search, collective communication enhancement, fine-tuning of parallel group sizes, and the assessment of congestion control algorithms. These cases cover a wide range of cluster scales (ranging from 128 to 54,000 GPUs) and model sizes (from 13 billion to 175 billion parameters). We obtain the approximate number of experiments required for these four explorations from the production datacenters. For instance, topology search needs varying layers, switch radixes, and connectivity configurations to generate a myriad of topologies, requiring 10k simulation experiments.

Use case	GPU scale	Topology	Workload	Explored parameters	# of independent exp.
#1: Topology optimization	128 GPUs	Fattree-like	GPT-3 13B	Set different layers, switch radix, connections, *etc.*	10k
#2: Collective communication optimization	1,024 GPUs	Fattree k=16	LLaMA 65B	Set different flow priority and load balancing strategies.	500
#3: Selection of TP/DP/PP group size	8,192 GPUs	Fattree k=32	GPT-3 175B	Set different TP/DP/PP group size.	100
#4: Comparing congestion control algorithms	54,000 GPUs	Fattree k=60	GPT-dense 175B	Set different CC algorithm, such as DCQCN [63], HPCC [35].	4

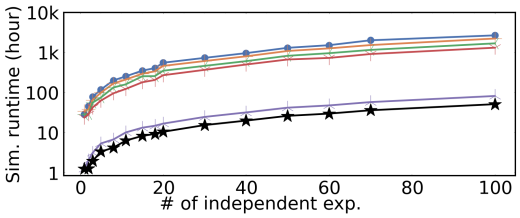


Table 1: The detailed setting for the four different use cases in evaluation.

(a) The total spent time of multiple simulation experiments for a cluster with 128 GPUs (use case #1).

(b) The total spent time of multiple simulation experiments for a cluster with 1,024 GPUs (use case #2).

(c) The total spent time of multiple simulation experiments for a cluster with 8,192 GPUs (use case #3).

Figure 10: The comparison of simulation speed.

6.1 Multiverse is Fast

We first compare the simulation speed of Multiverse, with other techniques across 3 use cases in Table 1. As depicted in Figure 10, Multiverse consistently outperforms all other methods, achieving speed increases of up to 73.2×, 67.6×, and 57.4× compared to other alternatives when simulating a cluster with 128 GPUs, 1,024 GPUs, and 8,192 GPUs, respectively. Furthermore, Multiverse surpasses Multiverse (SPSE), with speed improvements reaching up to 7.3×, 2.4×, and 1.7×, respectively. These speed enhancements can be attributed to the reduced cache miss ratio, as shown in Figure 11, a result of the DOD paradigm and batch and parallel simulation across multiple experiments. Additionally, Multiverse benefits from

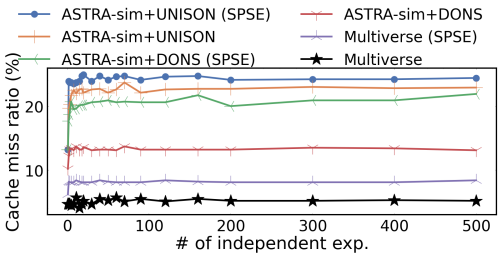

Figure 11: Cache miss ratio in use case #2.

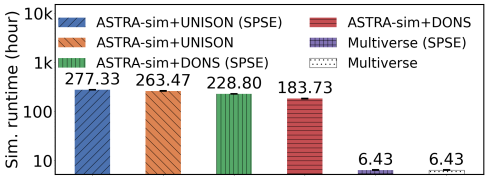

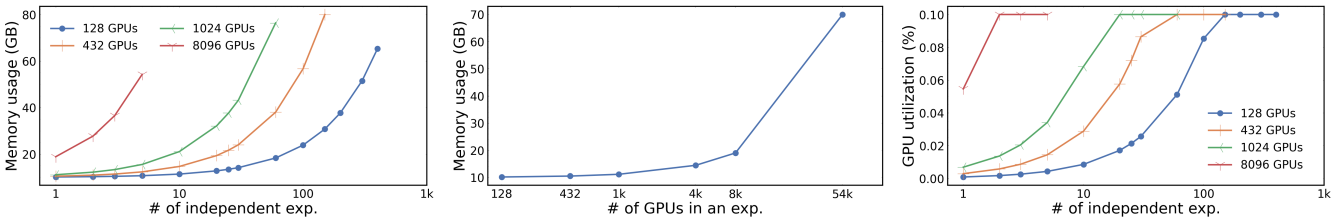

Figure 12: The speed comparison in simulating a large-scale cluster with 54k GPUs (use case #4).

reduced memory overhead as it distributes the inherent memory cost in all experiments. Together, these factors improve the parallel efficiency of Multiverse.

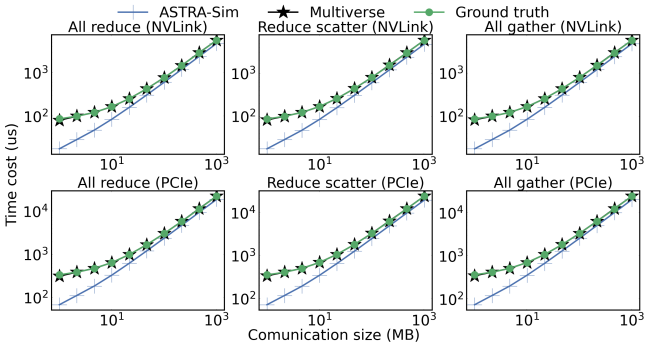
ASTRA-sim+DONS performs better than ASTRA-sim+UNISON, achieving a speedup of approximately 1.9−2.1×, as ECS programming abstractions are well suited for creating novel multi-experiment simulators. These ECS abstractions also provide essential structure over custom logic and state, enabling simulators to efficiently manage memory, distribute work, and identify coherent parallel computations within and across different experiments.

Multiverse also outperforms ASTRA-sim+DONS, with speed improvements of up to 25.1−47.2×. This is because ASTRA-sim+DONS, despite using batch simulation across multiple experiments to achieve good performance against ASTRA-sim+DONS (SPSE), has its parallelism constrained by the number of CPU cores. In contrast, Multiverse can leverage the extensive number of GPU cores to further accelerate the simulation. Moreover, Multiverse uses pull-based synchronization for lock-free data transfer, a fast analytical model, and a megakernel technique to enhance GPU efficiency.

Maximum scale. We test the maximum cluster that Multiverse can simulate using a single GPU. Subject to the constraints imposed by the GPU memory size in our testbed, Multiverse can simulate an LLM training cluster that includes up to 54k GPUs, 4.5k switches, and 162k links. This scale surpasses

(a) GPU memory usage. (b) GPU memory usage running 1 exp. (c) GPU utilization.

Figure 13: The performance of Multiverse.



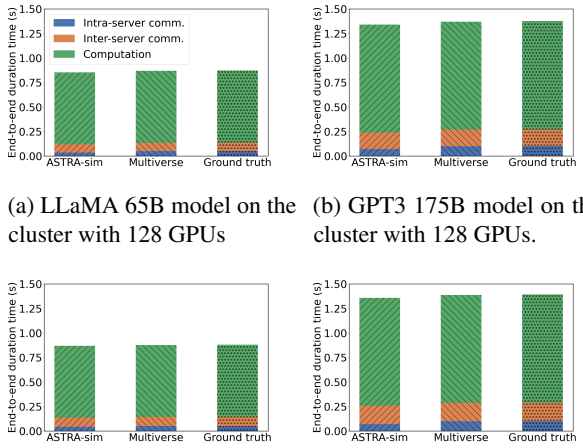


Figure 14: The time cost of intra-server collective communication operations.

(a) LLaMA 65B model on the cluster with 128 GPUs (b) GPT3 175B model on the cluster with 128 GPUs.

(c) LLaMA 65B model on the cluster with 1,024 GPUs (d) GPT3 175B model on the cluster with 1,024 GPUs.

Figure 15: The iteration time of different workloads running on ASTRA-sim, Multiverse, and real clusters.

that of most LLM training systems. Even under these conditions, Multiverse can significantly outperform alternative methods, achieving a speedup factor between 28.6× to 43.1×, as depicted in Figure 12.

The memory consumption and GPU utilization of Multiverse are illustrated in Figure 13. With the use of a single GPU, Multiverse can execute one simulation for a cluster with up to 54k GPUs at a time, this being limited by the GPU memory size, as demonstrated in Figure 13b. Furthermore, Multiverse can concurrently run 520 simulation experiments for a cluster of 128 GPUs, 70 simulation experiments for a cluster of 1,024 GPUs, and 5 simulation experiments for a cluster of 8,192 GPUs.

In terms of GPU utilization, Multiverse can fully engage all GPU cores when running a single simulation experiment for a cluster with more than 8,192 GPUs. Multiverse can also fully utilize all the GPU cores when running more than 30 simulation experiments for a cluster with 128 GPUs, and more than 10 simulation experiments for a cluster with 1,024 GPUs.

6.2 Multiverse is Accurate

The precision of intra-server communication simulation. As depicted in Figure 14, we evaluate the accuracy of Multiverse in simulating different sizes (2-2560MB) of collective communication on a server with 8 A100 GPUs(300GBps NVLink and PCIe5.0). For smaller communication sizes, ASTRA-sim can deviate by as much as 72.1% from the actual values. We test the accuracy of both NVLink and PCIe connected, respectively. Although this error decreases with increasing communication size, it remains above 22.0%. In contrast, Multiverse shows an error of 1.0-1.2% for small communication sizes, but this discrepancy reduces to less than 0.8% as the communication size increases.

From an end-to-end simulation perspective, the accuracy of intra-server communication for both ASTRA-sim and Multiverse improves with larger communication sizes, as seen in Figure 15. This is particularly noticeable with the collective communication operations of GPT-3 175B, which are larger and thus more accurately simulated. However, ASTRA-sim can still exhibit an error greater than 20.0% even when simulating GPT-3 175B, while Multiverse reduces the error to less than 1.0% for both LLaMA 65B and GPT-3 175B.

The precision of inter-server network simulation. As seen in Figure 15, due to the precision of DES, both using Multiverse and ASTRA-sim, the inter-server communication time closely approximates the real-world LLM training.

The precision of end-to-end simulation. We test the accuracy of Multiverse by examining its end-to-end metric across various workload and cluster sizes. Figure 15 demonstrates that the iteration time for all workloads when using Multiverse closely matches that of real LLM training tasks. The difference is less than 3.0%, even at the scale of 1,024 GPUs. Moreover, as the model size increases (for instance, from

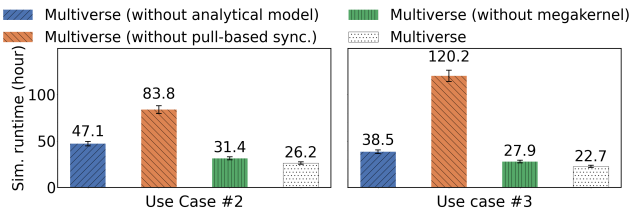

Figure 16: Performance breakdown of Multiverse.

LLaMA 65B to GPT-3 175B), Multiverse's accuracy improves correspondingly, because the message sizes of the collective communication operations in GPT-3 175B are larger.

6.3 Ablation Study of Multiverse

In Figure 16, we perform an ablation study to assess the impact of key features of Multiverse on its overall performance.

The term Multiverse (without analytical model) refers to the method that employs a packet-level DES to simulate intra-server communications, where all intra-server GPUs are interconnected via a switch. Compared to this method, Multiverse can achieve a speedup of 1.7-1.8×, because the calibrated analytical model has lighter computational loads.

Multiverse (without pull-based synchronization) uses the global synchronization method typically utilized in existing ECS frameworks. Compared to this approach, Multiverse can achieve a speedup of 3.2-5.4×. This is because pull-based synchronization allows all ports to execute the forward system in a lock-free parallel manner, significantly enhancing parallelism efficiency.

Lastly, Multiverse (without megakernel) is a method by which each ECS system is initialized as an independent kernel function in the GPU. Compared to this method, Multiverse can reduce the simulation time by 16.6%-18.6%, as shown in Figure 16. This is because using megakernel can substantially decrease the number of times the CPU needs to launch a kernel, resulting in lower CPU-GPU synchronization overhead.

7 Related Work

AI training simulation. ASTRA-sim [47, 60] is a comprehensive AI training simulator, which aims to simulate the software and hardware co-design stack of distributed training systems. Building upon ASTRA-sim, SimAI [7] enhances simulation accuracy, Dally [53] additionally simulates modern networking hardware. Approaches like [1, 9, 19] adopt a more coarse-grained simulation paradigm, such as operator-level or task-level, to achieve faster simulation speeds with the sacrifice of accuracy. SimBricks [34] and SplitSim [33] achieve end-to-end network system simulation by integrating multiple simulators, such as NS-2/3 [24, 49] and gem5 [6, 12, 41]. While they can be extended to simulate AI/LLM training, their performance is constrained. Notably, they fail to fully leverage the fine-grained parallelism opportunities provided by SPME.

Network simulation. Existing network simulators can be divided into three categories: discrete-event simulation (DES) [24, 38, 49, 57], mathematical model estimation [32, 39, 46] and AI-based estimation [50, 61, 62]. DES simulators offer high-fidelity packet-level simulation. Some work leverage parallel and distributed DES (PDES) [20, 25] approaches to accelerate simulation. However, multiple processes often come with poor performance and complex configurations. UNISON [8] introduces fine-grained partitioning and load-adaptive scheduling to enable efficient multi-threading. DONS [21] uses the data-oriented design to reduce cache miss and can be automatically parallelized.

Entity-Component-System (ECS). The ECS architecture has gained recent popularity through implementations in major game engines such as Unity [3] and Unreal [17], as well as a wide array of open-source implementations of the architecture [14, 40, 52]. The ECS architecture has been shown to provide performance benefits due to data access efficiency and parallelism [13, 56].

GPU-based DES. Many efforts employ GPUs to accelerate DES of queuing networks [44, 51, 55, 62], P2P networks [37], and mobile networks [10, 11]. However, they are still rooted in conventional PDES techniques, lacking the utilization of ECS architecture to optimize performance.

8 Conclusion

This paper demonstrate that the parallel strategy of Single-process Multi-experiment (SPME) achieves superior performance by reducing scheduling overhead and optimizing resource utilization, yet remains insufficient for current AI cluster scales. To enhance SPME's efficacy, we introduce Multiverse, a novel GPU-based AI training simulator. Using DOD/ECS modeling, Multiverse leverages the computing throughput of GPUs efficiently with optimizations such as a pull-based synchronization method, high-fidelity intra-server communication model, and a megakernel technique. Extensive experiments validate Multiverse 's accuracy and efficiency, achieving $43.1-73.2\times$ speedup over state-of-the-art CPU-based AI training simulators.

Abstract

We present RLHFuse, an efficient training system with *stage fusion* for Reinforcement Learning from Human Feedback (RLHF). Due to the intrinsic nature of RLHF training, *i.e.*, the data skewness in the generation stage and the pipeline bubbles in the training stage, existing RLHF systems suffer from low GPU utilization. RLHFuse breaks the traditional view of RLHF workflow as a composition of individual tasks, splitting each task into finer-grained subtasks, and performing *stage fusion* to improve GPU utilization. RLHFuse contains two key ideas. First, for generation and inference tasks, RLHFuse splits them into sample-level subtasks, enabling efficient *inter-stage fusion* to overlap the execution of generation and inference stages, thus mitigating the original generation bottleneck dominated by long-tailed samples. Second, for training tasks, RLHFuse breaks them into subtasks of micro-batches and performs *intra-stage fusion* to concurrently execute these subtasks in the training stage with a fused pipeline schedule, effectively mitigating the pipeline bubbles. The experiments show that RLHFuse increases the training throughput by up to 3.7×, compared to existing systems.

1 Introduction

The rise of Large Language Models (LLMs) marks a revolutionary leap in generative AI. Despite the impressive capabilities of LLMs, many studies [1–3] have shown that LLMs often display unintended behaviors. To address these issues, Reinforcement Learning from Human Feedback (RLHF) [4] has been introduced, aiming to align LLMs with human intent after pre-training. With a concrete and well-defined reward target, RLHF enhances the ability of LLMs in multiple domains. Figure 1 shows the typical RLHF training workflow, which involves six different tasks divided into three stages. The `Actor` model first generates samples with the input prompts and passes them to the `Reference`, `Critic`, and `Reward` models for inference, finally the loss is calculated to train both the `Actor` and `Critic` models, while the other two models remain frozen. There are barriers between stages due to the data and weight dependencies.

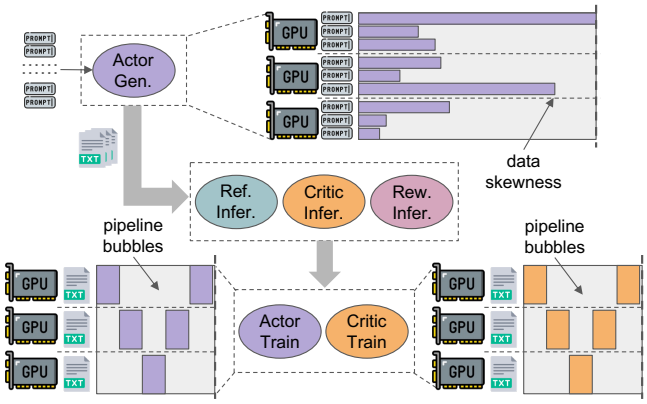

Figure 1: RLHF workflow [4] and the problems in the generation and training stages of existing RLHF training frameworks.

To enable efficient training of RLHF, existing frameworks [5–7] have proposed a series of optimizations, such as selecting tailored parallel strategies for each task and optimizing the data exchange during stage transitions. However, these techniques *fundamentally treat the RLHF workflow as a simple composition of individual tasks*, failing to delve into the inherent characteristics and structure inside the tasks, thereby missing significant optimization opportunities. In production deployments, we have observed two issues within current frameworks that severely impact training efficiency, as indicated by the grey area in Figure 1.

The first issue arises from the *data skewness* in the generation stage, where the output length of generated samples follows a long-tailed distribution. This phenomenon is broadly observed during LLM generation (§2.2) and this data diversity is critical to the robustness of RL training. On the one hand, during the latter part of the generation stage, only a small number of long-tailed samples remain processing, but a large batch size is required for generation to improve GPU utilization (§2.1). On the other hand, later tasks cannot start in advance due to data dependencies. As a result, the generation time is dominated by the longest sample and the GPU

utilization is low, as shown in the upper right of Figure 1. Although numerous optimization techniques [8–12] are proposed to improve the generation speed and throughput, they cannot alter the inherent long-tail phenomenon and thus fail to solve the problem. Making the problem even worse, as the maximum output length of LLMs continues to grow [13, 14], this long-tail phenomenon will become more significant.

The second issue stems from the *pipeline bubbles* in the training stage. With the explosive growth in the size of LLMs, higher pipeline parallelism (PP) size is needed to scale training. When LLMs reach hundreds of billions of parameters, it is quite common for PP size to reach a few dozen [15, 16]. However, the proportion of pipeline bubbles increases with PP size, significantly reducing training efficiency. In RLHF, there are two training tasks, each may evolve a specific LLM with hundreds of billions of parameters, which amplifies this inefficiency. Despite that various approaches have been proposed to reduce pipeline bubbles when training individual models [17–20], the remaining bubbles still pose a significant challenge under synchronous training semantics.

To this end, we propose RLHFuse, which tackles the *long-tailed generation issue* and *pipeline bubbles* by employing *subtask-level optimizations*. By breaking down the task into finer-grained subtasks, RLHFuse opens up new design space to *fuse the stage execution*. This is orthogonal to current RLHF frameworks [5–7] that optimizes on the task-level to choose the optimal parallel strategies for each task or reduce the task switching overhead. RLHFuse focuses on how to execute the RLHF workflow efficiently with stage fusion after the parallel strategies are chosen. RLHFuse exploits the opportunities at the subtask level and proposes two new techniques, i.e., *data-aware inter-stage fusion* and *model-aware intra-stage fusion*. These two techniques leverage the unique system characteristics of RLHF training to fuse the execution across different tasks, thus effectively addressing the data skewness and pipeline bubbles, respectively.

For data skewness, we split the generation and inference tasks into sample-level subtasks and then the dependency granularity between the generation and inference stage can be refined from stage-level to sample-level. This is due to the fact that the computation of the two stages is essentially independent for different samples. To leverage this insight, we design a lightweight and efficient migration algorithm to automatically detect when the generation stage enters the inefficient long-tail processing phase and migrate the remaining long-tailed samples to a limited number of GPUs. The freed-up resources are used to launch the inference tasks. This approach enables inter-stage fusion and dynamically adjusts the migration timing in each iteration according to the workload, thereby maximizing overall efficiency.

For pipeline bubbles, we break the training task into subtasks of micro-batches. Pipeline bubbles are essentially caused by dependencies between subtasks of the same model. Fortunately, in the RLHF training stage, there are two independent models, and their subtasks are mutually independent. Based on this observation, we employ a fused pipeline schedule to enable intra-stage fusion, which executes the training tasks on the same set of GPUs with bidirectional pipelines, effectively filling each other's pipeline bubbles. We design a lightweight schedule generation algorithm that can produce near-optimal schedules for `Actor` and `Critic` models of any size and parallel configurations.

In addition, we apply a series of system optimizations covering each RLHF stage, transforming RLHFuse into a production-ready framework to support the RLHF training of our internal products. We evaluate RLHFuse on various LLMs and real-world datasets. Compared to state-of-the-art solutions, RLHFuse improves the throughput up to 3.7×.

In summary, we make the following contributions:

- We identify the key issues within current RLHF training frameworks and propose to view the RLHF workflow from a finer-grained subtask-level perspective.
- We present RLHFuse, a highly efficient RLHF training framework that utilizes inter- and intra-stage fusion to improve the training throughput.
- We conduct a comprehensive evaluation of RLHFuse and compare it with state-of-the-art RLHF training solutions.

2 Motivation

In this section, we first introduce the basics of RLHF training (§2.1) and then point out the problems in existing RLHF training systems (§2.2).

2.1 Background

One complete RLHF process consists of three key steps: supervised fine-tuning, reward model training, and model alignment using the PPO algorithm [21]. The first two stages both train a single LLM, which has been studied by previous work like Megatron-LM [15] and MegaScale [16]. The third stage, which this paper focuses on, is unique and complex in terms that it involves multiple models and stages. Next, we provide a detailed overview of the RLHF models and workflow.

RLHF models. Typically, RLHF training involves four LLMs in total: `Actor`, `Ref`, `Critic`, and `RW`. The `Actor` model, which is the primary model to be trained and the final product after RLHF, serves as the *agent* in the RL semantics. Given a prompt, each token it generates autoregressively is considered an *action*, and the goal of the PPO algorithm is to guide it to produce actions that align with the reward target. The Reference model (`Ref`) is initialized from the original `Actor` model, but is frozen (*i.e.*, weights do not update) during training. It provides Kullback-Leibler (KL) divergence regularization to ensure the `Actor` model does not deviate excessively from its original version during training or generate nonsensical outputs. The Reward model (`RW`) is trained on human-labeled preference data to score each sample generated by the `Actor`

model, which guides the Actor model to generate responses that align with human preferences. It is also frozen during the RLHF training. The Critic model, initialized from the RW model, serves as the value model to evaluate the actions taken by the Actor. It provides finer-grained feedback on the action level to guide Actor towards better decisions.

RLHF workflow. The workflow of one RLHF training iteration contains three main stages:

Generation stage. The Actor model generates responses for the prompts in the current batch. This process involves a prefill phase and a decoding phase. The prefill phase processes the prompt to generate the first output token. Then the decoding phase sequentially generates subsequent tokens in multiple steps autoregressively (i.e., each decoding step generates a new token based on tokens generated in previous steps until reaching a termination token). Ultimately, each prompt and its corresponding response form one training sample for this iteration, referred to as a *rollout* or *trajectory* in the context of RL. To increase sample efficiency, it is common to generate many samples in one iteration.

Inference stage. The Ref, RW, and Critic models each perform a forward pass on the generated samples. It is similar to the prefill phase in the generation stage but does not generate the next token. Instead, the output logits are used to calculate the training loss in the *Training* stage. Note that the execution time of each inference task depends on the model size and is generally not the same.

Training stage. In the PPO algorithm, unlike traditional LLM training, all the samples are divided into several mini-batches and the model weights need to be updated after training on each mini-batch. Concretely, for each mini-batch, the Actor and Critic models first perform a forward pass, then calculate the loss using the results from the inference stage and performing a backward pass to update the parameters. After the Actor completes training on all mini-batches, it uses the *up-to-date* parameters for the generation in the next iteration.

LLM parallelization. Various parallelism methods are proposed to scale training, guided by the scaling law [22]. Data Parallelism (DP) replicates the model weights and distributes the data among the replicas to execute in parallel. It requires gradient synchronization across the replicas after each iteration. Tensor Parallelism (TP) assigns individual operators over multiple GPUs, with each executing part of the computation in parallel. It requires significant communication, so it is typically used within a node to leverage the high-bandwidth NVLINK connections. Pipeline Parallelism (PP) organizes LLM layers into stages, each running on a separate device or node. It partitions the input batch into multiple "micro-batches" to form pipeline execution and accumulate the gradients of the entire input batch. Each parallel method has its own advantages, so in practice all three parallel strategies are used together to scale training, such as Megatron-LM [15] and

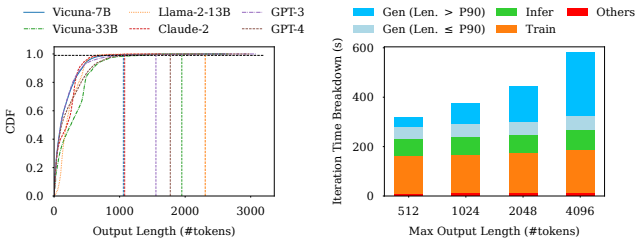

Figure 2: Left: The output length CDF of models in the LMSYS-Chat-1M dataset. The vertical dotted line indicates the P99.9 output length. Right: The RLHF training iteration breakdown on the internal model and datasets under different maximum output lengths.

MegaScale [16] in pre-training [15] as well as ReaLHF [6] and HybridFlow [5] in RLHF training.

2.2 Problems in RLHF Training

During our practical deployment of RLHF training, we identified two key issues in the *Generation* and *Training* stage within existing RLHF training systems that contribute to substantial GPU under-utilization.

Generation Stage: data skewness. One major problem in the generation stage is that the response length of generated samples exhibits a long-tailed distribution, meaning that a few samples are significantly longer than the others. Due to data dependencies, the inference tasks cannot start until the generation task finishes. Consequently, even only a few long-tailed samples force the inference tasks to wait. This leads to significantly low GPU utilization in the generation stage because the decoding phase of LLM generation is memory-bandwidth-bound, requiring a large batch size (typically a few hundred) to maintain high GPU utilization.

This long-tail phenomenon is prevalent and pronounced in the LLM generation. Figure 2 (left) shows the CDF of output length distribution in LMSYS-Chat-1M dataset [23], which collects one million user requests and corresponding responses from various models on the popular LLM evaluation platform Chatbot Arena. We observe this long-tail distribution across models of varying sizes, both open-source and proprietary. The vertical dotted lines mark the 99.9-th percentile length corresponding to each model, which is more than ten times the median length. In practice, it is common to generate over 1,000 samples in each iteration, meaning that almost every iteration will encounter long-tailed samples.

Internally, we also observe this pattern during the RLHF training of a proprietary model with hundreds of billions of parameters. Figure 2 (right) presents the iteration time breakdown under different maximum output length settings. The time spent generating long-tailed samples (dark blue bar) accounts for more than half of the total generation time. The situation gets worse as the maximum generation length increases, which leads to a substantial rise in iteration time. It is worth noting that this change only affects the long-tailed samples ($< 1\%$), but the results indicate that this very small

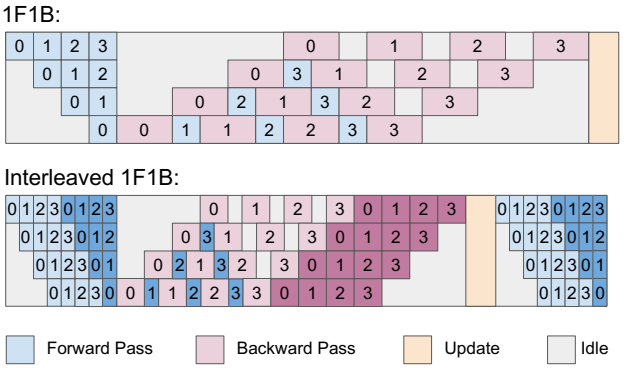

Figure 3: The timeline of 1F1B [18] and interleaved 1F1B [15] pipeline schedule with 4 pipeline stages and 4 micro-batches.

portion of long-tailed samples can have a significant impact on the overall system performance. As user applications increasingly demand lengthy outputs [13, 14, 24], the inclusion of samples with long response lengths in RLHF training becomes more common and important, making the long-tail phenomenon an urgent problem in real deployment.

Training Stage: pipeline bubbles. With the exponential growth in the size of LLMs, higher parallelism is required to scale training. While TP size is generally limited to the number of GPUs within a single node (typically 8) due to the significant communication overhead, and DP size increases the memory consumption of model weights linearly. Consequently, PP has become a critical method for scale training.

Scaling the PP size is not a free lunch, as pipeline bubbles can significantly impact training efficiency. Concretely, in the most commonly used 1F1B pipeline schedule [18] as shown in Figure 3 (upper), the *pipeline bubble percentage* is $\frac{N-1}{N-1+M}$ with N PP stages and M micro-batches. One simple way to reduce the bubble percentage is to increase M. However, the global batch size is constrained by the converging conditions and cannot be increased indefinitely. Additionally, in RLHF, the global batch is first divided into several mini-batches, then distributed among the DP groups, and finally split into micro-batches, further limiting M. As N scales with the model size to approach M, which is quite common when scaling LLMs to hundreds of billions of parameters, the bubble percentage is about 50%. This means that about half of the GPUs are idle during training, leading to a significant waste of resources.

Interleaved 1F1B scheduling [15] is proposed to mitigate the pipeline bubbles. As shown in Figure 3 (bottom), it divides the LLM into more fine-grained model chunks, with each stage hosting $K(K > 1)$ model chunks, reducing the pipeline bubble percentage to $\frac{N-1}{N-1+KM}$. However, it not only introduces a K-fold communication overhead but also exacerbates the imbalances across PP stages. As a result, K is typically set to a small constant in practice, leaving room for further optimizations.

Other works [18, 20] aim to eliminate pipeline bubbles; however, they either violate the synchronous training semantics [18] or rely on specific assumptions [20]. As a result, pipeline bubbles still pose a significant problem in LLM training, especially when the model size keeps scaling.

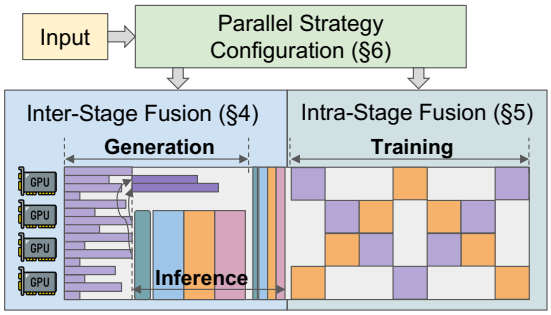

Figure 4: RLHFuse architecture.

Summary. Essentially, the above issues are caused by the inherent characteristics of RLHF, which are difficult to eliminate through task-level optimizations. Existing systems treat the task as the smallest execution unit and overlook its internal structure, thereby missing a huge optimization opportunities.

3 RLHFuse Overview

To this end, we present RLHFuse to address data skewness in the generation stage through data-aware inter-stage fusion (§4) and mitigates pipeline bubbles in the training stage with model-aware intra-stage fusion (§5). Additionally, RLHFuse adopts a series of system optimizations (§6) tailored for RLHF training. Here we provide a brief overview of RLHFuse as shown in Figure 4.

Workflow. With specific algorithm, model, and cluster configurations as input, RLHFuse first configures efficient parallel and deployment strategies following the approach in ReaLHF [6] and HybridFlow [5]. For each task within the RLHF workflow, RLHFuse assigns it a tailored parallel strategy to maximize GPU utilization. At runtime, RLHFuse launches each task with its corresponding parallel strategy on the designated device mesh following the workflow dependency and handle the weight redistribution and data transmission between different tasks to ensure synchronous training semantics. Meanwhile, RLHFuse utilizes data-aware inter-stage fusion to fuse the generation and inference tasks and model-aware intra-stage fusion to fuse the training tasks.

Inter-stage fusion. As depicted in the left part of Figure 4, during the generation stage, there are multiple model instances, each managing complete model weights and part of the samples. RLHFuse actively monitors each generation instance and triggers migration when the number of remaining samples is below a particular threshold. The remaining samples are migrated to some dedicated generation instances which are designated to handle long-tailed samples. Subsequently, the resources of the original generation instances are repurposed to launch inference tasks, thereby allowing for the

overlap of inference tasks with the generation of long-tailed samples and fusing the execution of the two stages.

Intra-stage fusion. As shown in the right part of Figure 4, in the training stage, RLHFuse leverages the insight that another inverse pipeline can complement current pipeline execution. It utilizes a lightweight algorithm to generate a fused pipeline schedule based on the model size and parallel strategies of the `Actor` and `Critic` model, which minimizes the pipeline bubbles and activation memory usage.

4 Data-aware Inter-Stage Fusion

In this section, we first analyze the opportunities of fusing the generation and inference stages (§4.1). We then introduce the fused execution plan to maximize the overlap between the two stages while preserving the data dependency (§4.2).

4.1 Opportunities and Challenges

Opportunities. The dependency between the two stages is predicated on the sample level, implying that once a sample completes its generation stage, it can seamlessly advance to the inference stage. This key observation motivates us to break the task into sample-level subtasks without violating original synchronous training semantics. Consequently, we can initiate inference tasks as soon as there exist completed samples in the generation stage.

Based on this, we design a fused execution plan that overlaps the generation and inference stages. Specifically, the fused plan first detects the point when the generation instance enters the long-tail decoding phase. At this juncture, most of the samples have finished their generation stage but are waiting for the inference stage to start. Each instance only leaves a few long-tailed samples to process, which is memory-bandwidth-bound as discussed in §2.2. This condition facilitates the migration of samples from all instances to a few designated instances. This migration not only consolidates the GPU utilization of the receiving instances but also releases resources from the sending instances. The released resources are then promptly utilized to launch inference tasks in advance. One example of a fused execution plan is shown in Figure 5. This approach greatly improves the GPU utilization and optimizes the overall execution time of the two stages.

Challenges. With the inter-stage fusion, the problem now lies in generating an efficient fused execution plan that decides the migration timing, destination, and mechanism. These three factors significantly affect the overall execution time of the two stages, and therefore must be chosen carefully.

Given that inter-stage fusion appears so promising, a natural question arises: can we break the synchronization between the inference and training stages similarly? Unfortunately, training tasks require each mini-batch to maintain the same data distribution, which necessitates random sampling from all the generated samples. To satisfy this requirement, it implicitly introduces an unavoidable synchronization boundary.

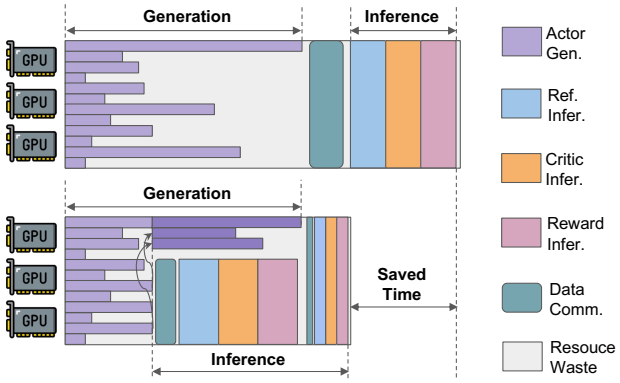

Figure 5: The timeline of serial (top) and fused (bottom) execution of generation and inference stages.

4.2 Fused Execution Plan

The objective of the inter-stage fusion is to overlap the execution of the two stages as much as possible without affecting the original generation task's execution time, thereby minimizing the overall execution time of the two stages. Following this objective, we detail the migration triggering, destination, and mechanism below.

Migration triggering. Triggering the migration significantly influences the efficiency of overlapping the two stages. If migration is triggered too early, there remain excessive generation samples. The migration results in only a few model instances remaining available to continue the generation task, as most are redirected to handle inference tasks. This scenario places an excessive load on the few generation instances, leading to prolonged execution times for the original generation task and ultimately extending the overall process. Conversely, if the migration is triggered too late, it loses most of the overlapping opportunity. Based on the above analysis, we propose a migration threshold, denoted as R_t. When *the number of remaining samples in the generation stages falls below* R_t, the migration is triggered. To optimize system performance and minimize total execution time, carefully determining R_t is essential to find the best trade-off.

To determine the optimal R_t, we initially conducted offline generation trials on the training dataset to analyze the length distribution of the generated samples. This analysis enables us to estimate the computational load for both the generation and inference stages accurately and simulate the execution time of the fused execution plan. Due to the determinism and reproducibility of LLM computation, the simulation technique for LLM training [25, 26] and inference [27, 28] is well-studied. We then systematically test R_t values ranging from 5% to 95% of the global batch size, simulating the overall execution time under each R_t. The optimal R_t is identified as the value that yields the minimum simulated execution time. Additionally,

during runtime, we refine the distribution by incorporating new generation samples, which allows us to update R_t as needed to continually optimize performance.

Note that it is possible to achieve finer-grained overlapping by triggering migration more than once. However, we find that in practice, the generation time of long-tailed samples often exceeds the execution time of inference tasks, so one migration is usually sufficient to fully overlap the entire inference stage, as shown in §7.2.

Migration destination. Once the migration timing is determined, we need to select m generation instances to handle the remaining samples. Assume there are n generation instances in total, then there will be $n-m$ instances to be repurposed for inference tasks. To determine m, we revisit the computation characteristics of the generation task. During the decoding phase of generation, which is highly memory-bandwidth-bound, as long as the batch size does not exceed a certain threshold that saturates the GPU (denoted as BS_{max}), the latency of each decoding iteration remains almost constant [28, 29] thanks to the massive parallel computing units of modern GPUs. The value of BS_{max} depends on the specific GPU hardware and can be determined through prior profiling. Based on this, we set the first constraint as $m \geq \frac{R_t}{BS_{max}}$, which ensures that the generation time of long-tailed samples remain unchanged as before the migration.

Another factor to consider is the memory constraint. During LLM generation, the key-value cache is maintained for each token position for autoregressive generation. When the sequence length is long, this memory consumption becomes non-negligible [30]. Therefore, we need to ensure that the target instances have sufficient memory to accommodate the remaining long-tailed samples, avoiding out-of-memory issue or blocking the sample processing. Thus, we set the second constraint as $m \geq \frac{R_t * M}{C}$, where M denotes the key-value cache consumption of the sample with the maximum output length and C is the available GPU memory of the target instance allocated for key-value cache. In summary, the final m is determined by the maximum of the two constraints.

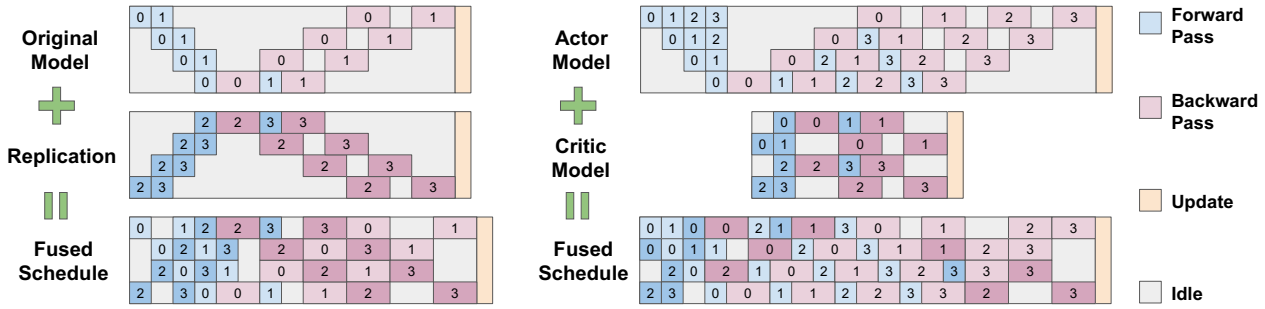
Next, we need to determine which m out of the n generation instances to process the remaining long-tailed samples. To minimize migration overhead, we select the top m instances that have the most samples remaining. This strategy minimizes the total number of samples requiring migration.

Migration mechanism. To migrate an unfinished sample to the target instance, we have two choices. The first approach is to transfer the generated key-value cache to the target instance over the network, allowing it to continue the subsequent generation immediately upon receipt. The overhead in this case primarily comes from the network transmission. The second approach is to discard the key-value cache and only transmit the generated tokens of the sample. Compared to the first approach, this method incurs minimal network latency but comes at the cost of rerunning the prefill phase to generate the key-value cache. The choice of migration mechanism depends on the GPU hardware and network bandwidth. In our experiments, thanks to the high-bandwidth RDMA connections, we choose the first approach and the migration overhead is negligible compared to the iteration time, as shown in §7.2.

After completing the migration, we can release the GPU resources of the remaining $n-m$ generation instances to launch inference tasks. This process involves weights redistribution and data transmission to prepare the context of inference tasks, which we discuss in §6. Once the inference tasks are launched, the remaining long-tailed samples can be streamed to the inference instances as soon as their generation stage is completed, allowing for seamless processing. Additionally, if the long-tail generation task finishes first, we release its resources for the inference tasks.

5 Model-aware Intra-Stage Fusion

In this section, we first analyze the opportunities of fusing the two tasks in the training stage (§5.1). Then we propose a lightweight algorithm to generate the fused pipeline schedule to minimize the pipeline bubbles and memory usage (§5.2).



5.1 Opportunities and Challenges

Opportunities. During the RLHF training stage, the `Actor` and `Critic` models are trained independently. Inspired by the bi-directional pipeline schedule [19] from Chimera, we can break the two training tasks into subtasks of micro-batches and co-locate these subtasks to mutually fill the pipeline bubbles of each other. Originally, Chimera enhances single-model training by replicating the model and trains the replicated model with 1F1B schedule in opposite pipeline directions, as depicted in Figure 6(a). This approach not only mitigates pipeline bubbles but also brings a balanced distribution of activation memory. RLHF training stage inherently involves two distinct models, enabling us to apply the fused pipeline schedule without extra model replication.

Challenges. In Chimera, the bi-directional pipeline schedule utilizes one identical model replica with uniform size and parallel strategy, resulting in a symmetric execution flow. In contrast, RLHF involves training heterogeneous `Actor` and `Critic` models, which differ not only in size but also in their optimal parallel strategies. Consequently, the symmetric schedule from Chimera is no longer applicable in the face of model heterogeneity in terms of size and parallel configuration. In the following, we introduce a lightweight and efficient algorithm to automatically generate the fused pipeline schedule under this more generalized setting.

5.2 Fused Pipeline Schedule

Problem transformation. Assume the parallel strategies for models A and B are (dp_1, pp_1, tp_1) and (dp_2, pp_2, tp_2),

(a) Chimera [19] (b) RLHFuse

Figure 6: (a) An example of the symmetric bi-directional pipeline schedule used in Chimera [19] with four pipeline stages and four micro-batchs. (b) An example to show our method can fuse two different models with different numbers of pipeline stages.

Symbol	Description
S	The fused pipeline schedule.
l_{ij}	The latency of subtask S_{ij}.
C	The activation memory capacity of each stage.
K_1	The fusion factor of model A.
K_2	The fusion factor of model B.
N	The total number of pipeline stages to be fused.
N_1	The number of pipeline stages of model A.
N_2	The number of pipeline stages of model B.
M_1	The number of micro-batches for model A.
M_2	The number of micro-batches for model B.

Table 1: Key notations in problem formulation.

which denotes the parallel degree of each 3D-parallelism dimension. Each will utilize all the GPUs in the cluster. We require that tp is the powers of two, which is commonly adopted in practice. For the case where $tp_1 \neq tp_2$, the challenge for a fused pipeline schedule lies in the fact that the pipeline stage of the two models contains a different number of GPUs. Without loss of generality, we assume $tp_1 = s \times tp_2$. In this situation, we merge every s consecutive pipeline stages of model B into one stage, redividing model B into $\frac{pp_2}{s}$ pipeline stages. This ensures that each stage of both models uses the same number of GPU resources. Note that here we require pp_2 to be divisible by s, which is easy to realize in practice. After that, we can transform the problem into fusing K_1 pipeline groups of model A with K_2 pipeline groups of model B, where K_i denotes the fusion factor and K_1 and K_2 are coprime. Figure 6(b) illustrates an example of $(K_1, K_2) = (1, 2)$. Next, we precisely define the fused pipeline schedule and formulate the problem. Table 1 summarizes the key notations.

Problem formulation. We assume the two models to be fused each has N_1 and N_2 pipeline stages ($K_1 \times N_1 = K2 \times N_2 = N$), and each pipeline needs to process M_1 and M_2 micro-batches, respectively. Since the global batch size is fixed, we have $K_1 \times M_1 = K2 \times M_2$. The fused pipeline schedule is represented as a matrix S, where S_{ij} represents the j-th subtask (micro-batch) to be scheduled in the i-th stage. Since there are N stages in total and each stage needs to process the forward and backward computation for all micro-batches of the two models exactly once, the shape of S is $N \times 2(M_1 + M_2)$. The latency of subtask S_{ij} can be profiled in advance and is denoted as l_{ij}. Note that not all S can be scheduled. A valid schedule must satisfy the following constraints:

1. Data dependency: the forward and backward of the same micro-batch across different stages must be executed following the original data dependency.
2. Deadlock avoidance: there exists no cycles in the overall dependency graph to avoid deadlocks.
3. Memory constraint: the peak activation memory usage of each stage must be less than C to avoid out-of-memory.

The main optimization target is to find a valid schedule S that has the minimum latency. Additionally, among schedules with the same latency, we prefer the ones with lower peak activation memory to optimize resource usage.

Algorithm 1 Generate Fused Pipeline Schedule.

```
function GenerateFusedPipelineSchedule(S_0)
    s_current ← S_0
    e_current ← ComputeEnergy(s)
    T ← e_current
    s* ← s_current
    e* ← e_current
    while T > ε do
        s_neighbor ← ComputeNeighbor(s_current)
        e_neighbor ← ComputeEnergy(s_neighbor)
        if e_neighbor < e* then
            s* ← s_neighbor
            e* ← e_neighbor
        if P(e_current, e_neighbor, T) > Rand(0,1) then
            s_current ← s_neighbor
            e_current ← e_neighbor
        T ← T × α
    return s*
```

Algorithm overview: The problem has many constraints and variables. A naive solution is to extend the bi-directional pipeline [19] greedily which always schedules feasible micro-batches. If the micro-batches of two models are both ready, it favors the larger model, with the expectation that the smaller

Algorithm 2 Generate A Random Neighbor Schedule.

```
1: function ComputeNeighbor(S)
2:     while True do
3:         i ← RandInt(1, N)
4:         j ← RandInt(1, 2(M1 + M2) − 1)
5:         S' = Swap(Sij, Si(j+1))
6:         if CheckValid(S') then
7:             return S'
```

one can flexibly fill in the bubbles later. However, the greedy method lacks a global perspective. For example, certain micro-batches could be deliberately delayed to fill the bubbles later. Moreover, it provides no optimization for memory usage. Thus, the greedy approach does not yield optimal performance, as we will demonstrate in §7.3.

Instead, we use simulated annealing [31] to search for a better solution. The motivation for using simulated annealing is that we have a huge search space with many variables. Simulated annealing is effective in finding acceptable local optimums in a reasonable amount of time while finding the global optimum is computationally expensive. Furthermore, we will show that our method can achieve the theoretical lower bound most of the time as shown in §7.3.

At a high level, we use the fused pipeline schedule S as the state in simulated annealing. We use the schedule found by the greedy algorithm mentioned above as the initial state and probabilistically jump to a neighbor state in each iteration, aiming to find a schedule with the lowest latency. Our approach has two benefits. First, it is easy to scale out. We can perform searching using different random seeds across hundreds of CPU cores and select the best result among them. Second, it can easily extend to more models, which arises in multimodal [32] and multi-agent [33] training scenarios. Now we describe the algorithm in more detail below.

Simulated Annealing (Algorithm 1): The algorithm uses the solution found by the greedy algorithm as the initial state S_0, and its execution time as the initial temperature (line 2-3). s^* is used to store the schedule with the lowest latency and e^* is the energy (latency) of s^*. The algorithm searches until temperature T is less than an epsilon value (lines 7-16). T is decreased by a factor of α in every iteration. At each iteration, it uses *ComputeNeighbor* subroutine to find a neighbor state of the current one and uses *ComputeEnergy* to compute the energy of the neighbor state. If the neighbor state has lower energy than s^*, it updates s^* (lines 10-12). The algorithm uses a probabilistic function P to decide whether to transition from the current state to the neighbor state. The probabilistic function P is defined as follows: if the neighbor state has a lower energy than the current state, the probability is 1; otherwise, the probability is $e^{(e_{current}-e_{neighbor})/T}$.

ComputeNeighbor (Algorithm 2): This routine finds a neighbor state of the current state. It randomly swaps two adjacent subtasks from a random stage. If the neighbor state is invalid, it will undo the change and repeat the random swapping until finding a valid schedule. We select adjacent subtasks rather than any two subtasks in one stage primarily to control the degree of disturbance, which is found to be more effective in practice.

Algorithm 3 Compute Energy

```
1: function ComputeEnergy(S)
2:     return max_{1≤i≤N} ComputeFinishTime(S_{i,M})
3: function ComputeFinishTime(Sij)
4:     if Sij ∈ Memo then return Memo.get(Sij)
5:     S^intra ← GetIntraDependency(Sij)
6:     S^inter ← GetInterDependency(Sij)
7:     IntraTime ← ComputeFinishTime(S^intra)
8:     InterTime ← ComputeFinishTime(S^inter)
9:     FinishTime = max(IntraTime, InterTime) + lij
10:    Memo.put(Sij, FinishTime)
11:    return FinishTime
```

ComputeEnergy (Algorithm 3): This function computes the execution time for a given valid schedule S. We use a memoized recursion to calculate the finish time of the last subtask in each stage and pick the maximum as the execution time. For subtask S_{ij}, its start time is decided by two dependencies: inter-stage data dependency and intra-stage data dependency. The inter-stage dependency is the completion of subtask in the upstream pipeline stage corresponding to the same micro-batch. The intra-stage dependency is the completion of the preceding subtask in the same pipeline stage. Consequently, the end time of S_{ij} is determined by the maximum of these two dependencies plus its own computation time, l_{ij}. The detailed algorithm is shown in Algorithm 3. It has time complexity of $O(N \times (M_1 + M_2))$.

Optimizing memory usage. When we obtain a latency-optimized solution S^*, we use it as the initial state to run another round of simulated annealing similar to Algorithm 1. However, this time we replace the *ComputeEnergy* function with one that calculates the peak activation memory for the given schedule. Additionally, we only allow state transitions when the neighbor's latency does not degrade. In this way, we can achieve a solution that not only has promising latency but also optimizes the activation memory usage.

6 Implementation

We implement RLHFuse based on Megatron-LM [15] with 7K lines of code in Python, C++, and CUDA. Megatron-LM applies 3D-parallelism for single-model training. We extend it to support multiple device meshes to launch different tasks asynchronously with tailored parallelism and deployment strategy.

Parallel strategy configuration. Optimizing the parallel strategy for LLM training task is a well-studied problem [6, 15, 26, 34]. Due to the deterministic nature of LLM computation [35],

the execution time and memory cost can be accurately modeled through minimal profiling [25, 27, 28]. An optimal solution can then be found through optimizations [6, 18, 26, 34]. The generation and inference task involves only the forward pass, which can be modeled as a simplified problem of LLM training [27, 28]. ReaLHF [6] is a state-of-the-art solution that optimizes the parallel strategy for RLHF tasks and we adopt a similar model-then-optimize approach. We build a simulator to accurately estimate the runtime statistics of the RLHF task under a specific parallel strategy and workload pattern. Then we follow the guidelines in the Megatron-LM [15] paper to prune the design space and brute-force search the optimal strategy for each RLHF task.

Inter-stage fusion. We extend the simulator mentioned above from the task level to the workflow level. Given the parallel strategies, workload pattern, and migration threshold R_t, it considers the task dependencies and data transmission overhead and simulates the overall execution time of the generation and inference stages. Then we can choose the best migration threshold R_t to minimize the fused execution time.

Intra-stage fusion. We use MPI [36] to parallelize the simulated annealing algorithm used for fused pipeline schedule generation (§5.2). Under different random seeds, the computations are completely independent, so that we can easily scale the computation to hundreds of CPU cores, making it highly likely to find the optimal solution (§7.3). After finding the best solution, it will generate the sequences of NCCL [37] operations on each device following the fused pipeline schedule. The underlying execution engine will follow the instruction flow to execute the exact schedule during runtime. The code of the intra-stage fusion algorithm is publicly available[1].

System optimizations. We adopt a series of system optimizations tailored for RLHF training. Since the RLHF training workflow is well-known, many of the following optimizations are also implemented or partially supported in a similar way in other RLHF frameworks like ReaLHF [6], HybridFlow [5], OpenRLHF [38], DeepSpeed-Chat [39], and PUZZLE [7].

For the generation stage, we implement an in-house inference engine which integrates most of the modern techniques optimized for LLM autoregressive generation like continuous batching [9], prefix sharing [10], and chunked-prefill [40]. For the inference stage, we optimize the computation for Generalized Advantage Estimation [41], which unrolls its original recursive formula along the output length dimension and transforms the recursive computation into a single matrix multiplication, greatly reducing the kernel launch overhead. For the training stage, we evenly distribute each mini-batch across the DP groups [6] based on the sequence length of the samples to ensure that the workloads are roughly balanced across the DP groups, effectively tackling the straggler issue. To reduce the task switching overhead [5–7], we minimize the cross-node communication [42] for the `Actor` and `Critic` models whose latest weights after the training stage need to be redistributed to the appropriate devices according to the new parallel strategies. For the `Ref` and `RW` models whose weights remain unchanged, we keep them in CPU memory and swap them into GPU memory as needed [5, 6], overlapping with the computation of previous tasks.

To separate the differences in low-level system implementations from the core techniques (inter-stage fusion in §4 and intra-stage fusion in §5), our evaluation in §7 uses RLHFuse-Base that includes these optimizations but without inter- and intra-stage fusion as an additional baseline.

[1] https://github.com/FlexFusion/FlexFusion

7 Evaluation

In this section, we evaluate RLHFuse under different sizes of LLMs ranging from 13B to 65B on real-world datasets.

Cluster testbed. We deploy RLHFuse on a production cluster for RLHF training with 32 nodes and 256 GPUs. Each node has 2TB of memory and 8 NVIDIA Hopper GPUs connected with NVLINK. Nodes are connected by $8 * 200$ Gbps RDMA network based on RoCEv2 with rail-optimized topology. The simulated annealing algorithm in §5 is conducted on four CPU nodes, each with 2 AMD 9654 CPUs and there are 768 physical cores in total.

Models and datasets. Following previous work [7], we choose the LLaMA models [43] ranging from 13B to 65B, which is a popular LLM family used in academia and industry. The detailed specifications are listed in Table 2. We use the HH-RLHF [44] dataset, which is open-sourced by Anthropic to train a helpful and harmless assistant with RLHF.

Settings. Since the `Actor` and `Ref` models are of the same size, as are the `Critic` and `RW` models, we choose four different model size settings for `Actor/Critic` pair : 13B/33B, 33B/13B, 33B/65B, and 65B/33B. We also vary the maximum output length to see the performance under different generation settings. In each training iteration, we use a global batch size of 512, a mini-batch size of 64, and take one gradient step per mini-batch following the LLaMA technical report [45].

Metrics. For the end-to-end experiment, we measure the *sample throughput* following previous work [7]. Sample throughput is defined as the average number of samples processed per second. Under each setting, we record the sample throughput over 20 consecutive training iterations after warm-up.

7.1 End-to-End Results

We compare the end-to-end performance of RLHFuse against the following RLHF training frameworks.

- **DeepSpeed-Chat [39]** (DSChat) colocates all the models on the same set of devices and only supports ZeRO-3 data parallelism [46] during training. It utilizes a *HybridEngine*

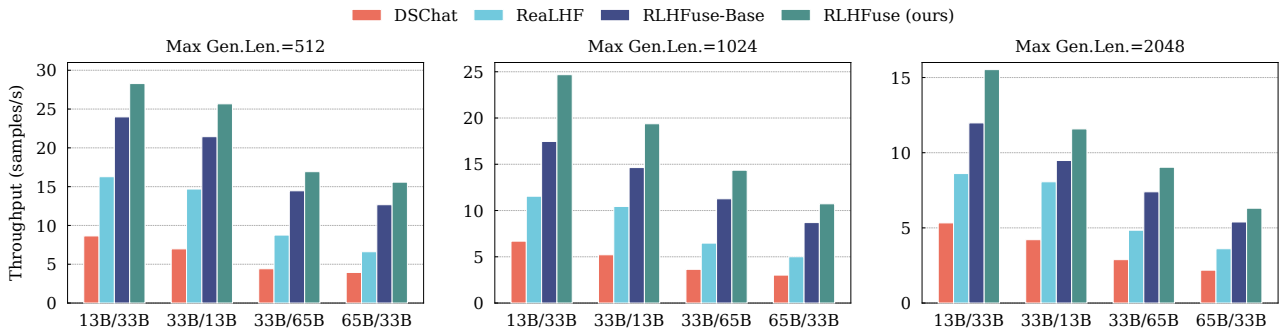


Figure 7: End-to-end throughput of RLHF training systems under different generation and model size settings.

Models	# of Layers	# of Heads	Hidden Size	Intermediate Size
LLaMA-13B	40	40	5120	20480
LLaMA-33B	60	52	6656	26624
LLaMA-65B	80	64	8192	32768

Table 2: LLM specifications.

to switch from ZeRO-3 DP to TP in the generation stage. Since each GPU requires at least one sample during training and it only supports ZeRO-3 DP, we increase its mini-batch size to 256 while maintaining the original global batch size in order to run it successfully on our testbed. Note that with a larger mini-batch size, this adjustment is more favorable for its throughput performance.

- **ReaLHF [6]** proposes parameter reallocation to flexibly redistribute parameters between tasks, enabling tailored 3D-parallel strategy for each task. However, as discussed in §2.2, it suffers from the issues of data skewness and pipeline bubbles without employing the subtask-level optimizations.
- **RLHFuse-Base** is RLHFuse without inter- and intra-stage fusion but with all the system optimizations enabled as described in §6. We include this baseline to demonstrate the performance improvements brought by our fusion techniques in §4 and §5, eliminating any unfair comparisons caused by the differences in underlying framework implementations and other optimization techniques in LLM generation and training which are orthogonal to the proposed stage fusion techniques.

Figure 7 shows the end-to-end performance of the RLHF training systems under three generation settings. We set the maximum generation length to 512, 1024, and 2048, respectively. Under a specific generation setting, the configuration X/Y denotes parameter counts in actor and critic models, mirrored in the reference and reward models, respectively. Compared to DSChat, RLHFuse achieves 2.5×–3.7× higher throughput. This is because DeepSpeed-Chat colocates all the models on the same set of GPUs, making it impossible to adopt the most suitable parallel strategy for each task, which introduces additional computation and communication overhead. ReaLHF implements a flexible execution plan generator, which selects the most efficient 3D-parallel strategy for each task, such as balancing between DP and PP sizes to reduce the number of pipeline stages while avoiding OOM, thereby partially mitigating pipeline bubbles. However, RLHFuse goes further by eliminating the vast majority of bubbles and addressing the long-tail issue in the generation stage with intra- and inter-stage fusion. Additionally, RLHFuse integrates production-grade optimizations in the underlying framework tailored for large-scale training scenarios (§6). As a result, RLHFuse achieves 1.4×–2.4× higher throughput compared to ReaLHF. Compared to RLHFuse-Base, our system achieves a relative improvement of 1.2×–1.4× on the throughput. This improvement is entirely from stage fusion, which significantly alleviates the issues of data skewness in the generation stage and pipeline bubbles in the training stage. In the following, we conduct a detailed breakdown analysis to show the performance improvement.

7.2 Performance Analysis

To further understand the performance improvement of RLHFuse, we show its RLHF iteration breakdown and compare it with RLHFuse-Base. As shown in Figure 8, each row represents a generation setting, and each column represents a model setting X/Y. We divide one RLHF iteration into three main parts: the generation plus inference stage (`Gen.+Inf.`), the training stage (`Train`), and all other overheads (`Others`), such as the data transmission and weights redistribution time.

For `Gen.+Inf.`, since RLHFuse-Base does not perform inter-stage fusion and executes the two stages in serial, we use light and dark colors to represent the time spent on the generation and inference stages respectively to better show the speedup of inter-stage fusion. It can be seen that as the maximum generation length increases, the processing time of long-tailed samples is long enough for RLHFuse to fully overlap the inference stage execution, achieving 1.2×–1.6× speedup. For the training stage, similarly, we use light and dark colors to represent the `Actor` and `Critic` training time in RLHFuse-Base. Through intra-stage fusion, RLHFuse greatly mitigates pipeline bubbles and reduces the execution time of the training stage by 1.2×–1.3×. As for the other overhead, thanks to our optimizations in task switching (§6), it only accounts for less than 3% of the total iteration time, and the migration overhead of inter-stage fusion is also negligible.

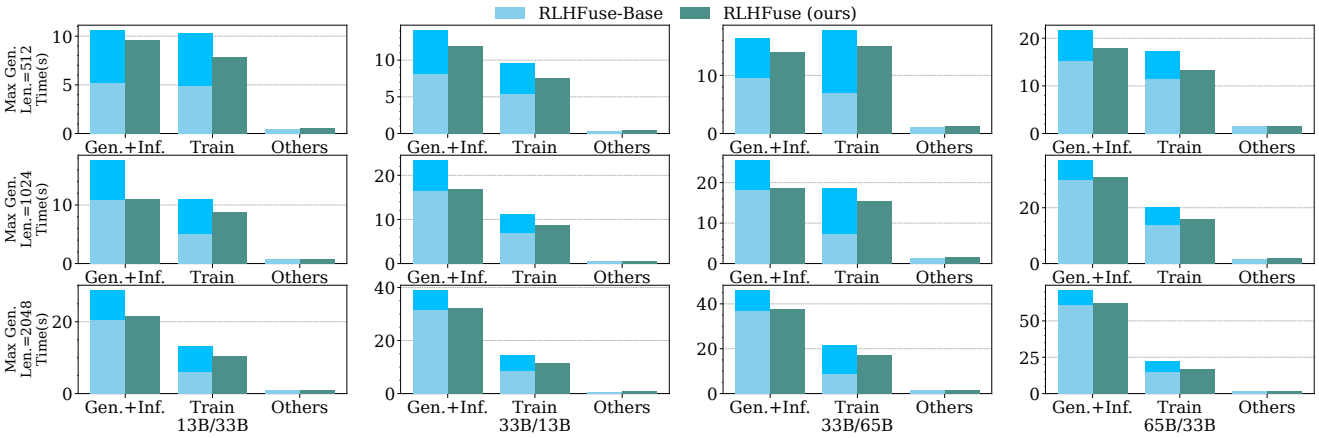

Figure 8: The RLHF iteration breakdown under different generation and model size settings.

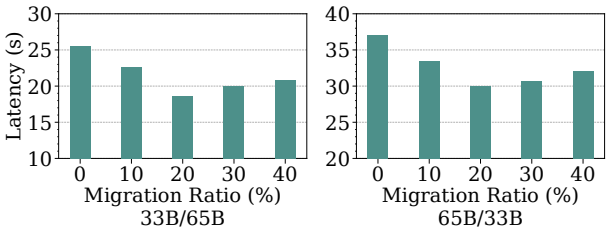

Figure 9: The fused generation and inference stage execution time of RLHFuse under different migration ratios and model settings. The maximum generation length is set to 1024.

7.3 Effectiveness of Stage Fusion

In this section, we show the effectiveness of RLHFuse's key techniques in §4 and §5.

Inter-stage fusion. One key parameter in inter-stage fusion is the migration threshold R_t. As R_t increases from zero, it shifts from fully serial execution to more aggressive fused execution. However, if R_t is set too large, the long-tail generation instances may be overloaded, extending the original generation time. We measure the execution time of the fused generation and inference stage under different migration ratios (R_t/BS) as shown in Figure 9. We can see the optimal latency is achieved when the remaining samples account for about 20% of the batch size. Note that R_t is related to the output length distribution of the model and this experiment is conducted during the early stage of training. As training progresses, R_t requires periodic adjustments to adapt to the distribution change. In practice, such changes are usually not too drastic, so the adjustment frequency remains low.

Intra-stage fusion. We compare RLHFuse's simulated annealing algorithm against the greedy approach mentioned in §5.2 and show the latency speedup and peak activation memory usage relative to the serial execution of the two models with 1F1B schedule in Table 3. For the latency, a naive solution (denoted as 1F1B+) that does not employ a fused pipeline involves using a smaller PP size without out-of-memory errors. However, this approach increases the DP size and results in fewer micro-batches allocated to each pipeline, thereby partially negating the benefits brought by shallower pipelines. Consequently, this solution is less effective compared to the fused pipeline schedule. We also include a lower bound (denoted as LB) estimation calculated as follows: we first compute the earliest possible completion time for each stage, which consists of three parts: the earliest possible arrival time of the first task, the total time required to process all the tasks, and the remaining time needed for the subsequent pipeline stages of the final task; we then take the maximum of these times across all stages as the lower bound of the fused pipeline schedule. Note that there may not necessarily exist a schedule that reaches this lower bound, but we can use it as a metric to assess how close our algorithm is to the optimal solution. Under all the settings, our approach outperforms the baseline methods and achieves the theoretical lower bound except for the last case.

Settings				Latency Speedup relative to 1F1B				Peak Memory relative to 1F1B	
Models	**PP0**	**PP1**	**GBS**	**1F1B+**	**Greedy**	**Ours**	**LB**	**Greedy**	**Ours**
33B/13B	8	4	8	1.10	1.29	**1.38**	**1.38**	1.51	**1.0**
			16	1.06	1.12	**1.30**	**1.30**	2.14	**1.0**
			32	1.03	1.10	**1.15**	**1.15**	2.75	1.26
		8	8	1.07	**1.4**	**1.4**	**1.4**	1.51	**1.0**
			16	1.05	1.15	**1.32**	**1.32**	2.00	1.19
			32	1.03	1.08	**1.17**	**1.17**	2.75	1.31
65B/33B	16	8	16	1.05	1.28	**1.48**	**1.48**	1.61	**1.0**
			32	1.03	1.14	**1.27**	**1.27**	2.23	**1.0**
			64	1.02	1.12	**1.15**	**1.15**	2.88	1.26
		16	16	1.03	1.27	**1.5**	**1.5**	1.57	**1.0**
			32	1.02	1.16	**1.33**	**1.33**	2.00	1.22
			64	1.01	1.09	1.16	**1.17**	2.88	1.47

Table 3: The latency speedup and peak activation memory cost of pipeline schedules found by different algorithms under different models, pipeline stages, and global batch size settings.

As for the memory cost, the serial 1F1B execution serves as the lower bound for the fused schedule. Our method also greatly outperforms the greedy approach and often reaches the lower bound. Even when it does not achieve the lower bound, the extra overhead remains within an acceptable range.

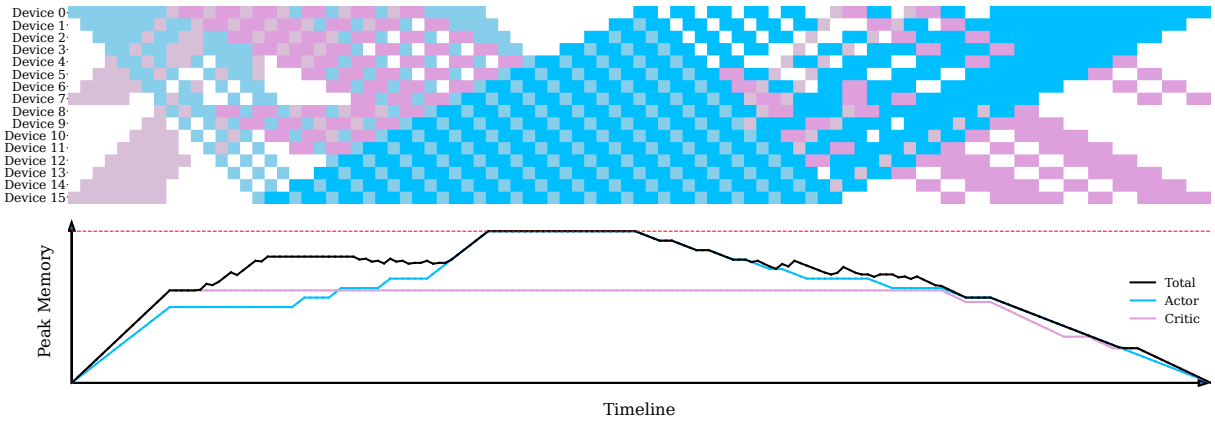

Figure 10: The fused pipeline schedule of 65B `Actor` and 33B `Critic` model generated by RLHFuse. The two models have 16 and 8 PP stages respectively and #micro-batches is set equal to PP. Top: the GPU execution timeline. Bottom: the peak activation memory usage timeline. The red dotted horizontal line denotes the memory cost of serial 1F1B execution, which is the lower bound.

7.4 Deep Dive

In this section, we deep dive into RLHFuse by showing a fused pipeline schedule produced by RLHFuse for the 65B/33B model setting. The upper of Figure 10 shows the GPU execution timeline, with forward and backward tasks in light and dark colors, respectively. With intra-stage fusion, RLHFuse strategically fuses one 65B model of 16 PP stages (blue grids) with two 33B models that each have 8 PP stages (pink grids) to fill the pipeline bubbles of each other in reversed pipeline directions. Ultimately, the execution time of this fused pipeline schedule is the same as individually executing the 65B model using the 1F1B schedule, which means we completely overlap the training of the 33B model, achieving the theoretical lower bound. Meanwhile, as shown at the bottom of Figure 10, the peak activation memory usage also achieves the lower bound of executing the two models in serial with 1F1B schedule.

8 Related Work

RLHF training systems. As RLHF gradually becomes the primary approach for LLM alignment, many frameworks are specifically designed for RLHF training. OpenRLHF [38] uses Ray [47] to distribute models onto separate GPUs and adopts vLLM [8] to accelerate the generation stage. HybridFlow [5] proposes a hierarchical hybrid programming model for the RLHF dataflow and optimizes the GPU allocation and placement of each RLHF model. ReaLHF [6] proposes to design custom parallel strategies for different RLHF tasks to avoid GPU under-utilization. PUZZLE [7] utilizes a lightweight context-switching algorithm to reduce the task switching overhead. These solutions do not consider subtask-level optimization opportunities, thus suffering from data skewness and pipeline bubble issues.

LLM generation optimizations. Many systems focus on optimizing the LLM generation performance [9, 10, 12, 30, 48], and most of them have been adopted by RLHFuse to accelerate the generation stage. Besides, AlpaServe [27] multiplexes the LLM execution with colocated parallelism to improve the throughput under the bursty workload. FastServe [29] proposes preemptive scheduling on iteration-level to mitigate the head-of-line blocking caused by long-tailed samples. Splitwise [49] and DistServe [28] split the prefill and decoding phases to avoid interference between them. These works are orthogonal to RLHFuse and can be integrated into RLHFuse.

LLM training optimizations. LLM training has been studied by many works from various aspects. In particular, [17, 20, 50, 51] use pipeline parallelism to improve the training throughput and reduce memory footprint. Alpa [26] automatically generates the optimal parallel strategy to improve training performance. MegaScale [16] provides a detailed experience in building a production LLM training system at a large scale. DistTrain [52] focuses on addressing the model and data heterogeneity in multimodal LLM training. These works are agnostic to RLHF thus do not utilizes the characteristics to optimize the RLHF training stage.

9 Conclusion

We present RLHFuse, an efficient RLHF training system. RLHFuse views the RLHF workflow from a finer-grained subtask-level perspective and opens up opportunities for efficient inter- and intra-stage fused execution, mitigating data skewness and pipeline bubbles in existing systems. The evaluation shows that RLHFuse can significantly increase GPU utilization, boosting training throughput by up to 3.7× compared to existing systems.

Acknowledgments. We thank our shepherd, Peter Pietzuch, and the anonymous reviewers for their valuable feedback. We thank Shihong Deng, Shilei Jiang, and Heng Wang for providing algorithmic and data support in this work. We thank Wei Fu and Yi Wu for their assistance in running the baseline and for their valuable feedback on the paper.

Abstract

Large-scale distributed model training requires simultaneous training on up to thousands of machines. Faulty machine detection is critical when an unexpected fault occurs in a machine. From our experience, a training task can encounter two faults per day on average, possibly leading to a halt for hours. To address the drawbacks of the time-consuming and labor-intensive manual scrutiny, we propose Minder, an automatic faulty machine detector for distributed training tasks. The key idea of Minder is to automatically and efficiently detect faulty distinctive monitoring metric patterns, which could last for a period before the entire training task comes to a halt. Minder has been deployed in our production environment for over one year, monitoring daily distributed training tasks where each involves up to thousands of machines. In our real-world fault detection scenarios, Minder can accurately and efficiently react to faults within 3.6 seconds on average, with a precision of 0.904 and F1-score of 0.893.

1 Introduction

Recent years have witnessed a rapid increase in dataset sizes and the number of parameters in models, especially in Large Language Models (LLMs). The GPT-4 model [18], an instance of the Mixture-of-Experts (MoE) paradigm, demonstrates this growth with its 1.8T parameters. Other latest models also exhibit this trend, with parameter counts exceeding 500 billion [24, 69]. The feasibility of training such extensive models efficiently has been realized through large-scale machines and GPUs [39, 40]. It has also been accompanied by advancements in distributed model training [49, 68], high-performance collective communication [48, 65], and fault-tolerant techniques [36]. A system of such vast size and complexity involves a huge amount of computation, communication, and storage resources as well as software support for a task. Consequently, the potential for faults is high, leading to the possibility of task failure.

Faulty machine detection thus has become a significant bottleneck in the maintenance of distributed tasks. In our production environment, an accidental hardware or software fault occurs twice a day on average. The entire task may be forced to stop for hours or days until fixed for retraining. The economic loss for a customer can reach more than $1700 in a 128-machine task for 40 minutes (case in 2.1). Training a GPT-2 model with 1.5 billion parameters and 40GB dataset [67], for instance, takes 200 days utilizing an NVIDIA V100 GPU [10] (or 12 days for a DGX-2H server). If the training process is frequently interrupted by such faults, operating expenses and time costs will increase significantly.

However, the current manual diagnosis method is unsatisfactory. Once a halted task notification is received, the engineer needs to check the training parameters. Meanwhile, engineers from the training, physical networking, storage, and hardware teams, are also involved in diagnosis, since a fault can occur in any machine component. Examining machine logs and conducting offline performance tests on relevant hardware devices are required until the fault is detected (usually for hours). Delayed notifications, incomplete log content, and the complicated process of manual diagnosis amplify the unpredictability of time and labor costs.

It's necessary to design effective and accurate faulty machine detection methods that can quickly react to faults at runtime, not only providing better reliability but also eliminating manual efforts. Achieving such goals is challenging because a machine can fail due to various types of faults. These faults can occur in any possible component, including hardware and software, and can be intra-host or inter-host. Besides, the abnormal pattern of monitoring metrics varies from task to task, making the traditional supervised anomaly detection methods impractical, because even the same behavior might be abnormal in a task with a different workload and machine scale. Additionally, there isn't an individual monitoring metric that necessarily signals a fault. For instance, CPU or GPU usage is the most sensitive metric for fault in-

The first two authors contributed equally to this paper. Zhuo Jiang and Minlan Yu are the corresponding authors. This work was done while Yangtao Deng and Xingjian Zhang were doing a joint research project at ByteDance.

dication, based on our observation from real production data. However, neither one is guaranteed to identify the faulty machine for Error Correction Code (ECC) errors. If noises exist in monitoring data, the detection may be even misguided. Therefore, faulty machine detection for distributed training is challenging.

Instead of creating a monolithic predictor with available monitoring data, we developed Minder by leveraging the ideas of similarity (3.1), continuity (3.2), training individual models for each monitoring metric (3.3), and metric prioritization (3.4). Minder resolves the challenges by recognizing that a machine with a fault displays an abnormal pattern in certain metric data that differs from other machines and lasts for a duration. We also train individual models for data denoising. We then track the dissimilarity between the denoised data for each machine and monitor its duration. By repeating this to individual metrics, the faulty machine is detected. To further expedite detection, we prioritize metrics to identify the most sensitive ones when a fault occurs.

We designed, implemented, and deployed Minder for all the distributed training tasks. Minder operates without interrupting the running of the training machines, only requiring the pulling of monitoring data from the Data APIs for backend run-time analysis. Host metrics used by Minder cover the aspects of computation, communication, and storage. Manual labors are released from the debugging process since Minder can react within 3.6 seconds (6.1), reducing over 99% of the time of manual debugging (shorter time by 500 ×). Minder has an overall precision and F1-score of 0.904 and 0.893.

We make the following contributions.

- An investigation of the fault types and their correlations with various monitoring metrics (2.3). We empirically explain why some metrics are more sensitive to faults and outline the challenges for the detection (2.4).
- The ideas of similarity, continuity, denoising models, and metric prioritization for the design of Minder (3, 4). Our thorough evaluation of Minder's implementation (5) and and ablation experiments highlight its fast reaction, high accuracy, and proper design choices (6).
- Lessons we encountered when deploying Minder in practical (7). We also point out future directions.

2 Motivation

2.1 Negative Impacts of Faults in Real-World Production Environments

Once an unexpected hardware or software fault occurs in a machine, it does harm to the entire distributed training task at the machine level.

Faults are frequent due to the long training duration and large scale. The relationship between a task's machine scale and the daily number of faults is illustrated in Figure 1. Based on our seven-month statistics, the machine scale could significantly exceed 1024, training on more than 10000 GPUs. The occurrence of unexpected faults is highly correlated with the task scale, with an average of two faults a day. If we cannot react quickly to these incidents, such a frequent fault is a burden for training large models.

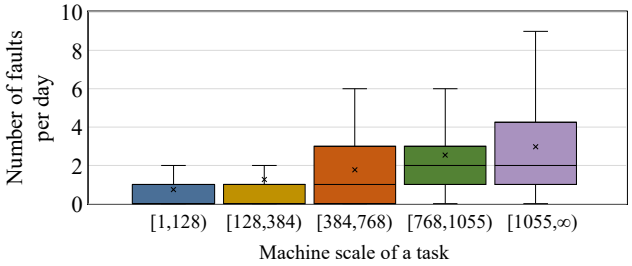

Figure 1: Fault frequency of tasks with different machine scale sizes.

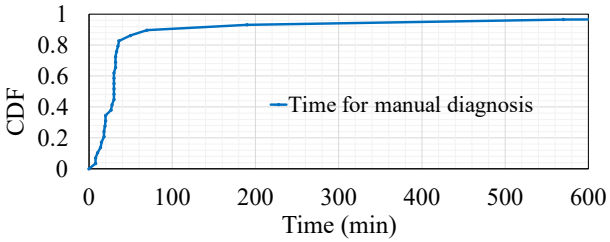

Figure 2: Time for task diagnosis in seven months.

A single fault can cause a large-scale task halt. Based on empirical observations, a fault during the training process often originates as a host problem (*e.g.,* CUDA error, NVLink error [5]). However, this issue can eventually cause a cascade effect, leading to the entire task being interrupted or a noticeable slowdown. For example, a hardware ECC error during communication will make the distributed systems interrupt (*e.g.,* when running in PS [48] or All-reduce [65]) due to NCCL timeout [12] or network disconnections, thereby could resulting in more than half thousand of machines to stop and be in idle state in the production environment.

Faults take a long time to diagnose, increasing labor and resource costs. Based on seven-month data in 2023, the time until the faulty machine can be manually diagnosed is shown in Figure 2. The time lasts over half an hour on average and can be days. It ultimately results in GPU and NIC resources being left idle, leading to additional time costs upon resolution. More delays can result in significantly increased costs and time requirements for users.

An example: PCIe downgrading. We highlight a real-world instance where a 128-machine training was forced to slow down severely for 40 minutes due to a PCIe degradation (PCIe is an intra-host, high-speed serial bus that connects a variety of devices, such as graphics cards, NICs, and solid-state drives). The faulty machine encountered PCIe degradation from 6.4Gbps to 4Gbps. The congested communication ultimately results in the underutilization of computational resources, where thousands of V100 GPUs were compelled to

remain slowed down for 40 minutes. Such cost wastes for customers can be $650 for 40 minutes (given the public renting price of $2.48 per GPU for an NVIDIA V100 [6]).

2.2 Today's Solution and Drawbacks

A straightforward approach after an unexpected fault occurs is inspecting the existing hardware and software logs on the machines, as well as `dmesg` [2], `netstat`, `top` commands. However, this process involves the following three limitations.

The notification of when to trigger a diagnosis is not timely. Firstly, engineers are only alerted once the task has stopped entirely. Certain faults will slow down the training speed in Model FLOPs Utilization (MFU) but are not severe enough to stop the task. The current approach fails to detect degradation in performance as long as the task continues to run. The task will continue running with deteriorated performance for a period in the PCIe downgrading example.

Scrutinized content is incomplete or redundant. Upon a fault notification, the logs or counters recorded during training will be reviewed. The logs are typically maintained in plain text, including built-in software-layer logs (*e.g.,* NCCL and CUDA logs), hardware-layer logs, and network logs. Previous knowledge and experience guide the decision on which logs to include and check, resulting in some log content being overlooked. Meanwhile, logs do not include monitoring metrics like GPU power, temperature, and NVLink bandwidth. In the PCIe degradation case (2.1), identifying the faulty machine was hard as critical monitoring data, like Priority-based Flow Control (PFC) packet rates, was not promptly inspected from the logs. Besides, the log content frequently includes redundant data, such as environmental parameters and warnings. The detection time will be lengthened.

The diagnosis analysis is a complicated and time-consuming process. Engineers from multiple teams are involved in the diagnosing process. Figure 2 presents the time-consuming diagnosis process. It could take as long as several days to detect the faulty machine.

Manual diagnosis procedure and fault propagation for the PCIe downgrading case (2.1). The detection took 40 minutes in total and involved multiple teams. The engineer in charge scrutinized model-related information, parallelism settings [40], dependencies, environmental, and framework (*e.g.,* Megatron-LM [68]) parameters. Meanwhile, the network team scrutinized intra-host throughput, Remote Direct Memory Access (RDMA) traffic, packet loss/randomness, congestion indicators, drivers, and routing. The storage and hardware teams inspected HDFS&SSD usage, GPU&CPU usage, NIC health, and machine scheduling.

The fault propagation initiated from PCIe downgrading to PFC surge. The NIC buffer of the faulty machine was filled after the PCIe degraded. The consequent bottleneck inter-host communication caused a PFC Tx packet surge. The congestion also raised both Explicit Congestion Notifications (ECN) received and Congestion Notification Packets (CNP) sent [17]. As a result, the NIC throughput across all machines dropped from 6.5Gbps to 4.9Gbps. Reduced computation data led to declined GPU tensor core usage [7]. Thus, the training performance was downgraded.

2.3 Real-world Faulty Case Studies

To address the drawbacks of the manual log analysis, we first conducted an in-depth review of the fault types that occurred over seven months. Table 1 shows the common types of faults, their frequencies, and the proportion of instances for each fault type that a metric could indicate. The proportions are determined empirically by examining the available instances and quantifying the number that exhibited abnormal patterns in the monitoring data following a fault. The monitoring data contains multiple metrics and is sampled per second.

We come up with the following observations. Firstly, hardware faults make up the majority of faults (55.8%), in which ECC errors constitute a large proportion (38.9%). Errors that happened in CUDA or GPU also make up a large proportion. Unfortunately, these errors are hard to predict or avoid.

Moreover, each metric displays varying probabilities of indicating a type of fault. There isn't a single metric that effectively signals all of them. ECC error, NIC dropout, GPU card drop, NVLink error, CUDA, and GPU execution error strongly correlate with CPU or GPU metrics. Likewise, PCIe downgrading, NIC dropout, and machine unreachable are most relevant to network metrics, such as PFC and throughput. We explain these observations from our experience. For the CPU metric, a fault on a machine will cease the CPU process, reducing its CPU usage. However, the other machines retain their processes for a while, waiting for data synchronization, due to the Kubernetes management, NCCL timeout setting, and heartbeat mechanism setting with a predefined time window. Thus, these machines maintain normal CPU usage before the task halts. For the GPU metric, a GPU drop or process kill during computation leads to low GPU usage. Conversely, other machines carry on running their CUDA kernels before the timeout and heartbeat check, maintaining normal GPU usage. For the PFC metric, PFC signals on the faulty machine surge abruptly when the NIC buffer is filled, due to congestion-related network errors. Other machines exhibit a low number of PFC packets. The same trend applies to memory usage. Nonetheless, disk usage does not exhibit significant fluctuations based on our experience. Therefore, most fault types strongly correlate with CPU, GPU, Memory, and PCIe metrics. As an exception, AOC errors happen on the switch or the machine-side cables. If a switch AOC error occurs, machines connected to this switch port will be affected instantly. Such a large scale of affected machines can quickly propagate adverse effects to others. It is hard to capture abnormal patterns with second-level monitoring data.

Table 1: Fault types and the proportion of instances for each fault type being indicated by a metric.

Fault type		Frequency of each fault type	Metrics					
			CPU	GPU	PFC	Throughput	Disk	Memory
Intra-host hardware faults (55.8%)	**ECC error**	**38.9%**	80.0%	65.7%	8.6%	45.7%	11.4%	57.1%
	PCIe downgrading	**6.6%**	0.0%	8.3%	100%	33.3%	8.3%	0.0%
	NIC dropout	**5.7%**	100%	100%	0.0%	100%	0.0%	100%
	GPU card drop	**2.0%**	75.0%	70.0%	5.0%	50.0%	20.0%	55.0%
	NVLink error	**1.7%**	83.3%	50.0%	16.7%	50.0%	0.0%	66.7%
	AOC error	**0.9%**	25.0%	25.0%	0.0%	25.0%	25.0%	25.0%
Intra-host software faults (28.0%)	**CUDA execution error**	**14.6%**	61.9%	57.1%	19.0%	33.3%	14.3%	61.9%
	GPU execution error	**7.7%**	50.0%	71.4%	14.3%	42.9%	21.4%	42.8%
	HDFS error	**5.7%**	57.1%	57.1%	0.0%	14.3%	0%	14.3%
Inter-host network faults (6.0%)	**Machine unreachable**	**6.0%**	47.4%	63.2%	0.0%	53.6%	26.3%	15.8%
Others (10.3%)	-	**10.3%**	-	-	-	-	-	-

Note: the introduction of each fault type is in Appendix A.

2.4 Challenges

Based on the observations, we discovered that the following challenges must be addressed:

Challenge 1: Any machine could fail in various ways. Advanced machines, such as Nvidia DGX-A100 [11], incorporate as many as 8 Nvidia A100 GPUs and 4 Mellanox 200 Gb/s RDMA NICs (RNIC), all of which are potential fault points. As presented in Table 1, a fault could happen from intra-host computation, and communication, to inter-host networks, or from hardware (GPU, CPU, PCIe, NVLink, RNIC, memory, and disk) to software communication libraries (*e.g.,* NCCL), and training frameworks (*e.g.,* CUDA). It is hard to detect a faulty machine under all the unknown circumstances.

Challenge 2: The normal state of a monitoring metric is task-dependent. Training tasks have various machine scales, data sizes, models, and training frameworks. Thus, a monitoring metric may have different normal states for various tasks. For instance, a GPU temperature of 70 degrees Celsius is abnormal where GPU clock frequency is 1350MHz, but is regarded as normal in a task where GPUs work with a high clock frequency of 1800MHz. Traditional supervised anomaly detection is inappropriate for differentiating between normal and faulty machine states because the same input monitoring data can be labeled as either normal or abnormal.

Challenge 3: The correlation between fault types and monitoring metrics is not necessarily one-to-one. On one hand, a metric anomaly may be caused by various fault types. For example, a decrease in CPU usage could be caused by ECC error, NVLink error, and other faults. On the other hand, for a fault type, there isn't a single metric that necessarily signals it. As an example in Table 1, ECC errors could potentially be noticed by either CPU or GPU usage of the faulty machine, yet neither metric guarantees nor necessarily both. Thus, a single fault type can be manifested via multiple abnormal metrics, with no solitary metric providing a guaranteed indication. Instead, the metrics exhibit an "or" correlation for a fault type. Consequently, we cannot simply use a model that incorporates the data from all metrics. Rather, we use individual per-metric models for detection (analysis in 6.3).

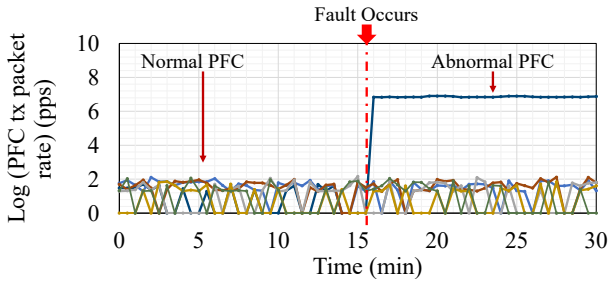

Figure 3: PFC tx packet rate pattern for each machine before and after a fault occurs.

Challenge 4: Noises exist in time series monitoring data. The monitoring data inevitably consists of noises due to jitters, inaccurate sensors, temperature, timestamp misalignment, network interruptions, or other issues. Short-term noises will mislead us to regard a machine as the faulty one, resulting in extra time and labor burden. Thus, the raw data cannot be used directly for detection (analysis in 6.3).

3 Design Overview

In this section, we introduce four design choices to address the challenges, revolving around Minder: an automatic, responsive, and accurate watcher to detect the machine with an unpredicted fault during distributed training that leads to a task halt. We examine the dissimilarity (3.1) among machines. Then we evaluate the continuity (3.2) of the detected faulty machine candidate for filtering out bursty jitters. Since metric data contains noises, we use models to denoise and reconstruct the raw data. Specifically, individual models corresponding to various monitoring metrics are trained, instead of integrating them into a single model (3.3). We also prioritize the metrics (3.4). The faulty machine can be detected swiftly by the top-prioritized metrics and corresponding models.

3.1 Machine-level Similarity

To address challenges 1 and 2, we notice that machine-level metric data exhibit similar behavior in parallel distributed training [68] at the second level.

Data parallelism (DP) operates by splitting data equally among GPUs that store duplicate model parameters and optimizer states. Pipeline parallelism (PP) assigns model layers to multiple GPUs in a pipelined manner. In tensor parallelism (TP), each GPU executes a portion of a computation process to improve hardware utilization in parallel.

By integrating these techniques into a 3D parallelism framework, large-scale model training, such as LLM training [40] or multi-modal training, can be effectively facilitated. TP is typically constrained within a single machine, whereas DP or PP groups involve inter-host communications. The computation, storage, and communication loads are evenly balanced across machines at the second level. Therefore, similar monitoring data fluctuations will be observed across machines. In the PCIe downgrading example, the initial `PFC Tx Packet Rate` patterns are notably uniform for all the machines in Figure 3. However, if a machine undergoes a fault, its monitoring data will display distinctive differences, offering an opportunity for detection. This principle can be extended to other metrics, as demonstrated by the possibilities offered in Table 1. Hence, the denoised metric data from each machine is used for calculating the similarity with others. The machine identified with the longest "distance" from others could be assumed to be faulty, regardless of the fault type.

Why not use a supervised learning model for faulty machine detection? Unlike many supervised learning-based anomaly detection approaches [21, 27, 45, 53], Minder uses unsupervised learning and similarity-based distance check, due to the different problem contexts. Firstly, labeling the data as normal or abnormal is impractical. As mentioned in challenge 2, the abnormal pattern is task-dependent. Different tasks present different normal ranges for the same monitoring metric under varying working conditions. Secondly, our objective is to identify which machine is to be blamed for the unexpected fault. This is not merely a classification problem of distinguishing normal or abnormal cases. Thus, developing a universal model via supervised training is challenging.

3.2 Machine-level Continuity

To further tackle challenge 2, we utilize the notion of abnormality continuity. Typically, abnormal performance persists for a few minutes upon a fault, but jitters typically last for a short duration. As illustrated in Figure 3, the machine with PCIe degradation experienced significantly higher `PFC Tx Packet Rate` for a period compared to other machines. By inspecting fault instances from seven-month data in 2023, the duration of abnormal performance after a fault occurs is depicted in Figure 4. Most abnormal patterns last for over five

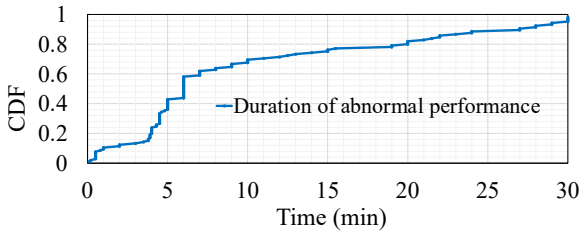

Figure 4: Duration of abnormal performance following a fault.

minutes. Thus, if we recognize a machine displaying such dissimilarity continuously for a period, the machine may be faulty. In the case of raw data containing bursty noises, they will be filtered out (as analyzed in 6.4).

3.3 Individual Learning-Based Denoising Models for Each Monitoring Metric

For challenge 4, we utilize simple learning models for data denoising and reconstruction, in addition to basic data alignment and normalization. Variational autoencoder (VAE) and other generative probabilistic models are recognized for learning time-series data patterns and features [52, 70]. They are also known for learning embedding schemes that can infer the generation factors for most of the training data. This makes unsupervised learning particularly suited for modeling normal behavior in an anomaly detection task. As such, raw data is denoised and reconstructed by our learning-based models before being fed into further detection (as analyzed in 6.3).

Meanwhile, based on challenge 3, no single metric provides a guaranteed indication for a specific fault type. The indication probability by a metric varies across different types of faults. For this reason, we opt for training individual models for each monitoring metric. These models and their corresponding metric data are used independently for denoising, similarity, and continuity detection.

We do not merge all potential metrics into a single model for two main reasons. First, the time series of multiple metrics do not fluctuate in the same manner when a fault arises. Moreover, metrics' indication capacity differs even for a particular fault type, and one metric's capability varies across different types. As a result, integrating them into one model could lead to the model being misdirected or confused by the array of metrics (as analyzed in 6.3).

3.4 Prioritized Metric Sequence

To expedite detection, we prioritize metrics and only use the models of the top ones, since plenty of metrics (in Appendix B) could be collected and each could be trained with a model. This ensures we use the metrics with higher indication probabilities earlier. The faulty machine could therefore be detected sooner. If a model and its associated metric data cannot detect a faulty machine, we then move to the next metric

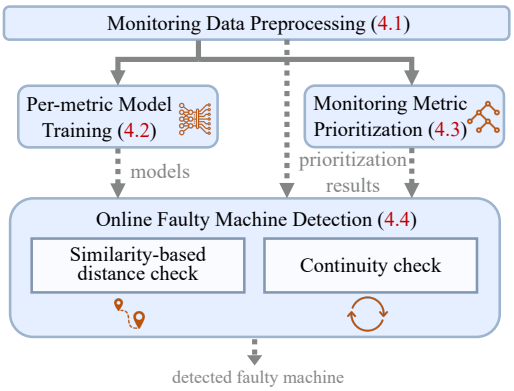

Figure 5: System architecture of Minder.

and its model, following the prioritization result. We repeat this process until a faulty machine is identified.

4 Minder Framework

The architecture of Minder is shown in Figure 5. Preprocessing (4.1) is required for raw data from each machine. Per-metric Model Training (4.2) and Monitoring Metric Prioritization (4.3) will train models and prioritize the metrics in their sensitivity to faults respectively, as two independent processes. The models and prioritization results are then used in Online Faulty Machine Detection (4.4) for run-time detection.

4.1 Preprocessing

Given a stream of monitoring data from each machine, Minder needs to aggregate them into a series of time windows. Within each window, Minder can do data denoising and machine-level similarity check on a set of metrics. By checking the anomaly continuity from consecutive time windows, Minder detects the faulty machine.

Thus, Minder preprocesses the collected monitoring data if it lacks alignment among certain metrics. Minder first aligns the sampling points across all machines based on the corresponding sampling timestamps. If sample points are missed, Minder uses data from the nearest sampling time for padding.

Normalization is adopted to ensure that the multi-dimensional monitoring data is integrated into an even distribution. Minder normalizes the monitoring data based on the upper and lower limits of each metric, using the Min-Max normalization technique.

4.2 Per-metric Model Training

As specified in 3.3, we train models for the learning-based denoising and reconstruction for subsequent detection. Since no single metric provides a guaranteed indication and a model incorporating various metrics might be misdirected, individual models should be trained for each metric.

The preprocessed per-machine data within a time window is used as input instances to train an unsupervised model. For

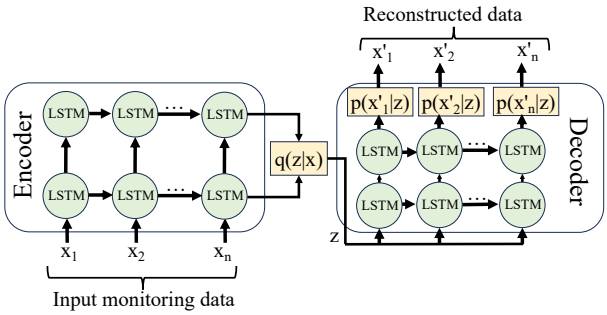

Figure 6: The LSTM-VAE structure for Minder.

example, to train a model for `CPU Usage`, we use `CPU Usage` sample data within a time window with a length of w (*e.g.,* 8) and a stride of 1 from each machine of the task. Multiple $1 \times w$ vectors are fed into the model respectively for training. Models for `CPU Usage`, `PFC Packet Rates`, and so on are individually trained. The parameters in the model include *hidden_size* (*e.g.,* 4), *latent_size* (*e.g.,* 8), and *lstm_layer* (*e.g.,* 1). With a model, the time series input of a monitoring metric from a machine could be reconstructed as a denoised vector for this machine.

Training choice: LSTM-VAE. Specifically, VAE models are trained for Minder. VAE is widely used for denoising [70] and compression of high-dimensional features [71], where normal vectors will be reconstructed into similar embeddings while abnormal ones will be reshaped into a more distinctive outlier. This highly effective unsupervised DL technique can reconstruct time series inputs into an arbitrary latent representation without sacrificing original characteristics. Consequently, VAE can enhance the accuracy and robustness of anomaly detection where labeling is absent [78]. When the input consists mainly of normal training state vectors and only a small proportion corresponds to a faulty period, the VAE learns the vector distribution and denoises the jitters.

As depicted in Figure 6, the VAE comprises an encoder and a decoder. The encoder extracts temporal features into a latent space embedding z. Subsequently, the decoder utilizes z to restore the data to a new dimension output as a reconstruction of the distribution. Various statistical or machine learning techniques can be employed in the encoder and decoder to determine the optimal distributions. Given that our data is temporal time series, we utilize LSTM as both the encoder and decoder to extract temporal characteristics [52]. LSTM considers both forward and backward information of a time series to obtain complete correspondence information. As such, LSTM is an ideal choice for VAE.

4.3 Monitoring Metric Prioritization

As introduced in 3.4, we aim to use only the most representative metrics and their models for quick faulty machine detection. Given a large number of metrics, pinpointing the metrics more sensitive to faults is critical. By using the top prioritized metrics and their associated models first, the faulty

machine will be detected more quickly.

Consequently, following the steps below, Minder will generate a prioritized list of metrics by their sensitivity to faults. The prioritization results can then be used in run-time detection, specifying which metrics and their models should be used first. Note that this process runs in parallel with the model training process in 4.2.

Step 1: Z-score calculation for evaluating metric sensitivity to faults. To identify the most sensitive metrics, Minder utilizes the Z-score [23], because it depicts the dispersion of data distribution. A metric with a higher Z-score relates to an imbalanced distribution, where a faulty machine shows a dissimilar pattern from others. For a monitoring metric, the Z-score is computed for each machine at a sampling data point from the preprocessed data. For the j-th monitoring metric:

$$Z_{ij} = \frac{x_{ij} - \bar{x_j}}{s_j}$$

where Z_{ij} is the Z-score of the i-th machine, x_{ij} is the sample value of the i-th machine, while $\bar{x_j}$ and s_j are the average value and the standard deviation of all machines on the j-th metric. When a fault occurs, the affected machine exhibits abnormal behavior, leading to outlier samples with high Z-scores.

For a time window of a training task, we use $max(Z_{ij})$ across all the machines for the j-th monitoring metric, indicating the extent of the dispersion among machines.

Step 2: Prioritization of the monitoring metrics. Based on the maximum Z-score for each monitoring metric, Minder uses a decision tree [32, 60] to prioritize the sensitivity of each metric in identifying the faulty machine. We resort to a decision tree for two primary reasons. Firstly, the logical structure of decision trees bears a resemblance to rule-based policies that are common in networking monitoring systems. For example, certain monitors utilize simple threshold rules, such as when `CPU Usage` drops to nearly zero [83]. Secondly, decision trees offer high expressiveness and faithfulness, attributed to their lack of parameters and the ability to represent complex decision-making [22].

To construct a decision tree, Minder gathers the maximum Z-score for each metric from step 1 as an individual instance for the time window of the training task. The instance is labeled manually as normal or abnormal depending on whether a faulty machine exists within this window. Instances across multiple time windows and multiple training tasks are used together to train a decision tree.

As shown in Figure 7, monitoring metrics are prioritized based on their sensitivity to faults. The decision tree employs a step-by-step approach to classify the instances by analyzing the Z-scores of each metric. Nodes located closer to the root of the tree indicate that the corresponding monitoring metrics are more sensitive to the occurrence of a faulty machine. PFC, CPU, GPU, and NVLink-related metrics are identified as the most informative ones. Specifically, `CPU Usage` is relevant to running process states, while the four GPU metrics relate

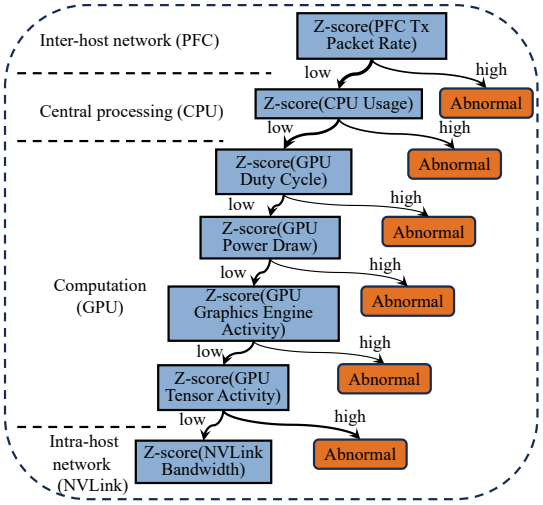

Figure 7: Top 7 layers of the decision tree for prioritization.

to the computation states. Additionally, `NVLink Bandwidth` and `PFC Packet Rates` are indicative of intra-host and inter-host network quality. The outcome aligns with Table 1, where CPU and GPU enjoy the highest priority.

4.4 Online Faulty Machine Detection

During run-time detection, Minder leverages the concepts of machine-level similarity (3.1) and continuity (3.2), since the faulty machine tends to exhibit an abnormal pattern over a period. Given the data from each machine, Minder follows the order of the decision tree prioritization results and selects a metric. The metric data is then denoised by the correlated model. Minder then runs step 1&2 introduced below for detection. If none is detected, Minder picks the next metric and repeats step 1&2 until one is detected. Fortunately, if no one is detected after passing all the models, Minder assumes no anomaly occurs up to this time.

Step 1: Similarity-based distance check per time window. To detect a faulty machine during a time window, Minder compares the similarity (3.1) among all the machines for the same metric. In the presence of a faulty machine, its denoised data from LSTM-VAE is distinguishable from others.

To initiate the detection for a time window, the monitoring data from each machine (*e.g.,* a $1 \times w$ vector for a machine) is fed into the corresponding model successively. The reconstructed embedding for the i-th machine is captured by Minder for the following distance calculation. Specifically, Minder calculates the pairwise Euclidean distances of embeddings between every two machines, as it expresses distinct differences between normal and abnormal samples and provides characterizations of various record types [76]. For each machine, Minder calculates the sum of the distances to other machines, representing its dissimilarity. Since the distance magnitude shifts with machine scales, we calculate the normal score for each sum value of the machines to normalize.

The machine with the maximum normal score is probably the faulty one. If the maximum normal score is higher than a *similarity threshold*, the machine is assumed as a candidate of the time window.

Step 2: Continuity check for consecutive time windows. The detected candidate of a time window might be a false alarm due to instant bursts or temporary counter noises, so the idea of continuity (3.2) is essential. This is because faults often lead to deteriorated performance for a period. Minder shifts the time window with a stride of one to detect the potentially faulty machine for new windows. If the same machine is detected with consecutive times that exceed a *continuity threshold*, it is considered a truly faulty machine. A proper *continuity threshold* can be set as 4 minutes as it is adequate to filter out short-term noises and will not exceed the typical lasting time of a deteriorated performance in Figure 3.

5 Implementation

Minder has been deployed in our ML system for a year. It runs on a dedicated machine with two dual-port ConnextX-6 25G-RNICs [9], 128 Intel Xeon Platinum 8336C CPUs, 512G memory, and 1.6T disk. The high-speed RNICs ensure the fast transmission of monitoring data, while computation and storage resources are adequate for real-time detection.

Minder monitors all the ongoing training tasks throughout their life cycles in our production environment. For a task, Minder is called at pre-determined intervals (*e.g.,* every 8 minutes). Upon a call, Minder pulls 15-minute data for the metrics listed in Appendix B from a database for all machines associated with the task. The metrics cover aspects of computation, communication, and storage. The database updates monitoring data per second from all the machines. If Minder identifies a faulty machine, an alert is triggered to a driver and relevant engineers. After the driver submits the machine IP to be blocked and the Pod information to Kubernetes, the faulty machine will be evicted and replaced by a new one, before a fast recovery from recent checkpoints [40]. Importantly, the running of Minder will not interfere with online distributed training tasks, as Minder works as a backend service.

Task workload. The monitored training tasks are distributed across four to over 1000 machines, with GPU numbers up to more than 10000 for a task. Concurrent tasks could be monitored by Minder. Each task is running on machines of homogeneous GPU and RNIC architectures on rail-optimized topology with up to three layers of switches. TP for computation, PP for gradient calculation and propagation, and DP that performs gradient synchronization are efficiently used for our LLM pre-training. These 3D parallelism strategies [40, 68] (3.1) facilitate balanced computation (GPU usage, power, temperature *etc.*), storage (memory usage *etc.*), and communication (intra-host and inter-host throughput) across machines. Models trained in our ML system include the Transformer [74] and so on. The model sizes range from under 32B to over 500B.

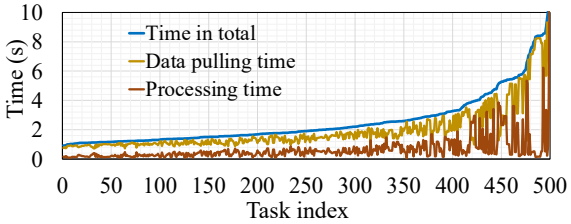

Figure 8: The total data processing time for a call of Minder.

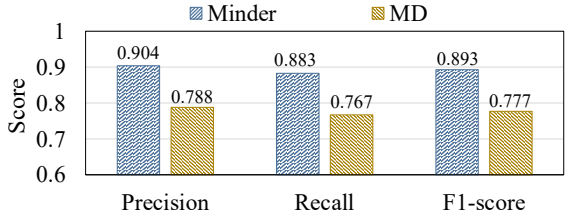

Figure 9: Comparison with a baseline algorithm MD [30, 46].

6 Evaluation

Dataset. Our dataset includes 150 run-time fault instances from online distributed training tasks with 3D parallelism [40]. The dataset includes instances over nine months. Each task involves 4 to over 1500 machines (up to 10,000 NVIDIA Ampere GPUs), covering all the scale groups in Figure 1. 30% of the tasks involve a minimum of 600 machines. All fault types listed in Table 1 are covered. The dominant ones are ECC error (25.7%), CUDA execution error (15%), GPU execution error (10%), and PCIe downgrading (8.6%). Our dataset focuses on faults in an individual machine, as they account for 99% of all faulty cases in the production environment (6.6 for concurrent faulty machine evaluation). The monitoring metrics in Appendix B were collected at the second-level granularity. Due to the fast eviction and recovery process, verifying whether all evicted machines are faulty is challenging. Consequently, our dataset encompasses the run-time instances where the actual faulty machine could be manually confirmed via offline log-checking, nccl-tests, or hardware tests (*e.g.,* [55]). For LSTM-VAE training, we use data from the first three months and the rest for evaluation.

Metrics. For a task, we denote true positives (TP) as the correct machine detection following a fault, and false negatives (FN) as errors in machine detection or missed detections during a fault. True negatives (TN) refer to the correct approvals when machines are running normally, while false positives (FP) refer to false detections when there is no fault. Then we calculate Precision, Recall, and F1-score as our metrics.

6.1 Overall Performance

Total data processing time. In Figure 8, a call of Minder takes 3.6 seconds on average to make an alert. It includes data pulling time (fetching the pertinent monitoring data from

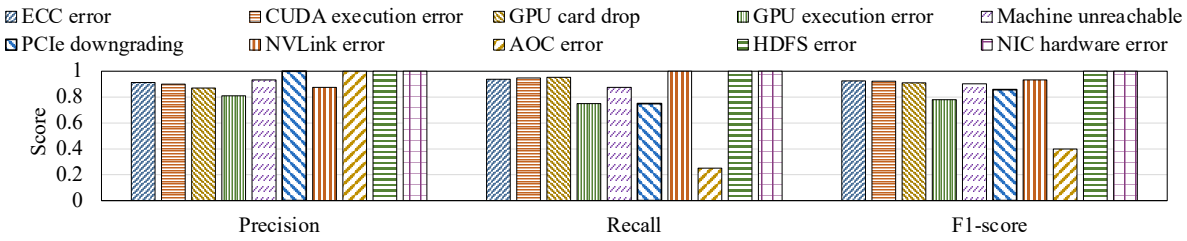

Figure 10: Accuracy for various fault types.

Data APIs) and processing time (preprocessing, and running inference for faulty machine detection). Due to Minder's deployment on an exclusive machine, it reduces the time by 99% (shorter time by 500 × compared with Figure 2) if engineers otherwise manually inspect machine information one by one.

Comparison with the baseline. The baseline for comparison is Mahalanobis Distance (MD) [30, 46, 57]. MD is widely used in identifying outliers. It considers the variable correlations in multi-dimensional data and calculates features like mean, variance, skewness, and kurtosis before applying principle component analysis (PCA) and computing the pairwise distances. We keep other processes the same for comparison.

In Figure 9, the precisions are 0.904&0.788, with recalls of 0.883&0.767, leading to F-1 scores of 0.893&0.777 for Minder and MD. These findings demonstrate that Minder effectively detects actual faults and lowers the rate of false alarms. MD detects the outlier machine from the statistical perspective but exhibits lower accuracy, indicating that jitters and noises interfere with statistical features. Minder outperforms MD by using LSTM-VAE for denoising and extracting the data patterns for a better distance calculation.

Performance breakdown with fault types. By considering individual fault types in Table 1, the results slightly differ. In Figure 10, Minder effectively handles faults like ECC error, CUDA execution error, GPU card drop, machine unreachable, NVLink error, HDFS error, and NIC hardware error. These faults are relative to CPU, GPU states, and networking performances that Minder monitors.

GPU execution error and PCIe downgrading present a lower recall, since some faulty instances have concurrent faulty GPUs or PCIe links within a machine. Owing to the 3D parallel topology, faults swiftly impact multiple machines in both the DP and PP groups, leading to an instant group effect. Thus, the time-series granularity at the second level is insufficient for Minder. Other fault types, such as AOC errors, are partially missed due to the current absence of optical cable-related counters for capturing useful monitoring metrics. We will continue to have more hardware counters in the future. Overall, AOC errors occupy only a small portion, so the overall accuracy is still high.

Upon examining the errors made by Minder, most of them were not entirely incorrect. In many error cases, the machine incorrectly detected showed short-term metric fluctuations or performance jitters before being normalized afterward. These detected fluctuations, however, were not the root cause of the task halt. Nonetheless, these errors should not be ignored as they led to short-term jitters in the training performance.

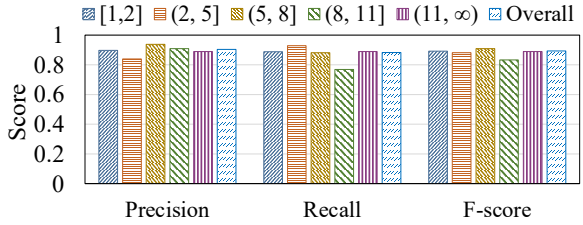

Figure 11: Accuracy for tasks with varied lifecycle fault occurrences.

Performance breakdown by fault occurrences of a task's lifetime. Training tasks with various workloads experience distinct occurrences of faults. Figure 11 categorizes the performance relative to the fault numbers throughout a task's lifetime, which may span up to months for extensive workloads. In our dataset, 70% of the tasks display no more than five faults, whereas over 15% face more than eight faults throughout their lifetime. Given the lack of interdependence among individual faults, the accuracy is not tied to the fault occurrences. Since faults are random and a faulty machine will be promptly auto-replaced in the production environment, the fault occurrences do not affect performance. Despite the lower recall for the (8, 11] group, it primarily originates from the limited task number of this group.

6.2 Analysis of Monitoring Metric Selection

To validate the proper selection of monitoring metrics in (4.3), we conduct experiments to show that fewer or more metrics do not improve accuracy. Notably, most of the remaining metrics not used by Minder are GPU-related, including `GPU Temperature`, `GPU Clocks`, `GPU Memory Bandwidth Usage`, and `GPU FP Engine Activity`. Thus, we use only `GPU Duty Cycle` to train a GPU model with fewer metrics, while adding these unused GPU-related monitoring metrics to train a GPU model with more metrics. We keep the other settings unchanged for the comparison.

Figure 12 reveals that including more monitoring metrics achieves a higher recall, but its precision is lower. More metrics may introduce mutual interference, since different metrics may indicate different patterns that will obfuscate the detection. On the other hand, using fewer metrics undermines outlier detection capacity due to the exclusion of key metrics.

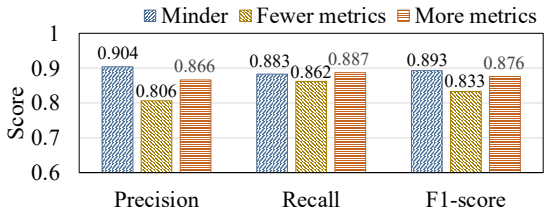

Figure 12: Comparison with different metric selections.

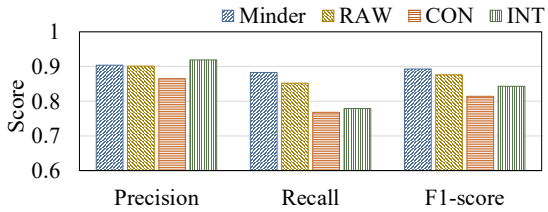

Figure 13: Comparison with different model selections.

Our optimal selection of metrics achieves the best precision, meaning that Minder alerts far fewer false alarms than others. Based on the metric priority result (4.3), the top metrics are sufficient to cover all components that might malfunction.

6.3 Analysis of Model Selection

We contrast Minder against other statistical methods or model variations to show the proper choice of LSTM-VAE. A simple approach is calculating the Euclidean Distances of the preprocessed raw data (RAW) without using VAE. Variants of LSTM-VAE include concatenating the embeddings of all the models as a whole for distance calculation (CON) or training an integrated LSTM-VAE model with all the monitoring metrics (INT).

In Figure 13, Minder outperforms others in recall and F1-score. Their recalls vary. Worse recall generated by RAW illustrates the significance of eliminating noises. Minder, in contrast, reconstructs for denoising. CON and INT show worse recall because they consider multiple metrics with equal significance by calculating distances from evenly concatenated embeddings or regarding all the metrics as a whole for input. However, not all monitoring metrics have an equal sensitivity to faults. Mutual interference exacerbates the performance of CON and INT. Minder, on the other hand, leverages the VAE for denoising and separates metrics to enhance the performance. Besides, comparing the input and reconstructed data of LSTM-VAE yields a Mean Squared Error (MSE) lower than 0.0001, demonstrating effective reconstruction.

6.4 Analysis of Continuity and Threshold

To verify the feasibility of continuous detection, we compare Minder without the application of continuity (3.2). Minder ensures the same machine is detected multiple times. Without continuity, an alert will be made immediately upon a fault detection during the time window. The results in Figure 14 imply that the overall performance is worse without continuity.

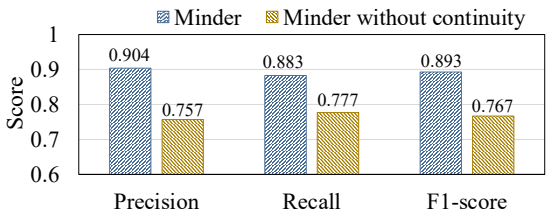

Figure 14: Accuracy with/without continuity.

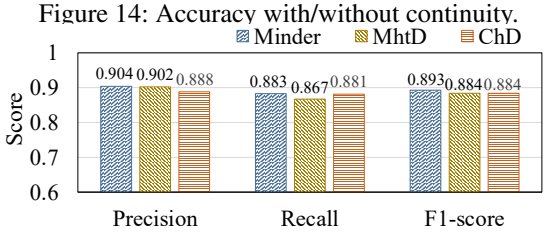

Figure 15: Comparison with different distance measures.

More false alarms are triggered due to occasional short-term jitters. The continuity emphasizes the degraded performance for a period caused by a fault's gradual impact on other machines. Thus, Minder filters discrete bugs, noises, or jitters.

Note that we set the *continuity threshold* (4.4) as four minutes to reduce false alarms caused by jitters or noises. That means Minder only alerts when a detected machine endures dissimilarity for four minutes. The threshold is chosen empirically based on the fault duration in Figure 4. Most of the faults last longer than four minutes before the halt. A shorter continuity threshold introduces more false alarms, while a longer one excludes more actual faulty detection results.

6.5 Choice of Distance Measures

We compare Minder 's pair-wise Euclidean Distance algorithm with Manhattan Distance (MhtD) and Chebyshev Distance (ChD). MhtD adds up the absolute distances from each dimension of the embeddings while ChD uses the largest difference in their coordinates. We replace the distance algorithm to rerun the experiments.

In Figure 15, Minder achieves similar performance to others, suggesting that the embeddings from LSTM-VAE are already representative and the outlier is distinctive for any distance calculation method. The comparison with MhtD implies that spatial distribution is a solid representation because both methods use the distances of multiple dimensions. ChD's worse precision suggests that a single spatial difference is insufficient for comparing dissimilarity. Minder considers the overall distance from the outlier to other normal ones and the dissimilarity will be intensified by summing the distances.

6.6 Performance with Multiple Concurrent Faulty Machines

Analyzing Minder's ability to handle multiple faults is intuitive. Such detection capability largely depends on the faulty machine scale ratio and the granularity of monitoring data.

Given the 3D parallelism [40], a machine participates in multiple DP and PP groups. More faulty machines impact more groups, inducing faster negative propagation across the entire cluster. The data granularity determines the visibility of the propagation process. With a brief duration of less than 100 milliseconds per interaction, the dissimilar pattern may be overlooked due to coarse-grained monitoring. Yet, millisecond-level monitoring is not widely deployed due to the high overhead.

In our production environment, concurrent faulty machine instances only occur due to automatic switch reboots or switch-related AOC errors. A switch reboots in response to high temperatures, extreme port congestion, and so on. Thirty-two connected machines will be forced to go offline out of a total of 600 machines in our environment. However, Minder hardly distinguishes the faulty outliers. Firstly, the fault ratio is relatively high. Given our rail-optimized topology and 3D parallelism mechanism, communication among 32 machines contains at most 256 DP groups, quickly propagating across other machines. Moreover, the current second-level time granularity monitoring limits Minder's ability. The rapid spread is only observable at the millisecond level following several training interactions. However, the rate of such multiple faulty machine instances is less than 1%, sometimes zero a month. Should a switch reboot, the switch monitoring system will automatically alert the engineers.

To demonstrate Minder's ability to detect multiple faulty machines, we injected PCIe downgrading into two of four machines simultaneously, with customized millisecond-level monitoring. Thus, the ratio of faulty machines is higher and the data granularity is finer than the switch-reboot instance. In the experiment, each machine was equipped with eight NVIDIA Ampere GPUs, running Reduce-Scatter collectively. Two PCIe links on two machines were purposely degraded. With the millisecond-level data from the NICs, Minder could detect the two NICs connected to the faulty PCIe links. These two NICs presented the largest outlier distances during Reduce-Scatter. Figure 16 shows the millisecond-level monitoring, where normal NICs demonstrate a high throughput at the beginning of each Reduce-Scatter step to transmit their data to the next node. In contrast, the NICs with downgraded PCIe links exhibit steady and low throughput. Thereafter, normal ones drop to zero, after transmitting their data, waiting for the slow NICs for synchronization. Minder can capture this dissimilarity, thanks to the granularity of milliseconds. Our injection experiments also show Minder's ability to detect other concurrent faults, such as GPU degradation and NIC throughput downgrading.

7 Discussion

In this section, we discuss the lessons we learned during implementation and potential future works.

Minder and other monitoring tools. Large-scale model training involves the cooperative efforts of multiple teams.

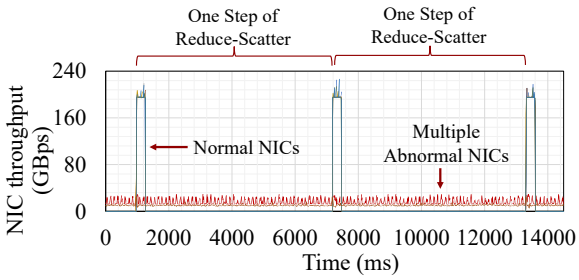

Figure 16: Millisecond-level NIC throughput for all machines after injection of PCIe downgrading on two NICs.

Other monitoring tools used along with Minder include switch state monitoring, periodic heartbeat messages (IP, hardware states, Pod names *etc.*), RDMA traffic down-limit alerts, R-Pingmesh [54] (a pingmesh-like [33] connection testing), and automatic text analysis for GPU error detection. As described in 5, a detected machine will be replaced before restarting the task. These approaches primarily target network connection and jitters or GPU states, whereas Minder provides metrics covering computation, storage, and communication resources. The combined use of them enhances the detection efficacy. Meanwhile, offline testing tools, such as DCGM [1], EUD [3], are used for intra-host bottlenecks diagnosis, though not feasible for run-time fault identification.

Similar systems and tools are introduced. For example, SuperBench [77] is a proactive system to ensure cloud AI infrastructure reliability. It runs model training and component benchmarks to identify incremental performance degradation on defective machines. The first difference is that it works proactively because incremental performance degradation exists due to hardware redundancy. However, such gradual degradation process before a fault occurs is hardly observed in our distributed training. Second, SuperBench mainly improves the hardware-side reliability. Real-time software errors also occur frequently during model training. Besides, SuperBench performs offline validation by running benchmarks. Minder otherwise monitors the tasks throughout their life cycles. Thus, the integration of such a proactive system with Minder is a more promising debugging solution. By executing benchmarks on the machines in a job and monitoring their running status, faults might be largely prevented and rapidly detected.

Minder's Generality. Minder can be extended in data granularity and the spectrum of available metrics. Second-level monitoring is currently deployed and used by Minder. Minder has demonstrated improved detection capability for concurrent faulty machines with millisecond-level monitoring data in 6.6. With finer-grained data, the annihilated rapid propagation from the straggler will be revealed, as a training iteration only lasts tens of milliseconds. Besides, the currently available metrics for Minder are out-of-band hardware counters. Other metrics (*e.g.,* AOC counters) and in-band traces (Torch Profiler [16], the Megatron-LM timer, or CUDA event timer [40]) could also be utilized by Minder. These new traces offer

fine-grained training and collective communication operation information for comprehensive performance monitoring.

Minder's robustness of other faults. Notably, Minder is allowed to detect new or rare fault types not covered in training, as long as the monitoring data presents discernible dissimilarities. For concurrent faulty machines, provided multiple machines present a distinctive dissimilarity, Minder can detect them simultaneously.

Machine-level similarity. Large models such as those in LLM training and multi-modal tasks often employ 3D parallelism. This results in a trend of consistency across machines for computation, communication, and storage, allowing Minder to detect faulty machines. As a result, we focus on machine-level detection instead of finer granularity. We also consider Minder in other workloads, such as large-scale inference and fine-tuning. As long as these workloads satisfy the requirements of inter-machine metric similarity and fault continuity, Minder could be applied. Future work will explore Minder's effectiveness in other workloads.

Not all failed tasks have the right label. Although the labeled machine is the root cause, the Minder-detected machine may also have temporary performance fluctuations. It is necessary to inform engineers of such performance jitters.

Root cause analysis. Minder detects faults at the machine level. The root cause for a fault indicated by a metric is uncertain. Extra labor is employed for further network jitter and short-term straggler analysis. In the future, we plan to design fine-grained run-time monitoring for root cause identification.

8 Related Work

In this section, we briefly introduce related works on anomaly diagnosis [20, 28, 29, 31, 37, 38, 41, 59, 61, 72, 84].

Intra-host diagnosis. Run-time diagnosis detects anomalies without disturbing the running tasks. Leveraging the existing counters [8, 14] from the machine is a direct method [70, 71, 78]. For example, BRCA [63], MonitorRank [43], and FChain [62] construct a dependency graph based on historical monitoring data or traces for anomaly alerts. These DL algorithms have been proven to be automatic, robust, and flexible. Another naive but effective way is to check logs or `dmesg` [2] using natural language processing (NLP)-based methods [19]. However, log-based approaches are limited to their log content and information processing abilities.

Offline diagnosis requires specific tools to detect possible intra-host bottlenecks when the machine is not running tasks. Liu *et al.* [55] and Martinasso *et al.* [58] implement tools to test if there is NVLink [13] or PCIe link [15] degradation or congestion. Collie [44] is a "fuzzing"-like implementation to help uncover potential performance bottlenecks in RNICs. Deepview [82] is designed for virtual hard disk failure localization. These approaches are useful ahead of running tasks, so they cannot be directly used during the large-scale training process.

Inter-host diagnosis. NetBouncer [73] leverages the IP-in-IP technique to actively localize failure devices or links among millions of servers in a data center network. Similarly, SNAP [79] monitors TCP statistics and socket logs for network diagnosis. Pingmesh [33], Haecki [34], and Fathom [66] monitor end-to-end latencies between arbitrary servers or detailed RPC performance in data centers. Nonetheless, they only detect failures along the routes instead of intra-host hardware failures that degrade the training speed. Cloud system diagnosis [26, 35, 47, 81] are based on contextual data patterns and associations of microservices on multiple machines. Such patterns and dependencies are eliminated in distributed training, where machines exhibit similar workloads.

Algorithms for anomaly detection and diagnosis. The first type is statistics-based methods. Apart from Euclidean distance, Pearson Correlation [25], Kendall's tau [42], and Spearman Correlation [80] also quantify the similarity between two vectors and discover the deviating anomalies. Setting parameters as thresholds from experienced operators is usually required [56].

Supervised algorithms are widely used for anomaly detection [45, 53]. EGADS in Yahoo [45] leverages diverse machine learning methods for large-scale univariate time series anomaly detection. Machine learning algorithms like random forest [64] are used for incident routing [27], VM compromise detection [21]. However, supervised learning does not fit in our context, where the goal is to detect the faulty machine instead of classification.

Unsupervised learning [50, 51, 56, 70, 71, 75, 78] identifies outliers from monitoring data for root cause detection and machine state detection, or enables dialogue-based diagnosis chatting. Apart from VAE (4.2), clustering [50, 51, 56] is commonly used to cluster the machines with similar monitoring data change patterns or detect anomalies for time series.

9 Conclusion

This paper presents Minder, addressing the problem of faulty machine detection in distributed training tasks. Minder leverages the concept of similarity among machines and the continuity of a fault during training. Minder has been deployed in our production environment for a year to assist engineers in training diagnosis. Evaluation results demonstrate the reduced time required by Minder and the effectiveness of its design choices for training tasks.

This work does not raise any ethical issues.

Table 2: Monitoring metrics collected by Minder.

Monitoring Metrics	Description
CPU Usage	Percentage of CPU time being used.
PFC Tx Packet Rate	Periodic counts of PFC packets sent by RDMA-enabled devices.
Memory Usage	Percentage of memory being used.
Disk Usage	Percentage of storage space being used on a disk.
TCP Throughput	Periodic counts of the amount of TCP data being transmitted by a NIC.
TCP+RDMA Throughput	Periodic counts of the amount of TCP and RDMA data being transmitted by an NIC.
GPU Memory Used [4]	The amount of GPU memory being used by processes.
GPU Duty Cycle [4]	Percentage of time over the past sample period when the accelerator is active.
GPU Power Draw	Periodic counts of the GPU power consumption.
GPU Temperature	The temperature of a GPU while it is operating, measured in degrees Celsius.
GPU SM Activity [5]	Averaged percentage of time when at least one warp is active on a multiprocessor.
GPU Clocks	The clock speed of a GPU, reflecting the frequency of the GPU's processor.
GPU Tensor Core Activity [5]	Percentage of cycles when the tensor (HMMA / IMMA) pipe is active.
GPU Graphics Engine Activity [5]	Percentage of time when any portion of the graphics or compute engines are active.
GPU FP Engine Activity [5]	Percentage of cycles when the FP pipe is active.
GPU Memory Bandwidth Utilization [5]	Percentage of cycles when data is sent to or received from the device memory.
PCIe Bandwidth [5]	The rate of data transmitted/received over the PCIe bus.
PCIe Usage [5]	Percentage of the bandwidth being used on the PCIe bus.
GPU NVLink Bandwidth [5]	The rate of data transmitted/received over an NVLink.
ECN Packet Rate	Periodic counts of ECN packets transmitted/received by a NIC.
CNP Packet Rate	Periodic counts of CNP packets transmitted/received by a NIC.

Appendices are supporting material that has not been peer-reviewed.

A Fault Types

The fault types are listed in Table 1.ECC error: caused by corrupted or lost data in (GPU) memory. PCIe downgrading: a link fault leading to a slow PCIe sending/receiving rate. NIC dropout: a NIC is missing from the OS. GPU Card drop: a disconnected GPU card. NVLink error: a link fault between two Nvidia GPUs. AOC error: an error in high-speed active optical cables (AOC) on either the host network card or the switch side. CUDA execution error: an unexpected overflow or configuration leading to a failed CUDA program. GPU execution error: unexpected page-fault, out-of-memory, and other incorrect processing leading to GPU hang or other results. HDFS error: HDFS connection timeout, io error, and so on when loading or saving checkpoints. Machine unreachable: mostly due to malfunctioning SSH services or virtual machine services. Others: illegal memory access, failed scheduling, no disk storage, low resource usage, switch reboot, and so on.

B Collected Monitoring Metrics

Table 2 contains the monitoring metrics that we choose to collect in our production environment, though only a portion of them are used for training and detection. Other available host metrics could also be used by Minder.

Holmes: Localizing Irregularities in LLM Training with Mega-scale GPU Clusters

Abstract

Training Large Language Models (LLMs) on large-scale GPU clusters requires numerous iterations over several months. Existing works mainly focus on addressing failures that interrupt the iterative training process to improve the utilization of GPU clusters. However, our large-scale measurements over tens of thousands of GPUs show that the training process exhibits an unstable state with some *irregular* iterations taking even more than twice the time of a normal iteration. Surprisingly, we find that these irregular iterations greatly extend the time of LLM training, which is even more severe than the impact of failures. Meanwhile, the irregular phenomenon is silent, making it challenging to be accurately localized. In this paper, we propose a first-of-its-kind system called Holmes, leveraging communication operators to accurately localize these irregularities in real-time. The core of Holmes's approach is to employ an enhanced abnormal operator detection model and a novel communication operator graph to perform efficient irregularity localization. Furthermore, Holmes conducts cross-iteration analysis to improve localization accuracy. We evaluate Holmes using large-scale trace-driven simulations and a production-level prototype. Large-scale simulation results demonstrate that Holmes achieves irregularity localization accuracy of 97.21%. Production-level prototype evaluation results show Holmes can localize irregularity within 30.3 seconds, achieving a speedup of 6.52× as compared to traditional approaches.

1 Introduction

Large language models (LLMs) [7] are propelling the rapid evolution of efficient and reliable AI infrastructure. Since the model size explosively increased to hundreds of billions of parameters such as GPT-4 [42] and PaLM [10], the training clusters have scaled out to encompass thousands to even 10,000 GPUs [25]. Training LLMs over large-scale GPU clusters always requires hundreds of thousands of iterations. Each *iteration* is a cycle of parameter update and synchronization, consisting of a mixture of massive compute- and communication- intensive operators. Executing these iterations in the GPU cluster can last for months, making investment in LLM training entail significant costs. Efficient utilization of expensive GPUs is crucial since even small improvements can save millions of dollars at such a scale [5].

Unfortunately, LLM training is *fragile* in the sense that even a small failure in the GPU clusters can explicitly interrupt the training process. These failures will finally extend the training time, resulting in a considerable waste of hardware resources. Therefore, there are several works focusing on failure detection and diagnosis to improve the system reliability [18, 21, 23, 32, 35, 43, 54, 62]. In these works, once a failure is diagnosed, the anomalous device is isolated to recover the training process.

Generally, the time of each iteration in the LLM training is expected to be stable and regular because the computing and communication patterns are predetermined and repeated in each iteration. However, our production measurements over tens of thousands of GPUs indicate that the training process exhibits an unstable state with the time of each iteration varying. Some *irregular* iterations take even more than twice the time as a normal iteration. Here, the term "*irregularity*" describes the time of an iteration exceeding the reference value by a certain margin, yet without interrupting the training process. We then accumulate additional training time introduced by irregularity. Surprisingly, we observe that the additional time introduced by the irregularity is even more severe than the impact of failures. Our manual post hoc analyses show that the root causes of these irregularities encompass anomalous GPUs, network link issues, unstable switches, etc. (§ 3.1).

However, efficient irregularity localization in a large GPU cluster is very challenging. Firstly, these irregularities are *silent* and do not interrupt the training process, making traditional failure diagnosis approaches [21, 43, 54, 62] relying on error logs ineffective. As there will be no failure logs during the irregular iteration, traditional systems will even not react

*The authors contributed equally to the paper.
§Corresponding author: Yuedong Xu (ydxu@fudan.edu.cn).

to begin the diagnosis process. Secondly, the anomaly in the device causing longer training iteration will propagate to impact other GPUs. Specifically, since there are thousands of collective communications across GPUs in the cluster, once an anomaly occurs in a device, all the GPUs connected to this device will be impacted to exhibit a longer training time in one iteration. When there are a lot of irregular iteration logs among these GPUs, it is hard to identify the anomalous device. Thirdly, the irregularity localization approach should be accurate. When the normal device is mistakenly identified as an anomaly, the isolation process of the device will lead to the waste of precious computing resources.

Holmes architecture. To address the aforementioned issues, we present a first-of-its-kind system, called Holmes, to accurately localize these irregularities for LLM training on mega-scale GPU clusters. Holmes is a lightweight approach that only relies on the data from the communication operator, thereby introducing little overhead during the LLM training. Specifically, to explicitly capture the silent irregularity, we introduce an enhanced abnormal operator detection model. We first leverage a machine learning method (i.e., random forest) to analyze communication tracing logs to detect abnormal communication operators. As the time distribution of iteration may shift over a long-term training process, we further introduce an auto-tuning approach for the machine learning method to adapt to the changes (§ 4.2). To identify the anomalous device using a set of irregular iteration logs from GPUs, we build a novel communication operator graph and design a combination of breadth-first and depth-first search methods to localize the irregularity in the graph. Note that Holmes only collects logs from these GPUs which are traversed by the search methods to reduce collected data volume and localization time (§ 4.3). To further improve the localization accuracy, we conduct cross-iteration analysis among all the devices including GPUs, links, and switches in the training clusters, and utilize Maximum A Posteriori estimation to find the most possible anomalous devices (§ 4.4).

Contributions. Our main contributions are summarized as follows:

- We identify the irregularity phenomenon and observe that these irregularities greatly extend the time of LLM training, which is even more severe than the impact of failures. To the best of our knowledge, we are the first to study the irregularity phenomenon in large-scale LLM training (§ 3).
- We design Holmes that leverages communication operators to localize irregularity over a 10,000 GPU cluster in real-time. Holmes constructs a communication operator graph combined with a domain-specific search method (§ 4).
- Large-scale simulation results demonstrate that Holmes achieves an overall localization accuracy of 97.21%. Production-level prototype evaluation results show that Holmes can localize irregularity within 30.3 seconds, which is 6.52× faster than the baseline (§ 5).

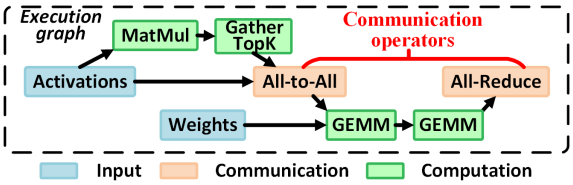

Figure 1: Compute- and communication- operators.

2 Background

Training Large Language Models (LLMs) relies on a large number of GPU machines and auxiliary resources to accelerate the execution of hundreds of thousands of iterations [21,60]. Each iteration is a cycle of parameter update and synchronization, consisting of a mixture of massive compute- and communication- intensive operators. These operators are repetitively executed following a fixed order, which can be represented in the form of an execution graph. Figure 1 depicts an example execution graph of a typical LLM training, where `Activations` and `Weights` are the input for the operators. The computation operators such as `MatMul` are executed on a single GPU without interference with other training nodes. In contrast, communication operators such as `All-to-All` involve a set of GPUs and will be executed only after all the GPUs have completed the execution of their respective dependent operators. Each GPU has its own execution graph and executes independently, and the communication operators will conduct synchronization among GPUs.

Communication operators. The communication operators serve for various parallel training strategies, which aim to better utilize GPUs and accelerate the training. These communication operators can be classified into two categories [37]: collective communication (CC) and point-to-point (P2P) communication. Collective communication including `All-Reduce`, `All-Gather`, `All-to-All` and `Reduce-Scatter`, is widely used in strategies like data parallelism (DP) [11,46], tensor parallelism (TP) [41,51] and expert parallelism (EP) [14,28]. During the training process, collective communication brings tight synchronization to massive GPUs involved, as it forces all the GPUs to initiate data transmission simultaneously. Different from collective communication, P2P communications like `Send` and `Recv`, do not need synchronization among massive GPUs. They are adopted in the pipeline parallelism (PP) [22,40], used to transmit the activations between the sub-models. Figure 2 depicts an example of LLM distributed training. The black arrows represent the P2P communication of GPUs, which communication only involves one sender and one receiver. Bidirectional arrows are collective communication, in which GPUs involved transmit data to each other.

3 Observation & Motivation

In this section, we first describe the overall performance degradation caused by irregularities in our production cluster and classify them into three categories (§ 3.1). We then elaborate

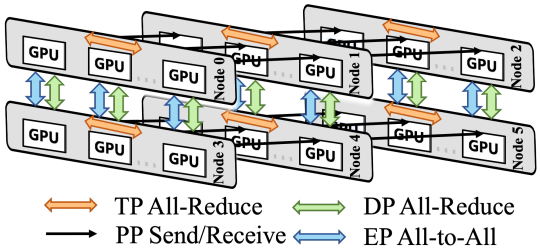

Figure 2: Communication of LLM distributed training.

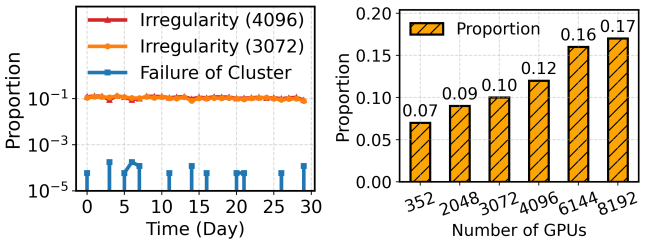
on the challenges of localizing the anomalous devices, which will cause the irregularity (§ 3.2).

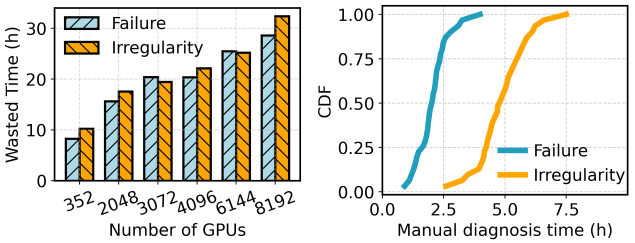
3.1 Irregularity in LLM Training



We define a novel metric to measure the irregularity in LLM training as below.

Definition 1 δ−*Irregularity refers to the phenomenon where training continues* ***uninterrupted****, but the duration of an iteration, i.e. time of every training step, is* δ *times longer than the average value within a given time window.*

The parameter δ (where $\delta > 1$) is tunable to account for subjective assessments of performance irregularities (by default δ is set to 1.1). The production cluster in our study comprises over 10,000 NVIDIA H800 GPUs. We keep tracing LLM training using a total number of GPUs ranging from 352 to 8192 in three months. The models of LLM training include LLaMA [56], LLaMA2 [57] and GPT3 [7] which vary in size. Their parallel training strategies employ hybrid parallelism incorporating tensor- [41], data- [11, 46], pipeline- [22, 40], sequence- [27], and expert- parallelism [28].



Irregularity occurs frequently. In Figure 3(a), we compare the numbers of irregularities and failures during the training of LLaMA+MoE using 3072 and 4096 GPUs for a month, respectively. The frequency is defined as the irregular iterations compared to the total iterations per day. On average, irregularities occur in 778 and 1047 iterations daily, in contrast to 6646 and 10165 total iterations per day. No more than three failures occur in one day throughout the entire training process, and only 40% of the days in a month encounter failure with a failure probability of less than 10^{-3}. It is evident that the frequency of failures is several orders of magnitude lower than that of irregularities. In Figure 3(b), we perform a statistical analysis of the frequencies of irregularities across various training. The frequency of irregularities increases as more GPUs are used, since more devices in training can lead to more potentially anomalous devices. Specifically, when training with 8192 GPUs, the irregularity frequency is 0.17, nearly three times that of training with 352 GPUs. More details and analysis of Figure 3(b) can be referred to appendix A.

Irregularity extends the training time. We highlight the *time wastage* caused by potential irregularities compared to training failures for a month in Figure 4(a). The wasted time due to failures is defined as the time interval between the

(a) Frequency across time (b) Frequency across training

Figure 3: Frequency of irregularity.

(a) Wasted time of irregularity (b) CDF of irregularity diagnosis time

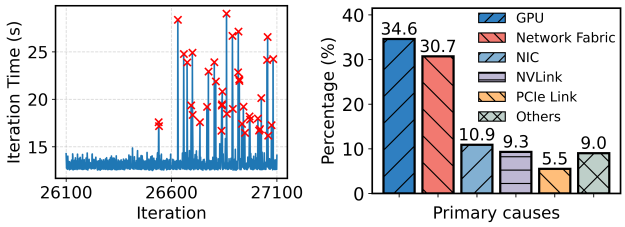


Figure 4: Impact of irregularity.

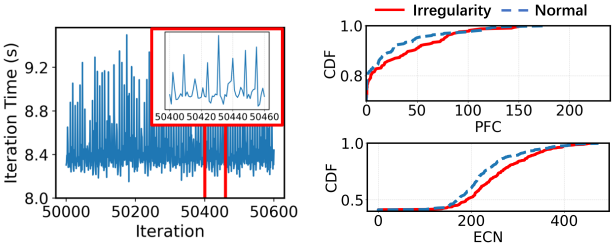
pause and resumption of training. As reported in [21], a training failure state usually lasts no more than three hours. The wasted time due to irregularities is calculated as the difference between the total actual training time and the hypothetical training time, where each irregular iteration is replaced with the time it would have taken without irregularities. An observation is that the time wastage of irregularities is comparable to or even greater than that of failures, with wasted time increasing as the number of GPUs scales up. For instance, when training with 8192 GPUs, the wasted time due to irregularities is as long as 32.38 hours, leading to a significant wastage of valuable GPU resources. This motivates us to explore the key behaviors of irregularities and identify the anomalous devices that induce such irregularities.

Irregularity localization is time-consuming. We then compare the manual irregularity localization time with the failure diagnosis time. As shown in Figure 4(b), around 86.2% of the irregularity localization time is larger than 4 hours. This is much longer than most of the time consumption on failure diagnosis, where approximately 84.7% of the diagnosis time is within 2.5 hours. This is attributed to that failure diagnosis has been extensively studied and standardized. In contrast, irregularity localization highly depends on human experience, leading to uncertainties in the time required for resolution. This motivates us to build an efficient system for automatic irregularity localization.



3.1.1 Abnormal Spikes

In this paper, we classify the irregularities into three categories according to their duration and frequency. The first type of irregularity, namely *abnormal spike*, occurs randomly and less frequently but significantly extends per-iteration training time. We study the pattern of abnormal spikes while training

(a) Iterations with abnormal spike (b) Causes of abnormal spike

Figure 5: Irregularity: abnormal spike.

(a) Iterations with fluctuation (b) CDF of PFC and ECN

Figure 6: Irregularity: performance fluctuation.

a LLaMA+MoE model using 3072 GPUs. The per-iteration times are shown in Figure 5(a), with a total of 1000 iterations recorded. Within this time window, abnormal spikes, marked with crosses, occur in 39 iterations. The iteration time with a spike is much longer than the normal value. For instance, at the 26803-rd iteration, the training time is 1.96× longer than the average. Over the entire training process for a month, the wasted time due to spikes amounts to 8.93 hours.

Manual diagnosis. When a *serious* abnormal spike occurs, our engineers will examine the states of training resources such as GPU and CPU utilization, ECN marks. Through comparison with empirical normal values, the suspicious anomalous devices will be isolated with further task-specific stress tests. In general, the entire process takes nearly 3-7 hours to resolve the abnormal spikes, while they continue to occur randomly until being resolved. We illustrate the primary causes of abnormal spikes and their respective percentages in Figure 5(b). Among them, GPU execution ranks first and is responsible for 34.6% of all abnormal spikes. The second major cause is the inter-machine networking issue, comprising network fabric problems, link flapping, network link failures, and NIC anomalies. Together, they account for 41.6% of the spikes, highlighting the severity of networking faults. This suggests that monitoring inter-machine transmission could be the key to identifying these faults.

3.1.2 Performance Fluctuation

Another type of irregularity is called *performance fluctuation* that is usually ignored due to their inconspicuous magnitudes of iteration time changes. Figure 6(a) shows a sequence of 600 iteration times of training with 4096 GPUs, where δ in this case is set to 1.05. The iteration times at the top may reach 9.45 seconds and those at the bottom are around 8.18 seconds, and the average iteration time is 8.40 seconds. As a result, there are 85 iterations with abnormal fluctuation among total 600 iterations. Even though the impact of performance fluctuation is smaller than abnormal spike on an individual iteration, the former is much more frequent than the latter (see appendix B). Overall, the training in Figure 6(a) is extended by performance fluctuation for 9.32 hours over a month, which is even more severe than abnormal spike. We also study the performance of network fabric when irregularities occur. Figure 6(b) shows the CDF of packets with ECN mark and pause frames within an iteration on all the ToR switches. The irregular iteration shows a clear shift to more ECN marks and PFCs, compared to the normal iteration. This phenomenon indicates that irregularities could affect the network traffic, which also inspires us to monitor irregularities through the network.

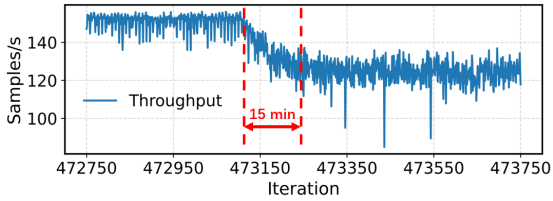


Figure 7: Irregularity: persistent degradation.

Manual diagnosis. The issues that could lead to fluctuations include link flapping and shared network fabrics for multiple jobs (e.g., periodic fluctuation occurs when jobs with different iteration times share spine or ToR switches [45]). Other causes that may also make the training process unstable with small and frequent fluctuations include load imbalance issues of MoE training [20, 31] and congestion [17]. However, this kind of analysis highly relies on the experience of engineers, leading to high and uncertain analytic costs.

3.1.3 Persistent Degradation

Different from the above irregularities, the third type of irregularity degrades the training efficiency persistently, which we call *persistent degradation*. Figure 7 shows the training throughput of 1000 iterations within a 4096 GPUs training. An observation is that the throughput decreases dramatically from around 150 samples per second to 125 samples per second, which means a persistent degradation occurs and results in a 16.72% training throughput degradation. Although the decreasing process of throughput lasts for only 15 minutes, the training will execute at a low efficiency if the irregularity is not addressed in time.

Manual diagnosis. Most of the root causes of persistent degradation are training-independent, such as GPU overheating [21] and abnormal CPU occupation of back-end services. Engineers have to analyze massive resource states and even operation logs of non-training systems to find the causes. For example, after several hours of analysis for the irregularity in Figure 7, we find that the CPU utilization in part of the machines is abnormally high. By tracking the operation logs,

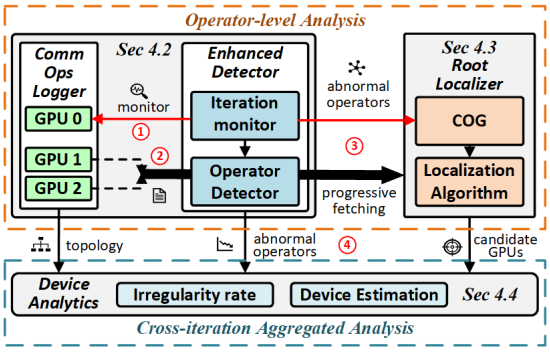

Figure 8: System overview.

the final root cause we identified is that the latest release of our network monitor system frequently scans all the NCCL ports abnormally, competing for the CPU cores. In our training cluster, each persistent degradation could result in 18.2% of training throughput decrease on average.

3.2 Challenges

Our goal is to design a system to accurately localize the above irregularities for LLM training. However, designing such a system in large GPU clusters is quite challenging.

Irregularity behaves silently. Since irregularities do not interrupt training, no error logs are generated. Network monitoring systems track real-time link throughput, which does not reflect the computing anomalies and the traffic interdependency across machines. GPU monitoring tools provide only coarse and noisy runtime states that limit their range of application. The training debugging system usually logs the execution process, while the logging granularity remains unresolved. For example, coarsely logging the iteration time [41,47] is insufficient. Fine-grained logging such as the torch profiler [3] may assist in localization. However, they record all the operators, which considerably slows down the training process [25].

Irregularities's impact propagates among GPUs. The irregularity tends to *propagate* its impact. For instance, if one GPU computes slowly before a DP `All-Reduce`, the other GPUs participating in the same `All-Reduce` must wait for it. As a result, similar irregular phenomena, i.e. extended iteration time, are observed across multiple GPUs, which can be confusing to diagnose. The irregularity can propagate *more than one hop*, further complicating its localization. Independently analyzing all the GPUs will introduce a lot of effort and is time-consuming since a lot of irregular training logs will be detected and hard to localize the anomalous device.

Misidentify the anomalous device is costly. The irregularity localization needs to be accurate, as isolating potentially anomalous devices is a costly countermeasure. While the irregularity occurs frequently, misidentifying anomalous devices causes the waste of precious computing resources, and leaves the irregularity unresolved. It is crucial to ensure high system accuracy while minimizing misidentification.

4 System Design

In this section, we first introduce the design principle and overall design of Holmes (§ 4.1). Then, we elaborate on the three key aspects of Holmes: enhanced abnormal operators detection model (§ 4.2), graph-based root causes localization (§ 4.3), and cross-iteration analysis (§ 4.4).

4.1 Overall Design

The goal of this paper is to accurately localize the anomalous devices that lead to the irregularity during LLM training.

Design principles. Our system design should follow these basic principles.

• *Accuracy.* High accuracy in pinpointing the irregularities and diagnose the root causes.

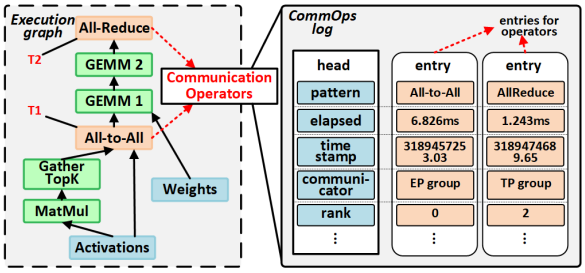
• *Real-time detection.* Capable of detecting and localizing irregularity in real time.

• *Low overhead.* Acceptable overhead brought by monitoring and localization, which has little impact on the LLM training.

• *Flexibility.* Capable of adapting to various parallel training strategies without any modifications.

System Overview. Following the above design goals, we design Holmes, a first-of-its-kind system to accurately localize the anomalous devices in a large-scale GPU cluster. Holmes is a lightweight approach that only relies on data from communication operators. More concretely, to explicitly observe silent irregularity, we propose an enhanced abnormal operator detection model. This model firstly leverages a communication operator logger to log the detailed process of communication operators (§ 4.2.1). Upon observing the irregularity, we propose an enhanced random forest model (RF) to analyze communication operator logs and capture the specific operator that causes the irregularity. Since the time distribution of iteration may shift over a long-term training and result in the RF performance degradation, we further introduce an auto-tuning approach to adapt to the changes (§ 4.2.2). To localize the anomalous device according to abnormal operators among GPUs, we construct a novel communication operator graph (COG), and design an effective algorithm that combines breadth-first search and depth-first search for traversing the collective communication and point-to-point operators respectively. Holmes only collects logs from the GPUs traversed by the search algorithm, minimizing the amount of data transmitted and localization time (§ 4.3). To ensure high localization accuracy, we introduce cross-iteration analysis among all devices within the training clusters, including GPUs, links, and switches, and employ Maximum A Posteriori estimation to identify the most possible anomalous device (§ 4.4).

Workflow. As shown in Figure 8, Holmes firstly embeds a communication operator logger for each GPU in the training cluster to record the data locally. Then we deploy our system modules including enhanced detector, root localizer and device analytics in an independent CPU server. ① The iteration



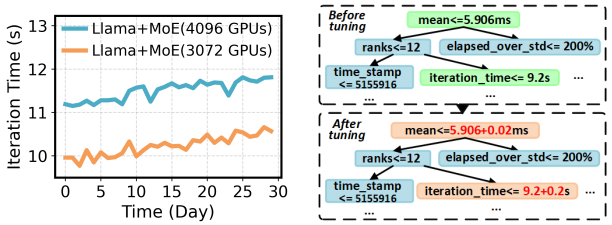


Figure 9: Communication operators and logging scheme.

(a) Distribution drift (b) Auto-tuning against mean shift

Figure 10: (a) Distribution drift and (b) Holmes's auto-tuning.

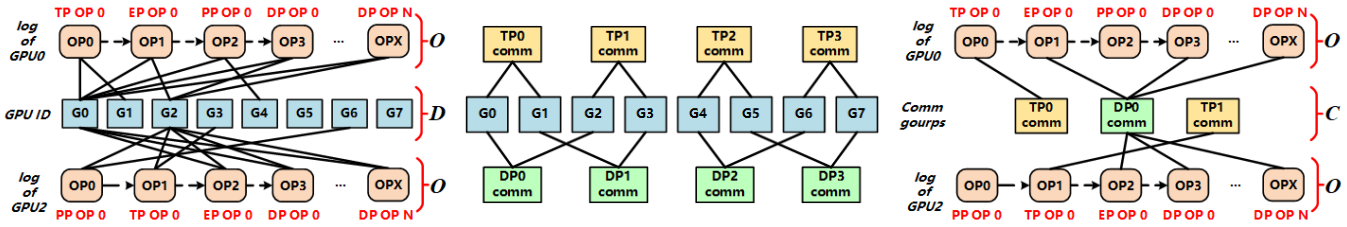
monitor keeps tracing the log of one pivot GPU for analysis in real time. ② Once the iteration monitor observes an irregularity, the operator detector will perform enhanced abnormal operator detection on the logs. ③ Then root localizer module searches the GPUs in COG and collects the log data of these GPUs that are correlated to the irregularity. ④ The device analytics module calculates the probability of anomaly for every device and identifies the top-K anomalous devices. Finally, the on-call technicians can further confirm and replace the anomalous devices.

4.2 Abnormal Operators Detection

4.2.1 Communication Operator Tracing

Since the irregularity does not generate any error logs, we are motivated to implement a logger to capture this phenomenon. However, logging all information during LLM training can significantly interfere with the training process. Therefore, it is challenging to develop a lightweight approach with minimal overhead on LLM training.

CommOps log. Figure 9 shows a typical execution graph of a single iteration when training LLMs. There are two communications, i.e., `All-to-All` ending at T_1 and `All-Reduce` starting at T_2. The computation operators are executed during T_1 and T_2. We find that both the computation issues and communication issues can be observed by monitoring communication operators. For instance, if the `GEMM` operator executes abnormally with longer computation time, the start time of the `All-Reduce` operator will be later than T_2. Even when computation and communication overlap during training, interdependent communication operators remain vulnerable to cascading delays. Furthermore, communication operators indicate data transmission among GPUs, which we can use to trace the propagation of irregularity's impact. However, popular communication libraries such as NCCL [1] do not provide the interface to record the communication operators directly. In Holmes, we introduce a logging scheme called CommOps log to keep tracing the communication operators as shown in the right part of Figure 9. Each entry of the log records the features of a specific communication operator, which includes the communication pattern, the elapsed time, time stamps, communicator, GPU rank, etc. Since the number of communication operators is much less than that of computation operators in the typical LLM training, CommOps log could trace the fine-grained training process with almost negligible overhead.



4.2.2 Automatic Operator Detection

Iteration monitor. As we present in § 3.1, the irregularities have apparent characteristics in end-to-end measurement, e.g. prolonged iteration time. For simplicity, we perform irregular iteration detection strictly according to our definition of δ-irregularity.

Unified operator detection. Typically, an iteration always contains tens of thousands of operators. Once an irregular iteration is detected, we need to trace the relevant operators. However, due to the operators' execution time varying dramatically, we can hardly leverage traditional anomaly detection methods such as the 3-sigma rule to detect them. For example, if the duration of an abnormal iteration increases from 7 seconds to 9 seconds, potentially caused by two abnormal operators. The elapsed time of one operator increases from 0.02 ms to 1 ms (by 50×), while the elapsed time of the other operator increases from 1000 ms to 3000 ms (by 3×). In this case, if we only consider the increasing ratio, the former operator will be detected as an abnormal operator rather than the latter. In Holmes, we choose to use Random Forest (RF) to train a prediction model for abnormal operator detection. We consider each entry in the operator log as an individual sample of the RF, while the features are the records of the entry. Since RF can effectively capture multiple features, we also incorporate global information, such as iteration time and average operator elapsed time within a time window into the features. In this way, Holmes can detect abnormal operators with the consideration of the importance and variation of operators.

Detection features. Each operator has specific features in a given iteration, however, detection requires analysis of global information. Below is a list of features we construct:

- *Mean and standard deviation (std).* The average value and standard deviation of operator execution time.
- *Z-Score.* For each point X in the time window, Z-Score is calculated as: $Z = (X - mean)/std$.
- *Quartiles.* The first quartile ($Q1$), the second quartile ($Q2$, i.e., median), and the third quartile ($Q3$) of feature.
- *IQR.* The interquartile range (IQR), calculated as $Q3 - Q1$.
- *Fixed features.* Ranks, data size, communication pattern.

(a) Original COG, (b) Communication grouping. (c) Reconstructed COG.

Figure 11: Communication operator graph.

Distribution drift adaptation. The RF can predict the abnormal operators based on training samples. However, due to the non-stationarity inherent in production, the trained RF model is prone to *distribution drift* [13, 19, 63], which subsequently degrades its forecasting performance over time. For example, we depict the average iteration times per day of two LLM training instances in Figure 10(a). An observation reveals that the average iteration time exhibits slight daily variations. Both iteration times increased by 5.92% and 7.03% respectively within a month, indicating a drift in the distribution of features (e.g., iteration time). Periodic tree model retraining mitigates drift, but RF training requires costly manual data labeling. Holmes counters this drift by enhancing tree-based predictions with an automatic tuning approach. In tree-based models such as RF, there are numerous interconnected tree nodes. Each node is capable of classifying data samples by utilizing trained attribute values associated with a specific feature. We directly tune the attribute values in the trained model periodically. For instance, as shown in Figure 10(b), a trained RF model contains nodes with specific features. We detect that the mean of iteration time right shifts for 0.2 seconds (from 9.0 seconds to 9.2 seconds). To cope with this mean shift, we adjust all attribute values associated with the shifted features, e.g. adding 0.2 seconds to the attribute value 9.0s in the node "iteration_time". This tuning approach allows Holmes to adapt to distribution drift during training without the need for additional efforts such as incremental training.

4.3 Graph-based Causes Localization

During the training, an anomaly in the device causing longer training iteration will propagate to impact other GPUs, appearing longer iteration time. When there are a lot of irregular iteration logs among these GPUs, it is challenging to identify the anomalous device. To address this, Holmes constructs a novel communication operator graph (COG), and then designs an effective algorithm to localize the irregularity.

4.3.1 Communication Operator Graph

Constructing the COG. Holmes designs a novel graph called the communication operator graph (COG) $G = (O, D, E)$, where O and D are the sets of operators and GPUs respectively, and E denotes the edges between O and D. Specifically, Figure 11(a) illustrates each $o \in O$ represents a communication operator in a log and each $g \in D$ represents an individual GPU. An edge $e = (o, g) \in E$ exists between o and g if g is participated in o. In addition, the operators in the same log are connected in the form of a linked list to represent the execution order, as the dash lines in Figure 11(a) show. However, this naive format of COG may result in an unacceptable complexity. For example, if an LLM training includes 4096 GPUs ($|D| = 4096$) and 4000 operators in each log ($|O| = 4000 * 4096$), the number of connections $|E| = |O| * |D|$ can be 6.71×10^{10}, which is prohibitively complicated.

Reconstructing the COG using communication grouping. To address the curse of dimensionality, Holmes leverages the grouping feature of communication operators to reduce the connections. In Figure 11(b), we take 8 GPUs training as an example, where the degrees of data, pipeline, and tensor parallelism are 2. With the communication pattern defined, all the communication operators are executed on fixed groups of GPUs. For instance, all the communication of data parallelism in GPU G0 are executed with G2, then G0 and G2 are called a DP group (labeled as "DP0 comm"). This group conception is used in various parallelism implementations and communication libraries, such as the *communicator* in NCCL [1]. In Holmes, we maintain a mapping of groups such as "DP comm" and their corresponding GPU sets. By substituting GPUs with groups, we reconstruct COG $\hat{G} = (O, C, E)$, where C represents the set of GPU groups. As shown in Figure 11(c)[1], the number of edges in the $\hat{G}$ is much lower than in G. Furthermore, since all the connections of O are sparse (only one to C), Holmes could use sparse storage for the edges, reducing the memory and processing overhead.

4.3.2 Graph-based Localization Algorithm

To localize the irregularity, we design a recursive algorithm (Algorithm 1) to identify the GPU or GPU sets where the root cause occurs. When a set of abnormal operators *OPs* is detected in the pivot GPU, we call the recursive `locateNeighbor` function for each operator (line 2). Given the low probability that multiple types of irregularities occur in the same operator, our algorithm treats input abnormal

[1] Typically, the GPUs performing DP communication will always perform the same EP communication. We group them together to further reduce the COG complexity. Furthermore, we do not group GPUs in PP communication as it is only executed among 2 GPUs.

Algorithm 1: Root cause localization

```
   Input: Ĝ = (O,C,E), OPs
   Output: OPERATORS, CAUSES
1  OPERATORS ← ∅, CAUSES ← ∅;
2  for all o of OPs do locateNeighbor(o) ;
3  Function locateNeighbor(o):
4      if o.type ∈ CC_OP then
5          ▷ Breadth First for CC
6          for all neighbors group of o do
7              if any neighbor operator n of group is normal then
8                  ▷ Track operators of the GPU g where n belongs to
9                  for all neighbors operators po of g before n do
10                     if any po is abnormal then
11                         locateNeighbor(po), break
12                     else
13                         OPERATORS.add(po),
                             CAUSES.add(COMPUTE), return;
14                     end
15                 end
16             else
17                 OPERATORS.add(o), CAUSES.add(NETWORK)
                     return;
18             end
19         end
20     else
21         ▷ Depth First for P2P
22         if o.peer = ∅ or o.peer operator is abnormal then
23             OPERATORS.add(o), CAUSES.add(NETWORK);
24             return;
25         end
26         ▷ Track operators of peer GPU
27         for all neighbors operator po of o.peer GPU do
28             if po before o.peer operator is abnormal then
                   locateNeighbor(po);
29         end
30     end
31 end
```

operators separately. For each communication operator, we use breadth-first search (BFS) and depth-first search (DFS) to traverse the operators in collective communication (CC) and point-to-point communication (P2P), respectively. For each GPU, we track the operators belonging to it and detect whether they are abnormal. We initialize the set of root cause operators and types of causes to $\emptyset$ (line 1).

BFS for Collective Communication. We perform a breadth-first search to traverse all the GPUs within a collective communication group. For an abnormal collective communication operator o, we identify its corresponding group c and verify all associated operators across group GPUs. These operators represent the same communication but are recorded from different GPUs. If all the operators are reported as abnormal, we confirm the communication itself as the root cause and terminate the analysis (line 17). Otherwise, there exists an operator n that is executed normally, i.e. normal execution duration. However, since the collective communication requires all the GPUs to be ready, this indicates that the abnormal operators in the rest of the GPUs take too much time waiting for the "normal" operator n to start. We can infer that irregularity occurs and delays n. In this case, we will track all the previous

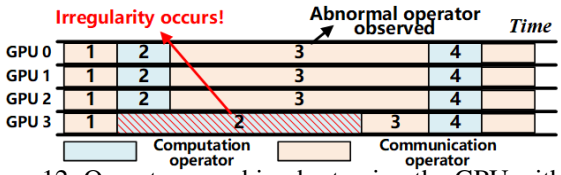


Figure 12: Operator searching by tracing the GPU with the normal collective operator.

operators before n (line 9). If any operator po is abnormal, we recursively analyze po (line 10), otherwise, we identify the causes as the computation prolongs and impacts n (line 13). Figure 12 demonstrates this principle through a 4-GPU scenario where GPU3's prolonged operator2 execution forces others to wait at operator3. Our algorithm correctly attributes the anomaly to GPU3's computational delay by observing abnormal operator3 executions in other GPUs versus GPU3's normal operator3.

DFS for P2P communication. In P2P communication, each operator involves two GPUs with peer relationships. We perform a depth-first search along with the pipeline stages. For each GPU, the other GPU is referred to as the peer GPU, and the corresponding operator in this peer GPU is termed the peer operator. For a specific P2P operator o, we directly detect its peer operator due to its inherent dependency. For example, if a `Recv` is abnormal, we can find its peer `Send` according to the COG. If both operator o and its peer operator are abnormal, then it can be confirmed that the cause of the irregularity is related to the abnormal P2P network communication (line 22). If only o is abnormal, its prolonged execution implies synchronization delays while awaiting the peer operator's readiness. In this case, we track the operators before the peer operator on the peer GPU and further locate the abnormal operators among them (lines 27-29). The readers can refer to appendix C for more details.

4.4 Cross-iteration Analysis

By combining the detection (§ 4.2) and localization (§ 4.3), we are able to find the root abnormal operators, involved GPUs and the cause type of an irregularity. However, there may be false positives if we localize the causes only based on a single iteration. Meanwhile, we can hardly identify multiple concurrent irregularities. To address these challenges, Holmes leverages a cross-iteration analysis in a time window T to find out the most possible anomalous devices.

Influence assessment of irregularities. Given detected irregularities $X = \{x\}$ within T, we first define a quality metric to evaluate the irregularity's influence on training. Since the irregularity prolongs the iteration time for δ times, Holmes calculates the impact of irregularity on the overall iteration time as a metric called *irregularity rate* $\mathcal{R}(x, t_s, T)$, where the time window starts at t_s. The impact of irregularity can be reflected in its corresponding abnormal operators. $\mathcal{R}(x, t_s, T)$ is calculated as the Pearson Correlation Coefficient [4, 59] of

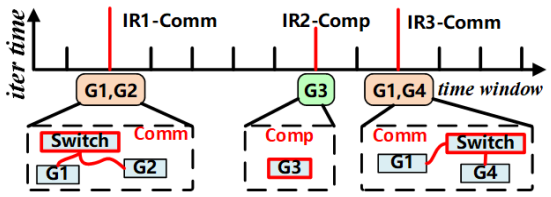

Figure 13: Cross-iteration analysis.

the abnormal operator duration and the iteration time:

$$\mathcal{R}(x,t_s,T) = \frac{Cov\left(\mathbb{T}^T_{t_s}(x), \mathbb{T}^T_{t_s}(I)\right)}{\sigma_{\mathbb{T}^T_{t_s}(x)}\sigma_{\mathbb{T}^T_{t_s}(I)}}$$

where $\mathbb{T}^T_{t_s}(x)$ denotes the series of the execution time of the abnormal operator involved in x, and $\mathbb{T}^T_{t_s}(I)$ denotes the series of the overall iteration time. The larger $\mathcal{R}$ an irregularity has, the more severe influence it has on training.

Anomalous device estimation. Any anomalous device in the cluster leads to the irregularities, we here to calculate the anomalous probability of each device. Noting that the abnormal operators may be different among iterations, they can be caused by the same anomalous device. We first define the device set $D = \{d\}$, including such as GPUs, links connecting GPU, NVLinks, and switches. Each device has an *accumulated index* $I(d)$ to indicate its possibility of being anomalous. With the irregularity rate $\mathcal{R}$ and involved GPUs of the irregularities, we can calculate all the $I(d)$ by accumulating $\mathcal{R}$. Specifically, for the irregularity that is identified as computation issues in a set of GPUs, we directly accumulate $\mathcal{R}$ into I of the GPUs. While for irregularity stemming from the network issues, we traverse all the network devices that lie on the communication paths among involved GPUs, and accumulate the $\mathcal{R}$ into their I. Given a device d and irregularities set X, we use the MAP estimation to perform the accumulation as described in appendix D, which exploits the prior probability of the devices being anomalous. Figure 13 depicts the communication irregularity "IR" involves GPU1 and GPU2. We accumulate the irregularity rate to all the communication devices between them, i.e. a switch and two links. While for the computation irregularity "IR" involving GPU3, we directly accumulate the irregularity rate to GPU3. Finally, Holmes ranks $I(d)$ and identifies the top K devices with the highest $I(d)$, which means that they are most likely to be anomalous and severely affect the training.

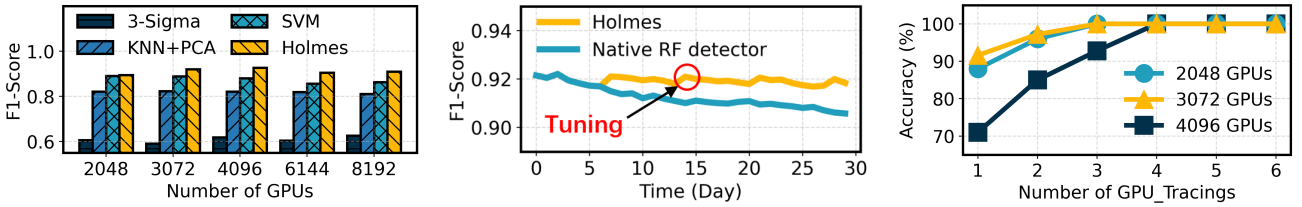
5 Evaluation

In this section, we present a series of experiments on Holmes. Experimental results manifest that Holmes can achieve the localization accuracy of 97.21% in the models (§ 5.1) trained in a mega-scale GPU cluster. Our production-level testbed simulations show that the irregularity localization can be completed within 30.3 seconds (§ 5.2). Finally, we study Holmes's localization details by a case from production (§ 5.3).

5.1 Large-scale Trace-driven Analysis

We collect CommOps logs over a three-month period from our production training cluster, which is equipped with over 10,000 GPUs, including NVIDIA H800. Each GPU is paired with an NVIDIA ConnectX-7 Dx NIC, providing a bandwidth of 400Gbps. The software systems include Megatron-LM [41], DeepSpeed [47], and the NCCL [1]. The training process adopts multi-dimensional parallelism strategies that encompass tensor- [41], data- [11,46], pipeline- [22,40], and expert- parallelism [28]. The LLMs are carefully designed models based on LLaMA [56], LLaMA2 [57] and GPT3 [7], with thousands of billions of parameters.

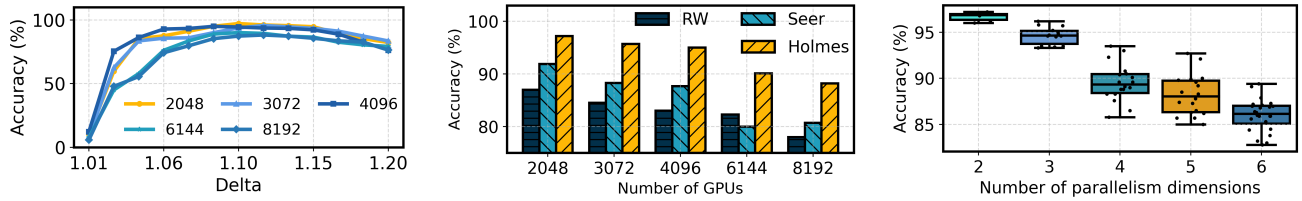
Dataset. We integrate our CommOps logger into our production cluster and generate the communication logs accordingly. Manual diagnosis is conducted to identify anomalous devices and corresponding irregularities. Firstly, we rely on expert knowledge to enumerate all the possible anomalous devices. Subsequent manual inspection evaluates device resource metrics (e.g., GPU usage). Suspected devices are isolated upon confirmation through stress testing.



System configuration. The training set of the detection tree model is the CommOps log data of LLM training. Specifically, we train a distinct tree model for every LLM training using their CommOps logs. Each sample represents the feature of a specific communication operator. Most of the LLM training spans several months and we manually construct the training dataset using a few hours' logs. For cross-iteration analysis, given the low probability of concurrent failures in multiple devices, K is defaulted to 2. The irregularity rate calculation spans 100 iterations by default.

5.1.1 Modular study

We present the key modular study results below and other supplementary experiments can be found in appendix E.



Abnormal operator detection accuracy. We first study the performance of abnormal operator detection in Holmes. Figure 14(a) compares our RF detector with three baseline methods, where higher F1-Score indicates better detection performance, the details of the setting can be referred to appendix F. For various scales of the training, the F1-Score of RF exceeds 0.89. Specifically, when training with 4096 GPUs, the F1-Score of RF reaches 0.93, surpassing the scores of the 3-sigma rule and K-Nearest Neighbor (KNN) by 0.31 and 0.11, respectively. Even when compared to SVM, Holmes still achieves a higher F1-Score by 0.07. These phenomena manifest that our RF detector could detect abnormal operators correctly even in large-scale training.

Distribution drift adaptation. We then study the auto-tuning of Holmes against the distribution drift. For a 3072 GPUs training lasting one month, we set the auto-tuning interval to one week and train the same RF model for Holmes and a naive RF detector without tuning. Figure 14(b) illustrates how the F1-Scores evolve over time. Starting from the second

(a) F1-Score of different detection methods (b) Distribution drift adaption (c) Localization accuracy

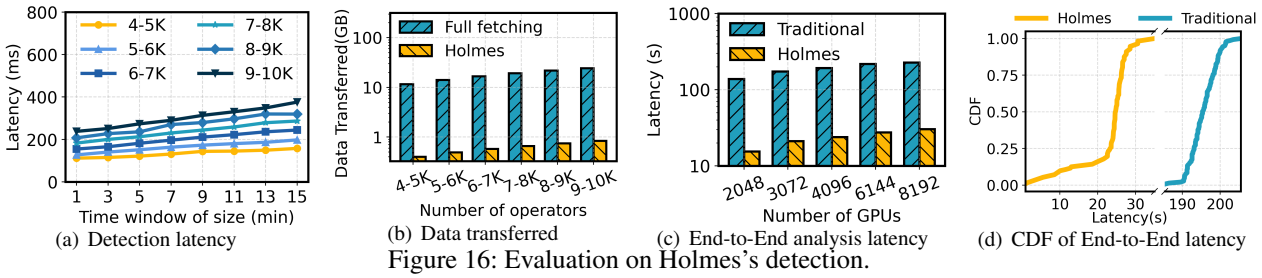
Figure 14: Performance of detection.

(a) Localization accuracy of δ (b) Scalability to number of GPUs (c) Scalability to number of parallel dimensions

Figure 15: End-to-end localization accuracy.

week, Holmes consistently outperforms the native RF. The F1-Score of Holmes is always above 0.917, while the score of native RF declines from 0.922 on the first day to 0.906 by the end of the month. Meanwhile, an increase in the F1-Score is clearly observed on each auto-tuning date. Holmes automatically collects the feature shift such as iteration time shift and tunes the attributed value for these features weekly, keeping high detection performance. Furthermore, the tuning frequency can be adapted according to the training.

Localization algorithm accuracy. To evaluate the localization algorithm, we present per-iteration localization accuracy on three training with thousands of GPUs. As shown in Figure 14(c), we run the localization algorithm several times independently, beginning with 1 to 6 randomly selected monitored GPUs. The GPUs that have the earliest executed abnormal operators are then chosen as the localization results. When monitoring a single GPU, Holmes achieves localization accuracy of 91.6%, 88.0%, and 71.1% with 2048, 3072 and 4096 GPUs, respectively. As the training involves more GPUs, GPUs are more likely to interfere with each other, which limits the localization accuracy. However, since the localization algorithm starts from few GPUs, we can monitor more GPUs to improve the localization accuracy in production. For example, in training with 4096 GPUs, the accuracy increases from 71.1% to 100% as the monitored GPUs increase.



5.1.2 End-to-end Performance

Baselines. Since there are no existing systems for irregularity localization during training, we adapt the idea of two anomaly diagnosis counterparts [16, 59] from the field of (micro-)service computing to irregularity localization. "Seer" is a neural network based method [16] that directly localizes the potential anomalous device using the CommOps logs. We further replace our graph-search algorithm with the ranking and random walk method [59], called "RW".

Accuracy of delta. The irregularity refers to the training iteration time prolongs for δ times. Hereby we evaluate Holmes's performance when δ varies. As shown in Figure 15(a), Holmes can detect the irregularities in most of the training when δ varies from 1.06 to 1.12. When the δ is less than 1.04, Holmes can not tell the normal iterations and irregular iterations since the training iteration time fluctuates. While δ is larger than 1.12, Holmes can not detect slight irregularities like performance fluctuations. We empirically set our default δ of the detection system as 1.1.

Scalability to GPU number. Figure 15(b) shows the end-to-end localization accuracy when training LLMs at various GPU scales. With 2048 GPUs, Holmes achieves a localization accuracy of 97.2%. Even in the extreme scenario of 8192 GPUs, Holmes maintains an accuracy of 88.2%, while RW and Seer attain only 78.0% and 80.7%, respectively. RW's random walk on COG effectively localizes anomalous *communication* devices but cannot detect computational anomalies, as CommOps logs do not explicitly provide their information. Seer exhibits rapid accuracy degradation with GPU scaling, as its CNN+LSTM architecture struggles to model inter-operator dependencies at extreme scales. Holmes explicitly models the operator relationships, thereby achieving superior localization accuracy and interpretability.

Scalability to parallelism dimension. We assess the localization accuracy of Holmes when the training parallelism varies. The parallelization strategies include the aforementioned strategies and customized approaches. The LLMs in our experiments implement various combinations of these strategies, so each test case is designated by the number of parallelism dimensions rather than the specific combinations, as shown in Figure 15(c). For the commonly used 3D and 4D parallelisms, Holmes achieves a median localization accuracy of 94.6% and 89.6%, with a first quartile of 93.6% and 88.3%, respectively. The more complex parallelism introduces the more complicated communication patterns, leading to an accuracy decline. However, even with 6D parallelism, Holmes's median localization accuracy reaches 86.0%, with a

(a) Detection latency (b) Data transferred (c) End-to-End analysis latency (d) CDF of End-to-End latency

Figure 16: Evaluation on Holmes's detection.

first quartile of 85.2%, which shows that Holmes is adaptable to existing parallelization strategies.

5.2 Production-level Testbed

Localization latency is evaluated in our production network environments through a simulation framework that enables dynamic GPU configuration adjustments. Holmes's prototype operates on production network infrastructure, employing CPU-based log generation to emulate GPU training processes while preserving real collective communication operator logs. This approach maintains temporal fidelity by substituting GPU computation durations with simulated equivalents, with log transmission mechanisms mirroring production environments. Our testbed consists of nine machines: one acts as the Holmes analytics server, while the others serve as training machines. For example, to simulate a virtual cluster with 2048 GPUs, each training machine runs 256 log writers, acting as 256 GPU training processes. Each machine is equipped with an AMD EPYC 7K83 64-Core Processor and a 200 Gbps NVIDIA ConnectX-6 Dx NIC. Machines are connected to a Clos network using 10 TCS8400 switches to simulate the data plane network in production (Figure 22). We compare Holmes to the 3-sigma rule approach, labeled as "Traditional", which uses all GPUs' logs.

Detection latency. We study the detection latency by adjusting the detection time window size and the number of communication operators. A larger window size means that more iterations are processed in Holmes. As shown in 16(a), the overall detection latency for a single GPU log remains within 400 ms. When the window size increases from 1 minute to 15 minutes, the detection latency increases from 111.7 ms to 157.6 ms with 4-5K operators inside a log. The detection latency increases linearly as more operators are involved, since each operator needs to be processed by the RF model. An observation is that even when the time window extends to 15 minutes and the number of operators reaches 9-10K, the detection latency remains as low as 375.7 ms.

Localization with progressive fetching. To reduce collected data volume and localization time, Holmes implements a progressive fetching scheme that only collects logs from the GPUs that are traversed by our localization algorithm. Figure 16(b) shows the collected logs from the training machines to the analytics server for one localization process. While full log analysis is used as our baseline. For cases with 9-10K operators, the average per-iteration traffic load is 24.36 GB, whereas Holmes's load is only 0.84 GB, with a reduction of 96.6%. This manifests that our progressive fetching scheme effectively utilizes only the necessary data, preventing network overload due to excessive CommOps log traffic.

End-to-end localization latency. We evaluate the overall localization latency of Holmes when training with different cluster scales. As shown in Figure 16(c), Holmes significantly outperforms the traditional approach in all scenarios. For instance, the average latency in Holmes is 21.2 seconds when training with 3072 GPUs, exhibiting an 87.8% reduction compared to the baseline. As the number of GPUs scales from 2048 to 8192, the overall latency of Holmes increases from 15.5 seconds to 30.3 seconds. This increase is due to the prolonged detection time for irregular operators and the increased transmission time for CommOps logs. Figure 16(d) shows the cumulative distribution of the latency for the training using 3072 GPUs. Nearly 96.2% of the overall latency values fall below 30.0 seconds, while the 99th percentile is at 32.8 seconds. This implies the absence of a heavy tail, which is advantageous for Holmes's practical operation.

5.3 Case Study

We use an irregularity example from the production to illustrate the workflow of Holmes in Figure 17. The training in this case is executed under typical 3D parallelism, where the degrees of DP, PP and TP are 96, 8 and 4, respectively.

1) Irregularity detection. At the beginning, Holmes keeps monitoring the training in GPU 0 (DP:0, PP:0, TP:0). Upon the detection of an irregular iteration (whose time extends to 10.1s), we perform the abnormal operator detection on GPU 0, and find a `Send` operator with extended execution time.

2) DFS inside PP group 0. As the `Send` is a P2P operator in PP group 0, Holmes fetches the CommOps log in the peer GPU (DP:0, PP:1, TP:0) according to the COG. We find that the P2P operator `Receive` is normal while another `Send` operator is abnormal. We keep searching on this `Send`. After repeating multiple rounds, we transit to GPU 2304 (DP:0, PP:6, TP:0) whose `All-Reduce` operator is found abnormal.

3) BFS inside DP group 24. The `All-Reduce` belongs to DP group 24, we then detect all the GPUs in this DP group according to the COG. Only one GPU's (GPU 2572) corresponding `All-Reduce` is normal, while the other GPUs have the same abnormal DP `All-Reduce` operator. This indicates

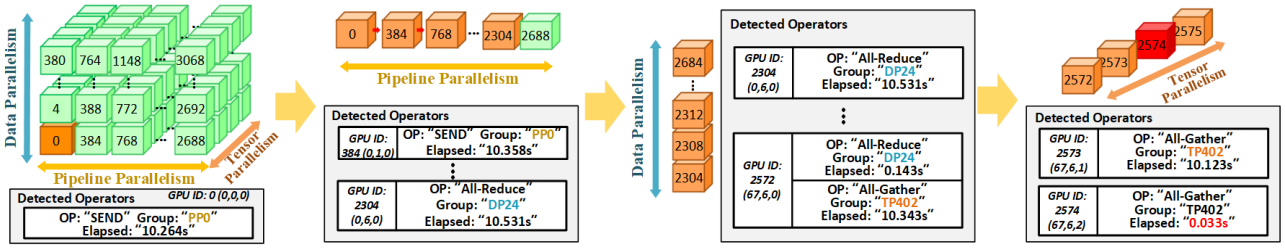


Figure 17: An example of irregularities detection with 3072 GPUs.

that GPU 2572 is the straggler and the rest of the GPUs start the `All-Reduce` ahead of GPU 2572 and wait till it is prepared. In GPU 2572, the abnormal operator we can detect is an `All-Gather` belonging to TP group 402.

4) BFS inside TP group 402. In this group, we find that the same `All-Gather` is normal only in GPU 2574, whereas no other abnormal operator in this GPU. We can infer that the irregularity is caused by the GPU 2574 computing slowly.

Summary. In this example, the number of GPUs we access is 106 (i.e., $6+96+4$), which is less than the total number of 3072. Combining with a long-term analysis during hundreds of iterations, Holmes suggests substituting the GPU 2574.

6 Discussion

Considering operator implementation. Communication operators have been implemented by various algorithms (e.g., All-Reduce variants [1, 50]) including ring [44, 55], recursive doubling [49, 55], and topology-aware optimizations [15, 34]. While operator-level behavioral discrepancies enable Holmes's straggler detection, integrating implementation-specific operator tracking could enhance network device localization. This refinement, however, risks excessive logging overhead during multi-hop transmission monitoring – a critical trade-off requiring future exploration between diagnostic precision and runtime efficiency.

Resource metric integration. Traditional hardware monitors provide coarse-grained metrics (GPU utilization, temperature) with inherent noise and limited LLM context awareness. Though augmenting Holmes with real-time resource traces could improve localization – for instance, validating GPU status during diagnostic – our current focus remains anomaly characterization and core detection framework development, reserving multi-source correlation for subsequent research.

Experience in using network telemetry. Initial experiments with RNIC queue-pair (QP) telemetry achieved full communication reconstruction via per-chunk logging, yet proved impractical for large clusters: 10,000 RNICs generated over 10TB/iteration of QP data, exceeding real-time processing capabilities. This scalability constraint motivated Holmes's communication library (CCL)-centric design, balancing observability with operational feasibility.

7 Related Work

Failure diagnosis in GPU cluster. Recent research on anomaly analysis in machine learning has focused on failure diagnosis. A series of works [21, 25, 43, 54, 62] employed error logs for diagnosis. For example, MegaScale [25] diagnosed the failure by visualizing the data collected with a custom CUDA event monitor. Different from them, Holmes localizes the irregularity according to the communication relationship between GPUs without error logs. Another failure diagnosis approach was made by resource monitoring, such as GPU utilization, memory usage, etc [2, 18, 23, 32]. However, they lacked awareness of the detailed training process, while the diagnosis performance highly depends on the granularity of resource monitoring. Holmes can learn the training process precisely at the operator level from the communication logs. Some works [8, 9, 48, 52, 53, 58] focus on develop performance debugging tools for high-performance computing (HPC). Holmes leverages domain-specific knowledge like parallel training strategies to detect irregularity.

Anomaly diagnosis in distributed applications. Research has focused on anomaly diagnosis in other distribution applications, which typically involve detection and localization. In anomaly detection, some work [24, 38, 39] directly analyzed the operational logs, while the others [12, 16, 26, 33, 36, 61] focused on leveraging machine learning. For example, Seer [16] trained a neural network to detect QoS violations. Holmes enhances the machine learning detection model to adapt to the distribution drift in LLM training. In anomaly localization, a series of research [6, 29, 30, 33, 59] proposed the idea of building a graph based on specific applications. MicroHECL [30] analyzed anomaly propagation chains based on a dynamically constructed service call graph. Holmes continues the idea of graph analysis and proposes a novel graph to model the communication relationship within LLM training.

8 Conclusion

In this paper, we systematically analyze the irregularity phenomenon in LLM training and propose a first-of-its-kind system called Holmes for irregularity localization. Holmes employs an enhanced abnormal operator detection model and a novel communication operator graph to perform efficient irregularity localization. Evaluation of production traces shows that Holmes achieves localization accuracy of 97.21%.

Appendix

A Irregularity statistics

During the three months of tracing LLM training, we manually diagnosed a total of 126 anomalous devices which led to irregularities. As shown in Table 1, the majority were primarily caused by anomalous GPUs, accounting for 58.7%. Anomalous NICs were responsible for 23 occurrences, making up to 18.3%. Additionally, there were other anomalous devices involved, such as links, switches and CPUs. For Figure 3(b), additionally, this increase of irregularity frequency is sub-linear with the increasing number of GPUs. This is attributed to the fact that although the expectation of the number of anomalous devices increases sharply, one irregularity in overall training can be induced by multiple anomalous devices when a large number of GPUs are used.

Table 1: Anomalous devices of irregularity during a three month of LLM training.

Anomalous Device	Count	Percentage
GPUs	74	58.7%
NICs	23	18.3%
Links	12	9.5%
Switches	6	4.8%
CPUs	4	3.2%
Others	7	5.5%

B Periodic feature of fluctuation

The performance fluctuations exhibit an interesting periodic feature. Recall in Figure 6(a), we zoom in the per-iteration times and scrutinize 60 iterations between 50400 and 50460. An observation is that performance fluctuation shows a periodicity, approximately occurs once every 6-9 iterations. At other times, the duration of iterations fluctuates within a small range between 8.18 seconds to 9.45 seconds. To investigate the fluctuation, we map the iteration time into the frequency domain by applying the Discrete Fourier Transform (DFT) and Figure 18 shows the corresponding amplitude spectrum. Significant frequency components can be observed at 0.144, 0.288, and 0.432, which corresponds to periods of 6.94, 3.47, and 2.31 iterations respectively. Although the periodicity may

not be strict and the impact of each performance fluctuation varies, this can indicate that performance fluctuation and abnormal spike are different irregularities.

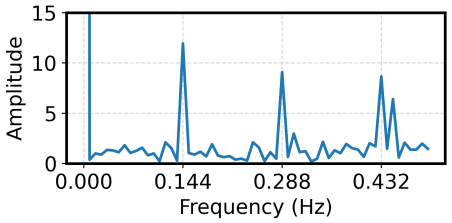

Figure 18: The frequency spectrum.

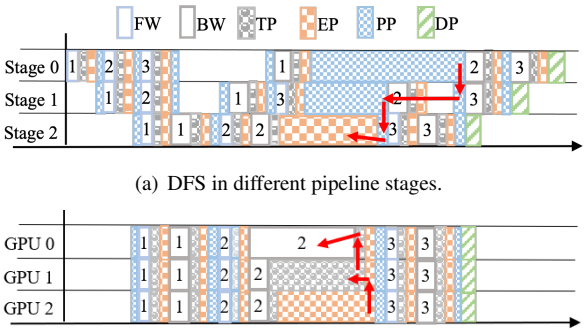


C Algorithm insights

We use two examples to explain our insights on the algorithm.

DFS for point-to-point communication. We illustrate an example in Figure 19(a), where an irregularity occurs in stage 2, leading to the overall training being prolonged. Suppose that the GPU at stage 0 is being monitored, and its "PP" operator has been identified as irregular. It is unclear whether this prolonged "PP" operator is due to the communication link anomaly at stage 0, or if it is influenced by the malfunctions on other GPUs. We then track the same "PP" operator on the downstream stage 1 and find that its execution time is normal, which excludes the inter-stage communication issue between stages 0 and 1. We further backtrack the communication operators on stage 1 and detect an anomalous "PP" operator. The reason for backtracking is intuitive, as the prolonged execution time of one operator is caused by anomalies in preceding operators or in the operator itself. By repeating the above procedure, we move to stage 2 and observe an abnormal "EP" operator, which is different from the previous "PP" operators. The DFS and the corresponding backtracking trajectories are illustrated as the arrow lines in Figure 19(a).

BFS for collective communication. As shown in Figure 19(b), where GPU 0 and GPU 1 are in the same TP group, GPU 1 and GPU 2 are in the same EP group. If the monitored anomalous operator in Holmes is the "EP" operator in GPU 2, we traverse the GPUs in the same EP group and locate the normal "EP" operator in GPU 1. To further diagnose the anomaly, we backtrack to the preceding communication operators and identify an anomalous "TP" operator. By traversing the other GPUs within the same TP group, we locate a normal "TP" operator in GPU 0. Since no other abnormal operators are detected in GPU 0, we can infer that the irregularity is likely caused by GPU 0 computing slowly. The BFS and the corresponding backtracking trajectories are illustrated as the arrow lines in Figure 19(b).

Correlation between operators and nodes Holmes localizes the irregularities with the correlations among operators and correlations between operators and nodes. To be specific, the correlations among operators help us to identify which operator belonging to a collective communication is the root

(a) DFS in different pipeline stages.

(b) BFS in collective communication groups.

Figure 19: Cause localization examples.

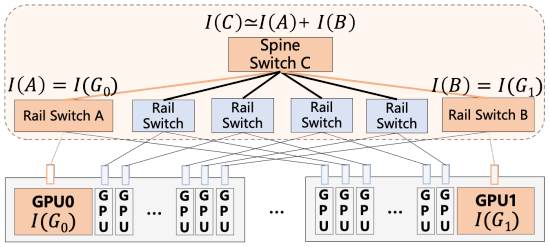
cause of the irregularity. The correlations between operators and nodes help us to recursively find the GPU where the irregularity takes place. However, deeper integration of these correlations and Holmes can be further taken into consideration. For example, investigating the local correlation of nodes and their operators. As this is not the main contribution of our paper, we leave this as our further research.

D Device-wise irregularity rate decay.

MAP-based $I(d)$ accumulation. The accumulation formula is shown as the following:

$$I(d) = \Big(\sum_{x \text{ uses } d} \mathcal{R}(x) + a(d)\Big) \Big/ \sum_{d} \sum_{x \text{ uses } d} \mathcal{R}(x) + a(d) + b(d)$$

where Beta distribution $I(d) \sim \mathrm{Be}(a(d), b(d))$ is used as the prior distribution. $a = \alpha \cdot p(d)$, $b = \alpha \cdot (1 - p(d))$, where $p(d)$ is the device irregularity ratio from our production experience and α is a scaling factor.



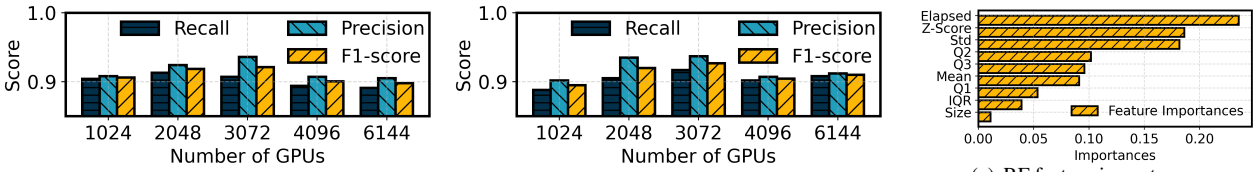


Figure 20: Topology-aware Irregularity rate decay.

In the estimation in § 4.4, we treat each device set equally. However, this could lead to unfairness since the connection of the network fabric is uneven. For example, assuming that irregularities are occurring in both rail switches A and B which slows down the upside transmission. If we traverse the network devices, we could detect irregularities that involve A, B and the spine switch C, and $I(C) \simeq I(A) + I(B)$, as shown in Figure 20. In this case, C will be identified as the most possible device in error. Holmes also designs a device-wise irregularity rate decay mechanism to address this issue. For a

(a) Accuracy with Gini Impurity (b) Accuracy with Entropy (c) RF feature importance

Figure 21: Evaluation on Holmes's detection.

network device d with connections $C(d)$ to downside NICs, we define its decay factor $H(d)$ as follows:

$$H(d) = \frac{\ln(C(d) + \varepsilon - 1)}{C(d)}$$

wherein $\varepsilon = 1e-6$. By substituting the irregularity rate as decayed irregularity rate, the final estimation of device anomalous probability is:

$$I(d) = \frac{\sum_{x \text{ uses } d} \mathcal{R}(x) \cdot H(d) + a(d)}{\sum_d \sum_{x \text{ uses } d} \mathcal{R}(x) \cdot H(d) + a(d) + b(d)}.$$

E Evaluation results

We hereby present the supplemental evaluation results of Holmes. The Network topology used in the testbed is shown in Figure 22.

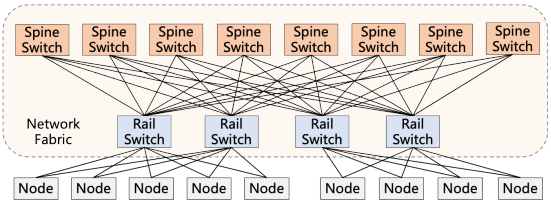

Figure 22: Network topology used in the testbed.

CommOps logger overhead. The communication logger's performance impact is evaluated across multiple training scales (Figure 23). Results show training speed degradation of only 0.064% and 0.083% for 1,024 and 3,072 GPU training when deploying CommOps logger, respectively. Even in the extreme scenario with 6144 GPUs, training time increases by 0.19%, with per-operator logging averaging under $2\mu s$. These metrics confirm the logger's ultra-lightweight design and negligible overhead across cluster scales.

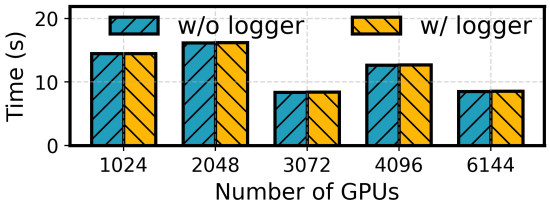

Figure 23: Impact on training with CommOps logger enabled.

Diagnosis of different types of irregularities. We present the diagnosis accuracy of the three types of irregularities across different training scales, as shown in Figure 24. The average diagnosis accuracy of Performance spike, Performance fluctuation, and Performance degradation is 90.7%, 93.0%, 93.2% respectively. Detecting Performance spikes is more challenging because they occur randomly over time, making it difficult to determine when a spike happening. Performance fluctuation and Performance degradation are easy to detect as they typically follow periodic or persistent patterns.

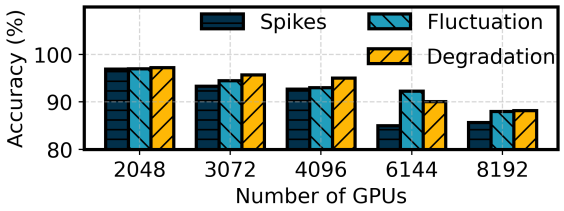

Figure 24: Accuracy for three types of irregularities.

Auto-tuning using different features. We compare Holmes's auto-tuning using different features including P75 (75th-percentile latency), P99 (99th-percentile latency), and mean operator execution time in Figure 25. Experimental results show that tail latency-based tuning (P75 and P99) performs worse than the mean-based strategy, due to their greater sensitivity to irregularities. For example, when training with 8192 GPUs, tuning the detection model using mean operator execution time achieves the highest F1-Score of 0.91, while all the others are less than 0.90. Notably, P99 performs slightly worse than P75, as it is more sensitive to extreme values.

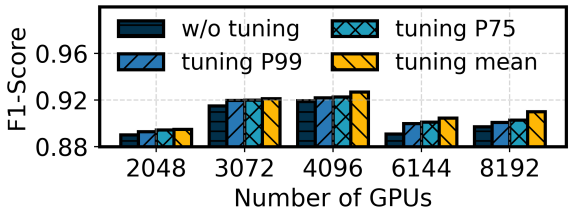

Figure 25: F1-Score of tail latency tuning.

MAP-based irregularity rate accumulation. We conducted comprehensive experiments to compare the accumulation approaches of $R(x)$ in cross-iteration device localization as shown in Figure26. To use the prior device irregularity ratio from our production experience, we employ a MAP-based irregularity rate accumulation approach, while we compare it with the naive linear accumulation without prior. In experiments of different scales, using the prior knowledge is proved

more effective than calculating the sum of the irregularity rate. The greatest improvement was observed in the setup with 8192 GPUs, where the accuracy was 3.3% higher.

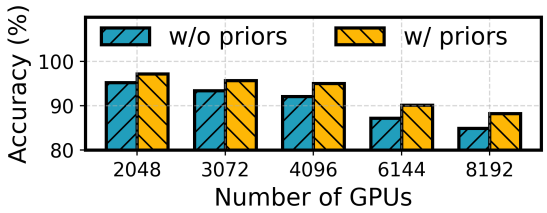

Figure 26: Impact of prior knowledge on localization.

Training throughput. In § 5.3 we illustrate an example of Holmes's localization and find the root cause of irregularity is that GPU 2574 computes slow. As shown in Figure 27. After we isolate the node containing GPU 2574, there are no spikes observed and the average training throughput increases from 85.43 samples/second to 90.62 samples/second.

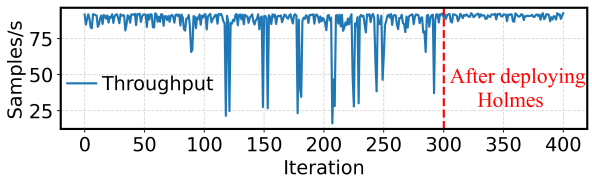

Figure 27: The example training throughput.

F Detailed evaluation of RF

Configuration of baselines of RF models. We compare our RF detection model with other machine learning models like 3-Sigma, KNN, KNN+PCA. The 3-sigma rule we used is performed over each individual operator's own time series. According to the 3-sigma rule, the operator elapsed time within the $(\mu-\sigma,\mu+\sigma)$ range accounts for 68.27% of all its own elapsed time series, and the others can be regarded as abnormal, where μ is the mean and σ is the standard deviation.

Model assessment. We also study the selection of RF models. Figure 21(a) and 21(b) show the Precision, Recall and F1-Score when we use Gini impurity and Entropy as the criterion of RF respectively. In all the evaluated training, the precision is higher than 0.9, while the Recall is higher than 0.85. In particular, we can observe that our RF detector obtains the best F1-Score in training with 3072 GPUs, which is 92.1% and 92.7% for Gini and Entropy. This means that our RF detector could detect the anomalous operators correctly even in large-scale training. Figure 21(c) further illustrates the feature importance distribution within the dataset, highlighting the key factors that contribute to the detection performance of the RF model.

SimAI: Unifying Architecture Design and Performance Tuning for Large-Scale Large Language Model Training with Scalability and Precision

Abstract

The large number of GPUs required for a single LLM training significantly hinders the validation of new designs, tunings, and optimizations, calling for the occurrence of efficient simulators. Existing simulators, however, only target a specific granularity of the entire training, intrinsically leading to imprecision. This paper presents SimAI, a unified simulator aiming at precisely and efficiently simulating the LLM training procedure at scale. Through selective and high-fidelity integration of the training frameworks, the kernel computation, and the collective communication library into the simulating procedure, SimAI achieves high precision in simulations. SimAI further conducts multi-thread acceleration and implements lock-free global context-sharing to accelerate the execution speed. The effectiveness of SimAI is validated by its performance results, which show an average of 98.1% alignment to real-world results under various test scenarios and affirm its robustness and adaptability from small-scale labs to large-scale industrial environments. SimAI delivers meaningful guidelines for new host designs and parameter settings, directly benefiting in-production LLM training. We also share experiences and lessons learned during the evolution of SimAI. SimAI is open sourced at https://github.com/aliyun/SimAI.

1 Introduction

As the field of Artificial Intelligence (AI) rapidly advances, particularly with the rise of large language models like OpenAI's GPT-4 [41], the need for scaling AI infrastructure has grown significantly. For instance, training GPT-4 reportedly requires around 25,000 state-of-the-art GPUs [19]. This massive resource demand presents a significant barrier to entry for organizations looking to compete in this high-stakes domain.

In this context, simulators become essential both before and after infrastructure investments. In the planning phase, simulators help organizations estimate the scale and architecture required to achieve performance goals. In the operation phase, they help increase resource utilization, ensuring a return on investment. Thus, simulators are not just tools for improving efficiency but are strategic assets that maximize resource use and ensure that infrastructure investments deliver measurable results.

Currently, it is common practice to use separate simulators for capacity planning and performance tuning. For capacity planning, simulation is typically performed at the flow or job level, ignoring packet-level behavior [32]. In contrast, performance tuning relies on packet-level simulations to analyze network traffic patterns, latency, and packet loss—factors critical for optimizing communication and computation in AI model training and inference.

However, our experience shows that using multiple simulators with different levels of granularity presents three main challenges. First, this approach leads to inaccurate cost-performance analyses, making it difficult to predict load-balancing performance and assess system failures. Second, the poor performance of detailed simulators and the low accuracy of coarse-grained simulators limit the ability to optimize model training in large-scale deployments. Finally, this fragmented approach complicates development and testing, increasing the risk of discrepancies between simulated and real-world performance.

To overcome these challenges, we developed a unified simulator that handles both capacity planning and performance tuning within a single framework. However, this approach introduces several difficulties:

- Generating workloads with high precision to reflect realistic AI training behaviors.
- Simulating computation accurately across various GPU architectures.
- Precisely modeling communication to account for network traffic patterns and latencies.

* Equal Contribution
† Corresponding Author

- Scaling the simulator to support diverse, large-scale AI infrastructure configurations.

In this paper, we share the development and operation experience of SimAI, a unified simulator designed for scalable, high-precision simulations of large-scale LLM training. SimAI addresses these challenges by introducing high-fidelity models across the entire AI training stack. To generate precise workloads for LLM training at any scale, SimAI "hijacks" mainstream training frameworks, such as Megatron [52] and DeepSpeed [46], to run on a single host and create fine-grained workloads (§3.2). Different solutions ensure accurate simulation of both computation and communication. For computation, we break the workload into fine-grained kernels, measuring execution times on existing GPUs and mapping them to other GPU types (§3.3). For communication, we "hijack" the NVIDIA Collective Communications Library (NCCL) [36] to accurately simulate packet-level behavior for collective communication (§3.4). To improve the simulator's efficiency, we implement multi-threaded acceleration and lock-free global context sharing among threads (§3.5).

The performance results of our unified simulator are a testament to its efficacy. In terms of accuracy, it achieves an average deviation of only 1.9% compared to real-world results across various test scenarios. On the scalability front, the simulator handles simulations from small-scale lab environments to large-scale industrial deployments, proving its robustness and adaptability (§4).

Since incorporating this unified simulator into our AI development pipeline, we have served various teams and gained valuable insights. It has improved our infrastructure management and accelerated AI model development and deployment. We share the benefits and contributions of SimAI, including guidelines for new host designs and accurate assessments of scaling benefits (§5). These guidelines have been adopted by engineering teams and incorporated into production deployments. Additionally, we share lessons learned in transforming SimAI from a standalone simulator to a widely used simulation service (§6).

SimAI is a high-precision, full-stack simulator designed to benefit researchers across various domains involved in Large Language Model (LLM) training. This versatile tool caters to multiple levels of the LLM training ecosystem. At the framework level, SimAI enables the exploration of optimal parallel strategies and communication-computation overlap techniques, facilitating parameter tuning to reduce end-to-end training time. For collective communication research, it offers a platform to validate and quantify novel algorithms' performance gains. SimAI's system architecture design allows for experimentation with diverse intra-host and inter-host configurations, helping identify the most cost-effective solutions. From a networking perspective, the simulator supports investigations into the impact of various congestion control algorithms (such as DCQCN [64], HPCC [26], etc.), network protocols (such as RoCEv2 [17], Solar [33], etc.), and routing strategies—including adaptive routing—across different architectural setups. By providing the flexibility to customize and fine-tune different components, SimAI empowers users to conduct multifaceted research accelerating LLM training processes, and is an invaluable tool for scholars and practitioners throughout the LLM development pipeline.

2 Background and Motivation

2.1 AI Training Infrastructure

Large language models (LLMs) require specialized infrastructure, often involving dozens to thousands of GPUs working together to handle pretraining or fine-tuning tasks. For instance, training a GPT-3 model with 175 billion parameters demands 1,024 high-end GPUs running continuously for 34 days [35]. To optimize GPU usage, mainstream training frameworks like Megatron [52] and DeepSpeed [46] offer parallelization techniques such as Data Parallelism (DP), Pipeline Parallelism (PP), and Tensor Parallelism (TP). These methods enable the efficient distribution of training tasks across multiple GPUs. The process relies on collective communication libraries (CCLs) to manage data exchanges, such as using `AllReduce` for gradient synchronization or `AllGather` for parameter sharing. The CCL breaks each collective communication task into a series of peer-to-peer `Send` and `Receive` operations to carry out the necessary data transfers between GPUs.

In Alibaba's clusters, each server contains multiple GPUs. GPUs within the same server are connected through a high-bandwidth intra-host network, such as NVLink or NVLink Switch [40], and each GPU connects to the inter-host RDMA network via network interface cards (NICs). For example, in line with [23], our A100 servers are equipped with eight NVIDIA A100 GPUs [1] and four NVIDIA CX6Dx NICs, each providing 2×100Gbps [6] bandwidth. Each GPU is linked to other GPUs in the same server via a 600GB/s NVLink and to GPUs in other servers via a 100Gbps RDMA network. In production, Megatron and DeepSpeed are the two dominant frameworks, NCCL [36] is the dominant CCL.

2.2 Demands for a Unified Simulator

The rapid evolution of LLMs necessitates advancements in AI training infrastructure and optimization methods. To address these challenges, simulations are crucial for three primary goals:

Comprehensive evaluation of AI infrastructure. To ensure the effective deployment of new hardware and configurations, AI infrastructure must be evaluated from multiple perspectives:

GPU Selection: Before adopting new GPU models, cloud service providers (CSPs) need to evaluate their performance on AI workloads at scale. Simulations allow for a detailed

preview of how different GPUs perform in large-scale deployments, guiding purchasing decisions and scaling strategies.

Network Architecture Design: Once specific GPUs and intra-host interconnects are chosen, the next challenge is optimizing network architecture for scalability. Key questions, such as the ideal network bandwidth per GPU, require high-precision simulations since large-scale experiments are cost-prohibitive.

Host Architecture Design: Evaluating different host configurations for each type of GPU is essential to determine the optimal number of GPUs per host and the best intra-host interconnect. Simulations help answer these questions without the need to physically build and test expensive hardware prototypes.

Cost-effective validation of optimizations. In addition to hardware evaluations, simulations are indispensable for validating new optimization techniques during model development and system upgrades. This involves:

Parameter Tuning: Testing a variety of model parameters and training framework settings is critical to achieving optimal performance. Simulations allow for quick and inexpensive parameter tuning.

Evaluating New Mechanisms: As innovative enhancements—such as new training frameworks, collective communication methods, and network congestion control algorithms—are introduced, simulations provide a low-cost method for evaluating their effectiveness in realistic settings. This ensures that new mechanisms can be thoroughly tested without the expense of large-scale deployments.

Development of a unified simulation framework. Given the diverse needs for simulations across different components and layers of the AI infrastructure, a unified simulation framework is essential. Building multiple specialized simulators for individual parts of the system often results in inconsistent or incomplete insights. For example, a simulator focused solely on GPUs may overlook critical aspects of network performance, leading to inaccurate conclusions.

Our goal is to develop a unified simulator that addresses all these requirements in a single platform. This unified approach will enable consistent, high-precision simulations across different layers of the AI infrastructure, ensuring that teams can validate new designs and optimizations accurately and efficiently.

2.3 Our Goals

Generating workloads that reflect real-world training. To achieve accurate simulation results, realistic input sources—capturing the detailed behaviors of training frameworks—are essential. Simply estimating workload based on the required floating-point operations is too coarse-grained. Some approaches, like Chakra [53], improve this by using trace-driven methods to extract function-level data from PyTorch Execution Trace. However, this only works for LLMs with the same parameters and scale, limiting the ability to simulate new models or configurations.

Goal 1: We need a flexible and precise workload generator that can handle various models, parameters, and scales.

High-fidelity communication simulation. Classical network simulators, such as NS-3 [47] and OMNET++ [55], offer packet-level network behavior simulations but don't address the collective communication used in distributed LLM training. To maximize performance, collective communication libraries (e.g., NCCL) apply various optimizations that affect traffic patterns. Simulating these from scratch can lead to low fidelity.

Goal 2: We need a high-precision collective communication simulator that incorporates key optimizations and enhancements.

High-fidelity computation simulation. Current solutions like GPGPU-Sim [2] simulate GPU kernel computations at a detailed level but are too time-consuming for large-scale LLM simulations. Other approaches, such as ASTRA-sim [45], fail to support different GPUs or lack the necessary precision.

Goal 3: We need an efficient computation simulator that delivers both precision and scalability for large-scale simulations.

Fast simulation speed. Using a combination of current methods (*i.e.*, PyTorch trace generator with ASTRA-sim), simulating a single iteration of GPT-3 training with 128 GPUs can take an entire day, while the same task on real hardware takes just two seconds. Efficiency is critical to scale simulations for practical use.

Goal 4: The simulator must not only meet Goals 1-3 but also be scalable and capable of running large-scale LLM simulations efficiently.

3 The SimAI Simulator

3.1 SimAI Overview

Figure 1 illustrates the key components of SimAI. Each simulation request includes detailed information about the training process, such as the model itself and parameters, training framework configurations, CCL parameters, and the intra/inter-host network topology.

Workload Generator (SimAI-WG) generates realistic workloads for each simulation request (§3.2). The output, called a workload description file, outlines algorithm modules, collective communication operations, and their dependencies.

The workload file is then processed by the **Execution Engine**, which simulates the execution of both computation and communication operations as discrete events. We utilize the **Computation Simulator** (SimAI-CP) and the **Communication Simulator** (SimAI-CM) to simulate computation and

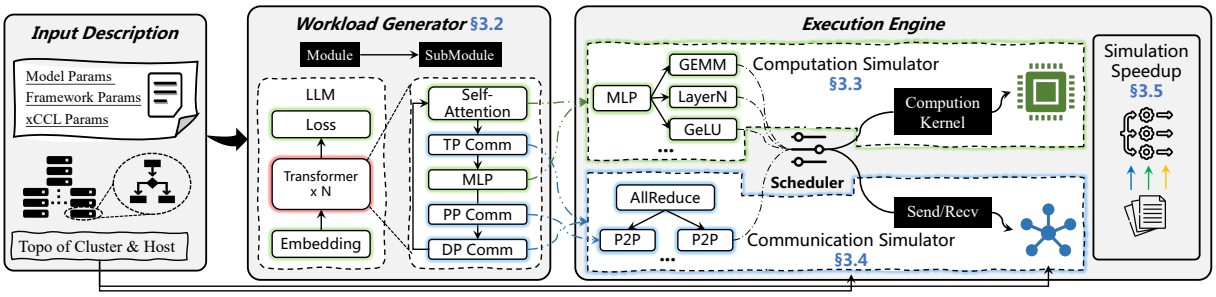

Figure 1: The SimAI architecture

communication tasks, respectively. SimAI-CP transforms submodules into detailed kernels, providing precise computation simulations using a self-built, fine-grained operation library (§3.3). SimAI-CM integrates parts of NCCL, breaking down each collective communication into peer-to-peer operations to deliver accurate communication simulation results (§3.4). Additionally, we implement multi-threaded acceleration and lock-free global context sharing to boost simulation speed further (§3.5).

3.2 Workload Generator

§3.2.1 outlines the process for generating precise workload files for a given model. To further maximize the benefits for real-world training scenarios, selecting a representative benchmark suite is crucial, as discussed in §3.2.2.

3.2.1 Generating workload files

Generating precise workload files is essential, as even small discrepancies between the workload file and actual training execution can lead to low simulation fidelity. While trace-based methods are highly accurate, they require physical clusters to run. SimAI-WG takes a different approach by "hijacking" existing training frameworks to produce workloads identical to real tasks. We have implemented this for Megatron and DeepSpeed, two of the most popular frameworks in our production environment.

Generating workloads using a single host. Without access to a large-scale GPU cluster, the key challenge for this "hijacking" approach is running it on a single host while considering the interactions of multiple peer hosts. To address this, we made two modifications to the framework and NCCL:

- The framework is tricked into believing it runs in a cluster with the target number of GPUs. The inter-host topology is also set to simulate a universal cluster configuration.
- All real communication in NCCL is skipped. For workloads involving pipeline parallelism, SimAI-WG must be configured with the appropriate rank number.

This allows the training framework to generate sequences of computation and communication operations, including algorithm submodules and collective or peer-to-peer communications. Table 1 provides examples of the typical operations used in LLMs. However, these operations lack dependency specifications, which need further specifications.

	Reducescatter	Write & write_with_imm
	Send	Send
	Recv	Recv

Table 1: List of computation and communication operations. ★ denotes memory-bandwidth-intensive operations and △ denotes computation-intensive operations.

Defining operation dependencies. Since computation and communication operations overlap during execution, we embed dependency information in the workload file to reflect this. Dependencies are determined based on the parallelization framework used and are validated using Nvidia Nsight Systems on a 1,024-GPU cluster. Figure 2 illustrates an example of dependencies when using TP, DP, and PP parallelisms. Solid arrows indicate a strict "happened-before" relationship, while dotted arrows represent overlapping operations where communication begins after the computation has started. The figure demonstrates how Megatron's attention and MLP backward phases benefit from overlapping optimizations. For example, the *MLPbackward* submodule starts only after the *Attentionbackward* submodule and the `AllReduce` operation are complete.

We decoupled the workload from the training framework for independent simulations. Instead of embedding simulation code directly into frameworks like Owl [9], we used SimAI-

Table 2: Proportions of tasks with different parameter sizes and scales.

WG to extract model workloads and simulate them within the SimAI execution engine. This approach avoids the substantial overhead of modifying training frameworks, which requires extensive changes to monitoring tools, data pipelines, and other critical components. By implementing core algorithms in SimAI-WG, we gain flexibility while understanding how different frameworks generate communication and computation operators.

Communication in large language models. In LLM training, metadata exchanges and barrier operation (under 1 KB) are negligible and not a focus of our simulations. Communication time is primarily introduced by various parallelism techniques, such as TP, PP, EP, and DP. TP, PP, and EP typically have fixed communication patterns and volumes, unaffected by cluster size, involving medium-sized messages ranging from tens to hundreds of megabytes. In contrast, the communication scope of DP expands with the increased cluster size, often involving gigabyte-scale collective communications (such as `AllGather` / `ReduceScatter`) across hundreds to thousands of nodes.

3.2.2 Determining the model-level benchmark suite

As a unified simulator designed to provide comprehensive evaluations of end-to-end performance in real-world LLM training scenarios, it's essential to establish a series of model-level benchmarks, referred to as the benchmark suite.

Model and framework selections. Table 2 shows the distribution of model parameters and task scales over the past six months. The models fall into three categories—small, medium, and large—each making up over 20% of the total. More than 94% of LLMs are variants of GPT-3 or LLaMA, with Megatron and DeepSpeed being the dominant frameworks. Although Megatron usage is on the rise, covering all models is impractical. Instead, we include a selection of open-source LLMs of varying sizes.

Parameter selections. We focus on the parameters that impact workload patterns:

- Model Parameters (e.g., hidden_size, num_layers, seq_len, etc.)
- Framework Parameters (e.g., world size, zero level, reduce_bucket_size/allgather_bucket_size, parallelization strategies like TP, PP, DP, and SP)

Based on the statistics in Table 2, we chose a minimal set of benchmarks that cover typical settings without exploring all possible combinations, as detailed in Table 3. Internal reports indicate that model architects frequently adjust framework parameters to optimize performance or precision. Users can also generate custom benchmarks with SimAI-WG as explained in §3.2.1.

We believe this benchmark suite accurately represents the real LLM training workloads commonly used by our customers. Unless otherwise specified, the benchmarks in this suite will be used for evaluation and discussion throughout the rest of the paper.

3.3 Precise Computation Simulation

Precisely simulating existing GPUs. As explained in § 3.2, by running the mocked framework on a single host, we obtain the detailed submodule workflow. For simulations targeting existing GPUs, SimAI-WG outputs the execution times for all submodules on a host with the corresponding GPU. Since each GPU in practical LLM training is dedicated to a single task, we can accurately simulate the entire computation procedure by following the workload file and filling in the execution times for each submodule. As shown in §4.3, the simulation precision ranges from 96.9% to 99.5%.

We maintain an operation database in SimAI-CP that records the execution times for all submodules in the benchmark suite. Table 4 lists common computation operators and their execution times on various GPUs and configurations. For workloads outside the benchmark suite, specific GPU tests are required to gather additional data.

Fine-grained kernel simulation. While submodule-level simulation works in many cases, it may not be suitable for all scenarios, especially when new parallelization strategies or optimizations reorganize or refine kernels for better performance. In such cases, fine-grained simulation is necessary.

Model		Model_hyperparameter				Framework	Parallel Parameter		Ds_config					
Name	Parameter size	Hidden size	Layers	Sequence length	FFN size	Name	TP	PP	Zero level	Reduce bucket size	Allgather bucket size	Prefetch bucket size	Max live parameters	Param persistence threshold
GPT-3 6.7B	6.7B	4096	32	2048	16384	Megatron	1	1	-	-	-	-	-	-
GPT-3 13B	13B	5120	40	2048	20480	Megatron	2	1	-	-	-	-	-	-
GPT-3 175B	175B	12288	96	2048	49152	Megatron	8	8	-	-	-	-	-	-
LLaMA 65B	65.2B	8192	80	4096	28672	Megatron	8	2	-	-	-	-	-	-
Llama3 405B	405B	16384	126	8192	53248	Megatron	8	16	-	-	-	-	-	-
LLaMA 7B	6.7B	4096	32	4096	11008	Deepspeed	1	-	2	1.00E+09	1.00E+09	-	-	-
LLaMA 65B	65.2B	8192	80	4096	28672	Deepspeed	1	-	3	1.00E+09	-	1.00E+09	6.00E+08	1.00E+06

Table 3: The SimAI benchmark suite v1.0

Operations / GPUs_ConfigParams	Embedding	LayerNorm	...	MLP-Linear
A100_Params1	3425(μs)	715(μs)	...	...
A100_Params2	3157(μs)	695(μs)	...	...
...	...	...	...	...

Table 4: SimAI-CP database format

We have designed a module-kernel converter to break down each submodule into smaller kernels, which are then tested on different GPUs. The third column in Table 1 shows an example of kernels used in different submodules. This further enriches the operation database, enabling precise simulation of advanced optimizations and new features.

Supporting unreleased GPUs. As a simulation service for CSPs, there is strong demand for simulating GPUs that have not yet been released. Decision-makers need to evaluate whether purchasing new GPUs is worth the investment, considering factors like budget, host architecture, and network architecture.

Although physical access to unreleased GPUs is not possible, we may have access to core specifications or a specification sheet. An initial approach might be to estimate computation times by scaling known values from existing GPUs, but this often results in significant inaccuracies—up to 25.1% deviation.

Our analysis shows that different kernels have different performance bottlenecks, typically falling into two categories: computation-intensive or memory-bandwidth-intensive. For example, the Gemm kernel, used for updating the KV cache, is memory-bandwidth-intensive, while flash attention is computation-intensive. Detailed classifications are listed in Table 1.

To improve accuracy, we propose using two equations tailored to these kernel types, based on data from our operation database and the Roofline performance model [58]. These equations, based on measured execution times of compute-bound and memory-bound kernels (subscript Comp_Known and Mem_Known, respectively) in the existing environment, allow us to calculate execution times for these kernels on new GPUs or configurations (subscript Comp_New and Mem_New, respectively):

- For computation-intensive kernels:

$$\text{Time}_{\text{Comp_New}} = \frac{\text{FLOPS}_{\text{Comp_New}}}{\text{FLOPS}_{\text{Comp_Known}}} \times \text{Time}_{\text{Comp_Known}}$$

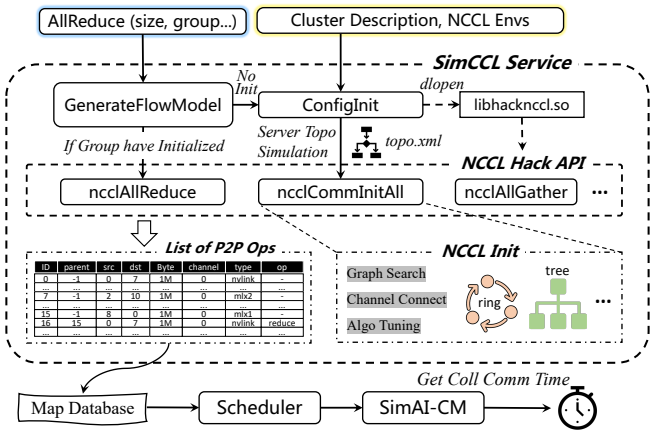

Figure 3: Illustration of how SimAI transforms a collective communication operation to a list of peer-to-peer communication operations.

- For memory-bandwidth-intensive kernels:

$$\text{Time}_{\text{Mem_New}} = \frac{\text{Bandwidth}_{\text{Mem_New}}}{\text{Bandwidth}_{\text{Mem_Known}}} \times \text{Time}_{\text{Mem_Known}}$$

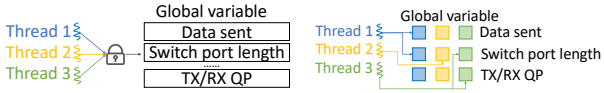
To ensure accurate results, we recommend using GPUs with similar architectures as baselines, rather than generalizing across different vendors. In our experiments, we use the Nvidia A100 as the baseline for calculating kernel execution times on other Nvidia GPUs. We refer to this method as SimAI-CP-Model.

3.4 Precise Simulation of Communication

Training frameworks rely on collective communication libraries, with NCCL [36] being the most widely used in production. NCCL translates collective communication operations (e.g., `AllReduce`, `AllGather`, `ReduceScatter`) into network-level operations (e.g., `Send`, `Receive`). This complex process involves selecting optimal algorithms based on factors like the number of nodes, message size, and configured parameters. Even small mismatches between practical execution and simulation can cause significant deviations in results. To accurately reproduce these algorithm selections, SimAI integrates key procedures from NCCL directly.

Reproducing NCCL's key procedures. SimAI-CM uses a modified version of NCCL, called SimCCL, to intercept

key operations. SimCCL captures the initialization and core interfaces of collective communication to generate peer-to-peer communication lists.



Since simulations typically run on a single host, SimCCL employs a "hijacking" technique to simulate the detailed peer-to-peer operations, similar to the approach discussed in §3.2.1, but at the collective communication level. Here's how SimCCL modifies NCCL's behavior:

1. *NCCL Initialization*: SimCCL intercepts the *NcclCommInitAll* function using the libhacknccl.so in Figure 3, creating virtual communicators for each GPU. This makes the system behave as though it's running in a real multi-GPU cluster, allowing for socket connections and data exchanges during the initialization phase. In the bootstrap and network initialization stages, multiple virtual communicators are created in the same communication group, while only one communicator is actually created.
2. *Topology Discovery*: Instead of searching actual PCIe devices, SimCCL reads a user-specified topology file that defines GPU, NIC, and PCIe switch configurations. Each virtual communicator processes the topology independently and no synchronization is required.
3. *Intra-Host Communication Channel Creation*: SimCCL sets up channels between virtual communicators within the host and stores the details in an isolated information table.
4. *Inter-Host Communication Channel Creation*: SimCCL bypasses gathering information from other GPUs using `AllGather` operations, as it already has information on all hosts. It creates inter-host channels directly.
5. *Collective Communication Transformation*: SimCCL intercepts collective communication calls, reconstructing the operations to trace lower-level communications. It skips actual data transfers and captures inter-GPU communication events, including data size, sender and receiver ranks, and routes, to simulate RDMA-layer behavior.

Supporting all NCCL parameters. SimCCL reflects the communication behavior for the vast majority of NCCL parameters [37]. SimAI-CM has been enhanced to support specific features like PCI × NVLink (PXN). PXN allows a GPU to use a non-local NIC (in the same node) through NVLINK connections for data transfers. This design is typically employed in rail-optimized network topologies, enabling cross-node network traffic to remain on the same rail (single-hop switch) to achieve message aggregation and network traffic optimization. By setting an appropriate NCCL_P2P_PXN_LEVEL, SimCCL can recognize these PXN traffic patterns and reflect them in the output FlowModel. For instance, if rank 1 sends data to rank 8 via rank 0 as an intermediary, the FlowModel represents this as two separate flows: 1->0 and 0->8. Subsequently, SimAI-CM extracts these patterns and simulates them accordingly.

Source file	Description	Lines of code
init.cc	The initialization procedures	364
topo.cc	The topology discovery, search, and synchronization	52
topo.xml	A custmoized topology file	~100
enqueue.cc	Chunk segmentation and task scheduling of collective communication	56

Table 5: Efforts of modifying NCCL.

(a) Multi-thread implementation. (b) Lock-free optimization

Figure 4: Multi-thread implementation and optimization in SimAI.

The SimCCL module is designed to emulate the communication operation processing workflow in NCCL or other CCL. It focuses on transforming collective communication operations into a set of easily interpretable point-to-point communications, without incorporating actual data verification or integrity checks. This approach generally does not affect the end-to-end training process, as it doesn't lead to exceptional workflows due to the absence of real data. In expert parallelism (EP), the gating module's token distribution is influenced by data values. In the simulation, we assume a balanced distribution, which has minimal impact on the simulation results.

Porting efforts. It took us over 10,000 lines of coding efforts for building the blocks shown in Figure 1. The majority of the efforts are intended for repeated use except for the SimCCL module. For example, to support a different version of NCCL or a new CCL, we need to re-adapt the SimCCL module. However, our design does not incur intrusive modifications on the original CCL codebase. As shown in Table 5, only 572 lines of codes (LOC) are essential based on the original NCCL codebase.

3.5 Large Scale Simulation Speedup

At the beginning of SimAI's development, simulating a single iteration of GPT-3 training with 128 GPUs took over 24 hours, compared to just two seconds on a physical GPU cluster. This challenge is similar to AstraSim, which also uses NS-3 for network simulation. To enable simulations of AI infrastructure with more than 1,000 GPUs, we implemented multi-threaded acceleration for SimAI-CM.

Several approaches have been proposed to speed up network simulations. For example, parallel discrete-event simulation (PDES) [10, 18] and UNISON [3] distribute network topologies across multiple logical processes, each running on separate CPU cores. We chose UNISON [3] for three key reasons: (1) It is open-source and builds on NS-3. (2) It automates the partitioning of network topologies and schedules each task to the appropriate thread. (3) It has superior scalability, as demonstrated in their evaluations.

Lock-free sharing of global variables. However, integrating UNISON into SimAI presented a significant challenge. As

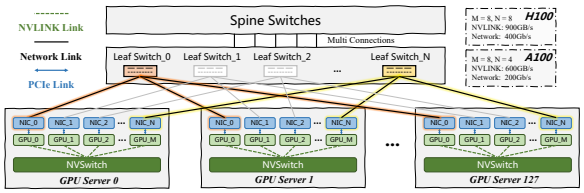


Figure 5: Multi-rail network topology of cluster H100. For cluster A100, two GPUs share a single NIC

the simulation scale increased, a large number of global configurations and contexts were shared across threads. Updating shared data structures with global locks, even atomic ones, caused performance bottlenecks. As shown in Figure 4(a), these global variables track metadata on inter-host communications, such as data volumes between nodes and queue lengths at switches. Atomic operations on these variables slowed down concurrent thread execution.

To solve this, we restructured SimAI to run without global locks. We observed that most global variables were accessed by specific threads. By managing these variables in a thread-independent way, we eliminated the need for global locks. Figure 4(b) illustrates how SimAI separates these variables, enabling lock-free operation. Since each node's simulation runs on a single thread, we isolate global variables in a node ID-indexed table. This allows threads to access the relevant data without locking, reducing the performance issues caused by concurrency. Our lock-free optimization resulted in a 23x speedup compared to the single-thread version and a 15% improvement over the multi-threaded version.

4 Evaluation

In this section, we evaluated SimAI based on the precision and scalability of simulations, using the open-source simulator ASTRA-sim for comparison. Furthermore, results from real-world clusters are used as the ground truth.

4.1 Testbeds and Benchmarks

We utilized two testbeds that share a similar multi-rail, fat-tree, inter-host RoCEv2 network, reminiscent of the Alibaba HPN architecture [44], as illustrated in Figure 5. Cluster A100 consisted of 128 GPU hosts, each equipped with eight NVIDIA A100 GPUs [1] and four Mellanox ConnectX-6 NICs (2×100 Gbps). Cluster H100 included 128 GPU servers, each with eight NVIDIA H100 GPUs [13] and eight Mellanox ConnectX-7 NICs (2×200 Gbps). The intra-host interconnect used NVLink, with bandwidths of 600 GBps for A100 and 900 GBps for H100. Both the simulations and physical clusters shared identical intra-host and inter-host network topologies.

The benchmarks were derived from the SimAI benchmark suite. We enhanced ASTRA-sim with a workload adapter that parsed workload files generated by SimAI-WG. For the physical GPU cluster, the benchmarks involved real LLM tasks that matched the model, framework, and NCCL parameters of the workload files. Our evaluation spanned cluster sizes of 128, 512, and 1024 GPUs. We executed all workloads, but due to space constraints, we only presented performance metrics for three representative models: GPT-3 13B, LLaMA 65B, and GPT-3 175B.

4.2 Precision of Communication Simulation

Figures 6 and 7 showed the performance of intra-host and inter-host collective communication operations across different message sizes (ranging from 8MB to 8GB) and cluster scales. In a multi-rail architecture [59], a collective communication group consists of the ranks on the same rail to minimize the latency across ranks and achieve optimal performance.

From Figure 6, we observed that SimAI was significantly more accurate than ASTRA-sim and closely aligned with the ground truth. The average deviations for SimAI and ASTRA-sim were 3.9% and 74.8% for A100, and 2.3% and 51.7% for H100, respectively. Notably, for `AllGather` and `ReduceScatter` operations on A100, ASTRA-sim achieved its best performance with 8GB messages, yet diverged from reality by over 21.8%, with error rates reaching up to 210.5% under adverse conditions. While there was slight improvement in the `AllGather` operation, ASTRA-sim still showed deviations of 204.3% and 35% for 8MB and 8GB messages, respectively. This discrepancy arose because small message performance is more susceptible to inaccuracies, as we did not simulate the runtime software (e.g., libibverbs) and the NIC pipelines. ASTRA-sim made significant simplifications in practical transmission procedures, leading to poor fidelity, particularly in small message scenarios.

Figure 7 presented the outcomes of collective communication between machines, reinforcing the finding that ASTRA-sim struggled to accurately simulate communications with small message sizes, while SimAI remained consistently close to the ground truth. Furthermore, as communication scaled up, the divergence between ASTRA-sim's simulations and the ground truth widened. For example, in an `AllGather` operation with 8MB messages on a cluster of 128 A100 GPUs, ASTRA-sim exhibited a simulation timing error of 45.9%. This error escalated to 530.2% when the scale increased to 512 GPUs. The results for `AllReduce` and `ReduceScatter` operations displayed similar trends as those observed with the `AllGather` operation.

4.3 Precision of Computation Simulation

We tested the precision of the computation simulation of SimAI and compared it with the ground truth of Nvidia A100, H100, and H20. As shown in Figure 8, SimAI-CP provided highly accurate estimations for all computation kernels. The gaps in total execution times were minimal (0.5%-3.1%) between SimAI-CP and the ground truth. However, for SimAI-CP-Model, the deviations were larger, ranging from 13%-15%, especially for the $Attention-QKV$ and $MLP-linear$ kernels. We recommend that users utilize SimAI-CP-Model only in scenarios where a GPU is not available.

Additionally, we were unable to run all computation kernels

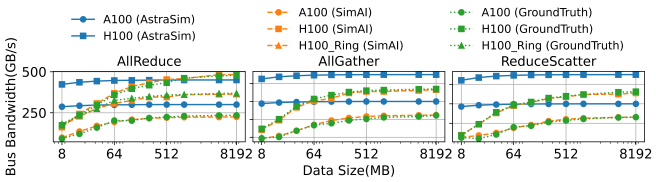

Figure 6: Bus bandwidths of intra-host collective communication operations vary with different message sizes and GPU types. Note that the performance is not related to the cluster scales.

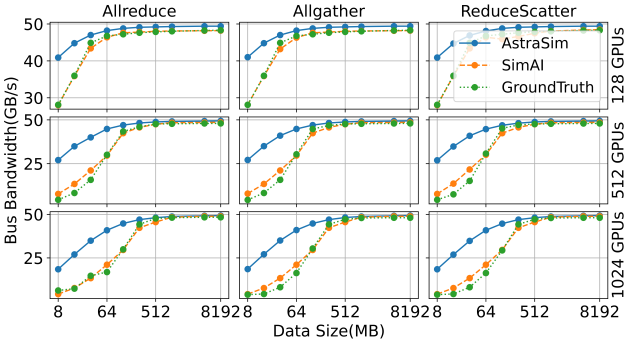

Figure 7: Bus bandwidths of inter-host collective communication operations with different message sizes and cluster scales.

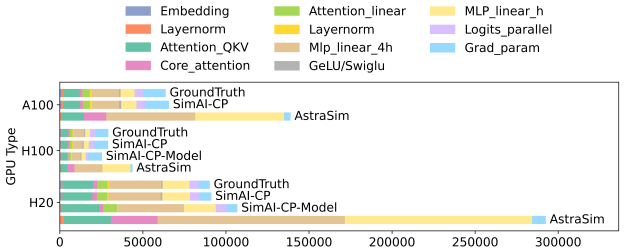

Figure 8: The execution time of the computation kernels of GPT-3 175B on different GPUs.

in SCALE-sim [50], which is used by ASTRA-sim. Only the matrix multiplication kernels ran successfully in SCALE-sim. The numbers for ASTRA-sim in Figure 8 included only these kernels, with execution times multiplied by the effective FLOPS of Nvidia GPUs divided by the effective FLOPS of TPUs. We observed that ASTRA-sim had a significant margin of error in simulating other GPUs, with total errors of 49.8% for H100, 117.9% for A100, and 224% for H20. As discussed in §3.3, the closed internal nature of the GPU computation pipeline caused these methods to fall short in precisely estimating computation times.

Moreover, we attempted to use another computation simulator, Accel-Sim [21], but ultimately failed to run the latest LLM tasks as it only supports PyTorch 0.4, which was released six years ago.

4.4 Precision of End-to-end Simulation

We validated the precision of SimAI in terms of the end-to-end performance on different cluster scales. Figure 9 shows

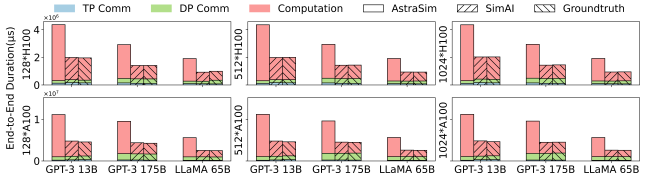

Figure 9: The iteration time of different workloads running on ASTRA-sim, SimAI, and real clusters.

that using SimAI the iteration time of all the workloads is quite close to that of real LLM tasks in real clusters. The gap is less than 4% even under the scale of 1024 GPUs. However, ASTRA-sim is imprecise in the iteration time for both A100 and H100 GPUs. The deviations between SimAI and ground truth are less than 3.9%, 36.1× better than ASTRA-sim. Furthermore, with the increase of the model size (i.e., from GPT-3 13B to GPT-3 175B), the precision of SimAI increases accordingly. It is because the message sizes of the collective communication operations of GPT-3 175B are larger, whose simulation is more precise as validated in §4.2.

5 In Production Benefits

5.1 Guiding Host Design for New GPUs

H100. In 2023, hosts equipped with A100 GPUs were designed to include eight A100 GPUs and four 2×100Gbps NICs (Mellanox-CX6), allowing each GPU to utilize 100Gbps of network bandwidth. With the release of the H100 at GTC 2023 [12], the performance of a single GPU significantly improved. This raises an important question: How much network bandwidth is needed to (1) fully utilize the enhanced performance of the H100 while (2) minimizing overall capital expenditure?

Answering this question is challenging because building multiple engineering prototype hosts with varying configurations is costly and time-consuming. Simply expanding network capacity in proportion to the increase in FLOPS is too simplistic to provide practical guidance.

To inform server design decisions, we utilized SimAI to simulate the performance of a training cluster with 1,024 H100 GPUs and varying network capacities. We tested network equipment configurations of 100Gbps, 200Gbps, and 400Gbps. As shown in Figure 10, the performance of the H100 cluster improves with increased network bandwidth, aligning with our expectations. Upgrading from 200Gbps to 400Gbps results in a 19% performance gain, which remains significant relative to the associated capital expenditure. These simulation results contributed to our final host design decision.

We did not simulate configurations with higher bandwidth than 400Gbps because the PCIe bandwidth of the H100 is 512Gbps (PCIe Gen5×16), indicating that the practical upper limit for a single H100 is approximately 400Gbps.

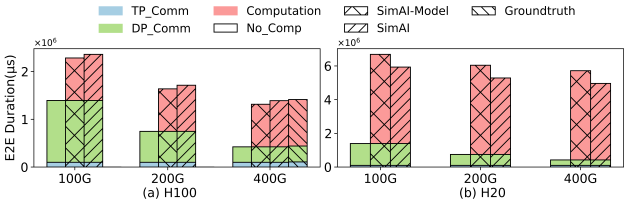

Figure 10: The iteration time of GPT-3 175B with different network bandwidths.

In production, hosts with H100 GPUs are designed to feature eight H100s and eight 2×200Gbps NICs (Mellanox-CX7). Comparatively, the simulation precision using SimAI-CP is over 98%, while SimAI-CP-model shows a precision that is more than 5% lower. Thus, we believe SimAI-CP-model could serve as a viable option when the target GPU type has not yet been released.

H20. With the release of H20 [14] in November 2023, we again used SimAI to guide host design. As shown in Figure 10, since the computational performance of H20 is lower than that of H100, the required network bandwidth also decreases. When network bandwidth is increased from 100Gbps to 200Gbps, end-to-end training performance improves by 11%. However, increasing from 200Gbps to 400Gbps yields only a 6% performance gain.

After thoroughly assessing the investment in networking equipment against performance improvements, we decided to equip each H20 with 200Gbps of network bandwidth (i.e., eight H20 GPUs and eight CX6 NICs per host). Additionally, using SimAI-CP-Model for computation simulation yielded similar conclusions, although with lower precision. This indicates that even for out-of-stock GPU devices where SimAI-CP cannot be used, SimAI can still provide meaningful results.

5.2 Quantifying Scaling-up Benefits

During the training of large language models (LLMs) in production, end-to-end performance is significantly influenced by model and framework parameters, particularly parallelization strategies. Using brute force to explore all parameter combinations in practical training clusters can result in considerable overhead. However, with SimAI, we can automatically identify optimal parameter settings.

In collaboration with the LLM team and the training optimization team, we conducted comprehensive simulations across various parameters. One surprising finding relates to the tensor parallelism (TP) configuration. Conventional wisdom suggests that using more GPUs in a single TP group can reduce the memory and computation load per GPU but may increase communication overhead. Typically, production practices set the TP group size to match the number of GPUs within a host connected via NVSwitch, yet this lacks quantitative analysis.

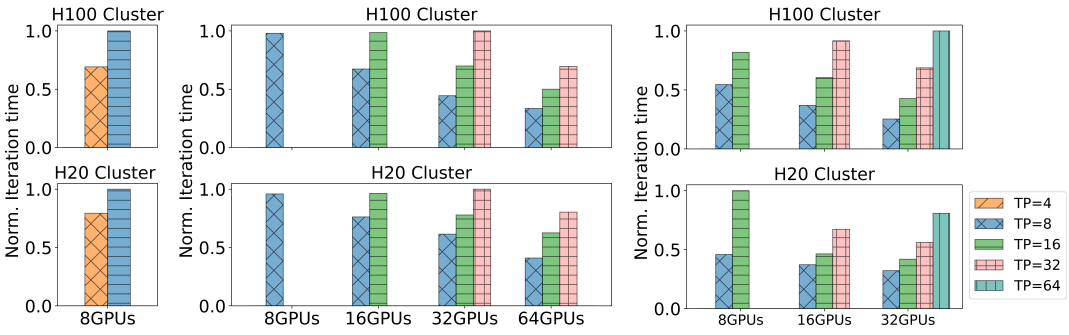
To understand the trade-offs associated with this parameter setting, we performed experiments within SimAI using GPU counts of 8, 16, 32, and 64, all interconnected with NVSwitch. For each configuration, we ran training tasks on three different models, aiming to identify performance trends and optimal setups. Figure 11 illustrates the following key points:

1. In an 8-GPU host, the optimal TP sizes for GPT-3 13B, LLaMA 65B, and GPT-3 175B are 4, 8, and 8, respectively.
2. For any specific TP size, performance improves with more GPUs in the host.
3. Even with a larger GPU count, performance may decline if the TP size is inappropriate.

These findings offer two valuable guidelines for practical LLM training:

1. The TP parameter should accommodate the entire model layer. However, increasing the TP size can reduce end-to-end throughput; a better strategy is to set up more data parallel (DP) groups for parallel training.
2. GPU host design must consider the evolving nature of LLMs. If a layer's maximum size is known, the number of GPUs within a host should be determined accordingly, prioritizing enhanced scale-out performance.

6 Experience



6.1 Evolution of Simulator

Maintaining precision from the very beginning. Initially, we used ASTRA-sim as the foundation for our simulator prototype. Our first challenge was to assess the training performance of emerging large language models (LLMs) like GPT-3 and LLaMA. However, suitable traces or workloads for simulating these models were unavailable, and the built-in DNN [56] workload in ASTRA-sim only provided a rough approximation, leading to significant discrepancies in simulations—ranging from 92.1% to 143.9% across different testbeds. This made it impractical to base our simulation model on the built-in workload.

To ensure accurate LLM workload simulations, we decided to build SimAI-WG from the ground up. We began by analyzing the open-source code of frameworks like Megatron [52] and DeepSpeed [46] to reconstruct their workflows in our simulator. While this improved precision, it had significant drawbacks: (1) It demanded extensive human resources, requiring our engineers to thoroughly understand each framework's components and execution details, which could take months. (2) Keeping our models updated proved challenging due to the rapid evolution of training frameworks, necessitating continuous engineering efforts without any automated update systems.

As a result, we abandoned this approach after our initial internal release and introduced the mock-framework method detailed in this paper. By accurately replicating all sub-modules and their relationships, we achieved substantial improvements in simulation precision.

Measurements from our cluster show that end-to-end training times fluctuate due to factors like network transmission

(a) GPT-3 13B. (b) GPT-3 175B. (c) LLaMA 65B.

Figure 11: Training performance of different hosts and different TP sizes. The x-axis denotes the number of GPUs in a single host. Because of the big model size and limited GPU memory, TP should be larger than 2 for GPT-3 13B and 4 for GPT-3 175B and LLaMA 65B. And we can not run TP = 64 or TP = 48 for GPT-3 175B because the TP size should be the factor of both the number of feedforward neural network (FNN) layers (96) and the world size (1024). We do not let TP exceed the number of GPUs in a single host as the RDMA network is the bottleneck.

and hardware status. Workflow tracking indicates these fluctuations are limited to 5%, with communication time accounting for only 30% of the total. As communication fluctuations contribute negligibly to overall variance, we input averaged parameter values into the SimAI-CP and SimAI-CM components to achieve more consistent performance estimates.

Enhancing computation simulation precision. With a precise workload as input, we still faced a considerable gap between practical execution and simulation results. Early attempts to derive execution times from theoretical models yielded low precision. Additionally, our GPU-acceleration team developed a fine-grained GPU simulator that provides detailed simulation timings for specific operations, but integrating it into our system resulted in excessive simulation latency.

To address this, we focused on the key factors influencing execution times and developed SimAI-CP. Our operation library construction unfolded in two phases. Initially, we extracted key sub-modules from LLMs and measured their execution times, achieving satisfactory precision. However, this approach was limited to specific GPU types. In the second phase, we split sub-modules into finer kernels categorized by computation and memory access intensity. This allowed us to estimate operation times on unavailable GPUs based on performance specifications, enhancing the simulator's applicability.

Improving collective communication simulation precision. We also encountered significant inaccuracies in collective communication simulations when using ASTRA-sim. A critical issue was the inconsistency between the collective communication algorithms in ASTRA-sim and those in NCCL. Even after implementing NCCL's algorithms, results remained unsatisfactory, prompting us to forgo optimizing ASTRA-sim and instead mock key NCCL behaviors from scratch.

The improvements in computation and communication simulations progressed concurrently. When both achieved optimal outcomes, we combined SimAI-CP and SimAI-CM, resulting in a simulator capable of simulating model training with over 93% precision.

Speeding up the entire simulator. After achieving high precision, our final challenge was ensuring efficient simulation execution. Built on NS-3, SimAI underwent a thorough review of existing acceleration solutions, ultimately integrating UNISON [3]. Although we encountered context-access conflicts and crashes during direct operation, implementing global locks to manage inter-thread context access reduced performance. We then analyzed context dependencies and implemented lock-free access, achieving up to a 23× performance improvement, making the simulator practically usable.

6.2 Simulation as a Service

The ultimate goal of developing this simulator is to meet the simulation needs of various teams, transforming it into an easy-to-use simulation service.

Running without GPUs. To achieve high simulation precision, we initially integrated original processing codes (e.g., PyTorch and NCCL) into SimAI. However, this required servers with specific GPUs and environments. To create a genuine simulation service that operates on any host, we decoupled SimAI from the GPU software stack, recognizing and hooking all CUDA-related functions.

Additionally, updating the operation library became an independent procedure. When a new GPU type is available, we conduct a full test of all defined operations on that GPU and update the library as needed.

Task management and scheduling. As a simulation service, SimAI must respond to concurrent simulation requests. To enhance system throughput, we maintain a cluster of hosts. Each request is assigned to an independent simulation task, scheduled on the host with the lightest workload. We use Kubernetes [29] for high scalability.

Parameter tuning. As mentioned in §5, adjusting the TP group size significantly affects end-to-end simulation results. In addition, SimAI allows fine-tuning various parameters influencing model training, including topology, model, and parallel strategy parameters. For example, modifying topology parameters alters the virtual topology within the simulation, impacting network behavior. Adjusting model parameters or parallel strategies affects the computation kernel execution time and communication volume, ultimately impacting training efficiency. Any input supported by SimAI can be fine-tuned to optimize overall performance.

Fine-grained monitoring. For each simulation, we not only generate reports detailing overall training time and throughput but also incorporate extensive monitoring statistics. We developed a front-end system to present the variations of different metrics during simulations.

7 Related work

AI infrastructure simulation. ASTRA-sim [45, 60] is the only comprehensive DNN training simulator designed to simulate the software and hardware co-design stack of distributed training systems. Dally [51] extends ASTRA-sim by incorporating simulations of modern networking hardware (e.g., NVIDIA Quantum [38] and Spectrum switches [39]). SimAI is inspired by ASTRA-sim but introduces significant improvements in workload generation, high-fidelity computation/communication simulation, and scalability.

GPU and computation simulation. Besides the roofline model [58], which provides coarse performance estimates for compute kernels or applications running on a GPU, other works offer instruction-level GPU simulations, such as GPGPU-Sim [2], Accel-Sim [22], SCALE-sim [50], and Gem5-GPU [43]. However, these simulations are very time-consuming for large-scale deployments.

Network simulators and scalability. Existing network simulators fall into three categories: discrete-event simulation (DES) (e.g., NS-3 [47], OMNeT++ [55], OPNET [28]), mathematical model estimation [24, 30, 42], and learning-based approximation (e.g., DeepQueueNet [61], MimicNet [63]). DES simulators offer high-fidelity packet-level simulation, and some works use parallel and distributed event simulation (PDES) approaches [10, 18] to accelerate these simulations. However, PDES often suffers from poor performance and complex configurations. DONS [11] employs a data-oriented design to reduce cache misses in simulation and can be automatically parallelized for intra-host and inter-host scenarios, though it currently lacks support for RDMA transports. UNISON [3] addresses this limitation with fine-grained partitioning and load-adaptive scheduling. SimAI's acceleration is based on UNISON, enhanced with lock-free sharing of global variables. In the future, SimAI will consider simulating network virtualization scenarios to evaluate various virtualization technologies (such as MasQ [15], etc.).

AI benchmarks. The recent surge in machine learning has led to the development of several benchmark suites, but many have limitations in LLM benchmarking. These suites typically include benchmarks for various application domains. MLPerf [31], ML-Bench [27], and AIBench [54] offer comprehensive machine learning benchmarks, while ParaDnn [57], DeepBench [7], and GNNMark [4] focus on deep learning and graph neural networks. However, these benchmarks only cover current applications, which may become obsolete as models evolve rapidly.

Learning-based simulator. Learning-based methods, commonly used as end-to-end performance estimators (EPE) [20, 25, 48, 49, 62, 63], improve scalability by predicting metrics like RTT and packet loss through deep learning models trained on real network traffic. However, these methods require extensive training data, creating significant overhead and limiting their applicability in large-scale simulations. In contrast, SimAI employs discrete event simulators (DES) to mimic the behavior of model training, enabling large-scale simulations and generating valuable data for training learning-based models.

Fault simulation. Fault simulation in model training is a feature worth exploring. Some existing works introduce various types of network faults in the NS-3 simulator to evaluate the impact on the network and the effectiveness of fault tolerance mechanisms [5, 8, 16, 34]. We plan to incorporate simulations for supporting model faults in future work.

8 Conclusion

In this paper, we introduce SimAI, a unified simulator designed to provide accurate and efficient simulations for large language model (LLM) training. SimAI integrates key processes from leading training frameworks and collective communication libraries, achieving an average of 98.1% alignment with real-world results across various test scenarios. To enhance scalability and performance, SimAI incorporates a lock-free, multi-threaded optimization. It is widely utilized in Alibaba Cloud production environments, where it has contributed to the development of valuable operational guidelines.

9 Appendix

9.1 NCCL environment variables

Table 6 lists all the NCCL environment variables that documented in the official website [37] and whether they are supported in the SimAI simulator. We can see besides those we think are unnecessary for simulation, only four environment variables are not yet supported, which are adaptive routing and Infiniband SHArP related features. We leave them as the future work of the communication simulator of SimAI.

Table 6: NCCL environment variables and how they affects the communication patterns

NCCL environment variable	Description	Support?
NCCL_IB_HCA	Specifies which RDMA interfaces to use for communication	Yes
NCCL_IB_TC	Specifies the InfiniBand Traffic Class to use	Yes
NCCL_IB_QPS_PER_CONNECTION	Number of IB queue pairs to use for each connection between two ranks	Yes
NCCL_NVLS_ENABLE	Enable the use of NVLink SHARP (NVLS)	Yes
NCCL_MAX_ NCHANNELS	Sets the maximum number of NCCL channels per GPU	Yes
NCCL_MIN_ NCHANNELS	Sets the minimum number of NCCL channels per GPU	Yes
NCCL_MIN_NRINGS	Sets the minimum number of NCCL rings per GPU	Yes
NCCL_MAX_NRINGS	Sets the maximum number of NCCL rings per GPU	Yes
NCCL_CROSS_NIC	Controls whether NCCL should allow rings/trees to use different NICs, causing inter-node communication to use different NICs on different nodes	Yes
NCCL_NET_GDR_LEVEL	Allows the user to finely control when to use GPU Direct RDMA between a NIC and a GPU	Yes
NCCL_ALGO	Defines which algorithms NCCL will use	Yes
NCCL_PXN_DISABLE	Disable inter-node communication using a non-local NIC, using NVLink and an intermediate GPU	Yes
NCCL_TOPO_FILE	Path to an XML file to load before detecting the topology	Yes
NCCL_P2P_DISABLE	The NCCL_P2P_DISABLE variable disables the peer to peer (P2P) transport, which uses CUDA direct access between GPUs, using NVLink or PCI.	Yes

Continued on next page

Table 6: NCCL environment variables and how they affects the communication patterns (Continued)

NCCL environment variable	Description	Support?
NCCL_P2P_LEVEL	Define the levelwhen to use the peer to peer (P2P) transport between GPUs.	Yes
NCCL_P2P_DIRECT_ DISABLE	Define and set to 1 to disable direct user buffer access across GPUs.	Yes
NCCL_SHM_DISABLE	NCCL will use the network (i.e. InfiniBand or IP sockets) to communicate between the CPU sockets when SHM is disabled.	Unnecessary
NCCL_SOCKET_IFNAME	Specifies which IP interfaces to use for communication.	Unnecessary
NCCL_SOCKET_FAMILY	The NCCL_SOCKET_FAMILY variable allows users to force NCCL to use only IPv4 or IPv6 interface.	Unnecessary
NCCL_SOCKET_ NTHREADS	Specifies the number of CPU helper threads used per network connection for socket transport	Unnecessary
NCCL_NSOCKS_ PERTHREAD	Specifies the number of sockets opened by each helper thread of the socket transport	Unnecessary
NCCL_DEBUG	Controls the debug information that is displayed from NCCL.	Unnecessary
NCCL_BUFFSIZE	Controls the size of the buffer used by NCCL when communicating data between pairs of GPUs.	Yes
NCCL_NTHREADS	Sets the number of CUDA threads per CUDA block	Unnecessary
NCCL_CHECKS_ DISABLE	Disable argument checks on each collective call.	Unnecessary
NCCL_CHECK_ POINTERS	Enables checking of the CUDA memory pointers on each collective call.	Unnecessary
NCCL_LAUNCH_MODE	Controls how NCCL launches CUDA kernels.	Unnecessary
NCCL_IB_DISABLE	Prevents the IB/RoCE transport from being used by NCCL	Yes
NCCL_IB_TIMEOUT	Controls the InfiniBand Verbs Timeout.	Yes
NCCL_IB_RETRY_CNT	Controls the InfiniBand retry count.	Yes
NCCL_IB_GID_INDEX	Defines the Global ID index used in RoCE mode	Yes
NCCL_IB_ADDR_ FAMILY	Defines the IP address family associated to the infiniband GID dynamically selected by NCCL when NCCL_IB_GID_INDEX is left unset.	Unnecessary

Continued on next page

Table 6: NCCL environment variables and how they affects the communication patterns (Continued)

NCCL environment variable	Description	Support?
NCCL_IB_ADDR_RANGE	The NCCL_IB_ADDR_RANGE variable defines the range of valid GIDs dynamically selected by NCCL when NCCL_IB_GID_INDEX is left unset.	Unnecessary
NCCL_IB_ROCE_ VERSION_NUM	Defines the RoCE version associated to the infiniband GID dynamically selected by NCCL when NCCL_IB_GID_INDEX is left unset.	Unnecessary
NCCL_IB_SL	Defines the InfiniBand Service Level.	Unnecessary
NCCL_IB_AR_ THRESHOLD	Threshold above which we send InfiniBand data in a separate message which can leverage adaptive routing.	No
NCCL_IB_CUDA_ SUPPORT	The NCCL_IB_CUDA_SUPPORT variable is used to force or disable the usage of GPU Direct RDMA	Unnecessary
NCCL_IB_SPLIT_ DATA_ON_QPS	This parameter controls how we use the queue pairs when we create more than one,	Yes
NCCL_IB_PCI_ RELAXED_ORDERING	Enable the use of Relaxed Ordering for the IB Verbs transport.	Unnecessary
NCCL_IB_ ADAPTIVE_ROUTING	Enable the use of Adaptive Routing capable data transfers for the IB Verbs transport.	No
NCCL_CUMEM_ENABLE	Use CUDA cuMem* functions to allocate memory in NCCL.	Unnecessary
NCCL_NET	Forces NCCL to use a specific network, for example to make sure NCCL uses an external plugin and doesn't automatically fall back on the internal IB or Socket implementation.	Yes
NCCL_NET_PLUGIN	Set it to a suffix string to choose among multiple NCCL net plugins	Unnecessary
NCCL_NET_ SHARED_BUFFERS	Allows the usage of shared buffers for inter-node point-to-point communication	Yes
NCCL_NET_ SHARED_COMMS	Reuse the same connections in the context of PXN.	Unnecessary
NCCL_PROTO	Defines which protocol NCCL will use.	Yes
NCCL_COLLNET_ ENABLE	Enable the use of the CollNet plugin.	No
NCCL_COLLNET_ NODE_THRESHOLD	A threshold for the number of nodes below which CollNet will not be enabled.	No
NCCL_TOPO_ DUMP_FILE	Path to a file to dump the XML topology to after detection.	Unnecessary

Continued on next page

Table 6: NCCL environment variables and how they affects the communication patterns (Continued)

NCCL environment variable	Description	Support?
NCCL_NVB_DISABLE	Disable intra-node communication through NVLink via an intermediate GPU.	Yes
NCCL_GRAPH_ REGISTER	Enable user buffer registration when NCCL calls are captured by CUDA Graphs.	Unnecessary
NCCL_SET_STACK_SIZE	Set CUDA kernel stack size to the maximum stack size amongst all NCCL kernels.	Unnecessary
NCCL_DMABUF_ ENABLE	Enable GPU Direct RDMA buffer registration using the Linux dma-buf subsystem.	Unnecessary
NCCL_P2P_NET_ CHUNKSIZE	The NCCL_P2P_NET_CHUNKSIZE controls the size of messages sent through the network for ncclSend/ncclRecv operations.	Yes

ByteCheckpoint: A Unified Checkpointing System for Large Foundation Model Development

Abstract

Checkpointing to preserve training states is crucial during the development of Large Foundation Models (LFMs), for training resumption upon various failures or changes in GPU resources and parallelism configurations. In addition, saved checkpoints are dispatched to evaluation tasks or transferred across different training stages (e.g., from pre-training to post-training). All these scenarios require resharding distributed checkpoints from one parallelism to another. In production environments, different LFMs are trained with various frameworks and storage backends, depending on model sizes and training scales. A high-performance checkpointing system is needed to enable efficient checkpoint management at scale throughout the lifecycle of LFM development.

We introduce ByteCheckpoint, an industrial-grade checkpointing system for large-scale LFM training. ByteCheckpoint features: a parallelism-agnostic checkpoint representation that enables efficient load-time checkpoint resharding; a generic checkpoint saving/loading workflow to accommodate multiple training frameworks and support different storage backends; full-stack optimizations to ensure high I/O efficiency and scalability; a suite of monitoring tools to streamline large-scale performance analysis and bottleneck detection. Compared to existing open-source checkpointing systems [52, 58], ByteCheckpoint significantly reduces runtime checkpoint stalls, achieving an average reduction of 54.20×. For saving and loading times, ByteCheckpoint achieves improvements of up to 9.96× and 8.80×, respectively.

1 Introduction

Large Foundation Models (LFMs) in language [5, 13, 33, 43], vision [40, 44], audio [59] and other modalities are revolutionizing today's AI landscape, spawning a variety of downstream applications such as conversational agents [49, 56], coding assistants [51], painting tools [53], and video [55] generators.

Unlike traditional deep learning model training, LFM training is significantly more complex. It has multiple training stages, including pre-training [9, 25] and post-training [38, 46, 67, 70]. Furthermore, evaluation tasks are integrated into these stages to effectively assess model quality. Beyond the complexity, the development of LFMs is notably resource-intensive and time-consuming, largely due to immense model sizes and massive training datasets (e.g., DeepSeek-V3 comprises 671 billion total parameters, and is pre-trained on 14.8 trillion tokens) [13, 33]. The scale of LFM training can even be up to running on 12,288 GPUs [25].

As a fundamental technique for preserving training states, checkpointing captures snapshots of these states and stores them in persistent storage to facilitate training resuming. Additionally, during LFM training, checkpoints are required for concurrent evaluation tasks that continually assess model quality. Another use-case of checkpoints is dispatching those snapshots from pre-training to downstream post-training tasks, such as Supervised Fine-Tuning (SFT) or reinforcement learning. The complex development pipeline, enormous scale, and prolonged duration of LFM training present significant challenges to designing a highly efficient checkpointing system.

First, efficient and unified checkpoint management is necessary throughout the life cycle of real-world LFM development. During training, checkpoint resharding is commonly required. This procedure transforms saved distributed checkpoints so they can be correctly loaded into a new parallelism configuration that differs from the one used for their creation. In pre-training, variations in parallelism occur when problematic machines are removed, the available GPU quota fluctuates [29, 72], or training configurations (e.g., context length) and system optimization techniques [25] (e.g., kernel fusion, computation and communication overlapping) are adjusted. Across different stages and tasks, parallelism varies according to the scales of resources and datasets in use. Highly efficient checkpoint resharding is needed to minimize extra overhead and maximize the end-to-end Effective Training Time Ratio (ETTR, calculated as the ratio between the productive training time and the wallclock time of a job) [27]. Moreover, on

*Equal contribution.

an industrial AI platform, LFM training jobs are initiated by various internal users or cloud customers who may choose different training frameworks (e.g., Megatron-LM [47], PyTorch FSDP [73], DDP [31], and others [63]) and select storage backends such as local disk, Hadoop Distributed File System (HDFS), or Network-Attached Storage (NAS) for storing checkpoints according to job characteristics and personal preferences. Crafting customized checkpointing modules and workflows to accommodate these ad-hoc implementations complicates system development and substantially increases maintenance costs. It is vital to provide generic workflows for different training frameworks and storage backends.

Second, Substantial I/O operations are involved in the checkpointing system for saving distributed checkpoints into persistent storage and loading them back for model training under various scenarios. To minimize I/O blocking time and promptly save training states to persistent storage, it is crucial to expedite the I/O workloads. In addition, ensuring the scalability of the checkpointing system is also essential since modern LFM training typically operates at large scales.

Existing checkpointing systems [14, 19, 35, 66] assume consistent parallelism, and fail to address the demands for checkpoint resharding. Although some efforts from the open-source community are devoted to developing checkpointing systems capable of resharding, they have several limitations. Some perform resharding in an inefficient offline manner [32], while others only support specific training frameworks and storage backends [52, 58]. Moreover, without customized optimizations and deployment experience, they suffer from sub-optimal I/O performance and lack the scalability to support large-scale LFM training in real-world production.

This paper presents the design, implementation, and deployment experience of ByteCheckpoint, a checkpointing system crafted for LFM development. ByteCheckpoint incorporates a unified architecture (Sec. 3.1) featuring an automatic *resharding-on-loading* mechanism for distributed checkpoints (load-time checkpoint resharding) and supports multiple training frameworks and storage backends. It integrates full-stack I/O performance and scalability optimization techniques.

▷ ByteCheckpoint's checkpoint representation is decoupled from the specific parallelism adopted during training (Sec. 3.2), enabling efficient load-time checkpoint resharding. For model and optimizer state representation, we separate each tensor shard's metadata from its numerical values and consolidate all the metadata into one global file. The metadata of a tensor shard includes its basic runtime, position, and storage information. For the representation of dataloader states, we divide them into *replicated* and *sharded* states, storing sharded states in individual files while the replicated ones are only saved by the training worker whose global rank is 0.

▷ ByteCheckpoint offers a generic workflow for LFM training tasks employing different training frameworks and various storage backends (Sec. 3.3). It tailors a planner for each framework to generate unified saving/loading plans. These plans

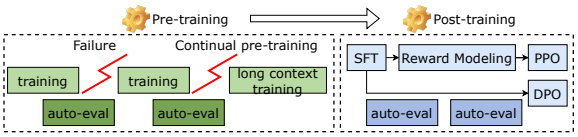

Figure 1: An overview of the training pipeline of LFM.

are then passed to a framework and storage backend agnostic engine to execute the I/O tasks. ByteCheckpoint's workflow utilizes this isolation in architecture, executing the same saving/loading steps for users with different training frameworks and storage backends.

▷ ByteCheckpoint implements multiple optimizations (Sec. 4) to enhance I/O performance, including balanced and zero-redundancy plan generation, fully asynchronous execution pipelines, and efficient irregular tensor processing. We share our engineering experience in optimizing storage systems to support massive I/O requests, optimizing collective communications to guarantee stability, and designing monitoring and visualization tools for performance analysis and bottleneck detection (Sec. 5). This full-stack approach scales ByteCheckpoint to support the training of a 405B LFM on 8,960 GPUs while still maintaining high efficiency.

ByteCheckpoint is deployed on our industrial AI platform with tens of thousands of GPUs for various LFM training tasks, including pre-training and post-training of language models, multi-modal understanding, and generation models (e.g., for video generation). ByteCheckpoint demonstrates significant advantages over existing open-source checkpointing systems, including PyTorch DCP [58] and Megatron Distributed Checkpoint [52] (MCP). Compared to the baselines, ByteCheckpoint achieves improvements ranging from 12.13× to 161.50× in terms of checkpoint stalls reduction, making the end-to-end checkpoint saving and loading procedures 6.05× and 3.88× faster on average, respectively.

2 Background and Motivation

2.1 LFM development

Production pipeline. As depicted in Fig. 1, the development of LFM comprises pre-training and post-training stages. During the initial pre-training phase, The LFM is iteratively trained on extensive data collected from multiple sources to absorb knowledge about the world. Subsequently, continual pre-training is employed to enhance the foundation model's capabilities. For instance, the pre-training of large language models (LLMs) typically involves long-context continual training to gradually increase the supported context length of LLMs. Post-training is employed to align the pre-trained model with human feedback or enhance the model's reasoning capabilities [18, 57]. Various task-specific labeled datasets (e.g., multilingual, code, math, reasoning, etc.) are involved in fine-tuning the LFMs, followed by reinforcement learning,

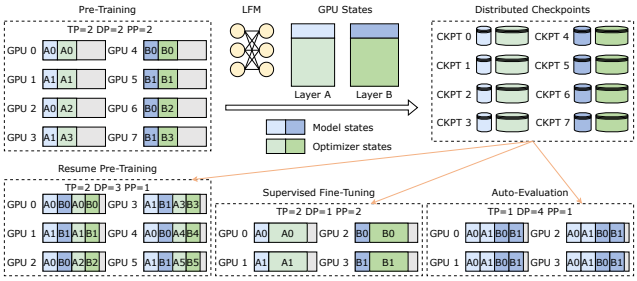

Figure 2: Checkpoint resharding scenarios in LFM training. We only show GPU states for clarity of the figure.

typically including the reward modeling and then performing Proximal Policy Optimization [45] (PPO), or directly conducting Direct Preference Optimization [41] (DPO). Due to the reduced size of these datasets, relatively fewer GPUs are involved in post-training. Automatic evaluation [14, 22] is periodically triggered to get intermediate model checkpoints and assess the quality with diverse criteria.

Checkpointing. Training states of LFM training jobs to be checkpointed include GPU and CPU states. GPU states are learnable parameters in the LFM model and optimizer information (e.g., the float32 precision replica of the model and its momentum and variance in Adam [26]). In state-of-the-art parallel training [28], these states are sharded and placed across multiple GPUs. CPU states include dataloader module, Random Number Generator (RNG) state, global training step number, and learning-rate scheduler, all stored in CPU memory. Our dataloader module incorporates a token buffer to cache input samples of varying lengths read from the data sources; when the number of accumulated tokens reaches the context window size [13, 25, 69, 71], the dataloader assembles all cached samples into a batch (micro-batch). Due to the volatile nature of GPU and CPU memory, these training states should be periodically saved into persistent storage to tolerate any faults and prepare for evaluation tasks.

Storage backends. In production environments, separate distributed file systems (such as Tectonic [39] for Llama 3.1 training [13]) are employed to store checkpoints [14, 20] for formal tasks. Given that various hardware failures and software bugs are inevitable during training [13, 22, 25], storing checkpoints at different global training steps is necessary to safeguard training. Distributed file systems (e.g., HDFS, NAS) provide adequate storage capacity to accommodate multiple checkpoints of large models.

2.2 Checkpoint Resharding Scenarios

During the life cycle of LFM development, checkpoint resharding is consistently required due to changes in parallelism under different scenarios (Fig. 2):

(1) Training Resumption. GPU quota allocated for an LFM training job can vary due to the removal of faulty machines [22, 25], adding new machines released from completed tasks, or running on tidal resources [12, 29, 68, 72]. It is often necessary to adjust training parallelism in response to the resource changes, to maximize resource utilization. Additionally, at the onset of large-scale pre-training, AI engineers often need to experiment with various model configurations and optimization techniques [25], since conclusions from small-scale profiling or simulations do not always translate to optimal performance in large-scale training. In this phase, adjusting parallelism configurations is common, resulting in frequent training resumption. Moreover, long-context training changes the context length, which also requires GPU quota or parallelism adjustment. As shown in the example in Fig. 2, 8 distributed checkpoint files are initially stored, then loaded into 6 training workers upon resuming.

(2) Cross-Stage Transition. When entering post-training , the number of GPUs involved typically decreases due to reduced training data in the latter. Checkpoints saved from pre-training are frequently resharded to align with the specific workloads of each post-training task. As depicted in Fig. 2, only 4 GPUs are involved for a fine-tuning task in the post-training stage, so the checkpoints are resharded accordingly.

(3) Evaluation. Evaluation tasks in both stages require loading model checkpoints and conducting inference on separate resources; their parallelism needs to be adjusted to align with assigned GPUs used for specific datasets. Fig. 2 shows a 4-GPU eval task reshards model checkpoints from pre-training.

We collected the number of times of checkpoint resharding demands on our AI platform (training text, image, and video generation models) over the past six months and identified 1,870 instances of checkpoint resharding during pre-training resumption, 13,080 due to cross-stage reconfiguration, and 19,844 for running evaluation tasks.

2.3 LFM Checkpointing Requirements

Load-time checkpoint resharding. As a critical step in the life cycle of LFM development, the efficiency of checkpoint resharding is vital to minimize extra overheads. In our AI platform, the previous common practice is to develop offline checkpoint resharding scripts and adapt the scripts whenever a new checkpoint resharding scenario arises. This approach is inefficient and labor-intensive (see Appendix A for further details). In addition to the development costs, running resharding scripts leads to a substantial waste of GPU time and resources. Table 1 presents the cost of executing resharding jobs in various scenarios. Before training can resume or new evaluation tasks can begin, independent jobs that execute the resharding scripts must be submitted in advance. These jobs download checkpoints from the storage systems, reshard distributed checkpoints to given parallelism configurations and upload new checkpoints back to the storage systems. The targeted training or evaluation jobs cannot be executed until the completion of resharding jobs, resulting in prolonged pend-

Table 1: Average completion time of executing offline resharding jobs under different scenarios.

Training Resumption	Cross-Stage Transition	Evaluation
1870.38s	650.34s	593.21s

Table 2: Top three training frameworks used on our platform

Framework	Pre-training	Post-training	Average #GPUs Per Job
Megatron-LM	13727	68621	301
FSDP	16842	†	25
DDP	25393	†	6

ing time. Moreover, since checkpoints created by resharding scripts are coupled with specific parallelism, they cannot be reused freely, which in turn increases the storage overhead.

Instead of executing scripts in independent jobs for checkpoint resharding, *load-time checkpoint resharding* [58] (also known as online resharding) is preferred for LFM training. It automatically identifies and retrieves necessary data from existing distributed checkpoints during the loading procedure. To achieve this, the storage representation of checkpoints should be designed to be independent of specific parallelism.

Multiple frameworks and storage backends. On our AI platform, a wide range of training frameworks are used, such as Megatron-LM [47], DDP [31], FSDP [73], veScale [25,63], etc. Table 2 lists the top three preferred training frameworks on our platform, based on six months of trace analysis. Users typically adopt Megatron-LM [47] for training large language foundation models. FSDP [73] is preferred for training tasks involving text-to-video or text-to-speech models, and DDP [31] is commonly used to train image encoder components of multimodal foundation models or for routine algorithm testing. In addition, users can choose from various storage backends for checkpoint persistence depending on the scenario, ranging from local disks for debugging to HDFS or NAS for formal training tasks. Each training framework comes with its own checkpoint module, file format, and ad-hoc implementation of the save/load logic. However, these modules lack critical features for production, such as load-time resharding, asynchronous checkpointing, and support for remote persistent storage. Integrating these features for each framework's checkpoint module and tailoring optimized implementations requires repeated engineering efforts. This leads to inconsistent checkpointing interfaces across training frameworks and storage backends, complicating the codebase. Moreover, the maintenance of diverse checkpoint file formats from different frameworks adds to the complexity of implementing checkpoint transfer logic across training stages and deploying models for evaluation and inference tasks. Therefore, it is vital to provide generic workflows for different training frameworks and storage backends.

Efficient and scalable I/O performance. Mainstream LFMs

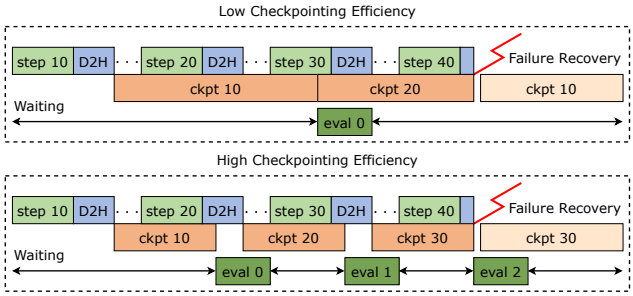

Figure 3: Checkpointing efficiency impacts failure recovery and evaluation tasks. D2H denotes the Device-to-Host copy.

feature extensive model sizes, reaching hundreds of billions of parameters [13]. Consequently, the size of training states also increases significantly, imposing substantial overhead for checkpoint saving and loading. By analyzing our previous LFM training jobs, we observe that the average end-to-end time required to save checkpoints of a GPT 175B model, trained on 4096 GPUs, to HDFS can be 200 seconds. This duration substantially exceeds the time required for a single training iteration. Even though this time-consuming procedure can be partially removed from the critical path of model training by adopting asynchronous checkpointing [25, 34, 35, 65], expediting end-to-end checkpointing remains crucial to minimize training progress loss [66] caused by inevitable frequent failures in large-scale training [25]. As depicted in Fig. 3, although checkpointing overlaps with training, its rapid completion allows more intermediate checkpoints to be stored before a failure occurs, enabling resumption from more recent states and improving ETTR. Besides, evaluation tasks are triggered during training, and intermediate checkpoints are periodically pulled for these tasks. Faster checkpointing ensures their timely execution, reducing blocking time due to preparing these checkpoints in remote persistent storage.

Scaling the checkpointing system while maintaining the high I/O performance is non-trivial. Sub-optimal and risky designs, which are hard to detect in small-scale settings, can lead to severe performance bottlenecks or even catastrophic job failures in large-scale training. For example, massive read/write requests for checkpoint files from the training cluster to the storage systems (e.g., HDFS) can overload the master node, causing delays in file metadata operations. Additionally, naive implementations of collective communications, such as integrity-checking barriers, introduce substantial initialization and synchronization overheads. These overheads can even result in communication timeouts, ultimately causing the entire training job to fail. Furthermore, as training scales up, efficiently analyzing system performance and detecting errors among training and I/O workers across multiple machines becomes increasingly challenging.

Existing checkpointing systems, such as CheckFreq [35], Check-N-Run [14], and Gemini [66], operate under the assumption of consistent parallelism and do not address the

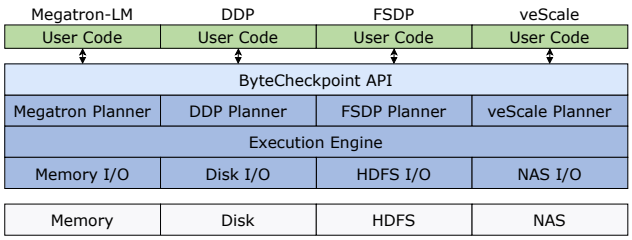

Figure 4: Architecture of ByteCheckpoint.

Loading and saving distributed checkpoints with ByteCheckpoint

```
# Import the ByteCheckpoint library
import bytecheckpoint
# Prepare checkpoint states
ckpt_states = {"model": model, "optimizer": optimizer, "dataloader": dataloader, "extra_states": extra_states}
# Load checkpoints of Megatron-LM from HDFS with overlapping mode
bytecheckpoint.load('hdfs://demo_0/checkpoints', ckpt_states, framework='megatron', overlap_loading=True)
# Train model for several steps.
# Save checkpoints of Megatron-LM to HDFS asynchronously
bytecheckpoint.save('hdfs://demo_0/checkpoints', ckpt_states, framework='megatron', async_checkpoint=True)
```

need for checkpoint resharding. DCP [58] and MCP [58] incorporate checkpoint resharding capabilities but are limited in terms of supported parallelism strategies and training frameworks, I/O performance, and scalability. A comprehensive discussion with related works is provided in Appendix F. In ByteCheckpoint, we design decoupled storage representation for efficient load-time checkpoint resharding, propose generic saving/loading workflows to support multiple frameworks and storage backends, integrate full-stack optimizations to enhance I/O performance and share our experience in scaling the checkpointing system to support real-world LFM training.

3 System Design

Based on the above observations, we design ByteCheckpoint according to the following key principles:
(1) Decoupling. The checkpoint representation remains independent of specific runtime parallelism. Interfaces of training frameworks and storage backends are separated from the core execution engine, ensuring robust extensibility.
(2) User-friendliness. The APIs should be concise, making it seamless for AI researchers and engineers to integrate them into their code and runtime environments.

3.1 Unified Architecture

The architecture of ByteCheckpoint is illustrated in Fig. 4. Each component is introduced in detail as follows:
API. ByteCheckpoint's APIs (`bytecheckpoint.save` and `bytecheckpoint.load`) provide a unified entrypoint for user code across various training frameworks. For instance, to save checkpoints, users first prepare the corresponding training states, checkpoint path, framework name, and performance-related options, then call `bytecheckpoint.save`. This high-level entrypoint abstracts underlying system complexities, such as sharding specification, save/reshard plan generation, and I/O operations.
Planner. The Planner serves as the interface for training frameworks. It receives arguments (training states, checkpoint path, etc.) from the API layer, creates ShardMeta (Sec. 3.2) for each tensor shard based on the worker's rank and framework-specific sharding specification such as *Megatron ShardedTensor* or *FSDP DTensor*, and determines the tensors and other states to save/load for each worker. Each worker leverages the Planner to initially create local plans and subsequently collaborates to create global plans. We implement a tailored planner for each training framework to extract information from these specifications and generate plans.
Execution Engine. The Engine, running on each training worker, executes the saving/loading plans generated by the Planner when the respective API is called. It analyzes the given checkpoint path to determine the appropriate storage backend, then interacts with the Storage I/O layer to execute the actual I/O tasks specified in the plans.
Storage I/O. Analogous to the design of the Planner layer, the Storage I/O layer encapsulates different storage backends and manages backend-specific read/write operations and optimizations. The interface between the Engine layer and the Storage I/O layer remains unified across different storage backends, facilitating the seamless integration of new storage backends. ByteCheckpoint supports multiple storage options, including in-memory checkpoint storage [66], local disk storage, and remote storage systems.

Fig. 5 illustrates a typical use case of ByteCheckpoint. Initially, users define a dictionary specifying the states to be saved or loaded, encompassing the model, optimizer, dataloader, and additional states. At the outset of training resumption, stage transition, or evaluation, `bytecheckpoint.load` is invoked to load saved checkpoints. Checkpoint resharding occurs automatically during loading when there are changes in parallelism. During training, `bytecheckpoint.save` is periodically invoked to save checkpoints.

3.2 Decoupled Checkpoint Representation

To achieve parallelism-agnostic checkpointing to enable automatic load-time resharding, we develop a formal specification of model and optimizer tensors in distributed training. Our design conforms to the Distributed Tensor and Checkpoint concepts in the *PyTorch Distributed* library [31].
Model and optimizer states. Each tensor is uniquely identified by a "fully qualified name" (FQN) and has a global shape, representing its original shape before sharding. Tensors can be either sharded or replicated across ranks (aka training workers). For sharded tensors, the specific shard held by a worker is determined by three factors: the parallelism (e.g., tensor parallelism) applied to the tensor, the sharding dimension, and

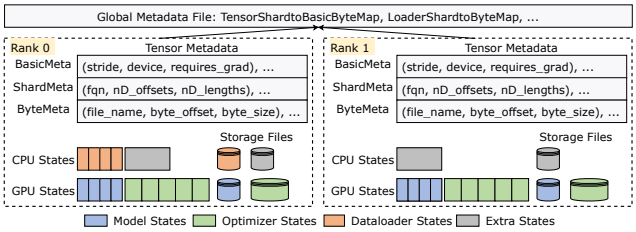

Figure 6: Checkpoint representation in ByteCheckpoint. The pipeline parallelism is applied in this example.

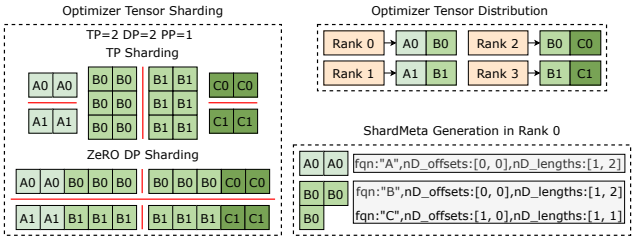

Figure 7: ShardMeta of irregular tensors in optimizer states.

the group rank within the corresponding parallelism group. Based on a tensor's FQN, global shape, and sharding specification, ByteCheckpoint creates the tensor shard metadata (ShardMeta) for each rank, which is utilized in checkpoint storage to represent the tensor shard, independent of parallelism. More precisely, ShardMeta for a tensor shard is an index tuple *(fqn, nD_offsets, nD_lengths)*, where *nD_offsets* and *nD_lengths* indicate the local shard's offsets and lengths along the original multi-dimensional axes in its global shape.

Dataloader and extra states. The dataloader states can be categorized into two types: *replicated* states and *sharded* states. Replicated states include the number of data reading workers, paths to source datasets, and sampling ratios, and are identical across all I/O workers (subprocesses) in different ranks. Sharded states are unique to each I/O worker, including the token buffer and data retrieval offsets for different data sources. In ByteCheckpoint, sharded states are saved in individual files, while replicated states are saved only by the I/O worker in rank 0. This reduces overall size of dataloader states to be saved and facilitates dataloader resharding when parallelism configurations change since the separation of data states into distinct files simplifies states merging and redistributing according to the new parallelism. For other extra states such as the RNG state, we pack and serialize them into one compact byte object before dumping them into storage.

Checkpoint representation. Fig. 6 illustrates the checkpoint representation in ByteCheckpoint. Distributed checkpoints comprise a *global metadata file* and multiple *storage files*. Each rank generates three distinct files: a model state file, an optimizer state file, and an extra state file. The Dataloader state file is generated only by training workers whose ranks for all parallelism degrees, except for DP degrees, are 0. For tensor shards in model and optimizer states, their *Metadata* consists of three parts: *BasicMeta*, which records essential information of individual tensor shards such as stride and device, critical for recovering the runtime state; *ShardMeta*, as previously introduced, recording relative position information of shards in the complete tensor; *ByteMeta*, which specifies the byte start offset and length of each tensor shard within the storage file. All tensor metadata are consolidated into the global metadata file, and a mapping, termed *TensorShardtoBasicByteMap*, is established between saved tensor shards and storage files based on the ShardMeta, BasicMeta, and ByteMeta of each tensor shard, ensuring accurate data retrieval. The global metadata file also includes a *LoaderShardtoByteMap*, which records the file index information of sharded states in each dataloader. All storage files and the global metadata file are stored in the specified storage backend designated by the checkpoint path.

Decomposing irregular tensors. We define irregular tensors as those which, when flattened before sharding, cannot be reshaped back to their original dimensions. These tensors typically arise when applying the Zero Redundancy Optimizer (ZeRO) [42], as implemented in Megatron-LM ZeRO2 and FSDP ZeRO3 [73]. In these implementations, optimizer states within a DP group are flattened, concatenated, and sharded. Consequently, the resulting 1D tensor slices often cannot be directly represented using n-dimensional shapes and offsets. Fig. 7 illustrates an example of irregular tensor sharding: Unlike tensors A and C, tensor B, with an original shape of (3, 2), is evenly split into two shards. Each shard, containing three elements, cannot be directly represented as a two-dimensional shape with corresponding offsets. One intuitive approach to addressing the challenge of irregular tensor shards is to merge all tensor shards into complete tensors before saving checkpoints, thereby simplifying the generation of ShardMeta. For example, to eliminate potential irregular tensors in DCP [58], FSDP performs synchronous all-gather communication operations, interleaved with D2H copy operations for each tensor shard, regardless of whether the shard is irregularly sharded. However, this approach incurs significant communication overhead and requires frequent synchronization between GPU and CPU, substantially impeding efficiency.

To mitigate the overhead associated with merging tensor shards, ByteCheckpoint employs a tensor decomposition strategy for managing irregular tensor shards. Specifically, ByteCheckpoint decomposes an irregular tensor into a series of regular ones, representing each with index tuples. For example, consider the irregular tensor shard of tensor B with three elements on rank 0 in Fig. 7. ByteCheckpoint decomposes this shard into two regular tensors that can be directly represented by $nD_offsets$ and *nD_lengths*. This approach allows ByteCheckpoint to use multiple *ShardMeta* entries to represent a single irregular tensor shard. Although such decomposition slightly increases the metadata size and adds steps to the loading procedure, as reconstructing the target tensor may require looking up multiple smaller segments of

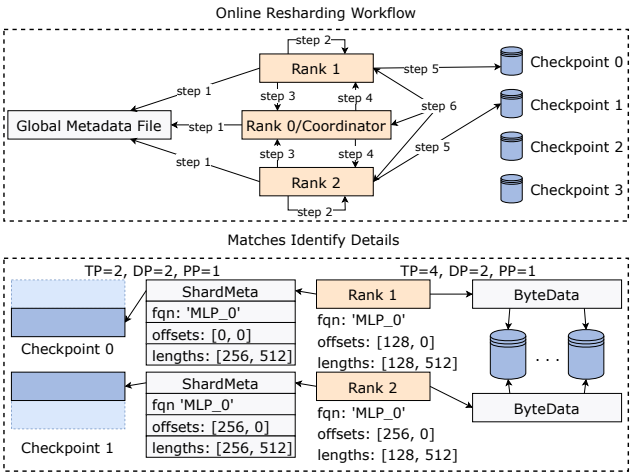

Figure 8: Load-time tensor resharding workflow. Checkpoint k denotes the checkpoint saved by a previous live worker k.

irregular shards, it avoids the costly communication of tensor shards without extra blocking time during saving.

3.3 Checkpoint Resharding Workflow

ByteCheckpoint implements a generic workflow for saving and loading, automatically resharding checkpoints during the loading process. Leveraging the independence between the Engine Layer, Planner Layer, and Storage I/O Layer, we can execute consistent saving and loading steps across different training frameworks and storage backends. We take tensor resharding as an example in Fig. 8, emphasizing how our checkpoint representation enables flexible load-time resharding. The process for checkpoint saving and loading without resharding follows a similar procedure.

Step 1. To initiate load-time checkpoint resharding, each rank invokes the `bytecheckpoint.load()` API, specifying the checkpoint path along with the model/optimizer to be restored. All ranks then load the global metadata file from the path.

Step 2. For each tensor shard in the given model/optimizer, each rank queries the TensorShardToBasicByteMap within the global metadata file, identifying matching segments between the saved tensor shards and the sharding specification of new shards. After identifying these matches, the planner constructs a local load plan, which includes BasicMeta and ByteMeta tailored to the specific shard. This identification mechanism is illustrated at the bottom of Fig. 8.

Step 3. The coordinator planner, typically residing in rank 0, initiates a gather operation to aggregate loading plans from all ranks. It then optimizes each local plan by applying the redundant elimination optimization (Sec. 4.1) to distribute tensor shard loading workloads for reduced completion time.

Step 4. The coordinator initiates a scatter operation to distribute the finalized loading plan. Each rank then receives its final loading plan from the coordinator.

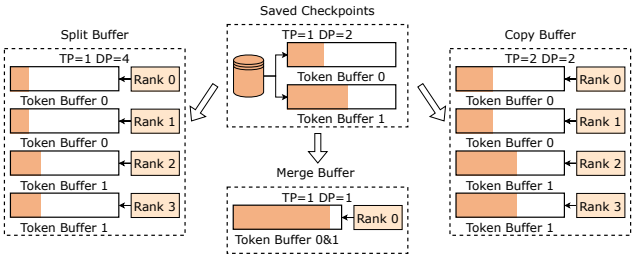

Figure 9: Examples of dataloader resharding. Sharded states such as cumulative token buffers are resharded according to the changes of parallelism configurations. We do not depict data retrieval offsets for clarity of the figure.

Step 5. The execution engine on each rank selects the storage backend wrapper in the Storage I/O layer based on the checkpoint path and then executes the loading pipeline (Sec. 4.2).

Step 6. Upon completion of the loading pipeline, each rank utilizes the optimized asynchronous collective barrier primitive ensuring the atomicity of the distributed loading. Further details can be found in Appendix B.

Dataloader resharding. Similar to tensor resharding in Fig 8, ByteCheckpoint reshards the dataloader by querying the LoaderShardtoByteMap. The illustration of dataloader resharding is depicted in Fig. 9. When parallelism configuration changes, for the dataloader checkpoints, common items in the dataloader checkpoints can be loaded directly, whereas unique items such as accumulative token buffers and data retrieval offsets require resharding. Specifically, when the DP degree size remains constant while other parallel degrees are altered (TP degree changes in the example of Fig. 9), the token buffers should be copied to the destination workers for bitwise-correct resuming. when there is a change in the DP degree size, the token buffers must be either split or merged accordingly to ensure that the resumed dataloaders do not discard cached data and do not retrain data that has already been sampled and fed. Thanks to the split storage strategy designed for the dataloader module, ByteCheckpoint can precisely identify the unique items that require resharding and process them efficiently.

4 Performance Optimization

We now elaborate on ByteCheckpoint's performance optimization techniques, focusing on minimizing the overhead associated with checkpoint saving and loading.

4.1 Optimized Plan Generation

Balancing saving workload. In training scenarios employing data parallelism (DP), model states are replicated across all DP groups, resulting in duplicated model states. Existing checkpointing systems [52, 58] address this issue by designat-

ing the first DP group to save all model states. However, this approach leads to workload imbalance, potentially causing training workers in the first DP group to become stragglers. To address this challenge, we implement a workload-balancing deduplication mechanism during the planning procedure, utilizing a Worst-Fit algorithm. Specifically, the coordinator planner distributes the saving workload based on the size of each tensor shard, assigning the current tensor shard to the rank with the smallest cumulative tensor shard size. This approach ensures a more equitable distribution of the saving workload across ranks. This balances workloads across all workers, improving saving efficiency.

Eliminating redundant loading. When loading checkpoints into parallelism configurations that include data parallelism, ByteCheckpoint optimizes the process by eliminating repetitive tensor reading across DP groups, effectively combining storage file reading with tensor transferring. A crucial observation is that idle inter-GPU bandwidth can be utilized to concurrently transfer loaded tensors to peer GPUs during the file reading process. As illustrated in Fig. 10, tensor reading workloads across DP groups are evenly distributed among training workers during the planning phase, thereby avoiding duplication of reads. Subsequently, I/O threads are launched to read the allocated tensor shards. Concurrently, in the main thread, shards read into CPU memory are first copied into GPU memory and then transferred to other workers that require them, utilizing all-to-all collective communication.

Plan and metadata cache. In large-scale training, the execution of the planning procedure can introduce significant communication overhead, particularly when checkpoint saving occurs frequently. For example, planning the saving procedure for a 405B transformer model distributed across 8960 GPUs requires 62 seconds. However, we have observed that both the save plans and the global metadata file, although coupled with specific parallelism, remain constant throughout a single training session. This allows for caching strategies to reduce planning times and associated overheads in subsequent checkpoint operations. We introduce plan metadata caching, transforming the planning into a one-time cost. Once established for the first time, the save plans and global metadata file are cached for future reuse, eliminating repetitive planning.

4.2 Fully Asynchronous Engine Pipeline

ByteCheckpoint Engine optimizes operation execution during checkpoint saving and loading (resharding) through pipelining. Using loading as an example (Fig. 10), we pipeline file reading, deserialization, Host-to-Device (H2D) copy, and inter-GPU communication for each tensor shard, thereby achieving higher efficiency. The *read* operation downloads files containing desired tensors from the storage system and places them into shared memory (e.g., the `dev/shm` directory). The *deserialize* operation deserializes tensors from shared memory. ByteCheckpoint employs multiple threads

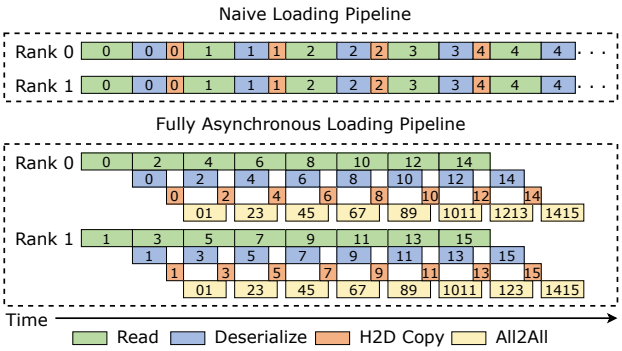

Figure 10: Comparison between ByteCheckpoint's loading pipeline and the naive implementation.

for parallel file downloading and deserialization. The *H2D copy* operation transfers tensors from CPU memory to GPUs, while *All2All* facilitates tensor transferring within the DP group. For saving, we implement a symmetrical, fully asynchronous pipeline comprising D2H copy, serialization, and file uploading operations. To mitigate the performance impact of D2H copy on training, we employ a pinned CPU memory pool combined with a Ping-Pong buffering mechanism to accelerate this operation. We run multiple parallel processes to serialize tensors and dump files into shared memory. Uploading threads actively monitor and initiate file uploading upon the completion of the dumping phase.

4.3 High Performance Read/Write

We optimize the read and write throughput of checkpointing by tailoring our implementation to optimal I/O usage of commonly used storage backends. For example, while HDFS is not primarily designed for random data access, it does offer some random read capabilities via its SDK, allowing applications to access specific file offsets and retrieve data from those positions. We leverage this feature and enable multi-threaded reading of a single file, significantly accelerating the download speed of checkpoint files from HDFS. In our production platform, single-file read speed has improved from 400 MB/s to 2-3 GB/s, all tested on H800 servers equipped with over 100 CPU cores, TB-level memory, and a 200Gbps NIC.

For file writing, HDFS's append-only write makes it impractical to split a single file into multiple parts based on offsets for multi-threaded writing. To overcome this limitation, we split the target file into several sub-files of fixed size and concurrently write them into HDFS using multi-threading. After the upload is complete, we perform metadata-level concatenation to seamlessly merge the sub-files back into a single entity, ensuring the integrity of the stored data blocks. Without network congestion, single-file upload speed can reach 3 GB/s, far exceeding the average read/write throughput of a single HDFS client (under 100 MB/s [48]).

4.4 Prefetching Dataloader States

Each dataloader employs multiple subprocesses, referred to as read workers, to handle data loading and preprocessing. When checkpointing is initiated, the main read worker signals all other read workers to prepare their states. The training process is paused until all states are collected to ensure accuracy, as any update in the main process would result in the state change of workers. The duration of this blocking period depends on both the number of workers and the size of the accumulated token buffers. For instance, when using a dataloader configured with 4 workers and a total state size of approximately 1GB, the state collection process typically takes around 8 seconds.

To alleviate this overhead, we adopt prefetching. Based on the pre-set checkpoint frequency, each read worker prepares its state during the training step just before checkpointing and puts the state into its state queue. At the checkpointing step, the main read worker gathers those prepared states immediately through queue polling. This optimization allows ByteCheckpoint to achieve near-zero dataloader state gathering delays.

5 Checkpointing at Scale

This section explores in depth the methods employed to optimize checkpointing for large-scale LFM training.

5.1 Storage Support

High throughput, scalable storage system. HDFS is the primary storage backend for ByteCheckpoint, we have implemented several optimizations to enhance throughput and scalability for large-scale checkpointing. We have rewritten all HDFS components, including NameNode, DataNode, and SDK [15], in C++, effectively doubling performance compared to the original Java-based implementation. Additionally, we have refined its architecture by introducing a new component named NNProxy [1]. NNProxy functions as a stateless RPC proxy for HDFS NameNode, facilitating large-scale federated deployments of NameNodes while maintaining minimal querying latency. The NNProxy design addresses the QPS bottleneck of HDFS NameNode metadata requests, a challenge intensified by the high volume of distributed checkpoints. NNProxy also provides additional features such as authentication, rate limiting, and metadata query caching. These capabilities enable more granular management of checkpoints in production environments. Our optimized HDFS achieves a substantial capacity of hundreds of PBs, 10 TB/s read/write bandwidth, and approximately 100,000 metadata QPS.

Checkpoint cool-down strategy. We have implemented a two-tier hot-cold storage architecture using a combination of SSD and HDD storage servers. Our key observation is that newly stored checkpoint files are typically downloaded by evaluation tasks shortly after their creation. However, where no training anomalies such as loss spikes occur, the access frequency of these files decreases significantly after being downloaded by evaluation tasks. Nonetheless, all checkpoint files must be preserved for traceability. To efficiently manage storage space while ensuring data availability, we have developed a data cool-down mechanism that migrates data from SSD to HDD storage, thus ensuring that high-performance hot storage consistently has sufficient space for operations. Specifically, we cool down all files that exceed the retention threshold based on their last modification time. We then remap the original file paths to the new HDD storage locations through pure metadata operations. This strategy applies to HDFS directories and preserves the original access paths of the cooled-down files, providing a seamless user experience.

5.2 Collective Communication

Collective communications (e.g., scatter, gather, barrier) are crucial in ByteCheckpoint's workflow (Sec.3.3), particularly for planning and checkpoint integrity guarantee. We initially used NCCL [54] as the communication backend to execute gather and scatter operations at the coordinator. However, when scaling a pre-training task to 8960 GPUs, we observed that NCCL requires a long time to lazily build communication channels and allocate GPU memory during the planning stage of ByteCheckpoint's saving workflow. In some cases, it becomes unresponsive or causes CUDA out-of-memory (OOM) errors, as scatter or gather operations necessitate establishing peer-to-peer communication with each GPU. These GPU OOM issues and long initialization times are not apparent in small-scale trials but become significant at larger scales.

To enhance communication stability during planning, we have re-implemented the procedure using the gRPC framework [17], which eliminates GPU memory usage during planning. However, when scaling training to tens of thousands of GPUs, centralized gathering and scattering operations continued to impose a significant burden on the coordinator, leading to communication failures. We further improved its stability by implementing a tree-based hierarchical communication topology. Training workers on a single machine are organized into first-level subtrees, with the worker of local rank 0 designated as the root. For inter-machine communication, we iteratively group multiple machines, designating the worker with the lowest global rank in each group as the root. This procedure continues until all workers are integrated into a hierarchy converging at the global root (i.e., the coordinator). In large-scale 3D parallel training scenarios, a TP-DP-PP communication tree naturally forms, removing extra connections.

5.3 Monitoring and Analysis

During training, ByteCheckpoint continuously collects critical performance measurements and visualize them for real-

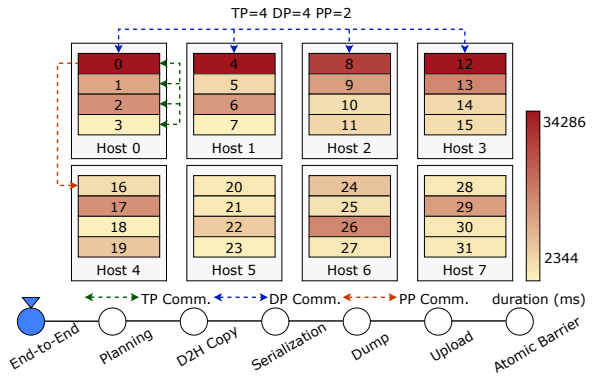

Figure 11: End-to-end checkpoint saving time heat map from a 3D parallel training task with Megatron-LM on 32 GPUs. The color denotes the time of a selected phase on a rank.

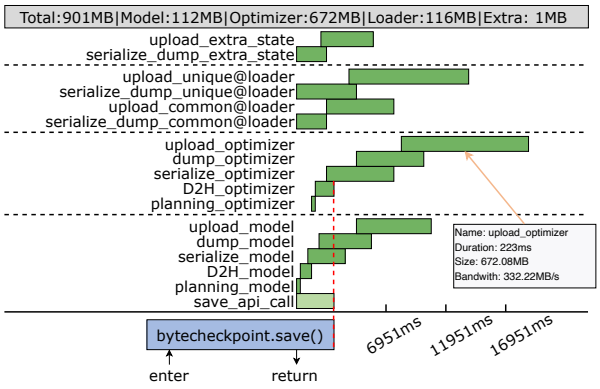

Figure 12: Time breakdown of checkpoint saving on rank 0.

time performance monitoring and analysis. This approach enables quick checkpointing issues detection, such as low read/write throughput, stragglers, and upload failures and retries.

Data collection. We have designed a user-friendly metrics system based on Python's context manager and decorator syntax to monitor critical procedures flexibly. It automatically captures the duration and I/O size of each operation, along with relevant metadata such as each worker's rank, the file path, and the current step. All collected metrics are transferred to a remote database via a background message queue.

Visualization. ByteCheckpoint provides users with a comprehensive topological performance overview of all ranks associated with different checkpoint phases, as well as detailed duration breakdowns for any specific rank. Fig. 11 presents an exemplary heat-map visualization of checkpoint saving times within a 3D parallel training topology. The visualization highlights that ranks 0, 4, 8, and 12 experience the longest saving times as their checkpoints including dataloader states. Additional metrics visualizations are also available for detailed analysis, such as blocking time and fine-grained phases like planning and D2H copy. These visualizations enable users to easily pinpoint straggler nodes or phases for both system development and in production environments. For instance, if certain nodes experience network issues, increased upload or download times during the HDFS transfer phase would be readily apparent. Furthermore, detailed timeline breakdowns of checkpointing procedures at each rank are accessible via the heat map topology overview, enabling users to thoroughly evaluate all optimizations in the system. Fig. 12 illustrates the execution details of each checkpoint-saving phase for a specific rank.

Storage-side monitoring. On the storage client side, we monitor the latency and I/O size of each atomic read/write operation at the I/O chunk level. All collected metrics are periodically transmitted via a message queue to a ClickHouse service, where the data are aggregated and analyzed. Unexpectedly high latency or low bandwidth triggers alerts to engineers for further investigation. On the storage cluster side, our primary focus is on overall performance metrics, including metadata request QPS, cluster-level read/write throughput, and storage capacity utilization. This comprehensive monitoring system plays a crucial role in identifying issues such as slow checkpoint reads and writes, and even complete system unavailability due to storage capacity exhaustion, facilitating the implementation of preventive measures for enhancing system reliability and efficiency.

6 Evaluation

In this section, we detail our deployment and operational experiences with ByteCheckpoint. ByteCheckpoint is built upon DCP [58] (commit hash: 80c07df), a state-of-the-art open-source checkpointing system that supports checkpoint resharding for FSDP [73]. The implementation of ByteCheckpoint consists of about 20,000 lines of Python code.

6.1 Checkpointing Efficiency

We demonstrate checkpointing performance of ByteCheckpoint relative to baselines [52, 58] with different workloads.

Workloads. We adopt two different transformer-based [62] structures, i.e. DiT [40] and GPT-3 [9] to implement two models referred to as *vDiT* and *tGPT*, respectively. The vDiT model is fine-tuned with the FSDP framework for video generation on a cluster of NVIDIA A100 80GB GPUs, while the tGPT model is trained for text generation with Megatron-LM [47] on NVIDIA H800 80GB GPUs. Detailed configurations for model and parallelism are provided in Table 3, where the source number of GPUs and parallelism pertain to the saving and loading evaluations, while the target number of GPUs and parallelism correspond to the configurations used for load-time resharding evaluations. All machines in the training clusters are interconnected via InfiniBand, with HDFS selected as the persistent storage solution for all experiments. We integrate the test models into our LFM training

Table 3: Model and parallelism configurations.

Model	Hidden Size	#Heads	#Layers	#Parameters	Source #GPUs	Soure Parallelism	Target #GPUs	Target Parallelism
vDiT	1664	16	48	4B	32	ZeRO-2	64	ZeRO-2
					128	ZeRO-2	64	ZeRO-2
tGPT	8192	64	80	70B	2400	TP=4, DP=75, PP=8	4800	TP=4, DP=150, PP=8
					4800	TP=4, DP=150, PP=8	2400	TP=4, DP=75, PP=8

Table 4: I/O performance comparison among ByteCheckpoint, DCP and MCP.

Model and Framework	Source #GPUs	Method	T_{Block} (s)	T_{Save} (s)	T_{Load} (s)	$T_{Reshard}$ (s)	ETTR (%)
vDiT 4B	32	DCP	16.25	86.82	50.12	74.89	38.60
		ByteCheckpoint (GPU states)	0.54 (**30.09**×)	27.47 (**3.16**×)	11.69 (**4.29**×)	16.01 (**4.68**×)	46.22 (**1.20**×)
FSDP	128	DCP	61.37	236.34	105.74	91.01	41.62
		ByteCheckpoint (GPU states)	0.38 (**161.50**×)	23.74 (**9.96**×)	12.01 (**8.80**×)	13.64 (**6.67**×)	48.92 (**1.18**×)
tGPT 70B	2400	MCP	4.73	28.97	69.87	126.30	34.61
		ByteCheckpoint (GPU states)	0.39 (**12.13**×)	13.11 (**2.21**×)	49.48 (**1.41**×)	62.10 (**2.03**×)	40.18 (**1.16**×)
		ByteCheckpoint (full states)	0.50	20.55	72.35	401.21	28.80
Megatron-LM	4800	MCP	4.70	76.21	123.80	64.62	31.28
		ByteCheckpoint (GPU states)	0.36 (**13.06**×)	8.59 (**8.87**×)	64.39 (**2.00**×)	54.31 (**1.19**×)	40.29 (**1.29**×)
		ByteCheckpoint (full states)	0.43	25.04	83.56	115.95	34.70

trials, conducting training over 500 steps and saving checkpoints every 100 steps. We then resume training under two scenarios: with and without changes in GPU numbers and parallelism configurations, to assess the performance of load-time resharding and standard checkpoint loading. Saving performance is evaluated based on average additional overheads, specifically checkpoint stalls (training blocking time) and end-to-end checkpoint saving time (from the save API call to the completion of checkpoint integrity checking). Additionally, we measure the end-to-end checkpoint loading time (the blocking time of the load API call) for both load-time resharding and standard loading scenarios. We use the average ETTR as the metric to evaluate the end-to-end system performance. Following GEMINI [66], we assume a consistent occurrence of failures within each checkpointing interval (100 steps), calculating the average wasted time to derive the achieved ETTR. Calculation details can be found in Appendix C.

Baselines. In experiments with FSDP, we use DCP (commit hash: c7338f4) as the baseline, while for Megatron-LM, MCP [52] (commit hash: 3fb5c51) serves as the baseline. We ensure that all hyper-parameters, such as batch size and context length, remain consistent across systems for a fair comparison. Both baselines support asynchronous checkpointing and load-time checkpoint resharding for the model and optimizer, but not for dataloader states. Consequently, we compare I/O performance with these baselines only for GPU states and additionally evaluate the performance of ByteCheckpoint for the full training states. Since neither DCP nor MCP supports HDFS, we implement the logic to enable HDFS access for them, using the same configurations (e.g., thread count, file chunk size, etc.) as those employed in ByteCheckpoint.

Saving performance. As shown in Table 4, ByteCheckpoint significantly reduces checkpoint stalls during runtime, with reductions ranging from 13.06× to 161.50×. This improvement reduces the average checkpoint stall time from minutes or seconds to sub-second durations, outperforming both DCP and MCP. In terms of end-to-end saving time, ByteCheckpoint delivers an average speedup of 6.05×, primarily driven by our fine-grained performance optimizations. Notably, the acceleration provided by ByteCheckpoint scales with the size of the training workload, increasing from 2.21× for 2400 GPUs to 8.87× for 4800 GPUs. This can be attributed to the workload balancing mechanism, which becomes more effective with larger DP sizes. Additionally, we observe a particularly significant reduction in blocking time for FSDP workloads. This results from the high communication and synchronization overheads caused by FSDP's irregular tensor shard processing when using DCP for distributed checkpoint storage. These overheads grow as the training scale increases, making DCP less suitable for large-scale training. In contrast, ByteCheckpoint's decomposition representation strategy incurs zero communication overhead during metadata generation, leading to improved training efficiency. We also provide a detailed overhead breakdown in Appendix D for further investigation. For training with Megatron-LM, we report I/O performance for the handling of full training states.

Loading and resharding performance. In experiments involving the loading of distributed checkpoints into unchanged parallelism configurations, ByteCheckpoint achieves performance improvements ranging from 1.41× to 8.80× compared to baseline methods. Our approach leverages an asynchronous loading pipeline, which overlaps tensor reading and transferring, significantly reducing blocking time before training begins. When it comes to the resharding efficiency of model and optimizer states, ByteCheckpoint delivers an average acceleration of 3.64×. By eliminating the need for running costly

Table 5: Saving optimization microbenchmark.

Workload	Parallel Config.	Optimization	Saving Time (s)
tGPT 13B	TP=2, DP=8, PP=2	No Optim.	50.26

tGPT 30B	TP=2, DP=8, PP=4	No Optim.	46.34
		Async.	25.56 (**1.81**×)
		Async. + W.B.	18.83 (**2.46**×)
		Async. + W.B. + Cache.	18.56 (**2.50**×)

Table 6: Loading optimization microbenchmark.

Model	Parallel Config.	Optimization	Loading Time (s)
tGPT 13B	TP=2, DP=8, PP=2	No Optim.	63.48
		Async.	48.43 (**1.31**×)
		Async. + Overlap.	41.38 (**1.53**×)
tGPT 30B	TP=2, DP=8, PP=4	No Optim.	77.02
		Async.	74.54 (**1.03**×)
		Async. + Overlap.	48.73 (**1.58**×)

Table 7: Resharding optimization microbenchmark.

Model	Parallel Config.	Optimization	Processing Time (s)
tGPT 13B	ZeRO-2 32 GPUs	All-gather + D2H.	4.12
		Decompose.	0.21 (**19.80**×)
tGPT 30B	ZeRO-2 64 GPUs	All-gather + D2H.	5.84
		Decompose.	0.19 (**30.50**×)

offline resharding jobs, ByteCheckpoint enables flexible and efficient checkpoint transformations across various scenarios. However, we observe that including CPU states, primarily dataloader states, increases the end-to-end load-time resharding time. This is largely due to the time-consuming processing of unique components within the dataloader states, such as the token buffer, which can grow as large as 20GB in text-to-video LFM training. Additionally, since only a subset of workers hold these dataloader states, they often become stragglers during the checkpoint saving and loading (resharding) procedures. We leave the design of a more efficient dataloader to our future works.

End-to-end performance. ByteCheckpoint outperforms both DCP and MCP in terms of the average end-to-end ETTR, achieving improvements ranging from 1.16× to 1.29×. Leveraging full-stack optimizations, ByteCheckpoint improves the execution efficiency of each checkpoint-related operation, thereby effectively minimizing training downtime.

6.2 Microbenchmarks

We conduct several micro-benchmarks (Table 5, Table 6 and Table 7) to highlight the performance improvements. To evaluate different model sizes, We modify the tGPT 70B model to create tGPT 13B and tGPT 30B. For saving and loading microbenchmarks, we used the Megatron-LM training framework, while for resharding, we employed FSDP.

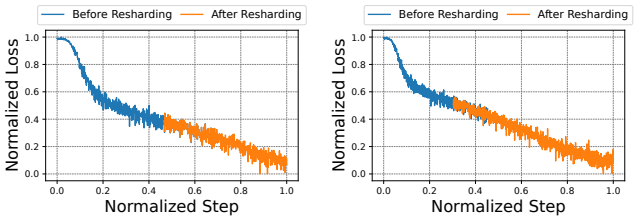
In Table 5, we compare the end-to-end saving times with and without ByteCheckpoint features, as described in Sec. 4. The results demonstrate that asynchronous saving pipeline achieves significant reduction in saving time compared to the unoptimized settings, yielding speedups of 1.45× and 1.81× for tGPT 13B and tGPT 30B, respectively. The workload balancing mechanism and plan cache of ByteCheckpoint can further boost these improvements. When applying all I/O optimization techniques to both model and optimizer states, the average saving time for these models is reduced from 48.3 seconds to 19.27 seconds. In Table 6, we present the performance gains achieved by the asynchronous loading pipeline and read-communication overlap techniques. For tGPT 13B and tGPT 30B, the baseline loading times were 1.53× and 1.58× longer than those achieved with ByteCheckpoint.

For load-time resharding, we compared the irregular tensor processing time between FSDP and ByteCheckpoint's irregular tensor decomposition strategy. As shown in Table 7, ByteCheckpoint incurs an average blocking time of just 0.20s, which is 25.15× shorter than that of FSDP. Moreover, our approach consistently achieves microsecond-level blocking times, regardless of the training scale. (see results in Sec. 6.1 and Sec. 6.4).

6.3 Correctness Verification

In Fig. 13, we depict normalized training loss curves of tGPT 13B before and after resharding with ByteCheckpoint in various situations. For PP and TP resharding, the normalized loss curve after resharding can smoothly match that in the previous phase and continue to display a consistent decline trend. Unit testing confirms that ByteCheckpoint can correctly transform distributed checkpoints across varying parallelism. Results of DP and hybrid resharding are in Appendix E.

We further verify the bit-wise alignment ability of ByteCheckpoint when training resumes without changes in parallelism configurations. We show the normalized loss curve from real production in Fig. 14, where a 175B language foundation model is trained. As highlighted, the normalized loss before and after resuming are exactly the same.



6.4 Checkpointing in Real LFM Production

We share our experience deploying ByteCheckpoint in real-world LFM production environments, highlighting the issues we encountered and resolved.

Scalabilty. As shown in Table 8, ByteCheckpoint was used to train two transformer-based LFMs for image and text generation on H800 GPUs, respectively. ByteCheckpoint consistently maintained average checkpoint stalls under 600ms, even at the largest scale with 8,960 GPUs. Additionally, end-to-end checkpointings were completed efficiently, typically within a few seconds.

Table 8: I/O performance of ByteCheckpoint in large-scale LFM training.

Model and Framework	#GPUs	Parallelism	T_{Block} (s)	T_{Save} (s)	T_{Load} (s)
Vision Transformer 7B FSDP	1488	ZeRO-2	0.34	20.13	265.73
Text Transformer 405B Megatron-LM	8960	TP=8, DP=70, PP=16	0.59	51.06	129.49

(a) PP resharding from TP=1, DP=4, PP=4 to TP=1, DP=4, PP=8.

(b) TP resharding from TP=1, DP=4, PP=4 to TP=2, DP=4, PP=4.

Figure 13: Resharding correctness verification.

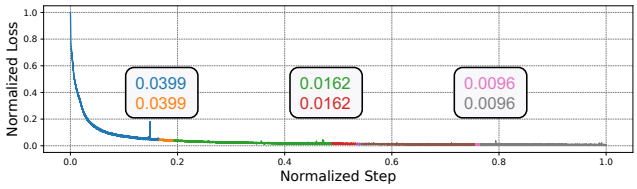


Figure 14: Training resuming with ByteCheckpoint in real production run on 2080 H800 GPUs for several days. Color changes indicate training resuming.

Dataloader stragglers. By analyzing the performance visualization results from our monitoring tools (Sec. 5.3), we identified prolonged uploading time for dataloader checkpoint files. To support dataloader state resharding, ByteCheckpoint divides the states of a dataloader into multiple parts (e.g., 6 parts for the tGPT experiments in Sec. 6.1) and stores them as individual files. These files can be independently loaded during resharding. However, uploading these small files sequentially leads to low bandwidth utilization, causing performance degradation. In cases like the 7B vision transformer, uploading time of dataloader states can account for 73.16% of total saving time. To fix this issue, we implemented a process pool for concurrent uploads, significantly reducing saving time.

HDFS metadata bottleneck. Through monitoring, we identified several bottlenecks related to HDFS. Despite applying the parallel optimization techniques for single-file uploads described in Sec. 4.3, the actual HDFS upload performance fell short of our expectations. A detailed profiling revealed that the metadata concatenation operation in the HDFS NameNode was performed serially, making it a significant performance bottleneck when large volumes of checkpoint files were generated. We mitigated this issue by enabling parallel execution of the concatenation operation. Another issue that emerged was related to our initial use of the HDFS SDK. For the convenience of the users, the SDK encapsulates a lot of safeguard logic, leading to unnecessary overheads introduced by checking, creating parent directories, and verifying target files. To address this, we optimized ByteCheckpoint by ensuring directory existence and file uniqueness prior to invoking HDFS APIs, reducing redundant metadata operations and improving performance significantly. By addressing these issues, we reduced the maximum metadata overhead of HDFS write operations for a single checkpoint file from 3s to 150ms.

7 Conclusion

This paper presents the design, implementation, and deployment of ByteCheckpoint, a production-grade checkpointing system built for LFM development. ByteCheckpoint advocates a unified architecture for checkpoint representation and workflow, enables efficient load-time resharding and supports multiple training frameworks and storage backends. It enables full-stack I/O performance and scalability optimizations and incorporates efficient performance monitoring and analysis tools for LFM development at scale. Compared to state-of-the-art baselines [52, 58], ByteCheckpoint reduces checkpoint stalls by up to 161.50× and shortens end-to-end checkpointing completion time by up to 9.96×. Additionally, the loading (resharding) procedure is optimized to be 3.88× faster on average. We believe our system not only provides valuable practical experience to those building checkpointing systems for real-world LFM development but also offers deep insights for future research in the community.

8 Acknowledgments

We would like to thank our shepherd Ayush Goel and the anonymous reviewers for their constructive feedback. We thank Juncai Liu and Xiang Li for their efforts in facilitating our large-scale experiments. We thank Shibiao Nong, Shuaishuai Cao, Wei Jia, Jingzhe Tang, Jun Wang, Xi Wang, Sa Wang, and other contributors for refining our system and extending its functionalities. We thank Liyang Zhao and the HDFS team of ByteDance for their support. This work was supported in part by a ByteDance Research Collaboration Project, and grants from Hong Kong RGC under the contracts HKU 17204423 and C7004-22G (CRF).

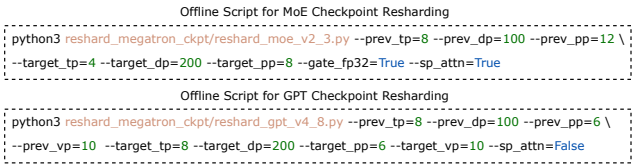

Figure 15: Examples of running offline scripts for checkpoint resharding.

A More Background on Maintaining Resharding Scripts

Examples of offline resharding with customized scripts are given in Fig. 15. Customizing offline scripts is labor-intensive. For GPU state resharding, the offline scripts must cover all different components in the LFM and its optimizer and cater to the diverse behavior of each component under different parallelism strategies. For example, with Tensor Parallelism (TP), GEMM operators in attention and MLP blocks are sharded along different dimensions, while other operators like LayerNorm [8] are replicated across GPUs. When hybrid 3D parallelism [36] is adopted, TP-sharded tensors of one layer (module) in the distributed optimizer are first flattened and then merged before being sharded according to the designated Data Parallelism (DP) degree. Offline scripts must implement resharding logic that is tightly coupled with combinations of model (optimizer) components and parallelism strategies. Additionally, special algorithmic optimization techniques such as GQA [23] and MLA [75] change the tensor layout of certain operators (e.g., the query-key-value projection GEMM operator in the attention block), necessitating corresponding resharding support. To handle various cases in our production environment, our largest script even includes 3193 lines of Python code. This complexity results in significant engineering efforts for both development and maintenance.

B Efficient Integrity Guarantee

A complete checkpoint consists of multiple files stored by different workers. The failure of any single worker can corrupt the entire checkpoint. To prevent such issues, a barrier mechanism is essential to achieve atomic save/load operations among all training workers.

Checkpointing modules in training frameworks like Megatron-LM [47] rely on the `barrier` function in `torch.distributed` to perform integrity checks. This approach synchronizes training workers to ensure that all checkpoint saving/loading operations are finished. We observed that when scaling training to involving approximately 10,000 GPUs, this behavior results in stalls of about 20 seconds each time. To address this inefficiency, we re-implement the `barrier` function using the aforementioned method (gRPC with tree-based communication topology) and conduct the integrity checks asynchronously, effectively eliminating the blocking time. We also incorporate upload/download retry mechanisms in ByteCheckpoint's I/O workers and integrate failure logging, which records the exact stage of failure within the checkpoint saving/loading pipelines in workers who fail to complete checkpointing tasks.

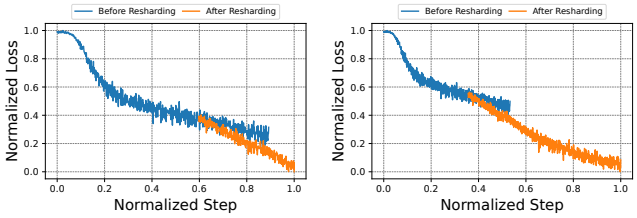
C Average ETTR Calculation

Failures that happened during training introduce progress loss and the last checkpoint loading overhead. Assume failures are evenly distributed within one checkpoint interval [66], the best case is that a failure occurs just after the completion of a checkpoint end-to-end saving procedure whereas the worst case is just before that. Given the per iteration training time T_{iter}, checkpoint interval N, end-to-end checkpoint saving time T_{save} and loading (resharding) time T_{load}, we derive the average wasted time T_{wasted} as:

$$T_{wasted} = T_{save} + T_{load} + \frac{N \cdot T_{iter}}{2} \tag{1}$$

Therefore, the average ETTR is:

$$ETTR = 1 - \frac{T_{wasted}}{T_{save} + T_{load} + N \cdot T_{iter}} \tag{2}$$



The end-to-end ETTR results presented in Table 4 are averaged across standard loading and resharding settings.

D Checkpointing Overhead Breakdown

We break down the end-to-end checkpoint saving time ($\mathbf{T_{save}}$) for rank 0 by dividing it into several phases and investigating the overhead of each part. The results are depicted in Table 9, where $\mathbf{T}^{\mathbf{First}}_{\mathbf{Plan}}$ denotes the initial planning cost while $\mathbf{T}^{\mathbf{Cache}}_{\mathbf{Plan}}$ refers to the overhead when using the plan and metadata cache for subsequent checkpointing operations. Costs of other phases are averaged over various checkpointing steps. We find that the communication overhead of planning increases as training scales up, leading to significant stalls. Thanks to the caching strategy (Sec. 4.1), it becomes a one-time expense for each (resumed) training session. In addition, the adoption of the pinned memory CPU pool renders the blocking time of D2H almost negligible, while our asynchronous engine pipeline overlaps the execution time of serialization, shared memory dumping, and HDFS uploading, diminishing the end-to-end time. Furthermore, the load-balancing mechanism exploits the capabilities for parallel uploading within each DP group and achieves more performance gains at larger training scales (e.g., the uploading speed of model states with 4800 GPUs is 3.03× faster than that with 2400 GPUs).

Table 9: Detailed overhead breakdown of the checkpoint saving procedure for rank 0.

Model and Framework	Source #GPUs	State	T^{First}_{Plan} (s)	T^{Cache}_{Plan} (s)	T_{D2H} (s)	$T_{Serialize}$ (s)	T_{Dump} (s)	T_{Upload} (s)

Figure 16: Resharding correctness verification.

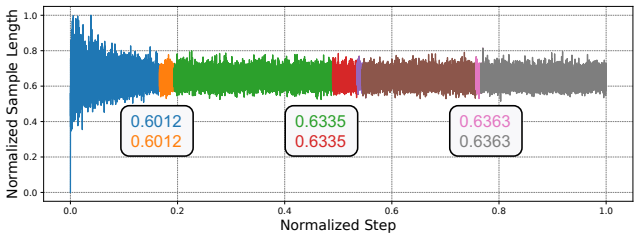

Figure 17: The normalized sample length curves of the dataloader with multiple training restarts.

E More Resharding Correctness Experiments

The normalized loss curves for DP and hybrid resharding correctness are shown in Fig. 16. In the case of DP and hybrid resharding, since we also increase the global batch size, the loss curve after resharding declines more rapidly.

We further show that ByteCheckpoint can achieve bit-wise correct resuming for dataloader states. Since the RNG state is fixed, correct resumptions should yield the same data sampling trajectory. Therefore, we use the normalized data sample length curve (Fig. 17) for evaluation. As highlighted, the normalized data sample length before and after restarts is identical.

F Related Work

Checkpointing frameworks. Some industrial initiatives focus on developing checkpointing systems for deep learning. Prior to DCP [58], PyTorch provided `torch.save` and `torch.load` APIs for local checkpoint management, without native resharding support. DCP [58] introduced resharding capabilities for FSDP but lacks support for parallelism strategies such as TP and PP. DeepSpeed-UCP [32] provides a unified format for DeepSpeed checkpoints and offers resharding capabilities through offline scripts. Megatron MCP [52] builds upon the workflow of DCP [58] and extends storage options to formats like Zarr [60]. All these frameworks provide limited support for various parallelism strategies and training frameworks, and their I/O performance does not scale well in large-scale training.

Checkpointing optimizations. Several works [10, 37] investigated reducing checkpointing costs from different perspectives. Check-N-Run [14], designed for recommendation models, employs differential checkpointing to store only the modified portions of the model, alongside quantization to reduce checkpoint size. CheckFreq [35] pipelines snapshot and save operations with computation to minimize checkpoint stalls and introduces an online algorithm for tuning checkpoint frequency to further lower costs. Gemini [66] advocates for in-memory checkpointing with inter-machine backup for fast recovery, interleaving checkpoint communication with training traffic to enable frequent checkpoints per iteration. JIT-Checkpointing [19] adopts just-in-time checkpointing for low-cost error recovery. In industrial use cases, it is crucial to store checkpoints in separate persistent storage for various tasks such as auto-evaluation [22], hyper-parameter tuning, and model debugging. ServerlessLLM [16] focuses on the demand for loading optimizations which is critical in serverless inference scenarios. It proposes a chunk-based, multi-tier loading pipeline to accelerate checkpoint loading. Unlike existing solutions, ByteCheckpoint champions both optimized I/O performance and flexible load-time checkpoint resharding, supporting general LFM development.

Checkpoint representation. PyTorch's `torch.save/load` functionality relies on `pickle` for serialization and deserial-

ization. This format lacks crucial tensor shard metadata, such as global shape information, precluding automatic resharding. DCP [58] addresses this limitation by introducing a disaggregated format that separates metadata from tensor data. This metadata, which includes global shape and offset details, enables automatic resharding in DCP. Tenplex [64] introduces Parallelizable Tensor Collection (PTC) to flexibly represent and transform tensor states across diverse parallelism configurations. To build a PyTorch-native checkpointing system, ByteCheckpoint adopts the representation of DCP and incorporates necessary adaptations to handle irregular tensor sharding. Array-based storage systems like Zarr [4] and TensorStore [3] allow tensors to be saved as individual arrays, supporting concurrent reads and writes. MCP [52] supports distributed checkpointing using the Zarr format. For secure and efficient tensor storage, Safetensors [2] is a file format for saving tensors safely and loading them efficiently. To improve compatibility with the Hugging Face open-source ecosystem, ByteCheckpoint incorporates functionality to export checkpoints in the Safetensors format.

Storage systems for LFM. Large-scale checkpointing requires robust storage systems. The LLaMA 3.1 report [13] highlights Tectonic [39], Meta's general-purpose file system, as the backbone for storing checkpoints during pre-training. One of the key challenges for this system is managing high-frequency checkpoint writes. Similarly, FireFlyer [6], the AI-HPC system developed by DeepSeek [11, 18, 33] for LFM training, utilizes the custom-built 3FS Distributed File System [50], which is akin to other parallel file systems like BeeGFS [21], to manage checkpoint storage.

Elastic training systems. Some orthogonal efforts are devoted to enhancing the elasticity of DL training jobs [7, 12, 24, 30, 61, 74]. For instance, Varuna introduces *job morphing* to reconfigure training jobs in both pipeline and data parallelism degrees, without changing the hyper-parameters. Bamboo [61] leverages cross-stage redundant computations into the pipeline for elastic training on spot instances. Oobleck [24] implements a pipeline instantiation mechanism via predefined templates to tolerate concurrent failures in different pipelines. These works are limited to specific parallelism strategies (e.g., DP without ZeRO), while ByteCheckpoint does not assume any specific parallelism, supporting real-world production. The flexibility of elastic training systems can be significantly enhanced by adopting our checkpoint representation for training state management.

Mowgli: Passively Learned Rate Control for Real-Time Video

Neil Agarwal[¶] Rui Pan[¶] Francis Y. Yan[†] Ravi Netravali[¶]

[¶]Princeton University [†]University of Illinois Urbana-Champaign

Abstract

Rate control algorithms are at the heart of video conferencing platforms, determining target bitrates that match dynamic network characteristics for high quality. Recent data-driven strategies have shown promise for this challenging task, but the performance degradation they introduce during training has been a nonstarter for many production services, precluding adoption. This paper aims to bolster the *practicality* of data-driven rate control by presenting an alternative avenue for experiential learning: leveraging purely existing telemetry logs produced by the incumbent algorithm in production. We observe that these logs contain effective decisions, although often at the wrong times or in the wrong order. To realize this approach despite the inherent uncertainty that log-based learning brings (i.e., lack of feedback for new decisions), our system, Mowgli, combines a variety of robust learning techniques (i.e., conservatively reasoning about alternate behavior to minimize risk and using a richer model formulation to account for environmental noise). Across diverse networks (emulated and real-world), Mowgli outperforms the widely deployed GCC algorithm, increasing average video bitrates by 15–39% while reducing freeze rates by 60–100%.

1 Introduction

Real-time video conferencing is integral to our daily lives, with widespread use cases across many societal pathways including healthcare, education, gaming, and more. Key to their functionality are the rate control algorithms (e.g., Google Congestion Control or GCC [21]) that conferencing platforms employ. These algorithms are tasked with quickly (e.g., every 50 ms) characterizing network performance based on recent transmissions and selecting a target bitrate for the upcoming frames that maximizes content quality without introducing undue latency or stalls. This value is then shared with the local video codec which performs best-effort compression of the raw frames to match the target prior to transmission.

Recent years have witnessed a flurry of proposals for improving conferencing quality via improved rate control. Most notably, data-driven approaches have shown how reinforcement learning (RL)-based algorithms can substantially outperform GCC's hand-tuned variants [54–56]. As in other networked-system domains [14, 35, 51, 52], the key is in making better use of dense application- and network-layer feedback signals to enable bitrate changes that more closely track rapid network fluctuations in the wild—a key challenge for GCC [21, 54–56].

Yet, despite their promise, data-driven rate control algorithms have seen minimal adoption in practice. Our conversations with operators of large-scale video conferencing platforms reveal that the primary showstopper is the impact that these schemes have on the performance or quality of experience (QoE) observed by real users. Indeed, the experiential learning that these schemes pursue *in real conferencing sessions* fundamentally involves exploring different rate decisions—both good and bad for QoE—and observing their effects in certain scenarios. Our experiments show that this trial-and-error process can increase video freeze rates up to 79% and degrade video bitrates by up to 77%, yielding unacceptable QoE (§2.2). Data-driven strategies could forego such user-facing training by relying on simulators and emulators, but this may jeopardize efficacy in production settings due to the "simulation to reality" gap [12, 20, 27, 51, 55].

This paper aims to build on recent data-driven rate control schemes, not by designing more performant algorithms, but instead by *bolstering their practicality*. Our key insight is that the fine-grained telemetry logs that production conferencing platforms routinely capture for debugging and retrospective optimization [1, 2, 4, 7, 10] already embed sufficient insight to guide data-driven algorithms to outperform their hand-tuned counterparts. The reason is that, while algorithms like GCC struggle to quickly match fluctuating network bandwidths, they often adjust target rates in the appropriate direction with delay (Fig. 1). Consequently, we find that simply reorganizing the same decisions that GCC makes during video sessions (without exploring any alternate rate values) boosts conferencing bitrates by 19% and decreases freezes by 80% (§3.3).

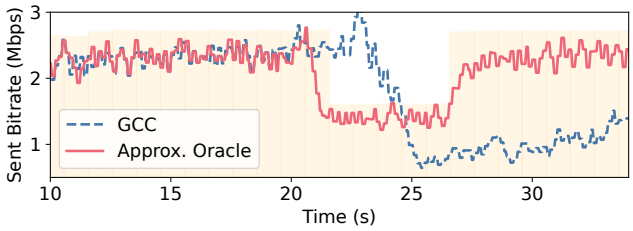
We present **Mowgli**, an end-to-end system that realizes such log-based learning to practically enhance rate control in video conferencing. Mowgli starts by representing production telemetry logs that reflect the behavior and performance of a deployed algorithm (e.g., GCC) as more traditional (state, action, reward) tuples for RL. These logs then guide Mowgli's experiential learning, which follows the soft actor-critic algorithm [30] to develop a lightweight neural network for rate control. Training occurs entirely offline using only logs (i.e., no video playback or simulation), and the resultant model is shipped to clients for deployment.

Though conceptually straightforward, learning in this offline manner faces several challenges centered around *uncertainty* (§3.4). As noted above, the feasible learned improvements are rooted in discovering alternate sequences of logged actions that perform better in certain scenarios. However, assessing such sequences is fundamentally risky as they involve applying previously-seen actions to new scenarios without guarantees that the benefits will port, i.e., unlike traditional RL, we lack direct feedback for these new sequences. This limitation is worsened by the fact that logs in confer-

encing systems (1) typically reflect singular deterministic policies with little variation in action for a given scenario, and (2) are inherently noisy in that observed performance can be influenced not only by rate decisions, but also external phenomena such as codec behavior and stochastic network variations [28, 50, 51, 53, 56].

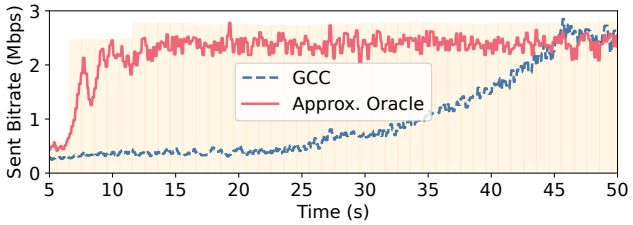
To manage uncertainty, Mowgli incorporates two key techniques. First, when estimating the consequence of an action in a given scenario, Mowgli takes a *conservative* approach—it lowers the estimated return if no similar state-action pair has been observed before, and proceeds only when the performance improvement outweighs the risk. Second, rather than estimating a single expected outcome, Mowgli explicitly tackles environmental variance by learning a *distribution* over all possible outcomes. This distributional perspective provides Mowgli with richer insights, enabling more informed decision-making. We detail the concrete algorithms in §4.2.

We evaluated Mowgli on a diverse set of emulated and real-world networks spanning 3G–5G cellular and wired broadband links. Overall, we observe that Mowgli consistently outperforms GCC, increasing average video bitrates by 15–39% while reducing freeze rates by 60–100%. Further, Mowgli's wins closely mimic those of recent (impractical) online RL algorithms [27, 54, 55], falling within 0.5–13.1% and 0–19% for average bitrates and freeze rates, respectively.



2 Background & Motivation

2.1 Prior Work



Rule-based heuristics are suboptimal. Today's video conferencing applications (e.g., Microsoft Teams, Google Hangouts, Zoom) rely on rule-based algorithms to provide network bandwidth estimates and guidance as to how to tune the encoding and sending bitrates over time. A widely used, publicly available algorithm is Google Congestion Control (GCC) [21]. GCC first characterizes the current network usage based on recent packet delay and loss measurements, and then updates the target bitrate according to a fixed set of rules (e.g., when the observed packet loss is less than 2%, increase the target bitrate by 5%, or when the system is in a "decrease" state, reduce the target bitrate by 15%).

Google Congestion Control (and other rule-based heuristics) have been widely observed to be suboptimal [27, 28, 54–56]. Recent reports have found that when using state-of-the-art rule-based heuristics, over 20% of over a million video conferencing sessions experience poor performance [56]. Digging deeper, we find that GCC performs particularly poorly in highly dynamic network conditions, where the available bandwidth fluctuates (e.g., in cellular networks). The general hardcoded set of rules fails to fully leverage dense application/network signals that are necessary for predicting the appropriate bitrate adjustments in highly variable regimes.

As a result, for example, when bandwidth drops, GCC can fail to rapidly and appropriately adjust the bandwidth, unnecessarily overshooting the available network capacity and incurring video freezes (Fig. 1a). Further, after an intermittent drop in bandwidth, GCC can be unnecessarily delayed in fully ramping up to the available bandwidth (Fig. 1b). As quality expectations for video conferencing steadily increase with its growing ubiquity, there is a pressing need to find improved rate control algorithms over today's rule-based heuristics.

(a) GCC overshoots network capacity after a bandwidth drop, causing video freezes.

(b) After an intermittent bandwidth drop, GCC ramps up slowly, leading to suboptimal bandwidth utilization.

Figure 1: Examples of GCC's pitfalls, which occur primarily in dynamic networks. To illustrate potential performance improvement opportunities, we plot an oracle algorithm.

Data-driven approaches are promising. In response, the community has explored data-driven approaches to generate alternative rate control algorithms (e.g., R3Net [27], OnRL [55], Loki [54]). Such machine learning-based approaches are particularly skilled at extracting patterns from highly-dense information and have been shown to deliver non-trivial improvements over today's state-of-the-art rule-based heuristics. Given the challenge of explicitly identifying the exact action an algorithm should take in each scenario and using standard supervised learning techniques to learn that mapping, recent proposals have opted to leverage reinforcement learning (RL). An RL agent learns by interacting with an environment and leveraging feedback to iteratively adjust its behavior to maximize cumulative reward over a horizon. In rate control for video conferencing, the RL agent outputs bitrate updates and leverages the transport/application layer feedback to update its decision-making policy.

2.2 Motivations

As confirmed by prior work [27, 54, 55] and our results in §5, data-driven methods can deliver significant wins over rule-based heuristics and are crucial to enabling the effective rate control that today's video conferencing applications demand. Surprisingly, despite their potential benefits, these solutions have yet to gain traction in production deployments. In conversations with the operators of major production video conferencing deployments, these solutions do not meet the

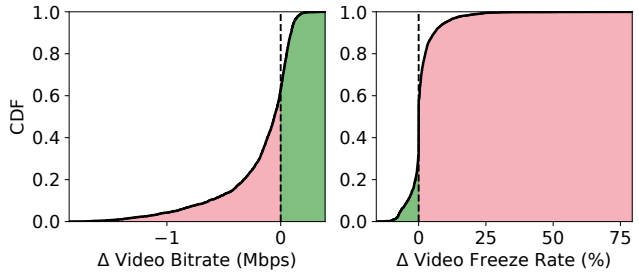


Figure 2: Distribution of changes to video QoE observed (relative to GCC) during online RL model training. Improvements are shaded in green; degradations are shaded in red.

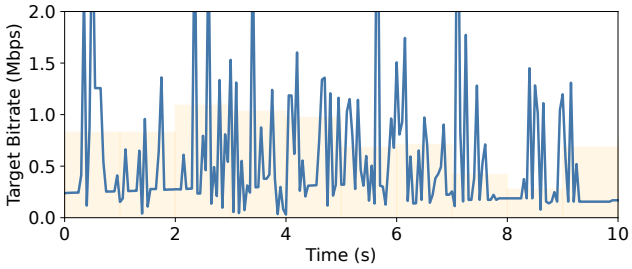

Figure 3: Example disruptive behavior observed during online RL training; network bandwidth is shaded in yellow.

practicality constraints of production environments. In particular, the biggest concern is the disruption of client video conferencing sessions during model training.

Fundamental to existing solutions is their use of reinforcement learning, a trial-and-error learning mechanism that trains a model by iteratively interacting with an environment and updating the model based on the interaction outcomes. For existing solutions, randomly initialized RL agents (models) are placed directly on client devices and are allowed to dictate the bitrate decisions for real user-facing video conferencing sessions. Over time, the models gain experience and converge to a high-performing policy; however, this comes at the cost of disruption to the quality of video conferencing calls during the training process. Prior approaches explicitly encourage exploration of different actions and behavior during training (by adding an entropy bonus to the learning objective); the bitrate decisions taken during exploration may be far from the ideal bitrate decision for that particular scenario and dramatically degrade the quality of a video call.

Quality disruptions of online learning. To observe how the performance of video conferencing sessions is affected during training, we ran a series of experiments. We train an online RL algorithm in our video conferencing testbed and periodically record the QoE metrics of affected sessions. More details about our video conferencing testbed, online RL implementation, and QoE metrics can be found in §5. Note that our implementation includes the temporary fallback mechanism introduced by OnRL [55] which switches back to the rule-based heuristic when overuse is detected in the hope of reducing catastrophic behavior.

Fig. 2 shows the effects on performance (relative to GCC) during model training for two key QoE metrics. We find that 62% of calls experience a worse average video bitrate, with degradations as low as −1.9 Mbps (for context, the average bitrate of a call is 1.03 Mbps). 43% of calls experience higher video freeze rates, with freeze rate increases as much as +79%. Intuitively, these performance degradations are due to the exploratory nature of online RL mechanisms. Fig. 3 highlights some of the disruptive behavior that causes performance degradations: repeated switching between low and high bitrates, bandwidth underutilization, and overaggressive bitrate ramp-ups. Fallback mechanisms fail to resolve these issues because they are only activated once catastrophic behavior is detected. Further, these degradations are exacerbated by the iterative development process of model optimization across different model designs and hyperparameters—the costs of training (e.g., QoE degradations) will be incurred every time.

2.3 Alternative Approaches

Training in simulation. Earlier work [27, 55, 56] has investigated training policies in simulated or emulated environments to avoid the user-facing quality degradations seen in previous approaches. However, they found that these models perform poorly in production due to the "simulation-to-reality" gap [12, 20], where simulated environments fail to fully and accurately capture the complexity of production systems and any slight deviation in system dynamics can lead to cascading performance issues. For more details, we refer readers to prior reports [27, 55]. Improving simulation fidelity in networked systems remains an active area of research [16, 19].

This gap also explains why starting with a "pre-trained model" from simulation and then fine-tuning it online in production is problematic. The disparity between simulated and real environments, combined with the significant experience required for fitting an RL model to a new distribution of environments, means the model typically needs major revisions rather than minor adjustments. This would disrupt production services and negate the benefits of "pre-training". Further, in our review of related work [27, 54, 55], we found that prior approaches always trained models from scratch in the deployment setting, starting with completely untrained models.

Tuning GCC knobs. Prior work [15] has shown the benefits of using data-driven parameter tuning for ABR heuristic algorithms. However, applying this approach to GCC faces three main challenges. First, GCC bakes in handcrafted rules that are inherently heuristic and suboptimal, thereby constraining the potential impact of hyperparameter tuning. Second, GCC does not support extracting insights from a richer set of network signals, depending instead primarily on a single, unreliable network signal (the gradient of queuing delay). Lastly, its codebase includes hundreds of tunable knobs, making it unclear how to prioritize or manage them effectively.

2.4 Summary

Recent data-driven approaches demonstrate considerable improvements over their rule-based counterparts. However, they

face minimal adoption in production due to the disruptive nature of their interactive trial-and-error-based online learning approach. Alternatively, policies trained in simulation perform poorly when deployed to production due to the "simulation to reality" gap. How to capitalize on the performance improvements offered by data-driven approaches while adhering to the constraints of production environments is an open question faced by video conferencing system operators.

3 Vision: Learning By Observation

In this paper, we claim that there is a viable path forward, but it requires rethinking the end-to-end design of data-driven rate control systems, from how we source the data to how we leverage and learn from it.

3.1 The Data of Prior Approaches

Prior data-driven approaches collect training data by iteratively deploying and continually updating DNN-based rate control policies in production video conferencing systems, and logging the resulting behavior and outcomes [27, 54, 55]. These logs are shipped from users to a central server, where they are processed and then fed to a training algorithm that updates the weights underlying the current version of the rate control policy. The updated weights are shipped out to the clients and the next round of training proceeds.

At the central server, data processing of the logs involves extracting structured sequential data, i.e., series of (state, action, reward) tuples. A (s_t, a_t, r_t) tuple represents the following: at a given time t, the rate control policy takes as input recently observed information about application and transport layers (captured as vector s_t) and outputs an updated target bitrate a_t. The effect of updating the target bitrate to a_t on application performance (e.g., the change in video throughput, freezes, frame delay, etc.) is quantified as r_t. Such sequences of (state, action, reward) tuples offer a structured way to reflect the experiences and effects of a rate control policy.

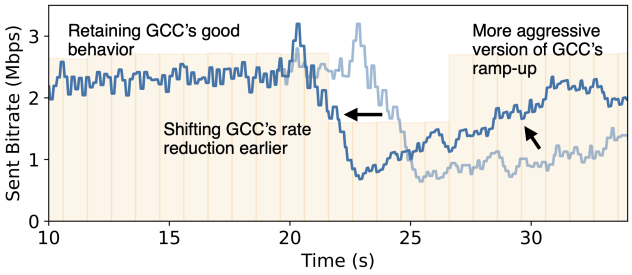
This data provides critical feedback to the training process by reinforcing decision-making that leads to good behavior (high reward) and penalizing decision-making that leads to poor behavior (low reward). Recall that the training algorithm initially knows nothing about the environment or the ideal behavior. As a result, the initial rate control policies take random actions. This exploratory behavior helps build a growing set of diverse experiences, each trajectory corresponding to a different sequence of possible decisions. Over time, as the weights of the rate control policies are updated and additional logs are collected, the model identifies high-potential paths and ultimately, converges to a policy that maximizes the cumulative reward. In the process, each step of deployment and data collection provides a critical feedback loop, enabling the training algorithm to (1) test out new behaviors, and (2) correct any misunderstandings in the learned model.

However, as quantified in §2.2, accumulating this rich and diverse dataset requires deploying partially trained policies to production environments and disrupting the quality of video conferencing sessions for users. From the perspective of a production deployment operator, this is not a viable option.

3.2 An Alternative Source of Data

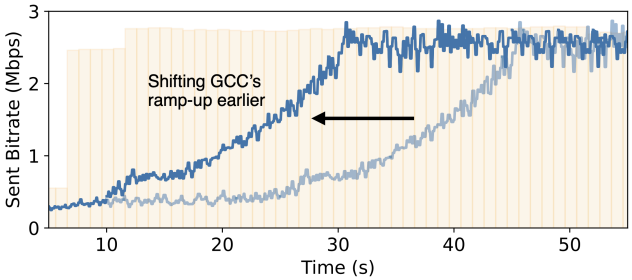
In this paper, we posit that there is a viable alternative source of data: the experiences of the rule-based algorithm *currently deployed* in production settings for rate control (e.g., Google Congestion Control). Unlike prior approaches, this data source can be obtained without deploying partially trained or untested rate control policies, thereby avoiding the disruptions outlined in §2.2. Instead, the data is collected from a rate control heuristic already in production, where it is logged at a fine granularity for purposes such as monitoring, debugging, and improving the heuristic algorithm [2, 6]. Similar to previous methods, these logs can be post-processed to extract sequences of (state, action, reward) tuples, capturing the experiences of the deployed rate control policy.

However, ultimately, these logs reflect the behavior of a single, static rate control policy (production systems typically deploy a single algorithm, e.g., the in-house rule-based heuristic). The logs of prior approaches, on the other hand, reflect the behavior of hundreds of rate control policies, learned and deployed over hundreds of epochs of training. As previously described, the diversity in behaviors enables the algorithm to learn an effective rate control policy. This begs the question: how we can learn a better rate control policy from the experiences of a single rate control policy?



Besides the interactive RL approaches of prior work, there exist alternative data-driven approaches such as imitation learning (e.g., behavior cloning) [31]. However, the goal of these methods is to learn the *same* behavior as reflected in the training data; our goal is to learn a *better* rate control strategy.

3.3 Opportunity



In this section, we introduce a novel approach to learning from the logs of GCC; we start by describing a key observation about the nature of GCC's shortcomings.

As discussed in §2.1, GCC's suboptimal performance stems from delayed or overly cautious responses to bandwidth changes. During sudden bandwidth drops (Fig. 4a), GCC's reliance on hand-tuned thresholds of limited network signals delays congestion detection and subsequent corrective actions. This lag results in network overutilization and video freezes. When network capacity increases, GCC exhibits overly cautious ramp-up behavior, hesitating to increase the bitrate for fear of overshooting the available capacity (Fig. 4b).

Notably, despite these issues, *GCC eventually makes the correct directional adjustments*— ramping down after detecting congestion or gradually increasing its bitrate when the network allows. This observation is crucial: it implies that, within the very logs where GCC performs poorly, there are also *positive* examples that demonstrate how timely or more aggressive actions could have prevented unnecessary freezes or underutilization. These examples present a unique opportunity to develop an improved rate control algorithm directly

(a) After the network bandwidth drops at `t=22`, it takes 3 seconds for GCC's sending bitrate to catch up. By shifting GCC's bitrate reduction earlier, we can reduce the degree of network overutilization.

(b) After the network bandwidth increases at `t=7`, it takes 40 seconds for GCC's sending bitrate to catch up. By shifting GCC's bitrate ramp-up earlier, we can increase network utilization.

Figure 4: Potential improvements by rearranging sequences of actions within GCC's logs.

from GCC's logs. Instead of considering entirely new actions or behaviors, we can improve through careful selection and application of actions already demonstrated in the logs.

For example, in Fig. 4a, as GCC eventually reduces its bitrate following a bandwidth drop, the trace captures a range of actions: initially, actions at the same bitrate and subsequently, actions at lower bitrates. These logs also capture detailed network telemetry data reflecting the state before and after each action. Together, this data provides valuable examples that can be analyzed and optimized. Specifically, these examples can be used to (1) identify congestion signals more effectively and (2) select lower target bitrates more promptly. Similarly, as illustrated in Fig. 4b, when GCC (conservatively) increases its bitrate in response to improved bandwidth, the telemetry traces capture a sequence of steadily increasing bitrate adjustments. These actions, paired with their corresponding telemetry signals, provide examples of different responses and ultimately, a path to achieving improved network utilization.

Both scenarios illustrate that, despite capturing suboptimal decisions, GCC's logs contain valuable data for achieving critical improvements. By systematically analyzing GCC's behavior alongside dense telemetry signals, it becomes possible to reorder its actions into a more optimal sequence without the need to devise entirely new strategies. The central insight lies in leveraging GCC's imperfect but fundamentally directionally correct decision sequences as foundational building blocks for constructing a more effective rate control policy.

To quantify the potential gains from this log-based learning approach, we implemented an approximate oracle algorithm that has access to ground-truth network dynamics but is restricted to the set of actions that appear in a given GCC log. On the network trace depicted in Fig. 4a, the oracle achieves a 52% increase in video bitrate and a 98% reduction in freeze rates. For the scenario in Fig. 4b, it achieves an 80% increase in video bitrate and a 79% reduction in freeze rates. Across our entire corpus of network traces (§5), this oracle-based approach yields a 19% improvement in video bitrate and an 80% decrease in freeze rates compared to GCC.

3.4 Challenges

However, realizing this approach in a way that is both practical and effective while adhering to the constraints of a production deployment setting requires addressing two key challenges.

Challenge #1: Lack of feedback. Ultimately, the goal is to learn an improved rate control policy without disrupting users (the main pitfall of prior approaches). However, producing an improved rate control policy requires learning a strategy that deviates from the behavior seen in the GCC logs (e.g., an alternative sequence of actions). Learning this alternative (and better) strategy requires reasoning about (and extrapolating) the expected outcomes of alternative behaviors. This is a risky proposition without access to feedback (i.e., testing the new strategy and validating the prediction). The greater the deviation, the greater the potential risk of extrapolation error; any errors in extrapolating will compound, as the resulting deviation will lead to more deviation. Ultimately, this comes at the detriment of the performance of the learned policy. In the field of learning sequential decision-making without feedback, this phenomenon is referred to as "distribution shift" [33]. In our evaluation ablation studies (§5.5), we find that failing to address distribution shift can dramatically cause performance degradations, increasing P90 video freeze rates over 12×. To address this issue in the context of learning improved rate control policies, we need a way to effectively balance decision-making deviations with risk mitigation.

Challenge #2: Environmental variance. Further complicating the ability to develop an understanding of how any given target bitrate update affects observed outcomes (rewards) is the presence of external phenomena outside the control of the bitrate decision-making policy that affect application behavior and ultimately, the outcomes of a given bitrate update. Unlike prior work [27, 56] that leverages emulation or simulation-based systems and can control for (or eliminate) the amount of noise introduced, production-based deployments do not have that luxury. Concretely, we find that this noise manifests in two ways. First, video conferencing applications apply additional downstream application logic after consuming a target bitrate update from the bitrate controller; this logic affects the *achieved* encoding and sending bitrate [28, 56]. Second, network conditions change rapidly (often in unpredictable ways [50, 51, 53])—taking the same action at the same state in two different instances could result in different outcomes because of rapid changes in network conditions (i.e., the band-

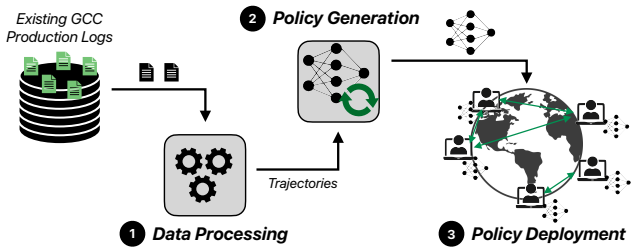


Figure 5: Overview of Mowgli's 3 phases: (1) data processing for extracting trajectories from GCC telemetry logs, (2) policy generation for model training, and (3) policy deployment.

width dropped). Ultimately, this makes it difficult to determine whether differences in the observed outcomes of two bitrate decisions arise from external factors or the effectiveness of the target bitrate decision itself. In our evaluation studies (§5.5), we find that failing to address the effects of environmental variance can increase P90 video freeze rates over 10×. To have an effective solution, we need a way to explicitly express and account for environmental noise.

4 Design

Fig. 5 describes Mowgli's workflow. First, Mowgli consumes existing production logs or builds on existing logging instrumentation to extract telemetry signals and generate trajectories of (state, action, reward) tuples that reflect the experiences of the underlying rate control algorithm (§4.1). Then, Mowgli uses these trajectories to train a lightweight neural network for rate control (§4.2). Training occurs entirely offline using only telemetry logs, i.e., no video playback or simulation is required; the resulting policy is then deployed on client devices (§4.3). We describe implementation details in §4.4.

4.1 Data Collection & Processing

Mowgli operates on production telemetry data that reflects the experiences of in-house rate control algorithms. These logs are typically already captured for other purposes such as debugging, observability, and quality assurance [2, 6]. For example, recently released logs from Microsoft Teams capture periodic (every 60 ms) application and transport layer metrics (e.g., packet loss, packet delay, received bitrate, and target bitrate) along with session-level QoE metrics (e.g., duration of video freezes, average media bitrate received) [2]. If the existing production logs do not provide the necessary data, we can build on existing instrumentation platforms to extract the additional data (e.g., Zoom, Microsoft Teams, WebRTC have built-in logging capabilities [1, 2, 4, 7, 9, 10]). Once logs are aggregated across clients to a central server, we apply Mowgli's processing logic to extract trajectories of (state, action, reward) tuples.

We define the state vector and action based on prior work [27, 54, 55]. The state vector is a window of periodically captured transport and application-level statistics (we use a window of 1 second). We describe the state vector in Table 1. We find that augmenting the state vector inputs with four additional features further improves performance: the previous bitrate action, the minimum RTT observed so far, the number of timesteps since the last transport feedback report was received, and the number of timesteps since the last packet loss report was received. We measure the impact of these additional features in §5.5. The action is the updated target bitrate that is consumed by the application. We define the reward as a function of the achieved bitrate, the average RTT, and the average packet loss. Inspired by prior work, we leverage the following formulation:

State Vector Inputs
Sent Bitrate
Acknowledged Bitrate
Previous Action
One-Way Packet Delay
One-Way Packet Delay Jitter
Inter-packet Arrival Delay Variation
Round Trip Time
Minimum Round Trip Time Observed So Far
Timesteps since Last Transport Feedback Report
Packet Loss
Timesteps since Last Packet Loss Report

Table 1: State vector of transport and application-layer statistics logged every ~ 50 ms.

$$R = \alpha \cdot throughput - \beta \cdot delay - \gamma \cdot loss \quad (1)$$

We normalize throughput to the range (0, 6 Mbps) and the delay to (0, 1000 ms); we set α to 2, β to 1, and γ to 1.

4.2 Policy Generation

Next, Mowgli leverages the aggregated and preprocessed logs to generate improved rate control policies. In §3, we described an approach to improve upon GCC by rearranging the actions within a GCC log. In this section, we explain how to realize this approach in practice. First, we describe Mowgli's use of a lightweight neural network to represent a rate control policy on client devices; we then detail how we overcome the challenges of realizing this approach presented in §3.4.

Leveraging neural networks. To reason about potential actions for a scenario, we need a way to estimate the expected outcomes for (state, action) pairs. We turn to neural networks that we can train offline (using GCC logs) and subsequently deploy to client devices. In particular, we leverage a state-of-the-art learning algorithm, Soft Actor-Critic (SAC) [30].

SAC consumes the trajectories of (state, action, reward) tuples previously experienced by GCC and trains two complementary functions (both represented by parameterizable neural networks): the actor and the critic. The actor network (π_θ) learns a deterministic policy that maps states to actions; the critic network (Q_ϕ) evaluates the expected long-term reward (return) for a given (state, action) pair. SAC leverages the critic to provide a learning signal (via the Q-value) for

the actor, enabling it to improve the policy by following the gradient of expected returns.

Following standard Q-Learning [48] techniques, we train the critic by minimizing the Mean Squared Bellman Error:

$$\mathbb{E}_{(s_t,a_t,r_t)\sim D}\Big[(Q_\phi(s_t,a_t)-(r_t+\gamma\cdot\max_{a'}Q_\phi(s_{t+1},a')))^2\Big] \quad (2)$$

The actor network is updated by maximizing the Q-value predicted by the critic:

$$\max_\theta \mathbb{E}_{s\sim D}[Q_\phi(s,\pi_\theta(s))] \quad (3)$$

We train Q_ϕ and π_θ in tandem, repeatedly iterating through the dataset of (state, action, reward) tuples. The pseudocode in Algorithm 1 describes the key components of the dual training process: updating the critic, and then updating the actor. Upon convergence (and during inference), we only need to retain π_θ: given state s, return $\pi_\theta(s)$.

Algorithm 1: Soft Actor Critic Algorithm

Input: Corpus of GCC Observations: $D \in \langle S,A,R\rangle$

repeat until convergence:
- Randomly sample a batch of transitions, $B=\{(s,a,r,s')\}$ from D
- Compute target:
  - $y \leftarrow r+\gamma\cdot Q_\phi(s',\pi_\theta(s'))$
- Update critic function:
  - $\nabla_\phi \frac{1}{|B|}\sum_{(s,a,r,s')\in B}(Q_\phi(s,a)-y)^2$
- Update actor network:
  - $\nabla_\theta \frac{1}{|B|}\sum_{s\in B} Q_\phi(s,\pi_\theta(s))$

def `update_bitrate(`*state s*`):`
- $a \leftarrow \pi_\theta(s)$
- **return** a;

Further, we prepend the actor and critic networks with a learned embedding over the raw state vector to take advantage of the temporal aspect of the state. Following prior work, the state is a windowed series of metrics—we incorporate a Gated Recurrent Unit (GRU) to extract trends over the window and reduce the raw state to a more condensed vector [23]. Implementation details can be found in §4.4.

Conservative learning. While the rate control policies are now trained offline in the cloud, the challenge of a lack of feedback persists **(Challenge #1)**. Learning an improved rate control policy requires learning a strategy that deviates from the behavior seen in GCC. The greater the deviation, the greater the potential risk of extrapolation error; any errors in extrapolating will compound and drastically harm performance. In this section, we describe how the errors come to be in the context of the actor and critic networks, and then we go on to describe a risk mitigation strategy.

Recall that the learned critic function ultimately guides the decision-making policy (actor) to select actions that optimize for the best behavior. The critic Q_ϕ is responsible for learning a regression to estimate the value of (state, action) pairs observed in the dataset. It is also responsible for learning a regression to estimate the value of (state, action) pairs *not seen* in the dataset. The latter is much harder because it requires extrapolating—that is, using values of observed (state, action) pairs to estimate values for unseen (state, action) pairs. As a result, the regressor is likely to be more error-prone for those unseen regions of the state-action space. This is particularly problematic because the actor is trained to learn actions that maximize the critic function (Equation 3). Any mistakes or erroneous value assignments can lead the actor astray; in particular, the actor becomes biased toward selecting actions that have been erroneously assigned high values. The result is a poor-performing policy, one that can be potentially worse than the one featured in the data used to train it.

To address this, we opt for the following approach: when leveraging the output of the learned critic to teach the actor, trust the estimates more when the regressor is confident (i.e., the estimate is based on (state, action) pairs seen or are close to those observed in the dataset) and trust the estimates less when the regressor is less confident (i.e., the estimate is heavily extrapolated). Recall that in cases where GCC performs poorly, it eventually makes adjustments in the correct direction (§3.3)—these sequences provide a sufficient number of examples to confidently extrapolate about alternate trajectories in areas that GCC needs improvement.

In practice, we can achieve this by penalizing the estimated values for low-confidence regions and elevating those for high-confidence regions. Consequently, when the actor is leveraging the output of the critic, it learns to select actions that maximize the modified estimated value instead (i.e., one that takes into account the accuracy of the estimate) and ultimately, avoid falling into a trap of taking actions with erroneously high estimates due to errors in the learned regressor.

In particular, we leverage a state-of-the-art technique known as Conservative Q-Learning (CQL) [32]. CQL adds a regularizer to the critic's loss function (Equation 2):

$$\alpha\cdot\mathbb{E}_{s\sim D}\Big[\mathbb{E}_{a\sim\pi(a|s)}Q(s,a)-\mathbb{E}_{a\sim D}Q(s,a)\Big] \quad (4)$$

The regularizer first guides the critic to learn a lower bound on estimated values for all (state, action) pairs (i.e., a "conservative" estimate); simultaneously, it "pushes up" the values for (state, action) pairs observed in the training dataset. CQL provides an adjustable parameter α to identify the appropriate magnitude of the conservative penalty: too high of a penalty creates a conservative, low-risk policy that performs similarly to the behavior featured in the logs; too low of a penalty negates the benefits of this approach altogether, resulting in a risky (and potentially, low-performing) policy. We empirically find that setting $\alpha = 0.01$ achieves the best tradeoff; in our ablation studies in §5.5, we compare different settings of α.

Distributional representation. The second main challenge of learning from heuristic data collected in production deploy-

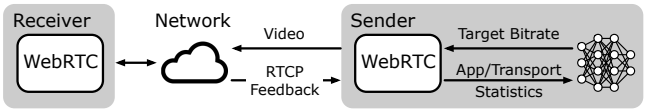

Figure 6: Mowgli deploys its model in the sender application's rate control logic.

ment settings is the presence of external phenomena outside the control of the rate control policy that ultimately complicates reasoning about the observed outcomes for a given (state, action) pair **(Challenge #2)**. To address this, we opt to explicitly account for the variance in expected return for a given (state, action) pair by modifying the way the learned value is represented. Traditionally, the critic learns a scalar value—i.e., the expected value of starting at state s and taking action a. We modify the critic function to learn a *distribution* over expected outcomes instead [18]. A probability distribution explicitly accounts for the possibility of multiple different futures, despite the bitrate agent taking the same action. Directly encoding a probability distribution into the model results in a more detailed representation of the environment's stochasticity and a more comprehensive way of capturing the effects of any given decision.

To implement this, we modify the output of the critic function to be a vector (representing a distribution) and update the loss function to support a vector representation. In line with prior work, we incorporate the Quantile Huber loss function, which compares distributions and penalizes estimates differently depending on which quantile they belong [24].

4.3 Policy Deployment

Based on insights from our generalization study (§5.3), Mowgli achieves performance wins across diverse network scenarios, provided that the corresponding state/action distributions are represented in the consumed telemetry logs. To adapt to new network environments, Mowgli continuously monitors these logs, and if a shift in the underlying state/action distribution is detected, the system triggers model retraining. Note that, unlike models trained in simulation (§2.3), Mowgli's model is amenable to further fine-tuning, as it is initially learned on the same distribution of environments and dynamics as the deployment setting. As a result, only minimal corrections are needed during online deployment (e.g., to account for environmental drift).

Deploying Mowgli's rate control algorithm requires modifying the application's rate control logic and sending over the weights parameterizing the learned model (Fig. 6). Inside the application, we spawn an additional Python process responsible for serving the model. The application code and Python process communicate via an interprocess pipe; the Python process consumes live telemetry data logged by the application instrumentation code and outputs an updated bitrate.

4.4 Implementation

Inspired by OpenNetLab [26], we implement Mowgli on top of WebRTC [8], an open-source framework for real-time video conferencing. Our current implementation, in line with prior work [28], targets unidirectional video without audio. Further, to isolate the effects of rate control in WebRTC, we set `DegradationPreference=DISABLED` [5]. We leverage the PyTorch [39] and d3rlpy [44] libraries to train and deploy Mowgli's learned rate control algorithm. We set the conservative loss penalty hyperparameter (α) to 0.01 and the number of quantiles (N) in our distributional value representation to 128. The actor and critic neural networks have 2 hidden layers of size 256; the GRU has a hidden unit size of 32.

5 Evaluation

We evaluated Mowgli on a diverse set of networks, both in emulation and in the wild. Our key findings are:

- Mowgli delivers substantial QoE improvements over GCC in emulated networks, increasing average video bitrates by 15–39% while reducing video freeze rates by 60–100%.
- Mowgli achieves similar performance to existing (impractical) data-driven online RL approaches, with average bitrates within 0.5–13.1% and freeze rates within 0–19%.
- Mowgli can achieve wins across diverse network scenarios if sufficiently represented in consumed telemetry logs.
- We deploy and evaluate Mowgli on real cellular networks across four U.S. cities. On target networks with high dynamism, Mowgli increases average video bitrates by 17.7% while maintaining similar levels of video freezes.

5.1 Methodology

Experiment setup and testbed. For lack of access to a production video conferencing deployment, we set up our own testbed to collect GCC logs and evaluate Mowgli. We extended the AlphaRTC [26] fork of WebRTC to run an end-to-end client-to-client video conferencing workflow. We run both clients on a single machine and use a network emulation tool (Mahimahi [37]) to emulate the network between clients.

To evaluate Mowgli on a diverse and challenging set of networks, we created a corpus of 87 hours of network bandwidth traces from two real-world datasets: FCC [3] broadband traces and Norway [42] cellular traces. We split each trace into 1-minute chunks. Following prior work [35], we filtered out traces with an average bandwidth of $<$0.2 Mbps or $>$6 Mbps. We used 60% of the traces for training, 20% for validation, and 20% for testing. Each network trace is randomly assigned to one of the following RTTs: 40, 100, and 160 ms. We use a queue length of 50 packets.

Similar to prior work [43], instead of recording and sending live video, we modify the WebRTC codebase to read from a prerecorded video. We use 9 different one-minute videos from a video conferencing dataset [38]; we randomly assign a video to each bandwidth trace. To create a corpus of "production logs," we collect logs from running GCC on the network traces in the training dataset. We note that although production logs from existing video conferencing platforms [2] exist, we

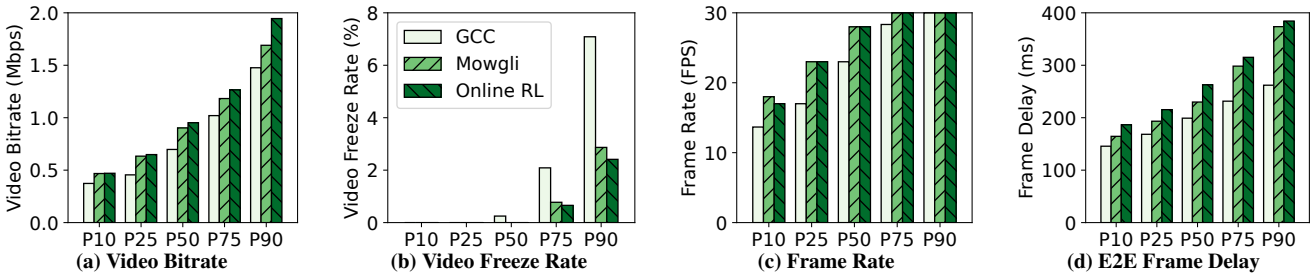

Figure 7: On emulated network traces, Mowgli consistently outperforms GCC and nearly matches the online RL baseline while avoiding QoE degradations during training.

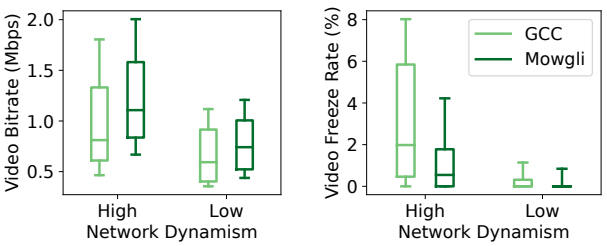
do not have access to their systems to perform an evaluation; therefore, we opt to use data from our own setup.

QoE metrics. We evaluate QoE across the following metrics: (1) average received *video bitrate* (Mbps), (2) *video freeze rate*—fraction of session experiencing freezes (as defined by WebRTC [13]), (3) *frame rate* (FPS), and (4) average end-to-end *frame delay*. The first three metrics are already available in the WebRTC application logs. To calculate the end-to-end frame delay, we embed a QR code into each video frame to indicate the frame ID. We then calculate the timestamp difference between when the frame is read and when the corresponding frame is displayed. Note that we only measure the end-to-end frame delay for experiments done on emulated networks because on real networks, the clients are located on different devices and require nontrivial time synchronization.

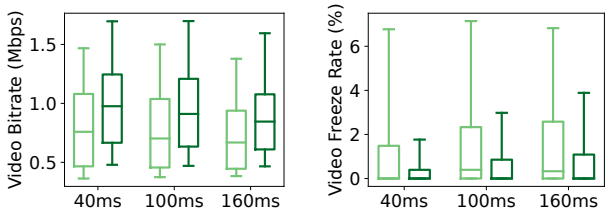
Baseline algorithms. We compare Mowgli against the following baselines:



- **Google Congestion Control (GCC)** [21]: the de facto rate control algorithm for video conferencing. It employs hand-tuned rule-based heuristics to characterize network behavior based on recent packet delay and loss measurements. We use the built-in implementation of GCC in WebRTC.
- **Online RL**: an online reinforcement learning-based approach. We implement an in-house solution following the design and methodology of prior work [27, 54, 55]. The details of our implementation are provided in §A.1. Note that the reported results exclude quality degradations incurred during training (see §2.2); instead, we only present results from the model that performs the best on the test dataset.
- **Behavior Cloning (BC)** [40, 49]: an offline learning strategy that trains a rate control policy by imitating the behavior featured in existing logs through supervised learning.
- **Critic Regularized Regression (CRR)** [47]: another offline learning strategy that relies exclusively on existing logs for training. It is the underlying mechanism for Sage [52], a related work aimed at learning improved TCP congestion control algorithms from logs generated by dozens of different existing CC algorithms. Whereas CQL focuses on conservatively adjusting the critic function to avoid overestimating out-of-distribution actions, CRR regularizes the policy by using the critic's estimated values to guide the actor toward high-value actions of the dataset.

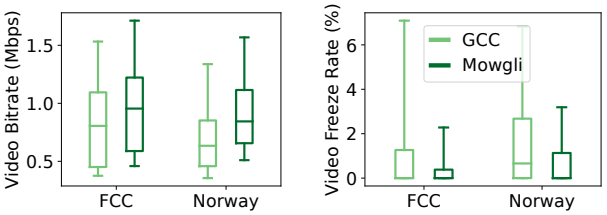
5.2 Overall Performance

Main results. Fig. 7 compares Mowgli with GCC and Online RL. There are two main takeaways. First, Mowgli consistently improves upon GCC; across reported percentiles, Mowgli increases the average bitrate by 14.5–39.2%, decreases the freeze rate by 59.5–100%, and increases the frame rate by 0–35.3%. End-to-end frame delays are within the 400 ms interactivity threshold [11], even with RTTs up to 160 ms. Second, despite learning completely offline, Mowgli's performance nearly matches that of the online RL baseline. Across percentiles, Mowgli achieves an average bitrate within 0.5–13.1% of Online RL's average. Mowgli's P75 and P90 video freeze rates are 0.77% and 2.87%, respectively, only slightly higher than Online RL's rates of 0.66% and 2.41%. For comparison, GCC's P75 and P90 freeze rates are 2.09% and 7.09%.



Breakdown by dynamism. To better understand how Mowgli performs in the network conditions where GCC performs poorly, we split the dataset of network traces based on the degree of network dynamism. Specifically, we calculate the standard deviation of 1-second network bandwidth chunks within each trace and split the dataset along the mean standard deviation across traces. We observe that Mowgli achieves its largest wins over GCC in traces with high bandwidth dynamism – across reported percentiles, Mowgli increases the average video bitrate by 10.8–43.8% and decreases the video freeze rate by 47.4–100% (Fig. 8). In contrast, for traces with less dynamism, Mowgli increases the average video bitrate by 8.0–29.6% and decreases the video freeze rate by 26.2–100%.

Breakdown by network dataset & delay. In Fig. 9, we break down the results from Fig. 7 based on different characterizations of the underlying network traces. We find that as network delay increases, Mowgli's P50 video bitrate decreases (976 kbps → 911 kbps → 845 kbps) and its P75 video freeze rates increase (0.39% → 0.86% → 1.09%). We report P75 video freeze rates because P50 video freeze rates are 0%. This is expected as higher network delays increase the time it takes for a model to receive feedback about potential network congestion and react appropriately; as a result, the model is less aggressive in its bandwidth ramp-ups. When split by



(a) Video Bitrate (b) Freeze Rate

Figure 8: Evaluating Mowgli's performance in network traces of varying network dynamism, measured by the degree of bandwidth variation. Whiskers show P10–P90. Mowgli's win relative to GCC is higher under high network dynamism.

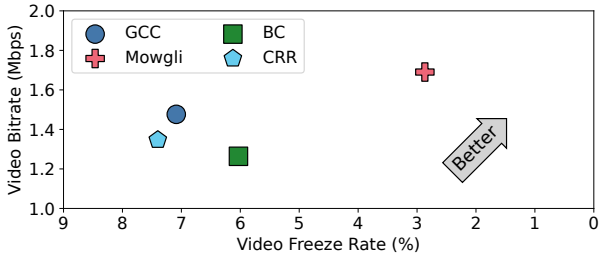
(a) Video Bitrate (Diff. RTT) (b) Freeze Rate (Diff. RTT)

(c) Video Bitrate (Diff. Dataset) (d) Freeze Rate (Diff. Dataset)

Figure 9: Evaluating Mowgli's performance in network traces of varying delay (RTT) and dataset. Whiskers show P10–P90.

dataset, Mowgli performs better in the FCC dataset than in the Norway dataset (954 kbps vs. 844 kbps P50 video bitrates, 0.39% vs. 1.13% P75 video freeze rates). The Norway dataset was collected over 3G cellular networks and therefore, features more network dynamism than the traces in the FCC dataset (which were captured on wired broadband networks).

Additional baselines. In Fig. 10, we compare Mowgli with two alternative learning strategies: Behavior Cloning (BC) and Critic Regularized Regression (CRR). We find that BC behaves less aggressively than Mowgli, achieving a P90 video bitrate that is 14.4% lower than GCC, whereas Mowgli increases the bitrate by 14.5% compared with GCC. This difference arises because BC only aims to imitate the behavior observed in the training logs and fails to effectively extrapolate to unseen scenarios. CRR, the underlying learning algorithm in Sage [52], performs worse than GCC on both metrics, with a 4.4% increase in the P90 video freeze rate and an 8.8% decrease in the P90 video bitrate. We hypothesize that this is due to the lack of state-action coverage featured in the logs of Google Congestion Control; the logs of Sage, on the other hand, contain the experience of dozens of different CC algorithms reducing the likelihood of erroneous estimates.



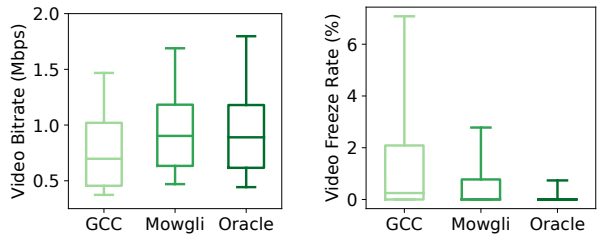


Figure 10: Mowgli outperforms additional baselines in bitrate and freezes (P90 performance is shown).

(a) Video Bitrate (b) Freeze Rate

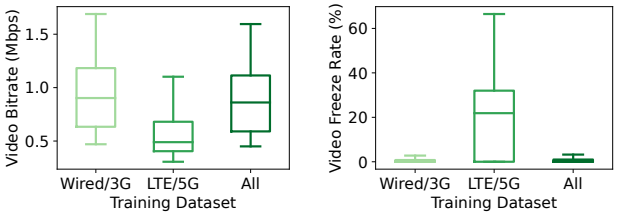

Figure 11: Comparing Mowgli against an approximate oracle algorithm that represents an upper bound on performance improvements over GCC; whiskers correspond to P10 and P90.

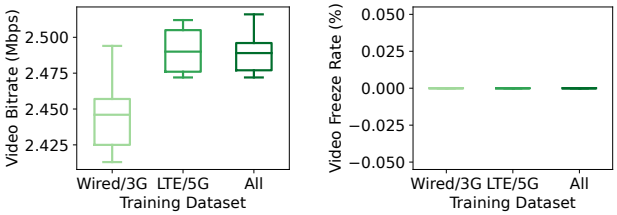
Comparison to approximate oracle. In §3.3, we implemented an approximate oracle algorithm to estimate the maximum possible improvement over GCC. This algorithm serves as an estimate of the (unattainable) upper bound on performance improvements. Fig. 11 compares this oracle with Mowgli. Across reported percentiles, Mowgli comes within 6% of the oracle's achieved video bitrate. Compared with GCC's video freeze rates of 2.1% at P75 and 7.1% at P90, Mowgli significantly reduces these rates to 0.8% and 2.9%, while the oracle further lowers them to 0% and 0.7%. These additional reductions are expected since the oracle algorithm has access to ground-truth network bandwidths in advance.

5.3 Generalization & Deployment Considerations



In this section, we examine the limits of Mowgli's ability to generalize to network conditions and types not represented in the production telemetry dataset. Additionally, we seek to quantify the benefits of model specialization for specific network conditions. To this end, we incorporate an additional set of network traces captured on LTE and 5G networks [29]. Following our established methodology, we collected GCC logs on these LTE/5G traces and trained a corresponding policy. We then evaluated this policy on network traces from the primary dataset, which consists of wired and 3G traces. The results are summarized in Fig. 12, with two key observations.

First, we find that Mowgli's generated policies perform poorly when evaluated on network conditions that significantly differ from those featured in the training telemetry logs. For instance, the LTE/5G-trained policy performs notably worse than the Wired/3G-trained policy when evaluated on Wired/3G network traces. This results in a 45.8% reduction in the P50 video bitrate and a 40.3× increase in the P75

(a) Video Bitrate (b) Freeze Rate

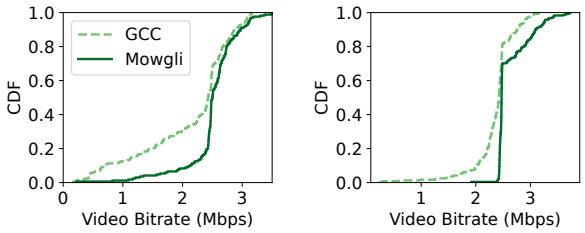
Figure 12: Evaluating Mowgli's performance on the Wired/3G network dataset when varying the network telemetry dataset consumed; whiskers show P10–P90.

(a) Video Bitrate (b) Freeze Rate

Figure 13: Evaluating Mowgli's performance on the LTE/5G network dataset when varying the content of the network telemetry dataset consumed; whiskers show P10–P90.

video freeze rate. Importantly, this is expected due to underlying state/action distribution differences in the corresponding GCC logs (e.g., GCC's average video bitrate is 1.6 Mbps higher in the LTE/5G dataset). We further discuss this in §7.

Second, we observe that specializing a model for a specific set of network traces is not strictly necessary. Instead, general models can achieve strong performance across network conditions, provided they are well-represented in the training data. For example, a model trained on both network datasets performs comparably to one trained solely on the Wired/3G dataset. While the Wired/3G-specific model achieves slightly better results (a 4.6% higher P50 video bitrate and a reduction in the P75 video freeze rate from 1.00% to 0.77%), the general model still performs effectively across conditions.



We conducted a similar analysis using the LTE/5G dataset, evaluating the same generalized model on these network traces (Fig. 13). The observed trends persist, with the Wired/3G-trained policy, for example, reducing the median video bitrate by 1.8%.

5.4 Real World Experiments

We evaluated Mowgli and GCC on real cellular networks in 4 different cities (Table 2). In these experiments, we set up conferencing sessions with a client running on a Macbook Pro (tethered to a Google Pixel) and a server in the cloud. Experiments were performed in several mobility scenarios (e.g., train, bus, car, walking, and stationary). To generate a dataset of GCC logs, we collected over 8 hours of video calls using GCC in Princeton, NJ and San Jose, CA on a 4G/LTE network. Once Mowgli generated a policy, we evaluated the resulting model in 2 different scenarios: (a) the same networks and cities and (b) different cities. During our evaluation, we

Scenario	Network	Cities
A	4G/LTE	Princeton, NJ; San Jose, CA
B (new cities)	4G/LTE	New York City, NY; Nashville, TN

Table 2: Cities and network types for in-the-wild evaluation.

(a) Scenario A (b) Scenario B

Figure 14: Evaluating Mowgli on real-world cellular networks; scenarios are described in Table 2. Mowgli outperforms GCC across bitrate percentiles, while freezes remain statistically indistinguishable between the two (not shown).

alternated running GCC and the generated policy, collecting over 4 hours of data for each scenario.

We observe that Mowgli's wins over GCC extend to cellular networks in both scenarios, increasing video bitrates across reported percentiles by 3.0%–2.1× (Fig. 14a) and 2.0%–20.8% Fig. 14b). Video freezes—as a rare event—are inherently challenging to measure reliably [51]. While we currently lack sufficient evidence to draw definitive conclusions, the observed rates across 120 runs per policy/scenario appear statistically indistinguishable (results not shown).

5.5 Ablation Studies and Microbenchmarks

Algorithm design ablation. Fig. 15a compares Mowgli with two variants: (1) Mowgli without the conservative learning regularizer, and (2) Mowgli without the distributional representation. Removing the regularizer, which adjusts the learned estimates of the critic function based on sample confidence, makes the model prone to actions with erroneously high estimated values and results in 11.3× higher P90 video freeze rate. Without the distributional representation, which accounts for external phenomena outside the control of the bitrate decision-making policy, P90 video bitrates drop by 5.6% and P90 video freeze rates increase by 9.9×.

Varying state design. Fig. 15b shows the benefits of the additional state features. Removing "Report Intervals", which indicates the staleness of the sender-side transport feedback report, leads to an 8.7% lower video bitrate. Removing "Min RTT", which indicates how fast the client can receive (and react to) feedback and helps control the model's aggression, leads to a 1.2× higher freeze rate. Removing "Prev Action", which enables smooth rate control, results in a 3.1× increase in the video freeze rate.

CQL α parameter sensitivity. α dictates the relative weight of the conservative penalty in the learning algorithm. In Fig. 15c, a larger α creates a conservative, low-risk policy (∼57% lower freeze rates), but lowers video bitrates by 34.9%

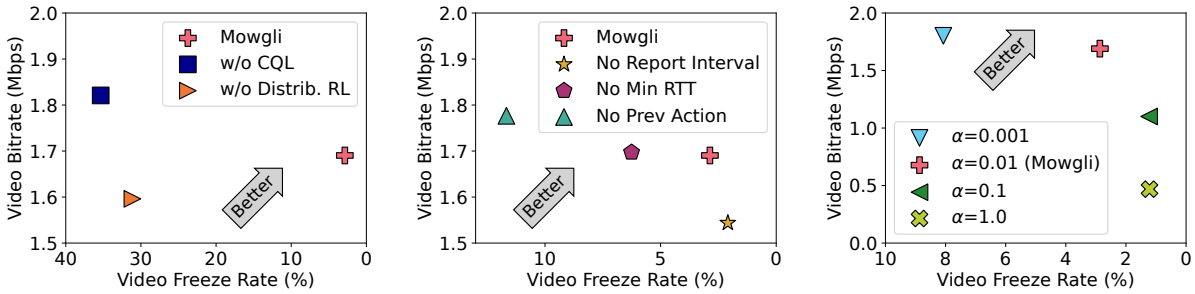


Figure 15: Ablation results varying the algorithm design, state design, and alpha. Markers correspond to P90. Mowgli's design achieves the best bitrate-freeze tradeoff.

and 72.3%, respectively. In contrast, $\alpha < 0.01$ increases the amount of deviation (and therefore risks: 1.8× higher video freeze rate) albeit increasing bitrate by 6.6%.

System overheads. We study the compute and storage overhead of deploying Mowgli. The compressed (state, action, reward) logs take ∼117 kB for a 1-minute call. Mowgli's generated policy (weights) is 316 kB (corresponding to 79k parameters) and takes ∼6 ms to run on the CPU.

6 Related Work

Alternative designs and knobs for video conferencing. Recent work has explored different optimization dimensions in videoconferencing. Salsify [28] co-designs the video codec and transport protocol to quickly respond to changing network conditions and achieve low latency. Gemino [45] designs a neural codec for high perceptual quality in low bandwidth environments. Grace [22] designs a loss-resilient neural codec. AFR [36] adapts the frame rate for video conferencing applications with ultra-high-definition demand. Mowgli is complementary to these works and can be extended to incorporate these alternate dimensions, which we leave for future work.

ML for networked systems. Machine learning has been applied to various other challenges in networked systems. For example, to improve adaptive bitrate (ABR) selection in video streaming, Pensieve [35] trains a reinforcement learning agent in simulation, whereas Puffer [51] deploys a neural network-based model predictive control scheme under real-world conditions. Unlike video streaming, which deals with discrete bitrate adaptation, video conferencing requires continuous rate control, tighter latency constraints, and frequent (every 50 ms) decision-making for on-the-fly encoding and compression. Beyond ABR, ML has been explored for TCP congestion control; Orca [14] employs an online RL agent, while Sage [52] trains offline but requires additional data collection with multiple expert policies. In contrast, Mowgli leverages existing logs of a single policy (e.g., GCC).

7 Discussion

Pitfalls of leveraging production traces. Conceptually, the challenges described in §3.4 align with those in recent research on counterfactual reasoning in trace-driven simulations for adaptive bitrate selection [16,17,19,46], e.g., the impact of latent confounders (factors that impact system dynamics but are not explicitly featured in logs). Veritas [19] addresses this by employing advanced statistical methods to explicitly infer these variables. While these efforts aim to refine simulations for more reliable counterfactual reasoning, Mowgli focuses on generating an enhanced rate control policy derived from the behavior of an existing heuristic algorithm. Rather than depending on accurate counterfactual reasoning universally, Mowgli limits it to scenarios where sufficient data is available for reliable analysis (i.e., a conservative approach—§4.2). In cases lacking enough log data, Mowgli learns to mimic the baseline GCC behavior. Incorporating insights from these works into Mowgli and other video conferencing systems is a promising avenue for future exploration, such as improving the critic by explicitly inferring latent confounders.

Limitations of a data-driven approach. A limitation of any data-driven approach is that if the underlying data distribution shifts substantially from the one captured in training, the model must be updated [34]. In the case of Mowgli, encountering previously unseen network conditions (e.g., new bandwidth ranges) would necessitate a model update (§5.3). This limitation reflects the inherent trade-off of data-driven methods: Mowgli is constrained to perform well in environments it has been trained on, unlike GCC, which operates under a broader set of pre-designed assumptions. However, unlike models trained in simulation or from scratch, Mowgli's model—trained on real user interactions and dynamics—starts on a much closer distribution to its deployment setting. This makes it more amenable to fine-tuning, requiring only minimal adjustments to account for environmental drift.

8 Conclusion

In this paper, we presented Mowgli, a system for *practically* learning improved bitrate control algorithms for video conferencing. Whereas existing data-driven reinforcement learning-based approaches fall short of meeting the practicality constraints of production settings, Mowgli demonstrates the possibility of learning from data already collected in existing system telemetry logs (and avoiding the QoE disruptions of prior work) to generate improved bitrate control algorithms.

A Appendix

A.1 Online RL Setup

Experiment Setup and Testbed. Similar to prior work [14, 54], our online RL baseline relies on a cloud server to support the training. The centralized server has an AMD EPYC 7543P 32-core CPU, 256 GB of RAM, and an NVIDIA RTX A6000-48G GPU. We use 30 CloudLab [25] nodes ("workers") to emulate end users in our experiments, each with an Intel Xeon D-1548 8-core CPU and 64 GB of RAM. We modify Stable Baselines3 v2.1.0 [41] to support ingesting state-action-reward tuples from parsed traces and use PyTorch v2.0.1 to train and serve the neural network. Similar to prior work, we use a state-of-the-art off-policy algorithm [30]. Following OnRL [55], we implement a fallback mechanism that allows the sender to temporarily downgrade to the default heuristic (GCC) if catastrophic QoE degradations are detected during training.

In every round of online RL training, the RL server dispatches the latest model to all 30 worker nodes. Similar to how we collect GCC logs in our main experiments, we run both the sender and receiver client on the same node. Each worker uses Mahimahi [37] to replay a random one-minute network bandwidth trace from the same diverse dataset Mowgli uses. At the end of every video conferencing session, each node parses the sender/receiver logs to construct a state-action-reward trace and sends it back to the RL server. The RL server performs one training epoch based on the aggregated state-action-reward tuples across all workers and repeats this process. We enumerate the hyperparameters used by our online RL baseline in Table 3.

We retain the state and action formulation as defined in the main text. However, we observe that using the following reward definition for training the online RL policy further improves performance:

$$\begin{aligned} R = {} & throughput \cdot delay \cdot (1 - \gamma \cdot loss) \\ & - \zeta \cdot \max(prev_action - sending_bitrate, 0) \\ & - use_gcc \cdot gcc_penalty \end{aligned} \tag{5}$$

where $\gamma = 2$, and $\zeta = 3$. use_gcc acts as an indicator variable for whether the fallback mechanism was invoked; we set $gcc_penalty = 0.05$. We normalize $throughput$, $delay$, $loss$, $prev_action$, and $sending_bitrate$ to (0, 4.5 Mbps), (0, 1000 ms), (0, 1), (0, 4.5 Mbps), and (0, 4.5 Mbps).

Dissecting and Streamlining the Interactive Loop of Mobile Cloud Gaming

Abstract

With cloud-side computing and rendering, mobile cloud gaming (MCG) is expected to deliver high-quality gaming experiences to budget mobile devices. However, our measurement on representative MCG platforms reveals that even under good network conditions, all platforms exhibit high interactive latency of 112–403 *ms*, from a user-input action to its display response, that critically affects users' quality of experience. Moreover, jitters in network latency often lead to significant fluctuations in interactive latency.

In this work, we collaborate with a commercial MCG platform to conduct the first in-depth analysis on the interactive latency of cloud gaming. We identify VSync, the synchronization primitive of Android graphics pipeline, to be a key contributor to the excessive interactive latency; as many as five VSync events are intricately invoked, which serialize the complex graphics processing logic on both the client and cloud sides. To address this, we design an end-to-end VSync regulator, dubbed LoopTailor, which minimizes VSync events by decoupling game rendering from the lengthy cloud-side graphics pipeline and coordinating cloud game rendering directly with the client. We implement LoopTailor on the collaborated platform and commodity Android devices, reducing the interactive latency (by ∼34%) to stably below 100 *ms*.

1 Introduction

Recent years have witnessed the emergence and prosperity of cloud gaming for mobile games (termed *mobile cloud gaming*, or MCG), which enables high-quality gaming experiences on mid- to low-end devices. Typically, mobile games run in virtualized environments (e.g., an emulator/a container) hosted on cloud servers, and rendered frames are live-streamed over the network to a thin client app on the user device.

Motivation. To achieve smooth gaming experiences, MCG platforms are expected to provide users with a high media streaming bandwidth (e.g., 10+ Mbps) [23] and a low *interactive latency* (i.e., the delay between a user-input action and when the game's response to that action manifests at the client) within ∼100 *ms* [54]. In practice, the former has been largely fulfilled by the deployment of geo-distributed cloud/edge servers [24]. Nevertheless, the latter, as a key metric that directly determines the QoE of MCG, seems far from satisfactory [3, 54]. MCG's interactive latency has not been well understood—it is more than network latency due to the complexity of cloud-side processing and virtualization [72].

We conduct the first in-depth comparative measurement study of MCG and CCG (cloud gaming for console games, or *console cloud gaming*) on interactive latency characteristics in practice. Our measurement is based on eight representative cloud gaming platforms: GeForce Now [61], Boosteroid [20], JoyArk [41], CloudMoon [26], NetEase Cloud Gaming [58], Tencent Pioneer [78], Tencent Start [79], and X-MCG (anonymized due to their commercial concerns), regarding both mobile and console games under diverse scenarios. The study reveals important and surprising results:

- Our measured minimum interactive latency of MCG is as high as 112 *ms*, 42% larger than that of CCG. This implies that the processing logic of MCG should be more complex than that of CCG and the interactive latency of today's MCG cannot meet the users' requirements (<100 *ms*).
- The interactive latency has little to do with the user request workload but much to do with the game rendering workload. Specifically, the interactive latency looks similar during peak and non-peak hours (indicating sufficient scalability), but surprisingly (up to 48%) higher for simple 2D games than for complex 3D games (mostly relating to the unbalanced resource allocation strategy of a platform).
- On average, network latency only accounts for 17% of the interactive latency, indicating that network is not the key bottleneck. In fact, a jitter (≤2 *ms*) in network latency often has a "butterfly effect" on the interactive latency (≥10 *ms*).

The above drive us to go beyond RTT and understand the *interactive loop* of MCG, including every step in the back-and-forth MCG processing pipeline. However, the interactive loop of commercial MCG platforms is rarely studied in depth as it involves not only network links but also complex backend processings in the cloud, which are typically invisible.

Analysis. To deeply understand the interactive loop of MCG, we contacted developers of each platform. One platform X-MCG (anonymized due to their commercial concerns) shared their design and agreed to collaborate with us on improving interactive latency. Its cloud side relies on a state-of-the-art Android emulator *Trinity* [33] (optimized for high-performance graphics rendering) and a widely-used streaming tool *Sunshine* [51]. Its client side is extended from *Moonlight* (the client of Sunshine), supporting hardware-accelerated video decoding and High Dynamic Range (HDR) streaming. We

[*] Co-primary authors. Zhenhua Li is the corresponding author.

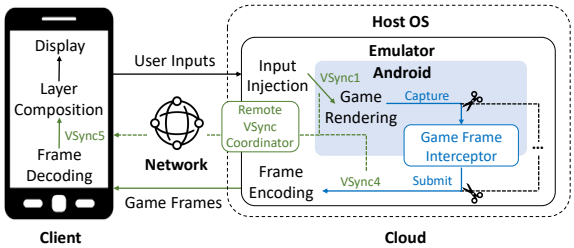

Figure 2: The interactive loop of X-MCG using LoopTailor.

take this unique opportunity to first expose to the public a state-of-the-art MCG system's interactive loop, and uncover the root cause of the unsatisfactory interactive latency.

To precisely trace the data flow of a game frame in X-MCG, we instrument relevant system services of Android, the GPU module of *Trinity*, and core modules of *Sunshine/Moonlight*. We find that the key bottleneck of the interactive latency is the cloud-side graphics pipeline. More in depth, the major latency of the cloud-side graphics pipeline does not lie in game rendering (23%), but the Vertical Synchronization (VSync) operations [2, 18, 53] (36%) in mobile OSes. As a synchronization primitive, VSync synchronizes frame production and consumption rates (e.g., the output frame rate of the GPU and the refresh rate of the display) among different stages in a graphics pipeline to avoid *screen tearing* [53] (i.e., a visual artefact that occurs when a display device shows pixels from multiple frames in a single screen draw). Given that graphics pipelines of mobile systems are designed to handle diverse workloads with power-constrained hardware and fixed-refresh-rate display [18], VSync is built into the Android graphics pipeline as a system-level always-on mechanism.

Given the multi-component and multi-stage nature of the MCG graphics pipeline, severe performance penalty is incurred as each VSync event may cause an uncertain latency. As shown in Figure 1, a game frame encounters as many as five VSync events, creating up to 83 *ms* extra latency. Given the periodicity of VSync events, even a slight network jitter (e.g., 1 *ms*) can lead to a frame deadline miss, resulting in a significant fluctuation (e.g., 13 *ms*) in interactive latency. Note that the tight coupling of VSync with Android makes it not limited to specific emulators or streaming tools, but affects other representative MCG solutions (e.g., DroidCloud [47]) as well, incurring even higher (20%+) latencies (§6).

We argue that the VSync overhead in the MCG graphics pipeline can be effectively optimized away with specialized system design. Basically, current uses of VSync are built for general-purpose mobile usage, where multiple apps and system services may render simultaneously and thus require sophisticated synchronizations to achieve smooth and correct rendering. However, in MCG, the game app process monopolizes the rendering pipeline, and thus game-irrelevant synchronizations within the cloud (i.e., VSync2 and VSync3) could be avoidable, given that layer composition and virtual display only append system UIs (e.g., a status bar) to a game frame. Essentially, only coordination with the client is a necessity, leaving considerable space for optimization inside the cloud.

Optimization. We present LoopTailor, an end-to-end VSync regulator to decouple game rendering from the lengthy cloud pipeline (thus reducing four cloud VSync events to two), and coordinate its pace directly with the client (VSync5). To do so, LoopTailor carefully streamlines MCG's interactive loop. As shown in Figure 2, LoopTailor consists of two modules: *Game Frame Interceptor* which extracts and reroutes game frames to bypass unnecessary VSyncs (VSync2 and VSync3), and *Remote VSync Coordinator* which coordinates ahead of time the remaining VSyncs (VSync1, VSync4, and VSync5) on both sides. LoopTailor's approach is transparent to specific VSync implementations, making it a generic approach requiring minimum modifications to the host/guest OS.

Nevertheless, realizing LoopTailor is challenging. First, extracting game frames halfway from the pipeline can introduce non-trivial guest-host frame copy overheads. Second, VSync coordination between the cloud and the client requires accurately predicting latencies of intervening stages, as a prediction error may cause a frame deadline miss at the client.

For intercepting game frames, conventional approaches like app-level render redirection [15, 87] and framework-level buffer hooking [83] induce substantial overheads of frame copies in the virtual mobile graphics stack. Our solution instead breaks the boundary of the guest system and the host virtual GPU to efficiently identify render instructions issued by the game and capture the game frames *in place*, thus minimizing frame copies between the CPU and the GPU. The Interceptor then immediately forwards the game frames to the encoder, so that VSync2 and VSync3 are bypassed.

For multi-stage latency prediction, we discover that the latencies (incurred by game rendering, frame encoding, network transmission, and frame decoding), despite heterogeneous and fluctuating, can be forecast hierarchically with a low standard deviation ($<$1.3 *ms*) based on their latent correlations. Thus, we devise a Synergetic VSync Alignment approach which proactively adjusts the execution time of rendering/encoding operations across the cloud-side pipeline, so as to minimize the client-side frame deadline miss rate (0.3%).

We implement LoopTailor atop X-MCG with 15K lines of C/C++/Python code and evaluate its real-world performance with 100 mobile devices. Our prototype is applicable to both single- and multi-player mobile games. The results

demonstrate that LoopTailor can achieve desirable interactive latencies of 82-96 *ms* (with X-MCG's geo-distributed edge servers), 34% lower than that of X-MCG's original solution. The average ratio of interactive latency fluctuation to network jitter is greatly reduced from 11.52 to merely 1.23.

Contribution. We make the following contributions:

- We make a month-long measurement study on 8 representative cloud gaming platforms, revealing important results on interactive latency and optimization opportunities.
- We conduct the first in-depth study of MCG's interactive loop. Our analysis identifies the VSync mechanism in the cloud-side graphics pipeline of MCG as a key contributor to the excessive interactive latency, which can be effectively optimized with specialized design for MCG.
- We design and implement LoopTailor to streamline X-MCG's interactive loop, achieving sub-100 *ms* interactive latency in real-world deployments. The code and data are released at https://MCGlatency.github.io.

2 Measurement Study in the Wild

In this section, we introduce our methodology of measuring the interactive latency of commercial cloud gaming platforms (§2.1), and present multifold data analysis results (§2.2).

2.1 Measurement Methodology

Due to commercial interests and security concerns, almost all the commercial cloud gaming platforms are closed-source systems and provide very limited technical documentation to the public. Therefore, we measure the interactive latency of a platform from the outside in a record-and-recognize approach.

First, we use high-speed cameras to record videos of user interactions with games with an ultra-high frame rate of 2000 FPS (Frame Per Second) and Full-HD resolution (1920×1080). We position 2 cameras in front of and at the side of the device screen respectively, so that both user actions and visual game contents can be clearly observed. For recorded videos, we examine each frame in a hybrid (manual and algorithmic) approach to recognize the timestamp when the user input action happens, as well as the timestamp when the corresponding response of the action manifests.

In detail, we record specific interaction patterns for each game (e.g., invoking game menus, changing views, and touching in-game buttons), which are performed with styluses instead of fingers to ease detection. After recording, we leverage conventional computer vision algorithms [43, 90, 92] to detect and track objects in the frames. We first detect the stylus and the screen from the side view of the device screen, and then recognize the very frame (when the distance between the stylus and the screen reaches the minimum) as the start of an interaction. After that, we track the pattern-specific response objects (e.g., button highlight) case-by-case in the front view of the device screen to identify the end of an interaction. Such an approach is common practice in existing work for collecting visual-related delays [31], and the accuracy of the algorithms can reach 99+% according to our random sampling-based manual checking. In this way, the interactive latency can be deemed as the time interval between the two timestamps, with a negligible error of up to two frames (∼1.0 *ms*) introduced by the camera.

Table 1: Eight representative cloud gaming platforms studied in this work, in alphabetical order by their names.

ID	Platform	Country	Type
1	Boosteroid	USA	CCG
2	CloudMoon	USA	MCG
3	GeForce Now	USA	CCG
4	JoyArk	USA	MCG+CCG
5	NetEase Cloud Gaming	China	MCG+CCG
6	Tencent Pioneer	China	MCG
7	Tencent Start	China	CCG
8	X-MCG	China	MCG

Further, we are curious about the network impact on the interactive latency since this is what common users are the most concerned with. Once a user suffers from high interactive latency, s/he is most likely to complain about the network latency. To address the concern, almost all the commercial cloud gaming platforms have on-screen widgets presenting the real-time network latency (via their client apps), which greatly facilitates our recording the network latency.[1] Since a low network bandwidth can also lead to high interactive latency, we periodically record the downlink bandwidth with the lightweight Android API *NetworkStatsManager.querySummaryForDevice()* in the meantime.

As listed in Table 1, we study 8 representative cloud gaming platforms that are highly popular in either the USA or China, using 100 mobile devices of 43 device models (1.8-3.3 GHz CPU frequency, 4-16 GB memory, and Android 9-13) geo-distributed in the corresponding countries (50 in 3 cities in the USA and 50 in 3 cities in China). Among them, three are CCG platforms, three are MCG platforms, and two support both CCG and MCG. We include CCG in our measurements to understand latency differences between MCG and CCG.

For each platform, we select its top-10 popular games to measure the interactive latencies with different radio access technologies (RATs): 5G (37%), 4G (29%), and WiFi (34%). We set the streaming resolution and frame rate of each platform to 1080P and 60 FPS respectively, which are the default settings of most platforms. Also, we use the 100 mobile devices to play games at different times (0:00, 3:00, ..., 21:00, UTC+8) every day during a whole month (May. 2023), so as to figure out the influence of user request workloads. The duration of game playing each time is five minutes.

Ethical Claim. All the measurements and analyses throughout this work are conducted with explicit permission of users and no ethical concern is raised in this work.

[1] Some platforms may not be reporting accurate latency values, and different platforms may have different methodologies to calculate the latency.

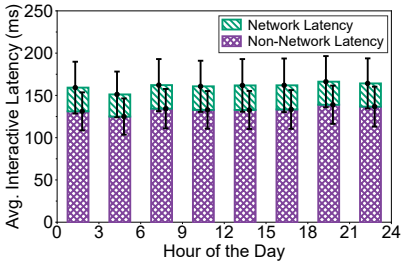

Figure 8: Average interactive latency of Tencent Pioneer at different times of a typical day (time zone: UTC+8).

2.2 Measurement Results

Among our records of individual measurements, a small portion (6%) are undesirable because it is difficult for us to analyze their relevant interactive latencies. For example, when the downlink bandwidth is insufficient, we can hardly quantify its remarkable and highly fluctuating influence on the interactive latency, thus making our analyses obscure. After ruling out such cases, we obtain a total of 20,096 valid records, which reveal quite a few surprising results with regard to interactive latencies of today's commercial MCG platforms.

General Statistics. All the studied MCG platforms suffer from unsatisfactory interactive latencies ranging from 112 *ms* to 403 *ms*—recall in §1 that smooth gaming experiences require a low interactive latency within 100 *ms*. In contrast, in non-negligible (35%) cases interactive latencies of CCG stay below 100 *ms*. Obviously shown in Figure 3 (in all the bar charts throughout this paper, each error bar denotes the standard deviation of the corresponding sub-bar), interactive latencies of MCG are generally higher than those of CCG.

As shown in Figure 4, our measured minimum interactive latency of MCG (112 *ms*) is 42% larger than that of CCG (79 *ms*), and the average interactive latency of MCG (163 *ms*) is 37% larger than that of CCG (119 *ms*). Regarding average interactive latency, even the fastest MCG platform (8M: X-MCG) is slower than the slowest CCG platform (4C: JoyArk). We attribute the above to the more complex processing logic of MCG compared with CCG, i.e., the mobile OS virtualization specially required by MCG. In fact, CCG platforms typically use hardware-assisted virtualization techniques (e.g., SR-IOV [62]) to share resources to VM instances, whose performance is close to direct hardware access. But for MCG, given the poor driver support of desktop GPUs in mobile OSes, para-virtualized GPUs with additional virtualization logic are usually required. Hence, there exists a gap in rendering performance between the CCG and MCG backends.

Network Impact. Contrary to most users' common beliefs, most of the excessive MCG latency is not attributed to the network. With the network latency excluded (then the remaining latency is referred to as the *non-network latency*), the minimum non-network latency of MCG is still as high as 104 *ms* (>100 *ms*), 46% larger than that of CCG (71 *ms*), as indicated in Figure 5. This is because all our studied platforms have deployed geo-distributed cloud and/or edge servers across either the USA or China, making the network latency pretty low in most cases. Concretely, in 81% of the valid records, the user device lies in the same city as the cloud/edge server. More in detail, no matter which RAT is used, the network latency (averaging between 24 *ms* and 31 *ms*) only takes up a small portion (averaging between 15% and 25%) of the interactive latency, as indicated in Figure 6.

Common wisdom suggests a positive correlation between interactive latency and network latency. Surprisingly, in a non-trivial portion (13%) of our measurements the interactive latency is negatively correlated with the network latency. To visualize this, Figure 7 depicts results during a typical measurement that includes such unexpected cases. Dots under

shadows denote cases of a negative correlation between interactive latency and network latency. The reason behind the above counter-intuitive phenomenon will be detailed in §3.3.

User Request Workload. Figure 8 presents average interactive latencies at different times of a typical day on Tencent Pioneer, the most popular MCG platform in our measurement. There is no significant difference between the interactive latencies during peak hours (12:00 – 21:00) and non-peak hours (00:00 – 12:00, 21:00 – 24:00). Further, we do not see notable variation among the interactive latencies in different days of a week, either. The above hold true for other MCG platforms as well, revealing that today's MCG platforms possess sufficient scalability to serve a fluctuating user request workload.

Game Rendering Workload. Recall that for each platform, we select its top-10 popular games to play and measure interactive latencies, including simple 2D games, complex 3D games, and so forth. Surprisingly, we note that on all MCG platforms, simple 2D games with light rendering workloads suffer from higher interactive latencies (10% on average) compared with graphics-intensive 3D games. Given that official documents of some MCG platforms mention that they selectively schedule GPU resources for different game types [80], we suspect that the surprising observation might be owing to unbalanced resource allocation strategies, i.e., overly prioritizing the QoE of complex 3D games while ignoring requirements of lightweight 2D games. To validate the conjecture, we consulted the customer service of each MCG platform, and two of them acknowledge that simple 2D games are oftentimes subject to insufficient GPU resource allocations.

3 Diagnosing the Undesirable Interactive Latency of MCG

To further discover the root causes behind the above observations, we contacted the developers of the five commercial MCG platforms. Eventually, the developers of X-MCG agreed to share their design with us and collaborate with us to diagnose the undesirable interactive latency atop their platform.

In this section, we first introduce important background knowledge regarding mobile graphics pipelines and VSync (§3.1). Then, we dissect the end-to-end interactive loop of X-MCG into 16 pipeline stages (§3.2). Afterwards, we measure the latencies of key stages in the X-MCG pipeline to quantitatively explain why the interactive latency is unsatisfactory (§3.3). We will discuss system architectures of other MCG solutions and the generalizability of our findings in §6.

3.1 Mobile Graphics Pipeline and VSync

The graphics pipelines of modern mobile OSes consist of multiple *stages* due to the users' diverse needs for graphics; each stage performs its unique functionality. When a game is played on an Android device, for instance, the game is typically the beginning of the graphics pipeline. The game performs graphics rendering by writing its contents into a frame buffer (or *frame* for short) from a buffer queue termed `Surface` [9]. At the same time, other system apps (e.g., system UI) may render contents into their own `Surfaces`.

Various `Surfaces` are connected to a compositor called `SurfaceFlinger` [10], whose job is to merge the contents of individual `Surface` layers into one or more graphic frames for display. In other words, after game frames are rendered, `SurfaceFlinger` conducts *Layer Composition* [14] on the frames. The composited result is then sent to a Hardware Composer (`HWcomposer`) module [13], which submits the contents to the actual display hardware.

It is worth noting that the stages usually work in their own paces, which can cause frame access issues. For example, while `SurfaceFlinger` regularly conducts Layer Composition at the refresh rate of the display, the pace of game rendering can be rather uncertain. When the game delivers a new frame to `SurfaceFlinger` while it is compositing, the composited result may contain portions of multiple game frames, leading to the *screen tearing* [53] problem.

To address screen tearing, modern mobile OSes typically adopt the VSync mechanism; other mechanisms (e.g., Triple Buffering [34]) have also been proposed, but each of them alone is generally unsuited to power-restrained mobile systems without the help of VSync [2]. As mentioned before, VSync is a classic access control mechanism (or synchronization primitive) for the graphics pipeline, which controls the frame intervals of two adjacent stages to make the frame access exclusive. It works in an event-driven manner: frame consumption is triggered periodically by VSync events at a pace specified by the consumer (e.g., when the display with a refresh rate of 60 FPS is the consumer, the period is 1/60 s). Note that the frequency and period of VSync events are determined by the frame rate of the consumer in a graphics pipeline, and thus cannot be adjusted freely.

In each period, when the producer finishes frame production, it waits for the *vertical blanking interval* [44] (i.e., the time interval between the end of a production and the next VSync event of the consumer). Then, it delivers the frame to the consumer only when no consumption (e.g., frame drawing) is in progress, so as to avoid screen tearing while saving its power (i.e., preventing the producer from generating too many frames that cannot be processed by the consumer). In other words, when the processing of one frame is finished, the graphics pipeline will not process a new frame immediately; instead, the processing of a new frame will be delayed till the signaling of the next VSync event, thus creating an uncertain latency. Worse still, the latencies can accumulate in a lengthy graphics pipeline, leading to unsatisfactory user experiences.

3.2 The Interactive Loop of X-MCG

X-MCG is developed and commercialized through the combinatory use of Trinity and Sunshine on the cloud side, as well as extending Moonlight (the client of Sunshine) as the client app. The developers of X-MCG carefully make the choice by conducting benchmarks on various existing MCG solu-

tions, which will be elaborated in §6. Further, they customize the AOSP (Android Open Source Project) [11] system that runs within the cloud servers by pruning unnecessary system services like `BatteryService` [76].

The high-level interactive loop of X-MCG is presented in Figure 1. It comprises as many as 16 stages as shown in Figure 9, which will be detailed below. The pipeline starts from the user interaction with the client display hardware, and the client app captures user inputs **(Stage 1: User Input Capture)**. Inputs are then sent to the cloud-side streaming component Sunshine **(Stage 2: User Input Transmission)**. Upon receiving inputs, Sunshine injects them into the mobile game application that runs on the guest OS **(Stage 3: Input Injection)**. As mentioned before, the guest OS is a customized AOSP system that runs within the Trinity emulator.

Afterwards, the game prepares to process the inputs and render the game graphics. To avoid screen tearing and conserve power, mobile games synchronize the game's frame rate to a portion of the display refresh rate of the device [28, 81]. As explained in §3.1, they use VSync events to control how quickly game frames should be produced, which is usually specified by the developer/user via an in-game option. Consequently, user inputs need to wait for a VSync event before it gets processed and the game rendering starts **(Stage 4: VSync1)**, and VSync1 cannot be disabled as it is built deep into the game rendering logic for supporting fixed-refresh-rate mobile display.

With regard to game rendering, modern mobile games usually use rendering APIs like OpenGL ES [16] to render into their `Surfaces` **(Stage 5: Game Rendering)**. In order to achieve GPU-accelerated rendering in AOSP, typical solutions (e.g., Google Android Emulator [8] and DroidCloud [47]) forward render instructions from the GPU driver in AOSP to the host-side virtual GPU device using remote procedure calls (RPCs), which turns out to be slow and expensive. In contrast, through the novel *graphics projection* mechanism [33], the Trinity emulator directly resolves the vast majority (>99%) of rendering API calls within the guest GPU driver, significantly reducing RPC calls and improving the rendering performance.

When game rendering finishes, the results are submitted to `SurfaceFlinger`. `SurfaceFlinger` has to work in the same pace with the display hardware, and therefore needs to wait for VSync **(Stage 6: VSync2)** before compositing the output of the **game app** including system UIs **(Stage 7: Layer Composition I)**. Subsequently, the composited frame is sent to `HWcomposer`, which waits until the display hardware has finished the scan-out [32] of the previous frame **(Stage 8: VSync3)**. Then, `HWcomposer` presents the frame to the virtual offscreen display device provided by the Trinity emulator **(Stage 9: Virtual Display)**. VSync2 and VSync3 can introduce fluctuating delays due to highly variable game rendering workloads as well as possible resource contention in commercial MCG platforms, given that hardware resources are typically shared to a large number of virtualized instances

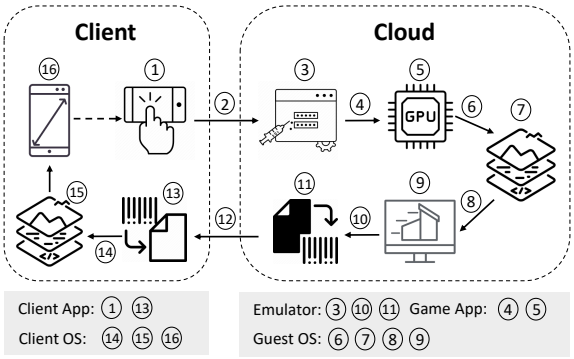

Figure 9: The 16 stages in the interactive loop of X-MCG.

with diverse game workloads.

Afterwards, Virtual Display forwards the frame to the Sunshine encoder. The encoder performs frame encoding according to the video frame rate set by the user, so a separate VSync is used **(Stage 10: VSync4)**. VSync4 exists because the client-side video frame rate may be different from the cloud-side game frame rate, and simple strategies like delivering frames immediately cannot satisfy the frame rate requirement of the client. The encoder and the Virtual Display are coordinated in the host virtual GPU, so that frame forwarding and encoding take place in the GPU with minimal frame copies between GPU and CPU **(Stage 11: Frame Encoding)**.

Over the network, the encoded game frame is transmitted to the client **(Stage 12: Game Frame Transmission)**, which collects and decodes the frame **(Stage 13: Frame Decoding)**. Then, similar to VSync2, the decoded frame waits for another VSync event triggered by the client `SurfaceFlinger` **(Stage 14: VSync5)** before conducting Layer Composition **(Stage 15: Layer Composition II)**. Note that VSync5, as a client-side VSync, can be disabled, but only with developer/root privileges. Furthermore, once it is disabled, the effect is global and other apps will also suffer from side-effects like screen tearing and increased power consumption, which is thus unacceptable to normal users. Finally, the composited frame is scanned out by the display hardware **(Stage 16: Display)**[2].

3.3 Root Cause Analysis

Among the 16 stages, we want to uncover which ones contribute the most to the interactive latency. To this end, we conduct an in-depth measurement on the end-to-end loop of X-MCG using 10 phones (with different device models) whose OSes are tailored for detailed latency recording. Given that delays of Stage 1 and Stage 16 are mostly induced by the display hardware and thus can hardly be measured by software means, we focus on measuring delays of Stages 2-15 (so that we can infer the sum delay of Stage 1 and Stage 16).

To precisely trace the data flow of a specific game frame in a lightweight manner, we measure passively by instru-

[2]Similar to VSync3, the composited frame needs to wait for another VSync event before the display scan-out, but as this VSync lies deep inside the client system and is invisible to user apps, we merge it to **Stage 16**.

Table 2: Latency breakdown of X-MCG (in unit of *ms*).

Others	2.6	2.3	1.6	3.9

menting relevant system (Android, AOSP, Trinity and Sunshine/Moonlight) modules and recording the timestamps of relevant network packets. Specifically, we measure the network latency (Stage 2 and Stage 12) by piggybacking timestamps with network packets between Sunshine and Moonlight. In the cloud-side AOSP system, we instrument system services including `InputDispatcher`, `SurfaceFlinger`, and `HWComposer` in the framework layer, as well as the OpenGL ES library in the Hardware Abstraction Layer (HAL). In this way, delays of Stages 3-8 can be accurately recorded. In Trinity, we instrument the virtual display module to obtain the delay of Stage 9. Further, through tracking the encoding process of Sunshine, delays of Stage 10 and Stage 11 can be clearly observed. Finally, we instrument Sunshine and the client Android system to measure the delays of Stages 13-15.

Based on the above fine-grained instrumentation throughout the pipeline, we collected data at various times of each day during a week, and obtained the latency traces for a total of 35 hours of game playing. The measurement overhead is confined to a negligible level: the average CPU utilization is 1%, and the average memory consumption is 703 KB. We classify the delays of the measurable stages (Stages 2-15) in the loop into six categories, including Network (Stage 2 and 12), VSync (Stages 4, 6, 8, 10, and 14), Game Rendering (Stage 5), Layer Composition (Stages 7 and 15), Video Processing (Stages 11 and 13), and Others (Stages 3 and 9).

As listed in Table 2, in terms of mean latency, the VSync mechanism (5 VSync events) contributes the most (35.7%) to the non-network latency, even more than Game Rendering (22.7%) and Video Processing (22.1%). Moreover, delays incurred by VSync events are highly fluctuating between 4.5 *ms* and 82.9 *ms* (even more fluctuating than the network latency in our measurements), causing the interactive latency to vary significantly even when the network latency is stable. The above findings explain the counter-intuitive phenomenon we observe in §2.2—a lower network latency does not necessarily translate to a better interactive latency, since network is usually not the deciding factor. As for the "butterfly effect" mentioned in §1, it happens mostly when network jitters cause subsequent pipeline stages to miss VSync events according to our observation.

As shown in Table 3, each VSync event is required by an individual stage. Delving deeper into the loop, we discover that 5 VSync events are tightly coupled with other stages. VSync1 has been built into modern game engines like Unity [82] and Unreal [29] (Stage 5). VSync2, VSync3, and VSync5 are required by core graphics modules of both cloud-side and client-side Android systems, (namely `SurfaceFlinger` and `HWComposer`) (Stages 7, 9, 15). VSync4 is necessitated by the video encoder to encode videos at user-defined frame rates (Stage 11). Unfortunately, a lack of coordination between the VSync events causes an uncertain delay for each game frame with respect to each event. According to our measurements, the latencies of 5 VSync events all exhibit a nearly uniform distribution between 0 and 16.7 *ms*.

Table 3: Specific roles of the five VSync events and the average latency incurred by each VSync event.

Stage	Caused By	Location	Latency
4	Game Rendering	Game	8.5 *ms*
6	Layer Composition I	Guest Android	9.0 *ms*
8	Virtual Display	Guest Android	9.5 *ms*
10	Frame Encoding	Encoder	9.1 *ms*
14	Layer Composition II	Client Android	7.9 *ms*

Fortunately, while all the VSync events are *structurally* required and are hard to disable from the perspective of an MCG platform, not every VSync event is *functionally* useful. In the context of MCG, games are usually the only foreground apps besides system UIs (e.g., Android task bar), so Layer Composition and Virtual Display (Stage 7 and Stage 9) in the guest Android system (AOSP) only append game-irrelevant system UIs to a frame in almost all cases. Thus, these stages (along with their VSync events) are *functionally* unnecessary for MCG, as the game frames are ready to be displayed on the client after Game Rendering (Stage 5). This motivates our attempt to bypass some VSync events and decouple game rendering from the lengthy graphics pipeline, hoping to avoid or reduce their impact on the interactive latency.

4 System Design

Since the VSync mechanism is the biggest contributor to the interactive latency of X-MCG, we wish to minimize its negative impact. Guided by our diagnosis insights in §3.3, we design LoopTailor, an adaptive whole-loop regulator of VSync events for lowering the interactive latency of X-MCG to a desirable level (<100 *ms*). In this section, we first present a brief overview of LoopTailor along with the design goals (§4.1). Then, we detail its two key components: Game Frame Interceptor (§4.2) and Remote VSync Coordinator (§4.3).

4.1 LoopTailor Overview

LoopTailor sets out to meet the following design goals:

- Bypassing VSync events that are functionally unnecessary without disrupting the frame access control of the graphics pipeline (i.e., without harming the game's visual display);
- Accurately predicting and aligning the remaining VSync events to minimize their incurred latency;
- Introducing very little computational overhead and negligible impact on the smoothness of game graphics.

Figure 2 shows the architectural overview of LoopTailor, which streamlines the interactive loop of X-MCG by cropping the cloud-side graphics pipeline and stitching it to the client-side pipeline in a fine-grained manner. At the heart of LoopTailor are two key components: 1) Game Frame Interceptor (GFI, §4.2) that efficiently captures the game frames ahead of schedule to bypass 2 (out of 5) VSync events; and 2) Remote VSync Coordinator (RVC, §4.3) that forecasts and synchronizes the remaining 3 VSync events by carefully coordinating the cloud and the client. Note that the five VSync events are necessitated by the Android system design and the nature of constant-frame-rate video codec; apart from our emulator-based solution, the high-level design of LoopTailor is applicable to other (potential) solutions like container-based or function-based serverless gaming as well.

4.2 Game Frame Interceptor (GFI)

GFI aims to capture raw frames from game rendering ahead of time, before any form of layer composition. In Android, the desired interception should take place between the game app and `SurfaceFlinger` (before Stage 6 in §3.2), and there exist multiple intuitive methods. App-level render redirection [17], for instance, redirects the app rendering `Surface` to a virtual display with hooking libraries such as XPosed [87], and uses the `MediaProjection` API [15] to directly record rendered contents. Framework-level buffer hooking [83] adds a hook inside `Surface`, and performs interceptions whenever a game-owned `Surface` delivers a frame to `SurfaceFlinger`.

Nevertheless, for MCG where captured frames need to be subsequently encoded and sent to the client device, such intuitive approaches incur considerable frame copy overheads (note that frame encoding in the original X-MCG pipeline is in-place, c.f., Stage 11 in §3.2). In essence, both approaches capture frames solely from *inside* the guest, but ultimately send the frames using the network provided by the host. Therefore, data copies between the guest and host are unavoidable.

To realize low-overhead frame interception, our solution breaks the virtualization boundary and captures game frames in place. Figure 10 plots the workflow of GFI. The high-level idea is to leverage cross-layer information from both the guest system and the host-side virtual GPU to intercept and forward *handles* (as opposed to the actual frame content), so as to minimize data copies. In detail, we customize the `gralloc` graphics allocator [12], the guest GPU driver, along with the virtual GPU device in Trinity. `Gralloc` provides crucial information regarding frame correlations across the virtualization boundary, so that we can identify the actual host-side GPU resources using the guest-side frame identifier. Meanwhile, in order to separate render instructions of the target game from other apps like Android system UI, we modify the guest GPU driver, adding Android framework-level `Surface` information into GPU render contexts.

Based on the above cross-layer information, we monitor

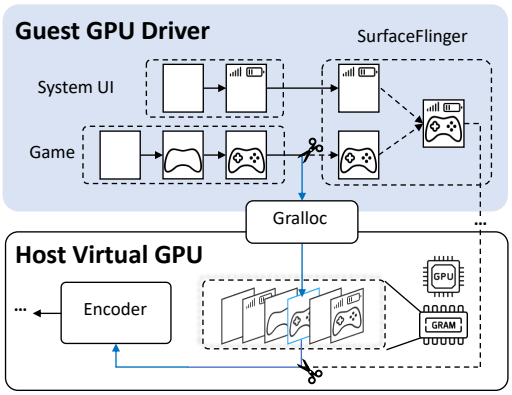

Figure 10: The workflow of GFI.

frame swap events (`eglSwapbuffers`) in the GPU driver, so that when a game-owned `Surface` delivers a frame to `SurfaceFlinger`, we can extract the actual resource handle(s) referring to the game frame in the host-side virtual GPU device. Afterwards, the intercepted resource handle(s) are immediately forwarded to the video encoder module, which utilizes the *interop* libraries provided by the GPU vendor (e.g., `nvenc` [60] for NVIDIA GPUs) to achieve in-place colorspace conversion and video encoding. In this way, data exchange between the CPU and the GPU, as well as between the guest and the host, is kept minimal.

With the game frames intercepted, Stages 6-9 (c.f. §3.2) in the original graphics pipeline can be bypassed, including two VSync events, Layer Composition I, and Virtual Display. Additionally, for `SurfaceFlinger` and the virtual display device in Trinity, we disable their rendering logic to reduce the GPU load, since the composited frames are no longer needed (frame swapping is preserved to not disrupt the data flow). Moreover, to support a minority of games that use multiple `Surfaces` for video playback or UI overlay, we add a trimmed-down compositor in the encoder to replace the original Android compositor in the VM, since the original Android compositor introduces considerable overheads (e.g., computing visible regions, matching display devices, and drawing layers). Specifically, we customize the Android compositor by 1) discarding game-irrelevant layers, 2) removing unnecessary post-processing (e.g., submitting frames to display), and 3) synchronizing the composition pace with the encoder to minimize latency overheads. Instead of relying on a standalone VSync (which defeats our original purpose of bypassing VSync events), frames are cached and composited right before encoding, so the delay caused by frame composition in these corner cases can be essentially reduced.

4.3 Remote VSync Coordinator (RVC)

Design Overview. With the informative help of GFI (Game Frame Interceptor), RVC aims to align the remaining three VSync events (VSync1, VSync4, and VSync5). As VSync5 is controlled by the client OS and cannot be changed by a user

app, RVC proactively synchronizes the timing of the cloud-side VSync1 and VSync4 with the client-side VSync5. To this end, RVC first obtains the timing information of VSync5 from the Android frame pacing library [6] in the client[3], and then predicts the delay of each intervening stage between VSync1 and VSync5 based on hierarchical time series forecasting [85] **(Hierarchical Latency Prediction)**.

Afterwards, RVC performs Synergetic VSync Alignment which exploits the latency forecasts to adaptively postpone VSync1 **(Synergetic VSync Alignment for VSync1)** and strategically perform reactive frame encoding by decoupling VSync4 **(Synergetic VSync Alignment for VSync4)**. Hence, a game frame (whose rendering and encoding are driven by VSync1 and VSync4 respectively) can arrive at the client (more specifically, arrive at VSync5) just in time, without waiting for the signaling of VSync4 and VSync5.

Hierarchical Latency Prediction. There are four stages happening between VSync1 and VSync5: game rendering, frame encoding, network transmission, and frame decoding. Although the latency of each stage can be independently forecast as a time series and summed directly to get the overall latency, the prediction result is oftentimes highly biased due to error propagation [39].

To minimize the prediction error, our key insight is that the stages have latent correlations within the end-to-end graphics pipeline. For example, if the game player suddenly enters a complex scene, game rendering will take longer time, the encoder will need more time to encode the frame as a standalone key frame (i.e., I frame) [74], and the encoded frame will be larger in size, leading to longer network transmission time and longer client-side frame decoding time. Also, we note that the involved latencies can be hierarchically organized as shown in Figure 11. Therefore, we adopt hierarchical time series forecasting [85] based on the MinT approach [85].

First, we adopt regression trees [52] to independently forecast the time series at all levels of the hierarchy (termed *base forecasts*). We resort to the regression tree algorithm as opposed to other algorithms because it is effective for both series with seasonal features [67] and fluctuating series like network latencies [89]. Moreover, it incurs low computation (<0.5 *ms*) and memory (<1 *MB*) overhead. Efficiency is of particular significance in our case, since the predictions need to be done at intervals of a few seconds.

Regarding the inputs of the regression trees, we follow common practice [67, 89] and feed them with the most recent latency data, as well as relevant data including the size of the encoded frame, network loss rate, and network bandwidth passively estimated from the media stream [89]. Since we need to make predictions at the frame-level granularity, the time window (i.e., the time unit in the forecast) is set as the smallest VSync interval among VSync1, VSync4 and VSync5 (typically 1/60 *s*). Accordingly, the information window size (i.e., the number of history time windows) and the forecast horizon (i.e., the number of future time windows) are typically set as 240 (=60×4) and 60, respectively. More details about the setting of hyperparameters will be provided later in §5.4.

[3]The timings of client-side stages (e.g., packet receiving, decoding, and VSync5) are synchronized with the cloud server's clock, leveraging a widely-used clock offset estimation approach [22] and a classic skew compensation algorithm [56]. The historical latency series (including the one-way network latency) are measured according to the calibrated timestamps.

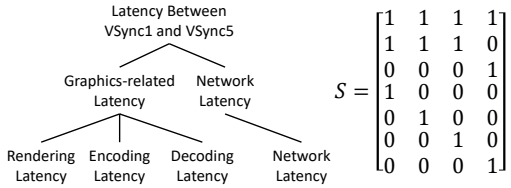

Figure 11: The tree and the matrix representation of the hierarchical latency series.

Given the base forecasts, we aim at minimizing the forecast errors by strategically reconciling the forecasts across the levels of the latency hierarchy. Let $\mathcal{D}_t = \{y_1, y_2, ..., y_t\}$ denote the history data observed up to time t, where y_i $(i = 1, 2, ..., t)$ is a vector containing all latencies in all levels of the hierarchy at time i. Let $\hat{y}_t(k)$ $(k = 1, 2, ..., K)$ denote forecasts of k future time windows based on $\mathcal{D}_t$, where k is the forecast horizon. Then, the optimal forecasts of k future time windows minimizing the conditional expectation

$$E[\| y_{t+k} - \hat{y}_t(k) \|_2^2 | \mathcal{D}_t], \tag{1}$$

where $\| \cdot \|_p$ is an L_p norm [30], is derived from

$$\mu_t(k) = E[y_{t+k} | \mathcal{D}_t]. \tag{2}$$

More details on optimal hierarchical forecasts are in [39].

If the conditional expectation (1) has errors, we wish to provide the best estimate of $\mu_t(k)$. Specifically, from the base forecasts $\hat{y}_t(k)$, we compute the revised forecasts as

$$\tilde{y}_t(k) = SP\hat{y}_t(k) \tag{3}$$

with a weight matrix $P \in \mathcal{P} \subseteq \mathbb{R}^{4\times 7}$, where $\mathcal{P}$ is the domain of P and S is a "summing" matrix of order 7×4 used to aggregate the lowest-level latency series, as shown in Figure 11. In detail, we compute the weight matrix P by solving the following optimization problem:

$$\min_{P \in \mathcal{P}} Tr(Var[y_{t+k} - \tilde{y}_t(k) | \mathcal{D}_t]) \text{ subject to } SPS = S; \tag{4}$$

$Tr(\cdot)$ is the trace of a matrix, based on MinT estimator [85].

To conclude, we realize combination forecasts for all levels of the latency series hierarchy through an optimal weight matrix P. In this way, we minimize the standard error of the coherent forecasts across the entire hierarchy.

Synergetic VSync Alignment for VSync1. With the predicted latencies in hand, the paces of VSync events can be adjusted in a synergetic fashion. In practice, we adjust the timing of VSync1 by blocking game rendering in the virtual GPU. As demonstrated in Figure 12, properly adjusting VSync1 can

reduce the interactive latency, by making the rendered frames reflect more recent user inputs (e.g., the first three arrows in Input Series 2). Specifically, once alignment occurs, user inputs that happen in the interval highlighted by the red box (i.e., the first 3 inputs in Input Series 2) will be processed by "Rendering1" instead of by the original "Rendering2". Consequently, the response of these user inputs can be displayed earlier, leading to a lower interactive latency.

We use Monte Carlo sampling [71] to minimize the delay expectation of n future frames in the pipeline, where n equals the forecast horizon. Specifically, we let V_c denote the timestamp of the most recent VSync5 event in the client, and let $x = \{x_1, x_2, ..., x_n\}$ denote predicted timestamps when the client finishes frame decoding, where x_i is the timestamp of the i-th future frame from now on. Then, we denote the timestamps of subsequent relevant VSync5 events as $V = \{V_1, V_2, ..., V_n\}$, where V_i is computed as

$$V_i = V_c + \left(1 + \left\lfloor \frac{x_i - V_c}{I_c} \right\rfloor\right) \cdot I_c, i = 1, 2, ..., n. \quad (5)$$

Here I_c is the time interval of VSync5. Given x and V, the problem is to obtain the minimum positive value of o (denoting the offset of the current blocking adjustment) that minimizes $E(x, V, o)$, which is the latency expectation of the subsequent n frame processings. It is computed as

$$E(x, V, o) = \sum_{i=1}^{n} f(x_i, V_i, o). \quad (6)$$

Here $f(x_i, V_i, o)$ is the expected delay induced by the VSync5 event on V_i, which is computed as

$$f(x_i, V_i, o) = (I_c - (V_i - x_i - o)) \mod I_c. \quad (7)$$

Given that the latency expectation (6) is a discontinuous function, we approximate the optimal value of o based on Monte Carlo sampling. Finally, the VSync1 events are postponed with an offset of o, completing the alignment. In reality, we perform the alignment for VSync1 periodically every n frames, where n is the forecast horizon.

Synergetic VSync Alignment for VSync4. Given that the cloud-side game frame rate and the client-side video frame rate might be different, frame encoding is normally driven by VSync4, whose interval matches the video frame rate. However, with the help of GFI, game frames can be encoded in a reactive manner without waiting for VSync4, while maintaining client-side frame rate stability based on the forecasts.

RVC decouples frame encoding from VSync4 events to reactively encode ready-to-consume frames in time. When the cloud-side game frame rate is lower than or equal to the client-side video frame rate, all produced game frames need to be encoded for streaming to satisfy the client-side requirement as much as possible. Otherwise, the forecasts are used to determine whether the encoder should encode or drop a game frame, to match the video frame rate requested by the user.

The encoder memorizes the timeline of the original VSync4 events, as well as the timestamp of the last encoded frame.

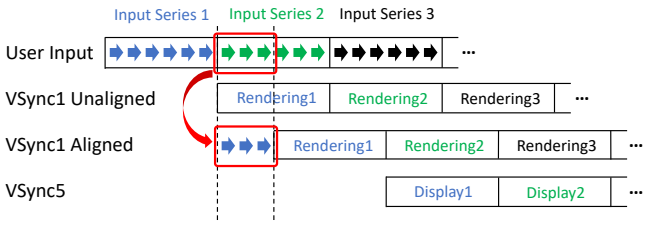

Figure 12: An example of Synergetic VSync Alignment. After the alignment, the first three inputs in Input Series 2 are processed ahead of schedule.

When a new game frame F_i arrives at T_i, it is encoded if the age of the last encoded frame exceeds one VSync interval, or if the predicted arrival time T_{i+1} of the next frame F_{i+1} satisfies $|T_{i+1} - T_v| \geq |T_i - T_v|$ (T_v is when the next VSync4 event occurs). If neither condition holds, F_i will be dropped since F_{i+1} better fits the client-side video pace. In this way, we can avoid delays incurred by VSync4 while adaptively maintaining the frame rate stability of the video.

5 Evaluation

We first describe our evaluation setup in §5.1, followed by evaluating the overall performance of LoopTailor in §5.2 and assessing the contributions of individual modules in §5.3. In §5.4, we present several micro-benchmarks to quantify the impact of key parameters and network dynamics.

5.1 Experimental Setup

Collaborating with X-MCG, we deploy LoopTailor on their cloud infrastructure. This facilitates fair comparisons between the original X-MCG and X-MCG enhanced with LoopTailor, which we refer to as LoopTailor for brevity. We also compare LoopTailor with other representative MCG platforms studied in §2.1: Tencent Pioneer, NetEase Cloud Gaming, JoyArk, and CloudMoon. Regarding client devices, we leverage the 100 mobile devices used in our measurement study (§2.1). Other settings (including camera settings, game types, game play duration, RAT, streaming resolution / frame rate, etc.) are the same as those in §2.1. We use the 100 mobile devices to collect evaluation data during a whole month (Nov. 2023), and collected a total of 21,743 valid records.

We also implement two intuitive baseline solutions based on the X-MCG architecture to evaluate the performance of LoopTailor in more depth. (1) Disable VSync: Since the client-side VSync5 and the in-game VSync1 cannot be controlled by an MCG platform, we disable VSync2/3/4 in the cloud. (2) In-VM Streaming: With the help of virtualized codec and NIC devices, videos are streamed in the guest OS (though the host NIC should still be used).

5.2 Overall Performance

Figure 13 plots the average interactive latency for X-MCG, LoopTailor, and four other MCG platforms (refer to Table 1 for their name-ID mappings), with a breakdown between

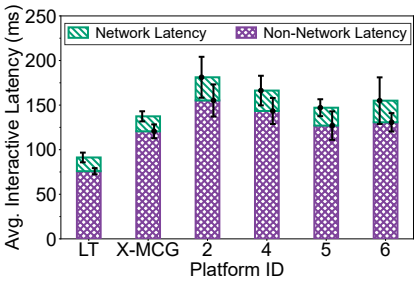

Figure 13: Average interactive latency. LT denotes LoopTailor.

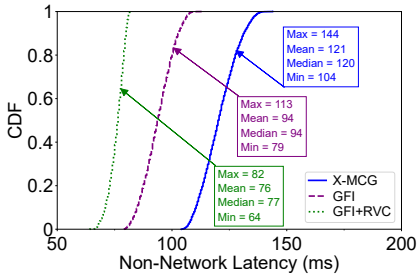

Figure 14: Performance breakdown with regard to non-network latency.

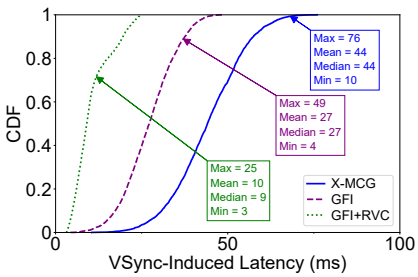

Figure 15: Performance breakdown regarding VSync-induced latency.

Table 4: Latency comparison (in milliseconds) between LoopTailor and baseline solutions. "Tail" refers to 99% percentile.

Solutions	Interactive Latency			Non-Network Latency		
	Avg.	Med.	Tail	Avg.	Med.	Tail
LoopTailor	91	91	95	76	77	82
Disable VSync	106	105	121	90	90	104
In-VM Streaming	141	139	162	125	124	146

the network vs. non-network latency. As shown, LoopTailor yields the lowest average interactive latency of 82-96 *ms* (91 *ms* on average, 95 *ms* in 99% percentile), 35% lower than the original X-MCG (139 *ms* on average, 158 *ms* in 99% percentile). Recall that a smooth gaming experience requires a sub-100 *ms* interactive latency, which is achieved by LoopTailor. Note that the desirable interactive latency of LoopTailor is also ascribed to X-MCG's wide deployment of edge servers in the latter half of 2023. The non-network latency of LoopTailor is only 64-82 *ms* (76 *ms* on average, 82 *ms* in 99% percentile), 37% lower than the original X-MCG (121 *ms* on average, 141 *ms* in 99% percentile) and 40% lower than the best of the other four MCG platforms (127 *ms* on average, 150 *ms* in 99% percentile).

As shown in Table 4, LoopTailor outperforms the baseline solutions in terms of interactive latency and non-network latency. Although it appears that LoopTailor has no significant latency advantage over Disable VSync, the latter introduces severe side effects including unstable frame rate and screen tearing [42]. As for In-VM Streaming, it performs the worst due to the additional overheads of virtualized codec and NIC devices for multiplexing hardware resources.

Regarding other QoE metrics for cloud gaming, we observe that the average client-side video frame rate stays high at an average of 59.8 FPS, with a small standard deviation of 0.6. This indicates that LoopTailor is capable of delivering a smooth game streaming experience. Regarding the image quality of LoopTailor, we do not observe jittery frames or degradation of image quality compared to original X-MCG.

5.3 Contributions of Individual Modules

We evaluate the performance gain brought by each module of LoopTailor: GFI (Game Frame Interceptor) and RVC (Remote VSync Coordinator), by enabling them incrementally. We exclude the network latency when reporting the results.

We begin with only enabling GFI. Recall that GFI eliminates VSync2 and VSync3. As shown in Figure 14, this results in an average non-network latency of 94 *ms*, a 22% reduction compared to X-MCG. The *maximum* non-network latency of GFI-only LoopTailor is even 7% lower than the *average* non-network latency of X-MCG. To delve deeper into benefits of GFI, we measure the latency reduction of different stages. First, we consider the latency incurred by only VSync events (termed VSync-induced latency) and plot its distributions in Figure 15. As shown, GFI reduces the VSync-induced latency by 38% on average. Second, GFI helps cut the layer composition latency by 52% since several unnecessary pipeline stages are bypassed. Third, GFI further helps accelerate game rendering by 6% because with a few pipeline stages bypassed, more resources can be allocated for rendering.

Next, we enable RVC to make a full-fledged LoopTailor system. As in Figure 14, RVC further reduces the average non-network latency by 19%, compared to using GFI alone. This translates to a 37% reduction in the total non-network latency compared to X-MCG. Through Synergetic VSync Alignment, RVC greatly reduces the average VSync-induced latency by 57% (73%) compared to using GFI alone (X-MCG). Unlike GFI which only optimizes the cloud side, RVC tackles both the cloud and the client side. It reduces the average latency incurred by VSync5 on the client side from 8 *ms* to 3 *ms*.

The above results demonstrate both GFI and RVC are essential for LoopTailor. Their synergy allows LoopTailor to reach a consistently low non-network latency of 64-82 *ms*.

5.4 Micro-benchmarks

Impact of the Information Window Size. Recall from §4.3 that the information window size (IWS) determines the number of time windows used in latency prediction. Figure 16 shows the relationship between the IWS and the standard error of latency prediction (the forecast horizon is set to 1 in this experiment). As shown, the standard error first decreases and then increases. The decrease is because larger information windows usually provide more sufficient obervations on history data, whereas the increase is explained by too many outdated history data within the window.

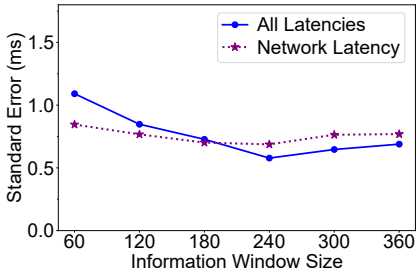

Figure 16: Avg. std error of RVC with different information windows.

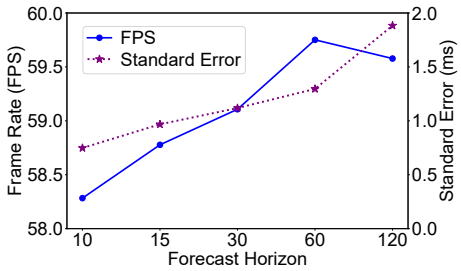

Figure 17: Avg. video frame rate & std error with different forecast horizons.

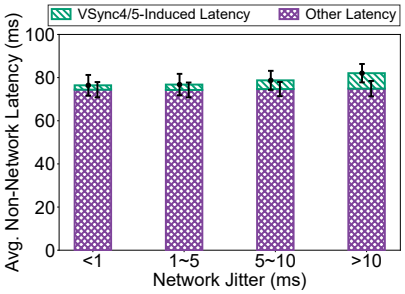

Figure 18: Avg. non-network latency with different network jitters.

Given the existence of key frames in game rendering, it is preferable to set the IWS to be larger than the intervals between each pair of key frames (usually about 10 to 20 VSync intervals based on our measurements). Meanwhile, IWS should not be too large considering both the forecasting errors and computation overheads. Figure 16 shows that RVC achieves the lowest standard error when IWS is around 240, which reaches the minimum standard error (0.6 *ms*) with a low computation overhead (<0.5 *ms*). Regarding the prediction of network latency, RVC achieves an average standard error of <1 *ms* (0.69-0.84 *ms* as shown in Figure 16) under different IWS settings. The standard errors exhibit tiny fluctuations given that the network condition in our evaluation is stable with only ∼2 *ms* jitters. The performance of LoopTailor under diverse network conditions is discussed later in this section.

Impact of the forecast horizon. The forecast horizon determines the number of future time windows produced by a prediction in RVC. On one hand, a smaller forecast horizon leads to a higher frequency of VSync1 adjustments, as illustrated in §4.3; adjusting VSync1 too frequently may result in a slight client-side video frame rate drop, because an incorrect forecast may cause a frame deadline miss at the client. On the other hand, a large forecast horizon may increase the forecasting error. We experimentally quantify this tradeoff in Figure 17, where the IWS is set to 240. Note that the slight drop in the frame rate at a forecast horizon of 120 is due to the sharp increase in the standard error. Based on the results, we select a forecast horizon of 60 to balance the above tradeoff.

Impact of Network Jitters. LoopTailor should ideally maintain a low non-network latency even when the network condition is highly dynamic. Figure 18 shows the average non-network latency under different network jitters (i.e., standard deviations of network latencies). The results demonstrate the robustness of LoopTailor under diverse network conditions: with ≤10 *ms* network jitters, there is only negligible fluctuation in the non-network latency (75-78 *ms*); even when the network jitter exceeds 10 *ms*, the non-network latency only increases marginally to 82 *ms*. The slight increase in the non-network latency is caused by the inflation of VSync4/5-induced latency, which is attributed to the elevated forecasting error under highly fluctuating network conditions.

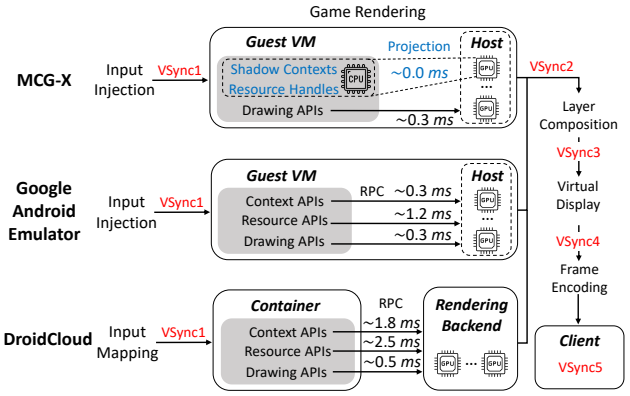

Figure 19: Architectural comparison of X-MCG and other representative MCG solutions. The numbers atop arrows refer to the average latency overhead per game frame.

6 Discussion

Generalizability. VSync1∼5 are not specific to X-MCG; in fact, it is impractical to disable them as they are necessitated by the design of the Android system (on both cloud and client sides) and the nature of constant-frame-rate video encoding (see §3.2). Thus, the defects of X-MCG are common to every Android- and video streaming-based MCG platform. Figure 19 illustrates a detailed comparison of the architectures of X-MCG and other representative MCG solutions. As shown, employing other solutions such as Google Android Emulator-based (abbreviated as GAE-based) and DroidCloud [47] also results in the five VSync events in the end-to-end graphics pipeline. Given the above facts, we believe that our insights and designs are widely applicable to other platforms.

The developers of X-MCG make a careful choice among existing MCG solutions by conducting comprehensive benchmarks on them. The experiment results reveal that the graphics virtualization mechanism of Trinity introduces ∼0.3 *ms* latency overhead per frame, 83%-94% less than other representative solutions [33]. Additionally, Sunshine exhibits 12.6%-26.7% lower end-to-end latency compared to other streaming tools [37, 59, 63] due to its efficient in-place frame processing capabilities. However, these advanced virtualization and frame processing techniques still need the VSync

mechanism for frame access synchronization with other stages in the graphics pipeline. Worse still, the high efficiency of rendering and frame processing of X-MCG may even amplify the impact of VSync events on the interactive latency.

Although we were unable to scrutinize other mobile OSes such as iOS, we believe our insights and design principles still apply, given that VSync is a graphics primitive and that the virtualization stack is widely used for the cloud gaming backend. In fact, the closed-source nature of iOS prompts many MCG applications running on iOS to leverage virtualized Android backends to stream mobile games [41]. Furthermore, iOS also uses layer compositors (e.g., Core Animation), and iOS cloud gaming backends must also use virtualization to achieve resource multiplexing.

Application scope. MCG platforms generally focus on enabling users with middle/low-end devices to smoothly play graphics-demanding mobile games. For budget reasons, the refresh rates of such devices are typically fixed and limited, allowing LoopTailor to fully exploit its capability to optimize the interactive latency for mainstream MCG users. For high-end user devices with adaptive/high refresh rates, things are different for VSync5 as the intervals between adjacent VSync5 events become variable/short.[4] In such cases, only part of RVC (i.e., Synergetic VSync Alignment for VSync1) is less effective. Other LoopTailor components are still effective, as VSync1∼4 are not on client devices.

7 Related Work

Cloud Gaming Systems. Based on where rendering instructions are executed, cloud gaming systems can be classified into two categories: host-rending and client-rendering. Host-rendering systems typically follow the thin-client architecture [19]. It offloads computation-intensive tasks to cloud servers, and livestreams rendered game frames as an encoded video to thin clients for display. Many systems follow this paradigm such as those proposed by the academia [37,40,47,48,64,76,86,88] and the industry [4,21,55,58,61,75,78,79].

Client-rendering systems, such as Games@Large [57] and LiveRender [49], intercept graphics instructions in the cloud and send them (along with graphics data such as vertices and textures) to the client for execution. While this paradigm can deliver high-fidelity graphics and enable secure GPU computing [38], it requires powerful client devices and networks [77], making it less attractive to low-end devices. Our work focuses on optimizing the performance of host-rendering systems given their dominant popularity.

Android in the Cloud. Landing Android onto cloud systems has become an emerging research topic. Existing cloud solutions typically run Android in virtual machines [7,8,91] or containers [21,47,76]. Considering the generality of both the Game Rendering Interceptor and Remote VSync Coordinator, we believe LoopTailor applies to most of the above systems. These systems generally use API remoting [27] or device emulation [65,69] for graphics virtualization, which can be laggy and inefficient due to, for example, excessive guest-host interactions [33]. To overcome such limitations, recent advances such as Trinity [33] (upon which we built LoopTailor) and vSoC [66] employ various techniques to reduce guest-host interactions, leading to higher graphics performance.

Another body of works set out to adapt Android to cloud environments. For instance, DroidCloud [47] enables Android to render on off-system GPU pools; CARE [76] cloudifies Android into a cloud-native system by streamlining Android system services. Our work instead operates on the graphics pipeline, and is orthogonal to the above research.

Latency Mitigation for Real-time Communication. Beyond VSync, there is a plethora of works on reducing the latency (incurred by rendering, network, and video coding) for real-time communication (RTC) systems such as MCG. They investigate a wide range of latency optimization dimensions including rendering acceleration [25,68], network congestion control [5,84], video coding [36,73,88], optimization model/metric [35,93,94], and cloud architecture [46,50,70]. Regarding graphics-related latency, recent studies [45,86] attempt to reduce it by predicting video frames, but they may fall short in real-world conditions due to the high randomness of user actions [45,86]. Contrasting above efforts, our work focuses on shortening the lengthy cloud-side graphics pipeline through a new dimension of regulating VSync events.

8 Conclusion

Mobile cloud gaming, as a highly interactive immersive application, faces new latency challenges due to its sophisticated backend graphics processing. In this paper, we identify VSync as a major contributor to the end-to-end interactive latency overhead and show that a specialized design can effectively minimize the VSync overhead. The result is a stable sub-100 *ms* interactive latency, leading to an average reduction of 35% compared with those provided by state-of-the-art MCG platforms. We believe that the ideas and key building blocks of LoopTailor, such as in-place frame capture and multi-stage latency prediction, have more profound implications to the design and implementation of emerging immersive applications, especially those operating in the edge/cloud-based model.

[4] In Android, variable refresh rate is supported by switching between multiple discrete refresh rates rather than continuously adapting refresh rates (as of Sep. 2024) [1], and thus the client-side VSync5 always exists.

Abstract

Video analytics is widespread in various applications serving our society. Recent advances of content enhancement in video analytics offer significant benefits for the bandwidth saving and accuracy improvement. However, existing content-enhanced video analytics systems are excessively computationally expensive and provide extremely low throughput. In this paper, we present region-based content enhancement, that enhances only the important regions in videos, to improve analytical accuracy. Our system, RegenHance, enables high-accuracy and high-throughput video analytics at the edge by 1) a macroblock-based region importance predictor that identifies the important regions fast and precisely, 2) a region-aware enhancer that stitches sparsely distributed regions into dense tensors and enhances them efficiently, and 3) a profile-based execution planer that allocates appropriate resources for enhancement and analytics components. We prototype RegenHance on five heterogeneous edge devices. Experiments on two analytical tasks reveal that region-based enhancement improves the overall accuracy of 10-19% and achieves 2-3× throughput compared to the state-of-the-art frame-based enhancement methods.

1 Introduction

Video cameras are widespread in our society, with numerous installations in major cities and organizations [3, 4, 12, 13, 16]. These cameras continuously collect vast amounts of video data for various applications such as traffic control [25], school security [42], crime investigation [15, 83], sports refereeing [5, 14], and more [17, 86]. Significant advances in deep neural networks (DNNs) for vision processing offer a tremendous opportunity to AI-powered automatic *video analytics* [44,45,56,89,92,101]. A typical video analytics pipeline follows the distributed paradigm as AI methods often require high computing power that cameras cannot offer [1, 18]. Cameras capture and deliver the live videos to the edge in proximity for real-time processing. However, the outdated hardware of cameras in use [62] and extremely limited uplink bandwidth between the camera and the edge [21, 43, 101] results in limited video quality and thus low analytical accuracy.

Content enhancement offers a promising solution to tackle this issue. It delivers a remarkable accuracy improvement [68,70,80,82,84,96,100] and bandwidth saving [41,60,79,93–95,97] by leveraging neural enhancement models (*e.g.*, super-resolution [24, 64], generative adversarial network [30, 48], image restoration [63]) to enhance the informative details of video frames prior to feeding them into the final analytical models. Different from previous model optimization methods (*e.g.*, model merging [55, 71], model updating [60, 74], and model switching [59, 95]), data-optimization content enhancement does not require modifying user-provide models [23, 31, 73]. Besides, even if the city government updates current low-end cameras to the latest ones that can offer high-quality video, content enhancement can still improve the details of small objects or blurred content.

Unfortunately, naively employing content enhancement in practice is excessively computationally expensive. Such straightforward ways of enhancements not only cause high latency but also compete for computational resources with final analytical models. For example, applying enhancement on one tail-accuracy frame or executing generative adversarial networks on hard-recognized human faces causes hundreds to thousands of milliseconds of latency [84, 96]. The state-of-the-art method, *selective enhancement* [93, 95], yields some throughput improvement by enhancing only sampled frames but results in substantial accuracy reduction (more in § 2.2).

Goal and observations. This paper asks the following research question: Can we integrate content enhancement into video analytics at the edge in a high-throughput manner? We argue that yes, but it requires a rethink of enhancement. Our key observations are that 1) the time cost of enhancement positively correlates to the input size, and 2) the regions after enhancement that benefit analytical accuracy only occupy a small portion in each frame (more details in §2.3). Therefore, we aim to develop a *region-based content-enhancement* method which only enhances the beneficial regions.

To this goal, we face three non-trivial challenges.

(C1) How to identify beneficial regions fast and accurately? Simply relying on DNN-based identification is too slow to the extent that it even exceeds the time required for the entire frame enhancement.

(C2) How to efficiently enhance regions? Characteristics of enhancement and heterogeneous accuracy gain of regions necessitate a novel enhancement mechanism that differs from the previous frame-based enhancement [60, 93–95].

*Weijun Wang and Liang Mi contributed equally to this work.
†This work was done while Liang Mi and Shaowei Cen were interns at the Institute for AI Industry Research (AIR), Tsinghua University.
‡Corresponding author: Yunxin Liu<liuyunxin@air.tsinghua.edu.cn>.

(C3) How to allocate resources among components? To maximize the overall performance, limited resources on edge must be best allocated among system components; however, typical schedulers cause imbalances among components, which in turn leads to noticeable throughput degradation.

RegenHance. This paper presents RegenHance, a system that efficiently identifies and enhances the most beneficial regions in video, enabling high-accuracy and high-throughput analytics at the edge. RegenHance addresses the above challenges by following techniques:

Macroblock-based region importance prediction. We propose a predictor to fast and accurately identify the regions that yield the highest accuracy improvements in videos (§3.2). We first analyze the advantages of predicting the region importance at the macroblock (MB, the video encoding unit) level and establish a metric to precisely measure the accuracy gain (importance) of each MB after enhancement in each frame. Next, we develop an ultra-lightweight prediction model and a prediction results reuse algorithm, achieving high throughput. Experiments show our method can predict the MB importance in 30 frames per second on a single CPU thread.

Region-aware enhancement. We design an enhancer that efficiently enhances the Tetris-like irregular regions composed of important macroblocks (§3.3). It prioritizes and selects the Top-K MBs of all video streams in order of their importance scores (K is estimated by §3.4). Then, considering the unique characteristic of the time cost of enhancement (§2.3) and the sparse distribution of important MBs (§3.2), the region-aware enhancer can be formulated as a two-dimensional bin-packing problem that minimizes the input size of the enhancement model to optimize the throughput. We propose a greedy algorithm that fast stitches the irregular regions into dense tensors before forwarding them into the enhancement model.

Profile-based execution planning. To balance the limited resources among components on the edge device, we propose an execution planer (§3.4), that profiles the capacity of the given edge device, and allocates resources among components by determining the parameters (*e.g.*, batch size of the input) for each component (*e.g.*, decoder, MB-based region importance prediction, region-aware enhancer, and analytical models) to maximize the end-to-end throughput.

We summarize our key contributions as follows:

- To the best of our knowledge, we are the first to identify the bottleneck of content-enhanced video analytics and propose a new idea: region-based content enhancement.
- We prototype RegenHance that enables region-based content enhancement video analytics at the edge. It involves three components, MB-level region importance prediction, region-aware enhancement, and profile-based execution planning.
- We implement RegenHance and conduct evaluations for two popular analytical tasks with real-world videos on five heterogeneous devices. Experimental results show that RegenHance improves 10-19% accuracy and achieves 2-3× throughput compared to the state-of-the-art methods. Our code is now available at https://github.com/mi150/RegenHance.

This work does not raise any ethical issues.

2 Motivation and Challenges

This section explores three questions: (1) How well are selective enhancement techniques in video analytics (§2.2)? (2) How much potential improvement can region-based content enhancement achieve (§2.3)? (3) What challenges must be tackled (§2.4)?

2.1 Background

Typical video analytics platforms [6, 9, 39], to support real-time applications, provide services on edge servers close to cameras that allow users to register custom video analytics jobs. To register a job, users specify video sources, analytical tasks, performance targets, and optionally upload their analytical models [23, 31, 73]. The camera captures and encodes multiple images into a video stream (*e.g.*, 30 images into a 1-second video chunk set up in prior studies [44, 62, 101]), and then transmits to the edge for analytics. Following the same scope, this paper also concentrates on optimizing the analytics platforms on edge servers.

Content-enhanced video analytics [41, 60, 68, 85, 93–97, 100] is a mainstream data optimization method, that utilizes DNN models to enhance low-resolution frames to high-definition ones. Pre-trained DNNs learn a pixel generator mapping neighboring pixels' values to the generated one from training data, then deployed in runtime systems analyzing real-world videos for accuracy improvement and bandwidth saving.

Selective enhancement is the state-of-the-art method to improve the throughput of content-enhanced Internet video streaming [93, 95, 104]. In this method, a few sampled frames (called anchors) are enhanced by the super-resolution model, while the remaining frames are quickly up-scaled by reusing enhanced ones via codec information. Such reuse causes video quality loss, due to the rate-distortion problem in codec [78], accumulated across consecutive non-enhanced frames, and thus the sampled frames need to be selected carefully.

2.2 Limitation of Frame-based Enhancement

Motivational study. To measure the performance of selective enhancement, we benchmark three analytics methods. Taking object detection as an example, 1) *Only infer* method purely detects objects in each frame, 2) *Per-frame SR* method applies super-resolution on each frame and then detects objects on them (as the ground truth). 3) *Selective SR* [95] applies super-resolution on a set of selected frames and reuses on other ones, then detects objects on all frames; this method will select enough frames until meeting preset target accuracy (*e.g.*, 90%). For fairness, all methods run on an edge

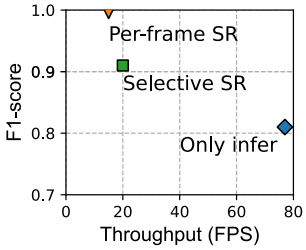

Figure 1: Performance of the frame-based methods. The state-of-the-art selective SR provides poor E2E throughput.

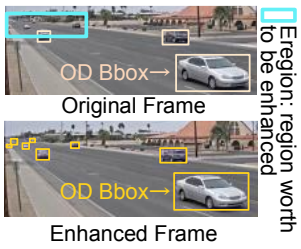

Figure 2: An example eregion worth to be enhanced for object detection (OD) bounding with a rectangle box.

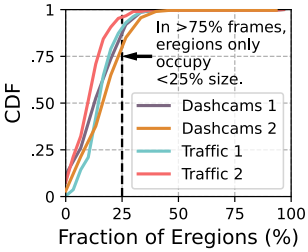

Figure 3: Distribution of eregions in various videos. In large amounts of frames, eregions occupy only a small portion.

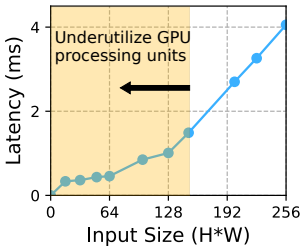

Figure 4: Latency of enhancement. The same H*W (*e.g.*, 64*64) input, no matter pixel values, yields the same latency.

device equipped with an NVIDIA T4 GPU [10] that upscales a 640 × 360 video to a 1920 × 1080 version via EDSR model [64] and detects objects with YOLO [46]. Both models compile with TensorRT [11].

Result: selective enhancement is too heavy for video analytics. As shown in Fig. 1, per-frame SR improves >10% accuracy but reduces >76% end-to-end throughput than only infer. Normalized with per-frame SR, selective SR indeed improves throughput from 15 to 20 (>33%) fps, but still far from the throughput of only infer and results in an undeniable accuracy drop. This is because, compared to human perception, analytical models are more sensitive to blur and distortion caused by accumulated loss of reuse. Small changes in several pixel values may flip the analytics result inversely [29]. So when presetting the accuracy target as 90%, selective SR methods choose 27-61 anchor frames in each 120-frame chunk on average. Such 24-51% fraction is much higher than that select and enhance only 2-13% frames in video applications for human vision.

2.3 Potential Improvement of Region-based Content Enhancement

Above *frame-based* optimizations fail to offer efficient analytics because they evenly enhance every pixel in each frame. We argue that this is unnecessary and causes a significant waste of computational resources.

Our first observation is that *the regions that are worth being enhanced in each frame occupy only a small portion.* In this paper, we name the region that provides higher analytical accuracy after enhancement, *Eregion*. As visualized in Fig. 2, the frame after enhancement (bottom) can provide more detected objects, and the eregion (blue rectangle) is a simple region (discussed more in Appx. C.1). Fig. 3 analyzes the distribution of eregions in experimental videos for Fig. 1. In >75% of frames over videos recording various scenarios, eregions for object detection task only occupy 10-25% of the spatial area of a frame; while for semantic segmentation, as illustrated in Appx. C.1, only 10-15% area in 70% frames is eregions. With careful design, eregions could minimize the enhanced area while offering comparable accuracy to per-frame SR. So ideally, only eregions should be enhanced in video analytics.

The second observation is that *the time cost of enhancement DNNs is positively correlated with input size.* As shown in Fig. 4, along with the enlarging input size, the enhancement latency initially experiences a gradual rise and then scales proportionally with the input size after making full use of processing units. This unique characteristic originates from the nature of enhancement models that generate new pixels from neighboring ones with the learned mapping. Thus, we must minimize the size to decrease enhancement latency.

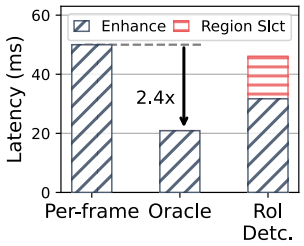
Our idea. With the above two observations in mind, we propose *region-based content enhancement* that aims to only enhance the eregions to maximize the throughput of content enhancement while providing comparable accuracy to per-frame enhancement. The question next is how to fully explore the potential room for improvement.

2.4 Challenges to Achieve Region-based Content Enhancement

Building an effective system based on region-based content enhancement involves three challenges.

C1: How to fast and accurately identify eregions on original frames? Enhancing only the eregions, as shown in Fig. 5, does save significant (2.4×) time cost. Unfortunately, such an oracle cannot be reached as eregions are calculated from the already-enhanced frames. During real-time analytics, only the original frames are accessible, thus we have to predict eregions on the original frames. Naively using a DNN-based method to identify regions, *e.g.*, DDS [44] identifies the Region of Interest (RoI) with a Region Proposal Network (RPN), can not meet our requirements. The imprecise identification spends too much time on the enhancement of unimportant regions in Fig. 5, and the high computing cost of the selection methods themselves (*e.g.*, the RPN), in turn, harms the possible time saving of region-based enhancement.

C2: How to enhance eregions in high throughput? High-throughput region-based enhancement is hardly achieved by existing frame-based enhancers [84, 93–97]. Three new contradictions that frame-based methods have never encountered



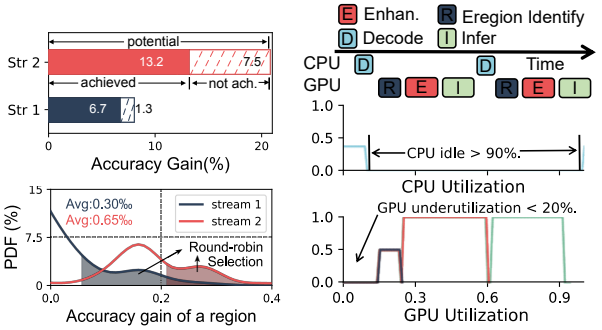


Figure 5: Region-based enhancement saves remarkable (2.4×) latency, but prior region selection methods themselves (*e.g.*, RoI detection [44]) produces too high computing cost.

(a) Round robin across streams (b) Sequential exec. of components

Figure 6: Limitation of region-agnostic resource management.

obstruct region-based enhancement. 1) Eregions are often in irregular size and sparsely distributed in each frame, but the enhancement models (DNNs) only accept rectangle (matrix) input. 2) One natural option, as DDS [44] used, is setting non-eregion pixels to black (zero value in the matrix); and yet it leads to the same latency as enhancing the original frame due to the pixel-value-agnostic characteristic of enhancement latency as demonstrated in Fig. 4. 3) Batch execution of enhancement DNNs benefits higher throughput [76], but requires every input matrix in the same size.

C3: How to allocate resources among components? To optimize the overall performance (accuracy and throughput), particularly for all video streams, 1) eregions must be carefully allocated across streams, and 2) computational resources must be balanced among computing components. However, this is challenging due to the heterogeneity of regions and components. First, the accuracy gains and enhancement overhead of regions are heterogeneous. Second, all runtime components on the edge server, including decoding, eregion identification, enhancement, and analytical inference, compete for computational resources, and their throughputs are heterogeneous. Using previous schedulers [8, 95] causes noticeable degradation in accuracy and throughput.

To demonstrate this, we benchmark a strawman scheduler that 1) parallelizes per-stream decoding on multiple CPU threads, 2) forwards decoded frames to GPU in a round-robin manner, 3) applies RegenHance's region enhancement strategy but pipelines computing components at batch size of four. Two streams that contain different sizes of eregions are delivered to an edge server equipped with an NVIDIA T4 GPU [10]. We measure the accuracy gain per stream and the resource utilization of computing units.

This strawman region-agnostic scheduler fails to achieve high accuracy gain and throughput. Fig. 6(a) (top) shows the potential (the accuracy of per-frame SR minus only infer), achieved (solid part), and not achieved (dotted part) accuracy gain of two streams. There is a remarkable gain (7.5%) not achieved in Stream 2 as the round-robin manner results in an even chance for enhancement across streams. The distributions of the region's accuracy gain in each stream are highly heterogeneous as the two curves shown in Fig. 6(a) (bottom). Suppose a scheduler enables Stream 2 to enhance more regions that provide higher gain (namely, in Fig. 6(a) (bottom), decrease some grey area under Stream 1 to fill the blank under Stream 2 into red), it can improve the overall accuracy. On the other hand, inappropriate execution plans underutilize the hardware, leading to low end-to-end throughput and, in turn, hindering higher accuracy improvement. As illustrated in Fig. 6(b), the region-agnostic scheduler leaves >90% CPU and >15% GPU idle time. The unsuitable batch size results in the Eregion Identification utilizing only <50% computing resource GPU, hence blocking the subsequent enhancement and analytics.

3 RegenHance Design

RegenHance aims to enhance only the regions (Eregions) that best benefit analytical accuracy, so as to maximize the overall accuracy gain among all streams in the optimal end-to-end throughput on a given edge server. To do so, it addresses the above challenges by three techniques: 1) a lightweight but precise algorithm to identify eregions on macroblock (MB) granularity, 2) a high-throughput enhancer that together considers the heterogeneous accuracy gain across streams and unique characteristics of enhancement, and 3) a holistic resource manager generating execution plan for all components on given edge servers. Fig. 7 depicts the design of RegenHance. We implement the techniques with three new components: MB-based region Importance Prediction, Region-aware Enhancement, and Profile-based Execution Planning.

3.1 Overview Workflow

RegenHance takes the original ingest videos and outputs high-resolution frames for downstream analytical tasks. During the offline phase, Profile-based Execution Planning ❶ profiles the budget of processors on the given edge server with the registered analytical tasks and optional uploaded corresponding models by users; next, ❷ generates the execution plan, *i.e.*, specifies every runtime component's execution hardware and their allocated resource meeting best pipelining and parallelization, to maximize the end-to-end throughput under the

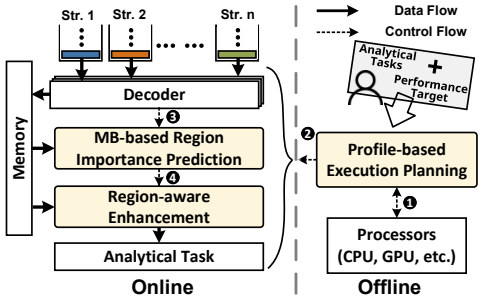

Figure 7: RegenHance overview.

constraints of performance targets (*e.g.*, accuracy and latency) that users specify (§3.4).

During the online phase, the decoder decodes compressed video streams in parallel to RGB frames and stores them in memory. MB-based region importance prediction ❸ selects frames during decoding, loads them from memory, predicts their MBs importance, and appends importance into MBs' indexes (§3.2). Region-aware enhancement ❹ aggregates and sorts all MBs over all streams based on their importance, constructs top N ones into regions, stitches them into dense tensors, and efficiently executes enhancement (§3.3). Lastly, forward the enhanced frames to analytical models for inference.

3.2 MB-based Region Importance Prediction

In order to identify eregions quickly and accurately, we propose an MB-based region importance prediction. It contains a lightweight predictor estimating MB importance in each frame (in spatial dimension) and an MB importance reuse algorithm among continuous frames (in temporal dimension).

3.2.1 Spatial MB Importance Predictor in Each Frame. Eregions can be arbitrary shapes, we need to determine the granularity to construct these regions first. One natural way is pixel granularity. The pixel-grain method, of course, provides the most precise importance prediction but costs too much computing resources (as demonstrated in Fig. 5).

Inspired by the video codec knowledge [45, 53], we argue that setting macroblock (MB) as the elementary unit of eregions is both efficient and accurate. Macroblock serves as the elementary unit for applying the quantization parameter (QP) to control the compression level of video quality. For example, in H.264 [7], frames are divided into an array of 16×16-pixel MBs, and each MB is assigned with different QPs to distribute more bits to regions demanding higher visual quality and fewer bits to less crucial regions.

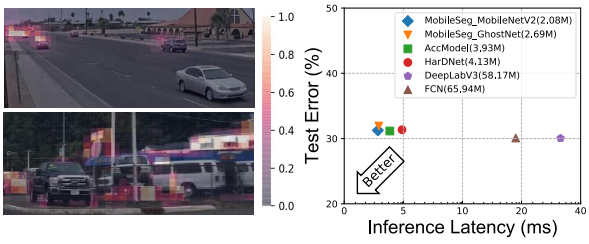
After setting MB as a unit, our problem transformed to: Given a video frame f containing a set of macroblocks MB, select partial MBs MB_s to be enhanced such that the accuracy of downstream analytical task is maximized:

$$max \quad Acc(I(SR(MB_s)+IN(\overline{MB_s})), I(SR(f))),$$

where $Acc(\cdot)$ is the accuracy of analytical task $I(\cdot)$ (*e.g.*, F1-score of object detection), $SR(\cdot)$ and $IN(\cdot)$ are the super-resolution and the bi-linear interpolation with the same enlarge factor, $\overline{MB_s}$ indicates the unselected MBs.

To select beneficial MBs, we need to quantify their importance. Ideally, MBs after enhancement leading to larger variations in inference results and greater differences in pixel values are more important. With this intuition, we utilize the following "importance" metric looking at the gradient of the accuracy with respect to changes in the pixels in each MB, and the magnitude of change in those pixel values due to enhancement.

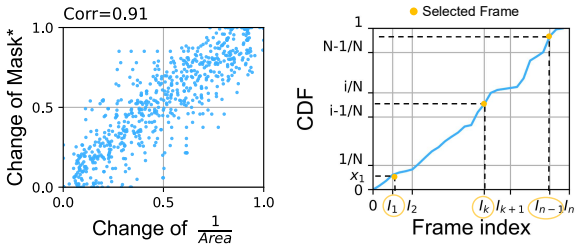
$$\sum_{i \in MB} || \underbrace{\frac{\partial Acc(I(IN(f)), I(SR(f)))}{\partial IN(f)}\Big|_i}_{\text{accuracy's gradients at pixel } i} ||_1 \cdot || \underbrace{(SR(f)_i - IN(f)_i)}_{\text{pixel value distance at } i} ||_1,$$



where i is a pixel within the certain MB and $||\cdot||_1$ is the L1-norm. This metric assigns an importance score to each MB. Fig. 8(a) shows the heat map of MB importance on the same frame with Fig. 2. Their similarity demonstrates the MB importance is a good representation of eregions*.

It seems straightforward to calculate the MB importance according to the above importance metric. Unfortunately, it needs the frames already enhanced. Such a chicken-egg paradox makes us predict the MB importance in the original frames with a learning-based method. We construct the training set by enhancing all video frames and calculating the importance metrics on each of them with one forward and backward propagation of the final analytical model. This resulting importance value of each MB is one item in the ground truth matrix of each frame, Mask*.

Next, we consider this problem a segmentation task and draw inspiration from their model designs. Our key observation is that the MB importance prediction resembles the problem of image segmentation. Image segmentation aims to semantically segment an image by assigning each pixel one predefined label, while MB importance prediction gives each MB an importance score. With this in mind, the MB importance prediction can be approximated as an image segmentation problem by boiling the importance value down to multiple importance levels. Suppose setting ten levels in this paper, MB importance prediction targets to assign each MB an importance level, like classification in image segmentation. Appx. B demonstrates such approximation yields good performance. This observation enables us to harness various techniques tailored for MB importance prediction, including learning-based semantic segmentation.



Aiming to predict MB importance precisely at high throughput, we train an ultra-lightweight segmentation model with the above importance metric. We retrained six models using

*Unlike the saliency map in computer vision that captures which pixel values have more influence on the DNN output, our loss function captures how the enhancement or non-enhancement of an MB (its content quality change) specifically changes the DNN inference accuracy.

(a) Heat map of MB importance (b) Model selection

Figure 8: Macroblock-level region importance prediction.

(a) Correlation ratio (b) Frame selection with CDF

Figure 9: Temporal MB importance reuse across frames.

the cross-entropy loss with piecewise Mask* (as importance level) to support MB importance prediction. Six models are an ultra-lightweight model MobileSeg [81] with two backbones, two lightweight models AccModel [45] and HarDNet [32], and two heavyweight models FCN [66] and DeepLabV3 [33]. As shown in Fig. 8(b), ultra-lightweight models provide almost the same accuracy as heavyweight ones while offering 4-18× throughput. This can be attributed to the significantly relaxed complexity of the MB-grained segmentation compared to traditional image segmentation. Predefined MB size in video codec supports this point. The 16×16-MB H.264 [7] codec makes 1920×1080 labels that output in traditional image segmentation models decrease to 120×68 ones in MB-grained. As the best performance of MobileSeg, we select it as our MB importance predictor. At the offline phase, RegenHance fine-tunes the predictor with the Mask* generated by user-uploaded analytical models.

3.2.2 Temporal MB Importance Reuse among Continuous Frames. Reusing DNN outputs on similar frames is popular [45, 90, 100] as discussed in §5. Reusing content of enhanced frames in region-based enhancement like selective SR will cause dramatic accuracy loss (demonstrated in §2.2), but the MB importance value is reusable. Hence, RegenHance predicts the MB importance of a set of frames and reuses their outputs on other frames, to offer the best approximation of per-frame MB importance prediction.

Our key choice is using an ultra-lightweight operator to represent the MB importance change then only predicts MB importance of the frames with large changes. We compared many lightweight features and proposed $\frac{1}{Area}$ operator (details in Appx. C.2). Area operator captures the large blocks in images [52, 62], whereas $\frac{1}{Area}$ captures the change of small objects just as the important MBs in Fig. 8(a) needed. Statistical analysis in Fig. 9(a) shows it is a nice representation to estimate the change of Mask* (with 0.91 correlation).

With the $\frac{1}{Area}$ operator, denoted by Φ, RegenHance selects frames to be predicted by the cumulative distribution function (CDF) of $\Delta\Phi$ between continuous frames in each chunk. It first accumulates the feature change with the following function during decoding a n-frame chunk.

$$\mathbf{S} = Norm(\Delta\Phi(Res_{Y_1}), \cdots, \Delta\Phi(Res_{Y_{n-1}})),$$

where Res_{Y_i} is Y-channel of each frame's residual[†], $\Delta\Phi(Res_{Y_i}) = \Phi(Res_{Y_{i+1}}) - \Phi(Res_{Y_i})$, $Norm(\cdot)$ is L1-normalization. Then, it selects N frames based on the CDF $\mathbf{M}$, where $\sum_i M_i = 1$, calculated from $\mathbf{S}$. As illustrated in Fig. 9(b), the y-axis is divided into N even intervals; and in each interval, it selects a value, *e.g.*, x_1, and then its corresponding frame index, *e.g.*, I_1, on the x-axis is a selected frame. The other frames in each interval reuse the predicted result of this frame. In multiple streams, the number of selected frames for given stream j is allocated by the ratio $\frac{\sum_i \Delta\Phi_{i,j}}{\sum_j \sum_i \Delta\Phi_{i,j}}$, and its total number is determined by the profile-based execution planning (§3.4). Fig 10 depicts the MB-based importance prediction first selects frames and then predicts their MB importance.

3.2.3 Discussion. *Generality of importance metric.* In this paper, each analytical task must retrain a specific MobileSeg for importance prediction, as the metric equation relies on the downstream models. We omit a general importance metric design in this paper because 1) the current specific metric offers good results (as shown in Fig. 8(a)) and 2) the fine-tuning time only costs 4 minutes on eight RTX3090 GPUs. We will explore a general metric in future work.

3.3 Region-aware Enhancement

To achieve optimal overall accuracy over all streams and end-to-end throughput, we propose a region-aware enhancement consisting of a cross-stream MB selection and a region-aware bin packing algorithm.

3.3.1 Cross-stream MB Selection. To maximize the overall accuracy improvement, RegenHance chooses the best MB st among all streams that offer the highest total accuracy gain. As shown in Fig. 10, it constructs a global queue that aggregates and sorts MBs from all streams in order of the importance (level) in the MB index $\{stream_{id}, frame_{id}, loc_x, loc_y, importance\}$, where loc_x, loc_y indicates coordination of the MB in the frame.

Next, it selects the top N MBs and delivers their indexes to the region-aware bin packing algorithm for further processing. The number of selected MBs is estimated as follows,

$$\max_N MB_{size} \cdot N \leq H \cdot W \cdot B,$$

[†]Residual is data existing in video codec representing the difference data between the original and compressed video frames.

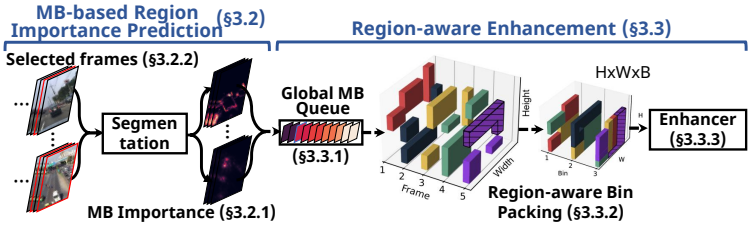


Figure 10: Runtime components of RegenHance.

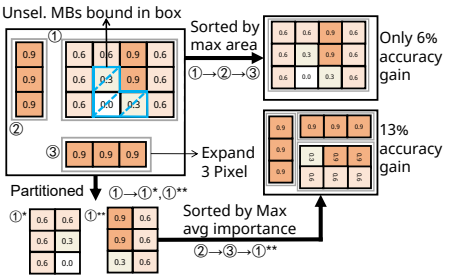

Figure 11: Large region is not always desirable. Classic large-item-first policy packs the MBs that are unselected but bounded in the large box into the bin (upper half), leading to a 7% accuracy drop compared to our importance-first policy (lower half).

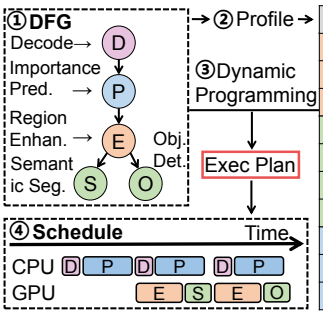
Algorithm 1 Region-aware Bin Packing

Input: Indexes of MBs, B Bins of $H \times W$ size
Output: Packing plan of MBs

```
1:  function PACKING(MBs, Bins)
2:      freeareas = Bins                    ▷ Initialize the list of free area as Bins
3:      regions = REGIONPROPS(MBs)
4:      boxes = BOUND(regions)
5:      boxes = PARTITION(boxes)            ▷ Partition big boxes to small ones
6:      SORT(boxes, reverse = True, order = Σ_{MB∈box} MB.importance / |{MB|MB∈box}|)
7:      for box in boxes do
8:          for farea in freeareas do
9:              if ROTATEPACKING(box, farea) then
10:                 UPDATE(farea, freeareas); break
11:         boxes.POP(box)
12: function ROTATEPACKING(box, farea)
13:     if farea.w≥box.w and farea.h≥box.h then return True
14:     else if farea.w≥box.h and farea.h≥box.w then return True
15:     else return False
16: function UPDATE(farea, freeareas, box)
17:     box.APPEND(loc)                     ▷ Append the placed location of box in Bins
18:     ifareas = INNERFREE(farea, box)     ▷ Find rest free areas in box after
                                              packing farea (more in Appx. A)
19:     freeareas = freeareas ∪ ifareas \ {farea}
```

where MB_{size} is the size of a MB, *e.g.*, 16×16 in H.264. H, W, B are the optimal height, width, and batch size for the enhancement model preset in the execution plan (§3.4).



3.3.2 Region-aware Bin Packing. Considering the sparse distribution of selected MBs, the unique characteristics of enhancement models (requires rectangle input and latency is pixel-value-agnostic proportional to the input size), and the helpful but complex batch execution, we propose a region-aware bin packing algorithm to construct selected MBs into irregular regions and stitch them into dense tensors.

The problem is formulated as a *two-dimensional bin-packing problem* [28] that packs the maximum number of selected MBs into given bins. The input are MB indexes and the number of bins B and their size $H \times W$, the output is the packing plan of MBs. We process MB indexes, not real images, to avoid frequent memory I/O. It is known to be NP-hard. Prior methods [37, 38, 76] batch the standard rectangle DNN inputs and thus can not handle irregular regions. To motivate our design, we first analyze two strawmen: 1) MB packing: directly packing selected MBs after expanding three pixels in each direction[‡] into bins, and 2) Irregular region packing: packing the (irregular) regions consisting of connected and selected MBs after extension into bins [67]. MB packing packs too many unimportant or repeated pixels due to extension, thus under-utilizing given bins compared to the irregular manner; whereas the high complexity of existing irregular region packing algorithms causes more than one order of magnitude of time cost than MB packing (more in Appx. C.4).

To strike a better balance between bin utilization and algorithm efficiency, we propose region-aware bin packing in Alg. 1. Its key design choices are: 1) bounding the irregular regions in rectangle boxes for efficient packing plan search (line #3-5); 2) cutting large boxes into small ones and sorting boxes in order of importance density, *i.e.*, the average importance of all MBs in it, for high bin utilization (line #6). Fig. 11 exemplifies that this prioritization leads to a higher (13%) accuracy gain, compared to 6% of traditional large-item-first (max-area-first) policies [57] (more results refer to Fig. 23). Region-aware bin packing first constructs regions by calculating the connected components of selected MB in line #3, and bounds each region in a rectangular box with extension (line #4), *e.g.*, ①②③ in Fig. 11. Next, it partitions the boxes larger than the preset size (line #5) in case of importing too many unimportant MBs, *i.e.*, box ① cut to ①* and ①**. Then, line #6 sorts boxes according to the priority we propose, *i.e.*, not (①,②,③) of max-area-first policy but (②,③,①**). Lastly, it iteratively packs them into bins. In each iteration (line #7-11), it rotates and packs a box into a free area in a bin, updates the box's placing location and the list of free areas, and then deletes the box from the boxes. For example, the "L" region in Fig. 10 and ①** in Fig. 11 is rotated and packed into bins.

3.3.3 Enhancement with Super-resolution Model. Based on the execution plan across various devices (§4.2), except for Jetson AGX Orin equipped with unified memory, the other devices need to transfer real frames from main memory to GPU memory. To save time, we hide this transfer at the same time as the MB selection and bin packing procedure. This idea works because, after processing the real frames by MB-

[‡]Such expansion can avoid the MB/region boundaries causing too many jagged edges and blocky artifacts [45] when pasting enhanced content back to the bi-linear-interpolated frames. For more results refer to Appendix C.3.

Model@HW	Bat	Cos	TPS
SR@CPU	1	270	3
SR@GPU	1	7	142
	4	27	148
OD@GPU	1	2	500
	4	7.8	512
SS@GPU	1	2.7	370
	4	8.3	481
P@CPU	16	27	592
P@GPU	1	1.7	588
	4	4.2	952

Figure 12: An example of execution planning process seven 30-fps streams s.t. <1s latency & >0.9 accuracy performance target. The throughputs (TPS) of one model executing on one hardware (Model@HW) in the right table are profiled with batch size (Bat) and time cost (Cos). The red boxes highlight the execution plan of each component of the given dataflow graph (DFG).

based region importance prediction, as shown in Fig. 7, all modules solely deal with MB indexes before super-resolution. Consequently, we stitch the real-content regions into tensors (bins) following the packing plan on the GPU, subsequently enhancing and stitching them back to bi-linear-interpolated non-regions for final analytics.

3.4 Profile-based Execution Planning

Given an edge server equipped with R computational resource (*i.e.*, R processing time of processors under 100% utilization) and the user's analytical jobs, profile-based executing planning aims to allocate the most appropriate resources to each component, maximizing the end-to-end throughput subject to performance targets. The problem is formulated as follows,

$$\max \ \ T_{e2e}, \ \ s.t. \sum R_u \leq R \ \ \forall u \in V(G).$$

where G is the dataflow graph (DFG) of components; u is the node in graph G and R_u indicates its allocated resource.

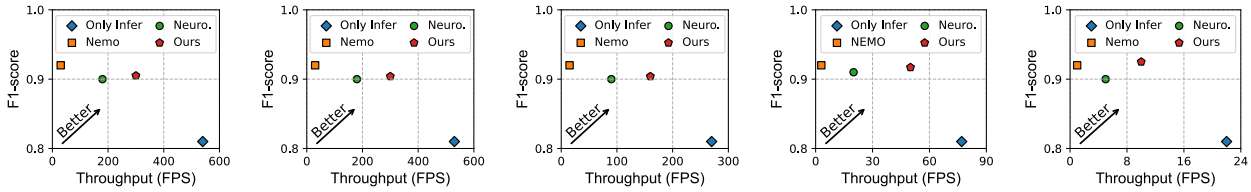
We present a profile-based execution planning, as the example of one CPU plus one GPU depicted in Fig. 12, that ① parses the DFG of user-specified analytical tasks, ② runs workload (*e.g.*, one-minute user-specified streams) on all components, including user-uploaded models to profile their capacity on all accessible hardware, ③ generates the execution plan that satisfies user-specified performance targets, and ④ loads each component into corresponding hardware. Our crucial choice is to assign each component's input tensor size (*e.g.*, batch size) for resource allocation. Batching execution, *i.e.*, grouping input matrices into one, is well known to achieve high processor utilization by DNNs; it also allows the inference engines to achieve various throughputs by adjusting different batch sizes [36, 37, 76].

As the DFG of any job, naturally, is a directed acyclic graph (DAG), we can always leverage *dynamic programming* to solve this optimization problem [75]. Define $T_u(r)$ as the maximum throughput of components represented by u and the subtree at u within the resource budget r, which numerically equals the minimum node in each path. For non-leaf node u, the algorithm allocates a resource budget r' for node u and at most $r-r'$ for the subtree, and it then enumerates all $r \leq R$ to find the optimal allocations that assign optimal batch size b for each node. Formally, $\forall (u,v) \in E(G)$,

$$T_u(r) = \max_{r:r\leq R} \left\{ \min(\max_{b:c_u(b)\leq r'} \frac{b}{c_u(b)}, T_v(r-r')) \right\}.$$

where $c_u(b)$ is the resource cost of node u at b batches. RegenHance allocates the least resources for analytical models that satisfy the user's latency target and then assigns other components' batch sizes with this equation.

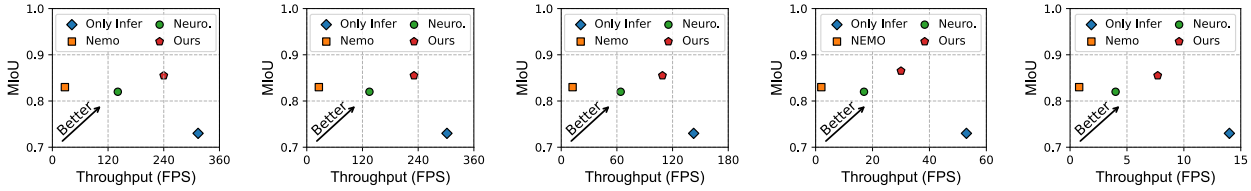
In general, the optimal solution always converges to the allocation that won't be bottlenecked by any node; in other words, each node in the graph generates the same throughput. Therefore, when users' registrations change frequently, the execution plan must be generated quickly. To this end, we will explore learning-related methods like online deep reinforcement learning [26] and combinatorial-optimization-related methods like local search [50] in future work.



4 Evaluation

We evaluate RegenHance with two video analytics tasks on five heterogeneous devices. Our key findings are:

- RegenHance improves 10-19% accuracy and achieves 2-3× end-to-end throughput compared to the state-of-the-art frame-based enhancement methods. (Sec. 4.3)
- RegenHance shows robust effectiveness on various devices with heterogeneous computational resources, different analytical tasks and models, diverse workloads and performance targets, and various resolutions. (Sec. 4.3)
- MB-based Region Importance Prediction and Region-aware Enhancement bring remarkable accuracy and throughput benefit, and Profile-based Execution Planning boosts great resource utilization and throughput. (Sec. 4.4)



4.1 Implementation

We implement RegenHance upon commercial frameworks including FFmpeg (v4.4.2) [19], Pytorch (v1.8.2) [20], Paddleseg (v2.7.0) [27], ONNX, OpenVINO (v2023.0.1) [22], TensorRT (v8.4.2.4) [11], and the mostly code is implemented by Python (v3.8). The MB-based region importance prediction and the region-aware enhancer are implemented as follows. (1) RegenHance implements the MB importance predictor by retraining MobileSeg (MobileNetV2 backbone) with importance metric and prunes its 50% parameters by L1-Norm pruner. It is further exported to the ONNX version (using `paddle.onnx.export` API) for efficient running on Intel CPU with OpenVINO Runtime, and exported to the TensorRT version for NVIDIA GPU (using `trtexec` library). If not mentioned, all TensorRT models are set as `FP16` in dynamic shape version, and the engine files are exported and inferred by PyCUDA (v2022.2). (2) We modify `ff_h264_idct_add` API in

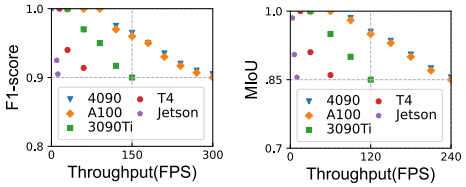
Table 1: Summary of downstream tasks and datasets.

FFmpeg to extract the residual for temporal MB importance reuse. (3) RegenHance uses a pre-trained super-resolution model [64] as enhancer, and also converts it to ONNX version and TensorRT version for efficiency.

Loading models into memory can cost hundreds of milliseconds to seconds. Therefore, at runtime, RegenHance preloads the DNN into the specified processors and then invokes it. RegenHance consists of ∼5.3K lines of code.

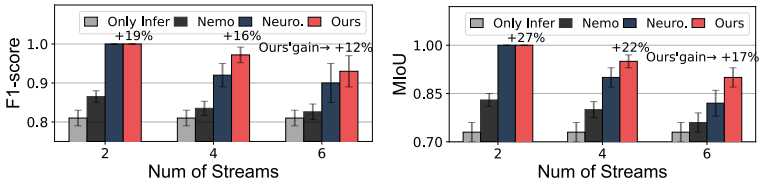
4.2 Experimental Setup



Downstream tasks and dataset. As summarized in Tab.1, we select two downstream analytical tasks, object detection and semantic segmentation, to evaluate the performance of RegenHance as they play the core role in a wide range of high-level tasks. Object detection aims to identify objects of interest (*i.e.*, locations and classes) on each video frame; its accuracy is measured by average *F1-score* in each stream with Intersection over Union (IoU) threshold at 0.5. Semantic segmentation labels each pixel with one class, and we measure its accuracy with *mIoU*. We also evaluate their *throughput*, *i.e.*, number of streams that can be processed in real-time.

Both of the tasks were separately tested with two models (light- and heavyweight) on two video sets. For the object detection, we used the Yoda dataset [88] and gathered 120 video clips from YouTube containing various scenes with diverse characteristics, *i.e.*, time, illumination, objects' density and speed, and road type. The labels to train importance predictor are generated with Mask R-CNN (Swin backbone) on per-frame enhancement since its SOTA performance; if users provide their self-tailored analytical models, we use their output as labels. Here, we use YOLO as an example. We will release this dataset after this paper is accepted. For semantic segmentation, we utilized the BDD100K [2] and Cityscape [35] public dataset. We re-encoded these datasets into 360P resolution, 30 fps, and 1024kbps bitrate videos in H.264 to avoid the impacts of various video codecs.

Devices. We conducted experiments on five heterogeneous devices divided into four categories. (1) As a comparison, we deployed and tested RegenHance on a cloud server with an NVIDIA A100 GPU and Intel(R) i9-12900K CPU. (2) As one of the most popular configurations of edge servers, we conducted experiments on an edge equipped with an NVIDIA Tesla T4 and Intel i7-8700 CPU. (3) To explore the capabilities of gaming cards and their generation gap, we tested an NVIDIA RTX4090 and an NVIDIA RTX3090Ti, respectively, with an Intel i9-13900K. (3) For the embedded edge, we used an NVIDIA Jetson AGX Orin 64GB as the platform.



Baselines. To show the superiority brought by RegenHance, we compare it with four different baselines:

- **Only infer** directly applies analytical DNNs on each original frame without enhancement.
- **NeuroScaler [95]** is the state-of-the-art frame-based enhancement method. It first enhances the anchors and reuses their quality gain on non-anchors, then infers all frames. It fast selects anchors in a heuristic manner.
- **Nemo [93]** also only enhances the anchors and reuses their quality gain, then infers all frames; but it iteratively selects the best anchors based on enhancement results.

Table 3: End-to-end throughput (FPS) breakdown of RegenHance.

4.3 End-to-End Performance

This section reports the E2E performance of RegenHance on various devices. If not mentioned, all results are tested on RTX4090 with 1s latency, 90% object detection, and 88% semantic segmentation (10% gain compared to only infer).

Performance on heterogeneous devices. As shown in Fig. 13 and Fig. 14, RegenHance achieves high accuracy and high throughput simultaneously on various devices. It of course cannot reach the throughput of only infer due to the additional enhancement time cost but provides significant throughput gain compared to SOTA NEMO and NeuroScale. On average, RegenHance outperforms their throughput by 12× and 2.1× in object detection and 11× and 1.9× in semantic segmentation, respectively. This larger performance gain in semantic segmentation stems from its heightened sensitivity to visual details. RegenHance can keep this superiority on all five heterogeneous devices because profile-based execution planning always generates the optimal throughput plans.

Trade-off between throughput and accuracy. RegenHance creates a trade-off space between accuracy and throughput, as shown in Fig. 15; it can offer service on edge servers with heterogeneous resources. Edge servers equipped with higher resources produce larger trade-off space. For example, RegenHance supports object detection for ten streams (300fps) with 91% accuracy on RTX4090 or A100 GPU; and if the accuracy constraint is more strict, RegenHance will make corresponding adjustments and serve the maximum number of streams, *e.g.*, six 95%-accuracy streams. On devices with lower available resources, *e.g.*, on NVIDIA T4 and Jetson AGX Orin, although the maximum frame rate decreases, RegenHance still delivers remarkable throughput under different accuracy targets.

Performance gain with multiple streams. With the increasing number of competing streams, RegenHance always achieves the highest accuracy compared to the other three frame-based enhancement methods. For example, in Fig. 16 tests on RTX4090, RegenHance improves accuracy by 8-14% compared to the selective enhancement in six streams. This is because, in such a highly competitive scenario where each stream is allocated limited resources, our method consistently enhances the most valuable regions; in contrast, the selective baseline and the per-frame baseline waste excessive resources on unimportant content. RegenHance significantly improves the throughput of content-enhanced video analytics.

Frame latency under diverse batch sizes. The latency is defined the same as prior studies (*e.g.*, DDS [44], AWStream [101], and Reducto [62]), *i.e.*, the time from encoding 1s video chunk (30 frames) on cameras to all 30 frames' inference results are available on edge. The left figure of Fig. 17 plots the latency of each frame with different batch sizes under the same workflow. The results imply that batch execution yields fewer high-latency frames because its average latency of 30 frames in each chunk is much lower than executed without batch, which stems from the batch's higher GPU utilization. For a deeper insight, the right figure of Fig. 17 evaluates the latency difference of each frame with and without batch execution. Compared to without batch, execution with batch may cause 75ms latency at most, which is the earliest frame (in video play order) in one batch; but on average, batch execution saves time cost.

Performance gain under different resolutions. When streaming 720p in object detection while 360p for semantic segmentation under a target of 90% accuracy, as shown in Table 2, 360p video costs only 31% bandwidth (0.96Mbps *v.s.*

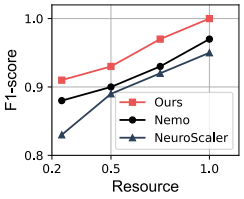

Figure 18: Accuracy on different resources.

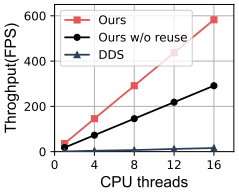

Figure 19: Throughput of region prediction.

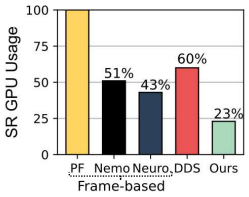

Figure 20: GPU resources usage.

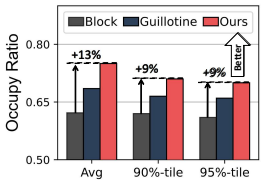

Figure 21: Perf. of different packing policies.

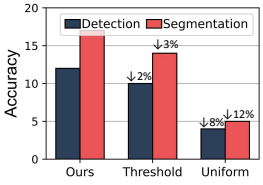

Figure 22: Acc gain of Cross-stream MB sel.

3Mbps) compared to 720p. RegenHance boosts accuracy gain of 360p video from 81% to 90%, while 720p video from 83% to 90%. Higher resolution yields higher accuracy; however, content enhancement can still improve the details of small objects or blurred content. The end-to-end throughput of 720p is almost the same as 360p (11 *v.s.* 10 streams). The reason is that although 720p needs to enhance fewer regions compared to 360p (17% *v.s.* 23% GPU usage for SR), its time cost of other runtime components (*e.g.*, MB importance prediction) is larger than 360p due to the larger input size.

Contributions by individual components. Table 3 shows the throughput breakdown of RegenHance. We tested multiple versions of RegenHance by selectively applying each component. The results show that each component significantly contributes to the improvements in the throughput. The execution planning enables a 1.2× throughput compared to per-frame enhancement by reasonable resource allocation (1st→2nd). Incorporating MB-based region importance prediction without region-aware enhancement fails to improve throughput because filling unimportant regions to black does not alter the enhancement latency (2nd→3rd row). The throughput is increased by 1.6× due to the region-aware enhancement (3rd→4th row) and by 1.7× from the best execution plan of profile-based execution planning (4th→5th row).

4.4 Comprehensive Component-wise Analysis

We provide an in-depth performance analysis of individual system components.

4.4.1 MB-based region Importance Prediction (§3.2) helps RegenHance achieve great throughput improvement while keeping high accuracy.

Accuracy: Fig. 18 illustrates the accuracy gain obtained by different enhancement methods, when assigned the same computational resource to complete object detection on six streams. RegenHance (region-based enhancement) can offer a 3-4% and 4-8% higher gain compared to (frame-based) Nemo and Neuralscaler, respectively, because our predictor identifies the most beneficial region precisely.

Thoughput: As shown in Fig. 19, our ultra-lightweight MB importance predictor can be executed at 30 fps on one single i7-8700 CPU core, which outperforms the RoI selection by RPN in DDS more than 60 times. On GPU, it achieves 973 fps, which outperforms DDS more than 12 times. The reuse contributes 2 times throughput improvement.

Resource saving: Fig. 20 shows that our method reduces 77%, 28%, and 20% GPU usage compared to the frame-based Per-frame enhancement, Nemo, and NeuroScaler, respectively, when enhancing a single stream (30FPS) to achieve an accuracy exceeding 90%. Compared to the RoI selection of DDS, our method saves 37% GPU usage as it identifies the most beneficial region for analytical accuracy more precisely.

4.4.2 Region-aware Enhancement (§3.3) yields significant throughput improvement and overall accuracy gain.

Throughput: Region-aware bin packing maximizes RegenHance's throughput with a high stability and occupy ratio, and thus effectively reducing the additional overhead of SR. We conducted experiments repeated 1,000 times by randomly shuffling the order of six video streams, and comparing the occupy ratio, *i.e.*, the ratio of selected MBs occupying all enhanced content, with the classic Guillotine policy [57] and the Block policy, *i.e.*, MB packing. Fig. 21 shows that the average, 90%-tile, and 95%-tile occupy ratio difference; our packing policy gets the highest occupy ratio of 75% that outperforms the comparisons by up to 13%, 9%, and 9%.

Accuracy: Cross-stream MB selection, especially our custom sorting order, leads to remarkable accuracy gain by considering the heterogeneous region accuracy gain across streams. We compared our MB selection with the Uniform method, which allocates the same MB number to each stream, and the Threshold method sets a fixed threshold, 0.5, to select MB importance for all streams. As shown in Fig. 22, our method outperforms the Uniform and Threshold methods by 8-12% and 2-3% accuracy gain, respectively. Fig 23 demonstrates the superiority of our custom sorting priority. Compared to the traditional large-item-first (max-region-first in our context) packing policy, our method yields a 50% accuracy gain.

4.4.3 Profile-based Execution Planning (§3.4) profiles different devices and allocates devices and resources to different components and models based on the results, thereby maximizing throughput.

Resources allocation: Profile-based execution planning makes RegenHance achieve the best performance on given devices and workloads by avoiding bottlenecked by any component. Fig. 24 visualizes the computational resource allocation of two different object detection models on i9-13900K+RTX4090 providing satisfied performance as Fig. 13(a). With distinct workloads of YOLOv5s (16.9GFLOPs)

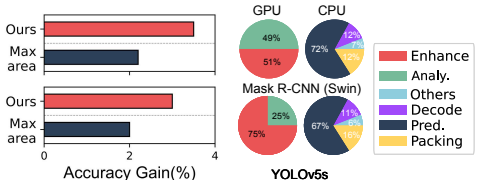

Figure 23: Acc gain of our MB selection.

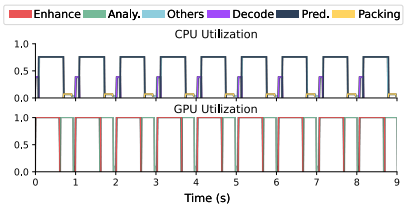

Figure 25: GPU & CPU usage.

Component	RRobin	Ours
MB Prediction	194	533
Enhancement	80	186
Analytics	220	186
Throughput	**80**	**186**

Table 4: Throughput (FPS) gain to region-agnostic strawman in §2.4.

and Mask R-CNN (Swin backbone, 267GFLOPS), it allocates more resources for the analytical task.

Resource usage: Fig. 25 shows the real-time utilization of CPU and GPU when detecting objects on six video streams. We used Nvidia Nsight to monitor GPU utilization and HTOP for CPU utilization. The GPU can reach full load approximately 95-99% of the time, while the CPU can reach high load around 81% of the time. This result indicates that the execution plan achieves an efficient GPU-CPU corporation.

Throughput: We avoid the enhancement bottleneck introduced by the round-robin manner (§2.4), which allocates equal resources to each component. The results in Table 4 indicate that our approach achieves 2.3× throughput.

Scalability and initialization: There are two types of preparation time in our system. If only the ingest video streams change, it needs approximately 0.6-2 seconds for initialization depending on the specific device and model requirements. When given a new device, it needs to take approximately 1-3 minutes to execute the Profile-based Execution Planning.

5 Related Work

Video analytics is facilitated by the advances of deep learning. However, the high analytical accuracy from deep learning comes at a prohibitive computing cost that most end devices cannot afford [87]. For example, today's deployed traffic cameras cost only $40 to $200, equipped with a single-core CPU that provides very scarce computational resources. To tackle this issue, today's video analytics apply a *distributed* architecture [45, 51, 58, 62, 65, 69, 91, 98–100, 102, 103].

Video compression saves bandwidth resources by adjusting video encoding configurations (*e.g.*, resolution, bitrate, and frame rate). Like traditional video streaming protocols like WebRTC [47] and DASH [77], distributed video analytics must tackle bandwidth constraints. Prior studies, no matter server-feedback accurate configuration setup [56, 69, 101, 103] or fast autonomy by video source (camera) itself [45, 65, 89, 91], addressed this issue well, saving considerable bandwidth resources but causing accuracy drop.

Selective inference, also called frame/image filtering, filters similar frames/images out to meet low resource cost and high throughput. Cameras leverage pixel-level difference [34, 40, 62] to filter frames for bandwidth saving; edge servers use light DNNs to select the frames to be detected by heavy DNNs, then reuse their output on filtered frames for throughput increment [51, 58, 98, 100, 102]. Selective inference achieves satisfactory throughput and resource-saving but lower accuracy. DDS [44] iteratively detects the selected images to avoid accuracy drop, but its twice cross-network transmission and detection imports too much delay. Turbo [68] seeks the same goal by enhancing frames on idle GPU slots. Differing from it, RegenHance boosts the enhancement method and fully uses heterogeneous resources on edge.

Model optimization meets high throughput by network pruning [61] and weights quantization [54], and achieves high accuracy by knowledge distillation [49]. However, the compressed model is easily affected by data drift, where the live video data diverges from the training data, leading to accuracy degradation [74]. To tackle this, continuous learning [60, 74], model switching [59, 95], and model merging [55, 71] are proposed by previous studies. Intuitively, continuous learning and model switching leverage small DNNs for high throughput and improve accuracy by matching the weights in DNN to the changed real-world videos. Model merging differs from traditional parameter sharing in one model [72]. It explores structural similarities between concurrent models and enables multiple models to share the same network components, *e.g.*, the backbone [71], by retraining.

6 Conclusion

In this paper, we look at content enhancement in video analytics applications. We found that frame-based content enhancement wastes too much computation on the analytics-agnostic image. We presented the region-based content enhancement technique and well-matched region-aware resource scheduler and implemented RegenHance. In our evaluation using five heterogeneous devices, we show that RegenHance can deliver an order of magnitude than frame-based content-enhanced video analytics.

            area = height * left[i][j]
            get the free area with max area
    return max free area
```

B Performance of Importance Level Approximation

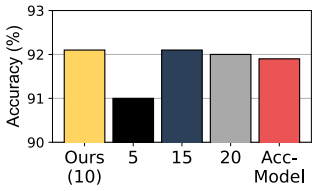

Figure 26: Importance level classification of MBs (*i.e.*, MB-grained image segmentation assigns each MB an importance level) yields comparable (even better) accuracy than AccModel, which predicts exact importance value.

Approximating the MB importance prediction as an image segmentation problem to assign each MB an importance level (class) is effective and produces good performance. We have trained four MB importance predictors (in MobileSeg architecture) with 5, 10, 15, and 20 important levels, respectively. Fig. 26 compares the final accuracy of inference task when predicting the exact MB importance (AccModel) and important levels. Experiment results demonstrate that important level classification yields precise MB importance prediction and hence high accuracy provided the level number is not very coarse, saying 5. The efficiency of this importance level classification is because such shallow model architecture is better at more manageable classification tasks (*e.g.*, segmentation) than regression tasks (*e.g.*, AccModel predicts the exact importance value). RegenHance set level number as 10.

C Additional Results

C.1 Example Eregions and the Distribution

Example eregions of object detection in §2.3 and semantic segmentation in Fig. 27 are generated by simply bounding the different analytical results between original and enhanced frames with a rectangle. Note that these example eregions are not the eregions used in RegenHance as they still contain much unnecessary content; this is why we propose to set fine-grained MB as the construction unit of eregions in RegenHance.

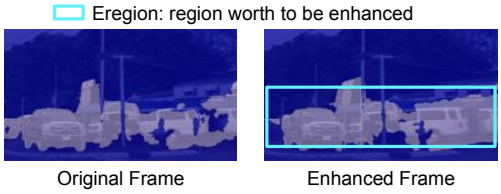

Figure 27: Example eregion worth to be enhanced for semantic segmentation (SS) bounding with a rectangle box.

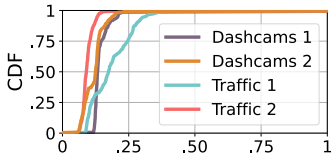
In semantic segmentation, as illustrated in Fig. 28, only 10-15% area in 70% frames are eregions.



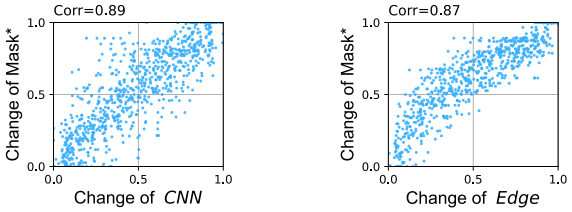


Figure 28: Distribution of eregions in Semantic segmentation.

C.2 Performance of Diverse Operators

(a) CNN [105] (b) Edge

Figure 29: Correlation ratio between the change of features.

As shown in Fig. 29, one-layer CNN [105] and the Edge operator (*i.e.*, edge detector in computer vision community) offer lower correlation ratios compared to the $\frac{1}{Area}$ operator, *i.e.*, 0.91. Fig. 30 exemplifies the characteristics of Area and $\frac{1}{Area}$. Images in the top raw demonstrate that the Area operator captures the change of large blocks, while the values of $\frac{1}{Area}$

change very small. On the contrary, $\frac{1}{Area}$ captures the change of small objects in two bottom images as RegenHance needs.

(a) $\frac{1}{Area}$: 0.002, Area: 0.665

(b) $\frac{1}{Area}$: 0.307, Area: 0.035

Figure 30: Correlation ratio between the change of features.

C.3 Performance *v.s.* Expanding Pixels

Pixel expanding in each direction can avoid the MB/region boundaries causing too many jagged edges and blocky artifacts when pasting enhanced content back to the bi-linear-interpolated frames. But it also introduces extra enhancement costs. We measure the accuracy gain and extra latency of the object detection task, as shown in Fig. 31. To balance the accuracy and the enhancement cost, we expand three pixels in this paper because the MB selection (§3.3.1) can control the number of enhanced MB to adjust the performance of RegenHance.

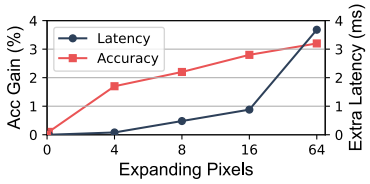

Figure 31: Both accuracy gain and enhancement cost increase with more expanding pixels. RegenHance expands 3 pixels in each direction surrounding every region.

C.4 Performance of MB Packing and Irregular Packing

Our region-aware packing algorithm spends almost the same time as MB packing and provides a close occupy ratio of irregular packing. As shown in Fig. 32, MB packing yields a low occupy ratio as packing too many unimportant or repeated pixels, while irregular packing leads to a large time cost of packing plan search.

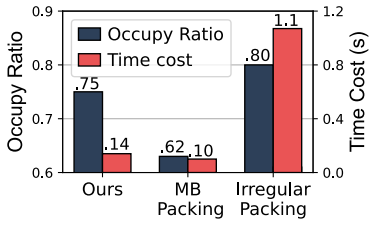

Figure 32: Our packing algorithm achieves a very good balance between bin utilization (occupy ratio) and the time cost of packing plan search.

C.5 An Example of Intermediate Results of RegenHance in Object Detection Task

Fig. 34 shows an example of packing five frames into one bin and pasting enhanced regions in the stitching image back to the interpolated frames. In particular, the region ④ is cut into two smaller ones by our region-aware bin-packing algorithm for better bin utilization. The green boxes in the left column bound the objects can be detected after enhancing the stitching image, *i.e.*, enhancing the selected regions. To the right column, region-based enhancement offers comparable accuracy with entire-frame enhancement.

C.6 Performance under Various Workloads and Users' Latency Targets

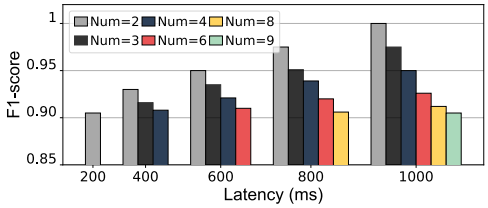

Figure 33: RegenHance supports various user-specified latency targets with adaptive batch sizes under different workloads (*i.e.*, stream numbers)

RegenHance supports various latency targets by automatically adjusting every component's batch size. Fig. 33 demonstrates that RegenHance can well analyze two 30-fps streams (60 frames) under 200ms latency budget and nine streams under 1s. The batch sizes of components change under different workloads. For example, under a 400ms budget, when stream numbers increase from 2 to 4, the batch sizes of (enhanced model, analytical model) are (8,4), (4,8), and (4,8); this implies more resources are allocated from region enhancement to final inference when workload increases, and hence lower accuracy. Note that the batch sizes of any components are no more than 8 among all latency targets; namely, in each batch, the earliest input won't wait for the last one more than 75ms as shown in Fig. 17.

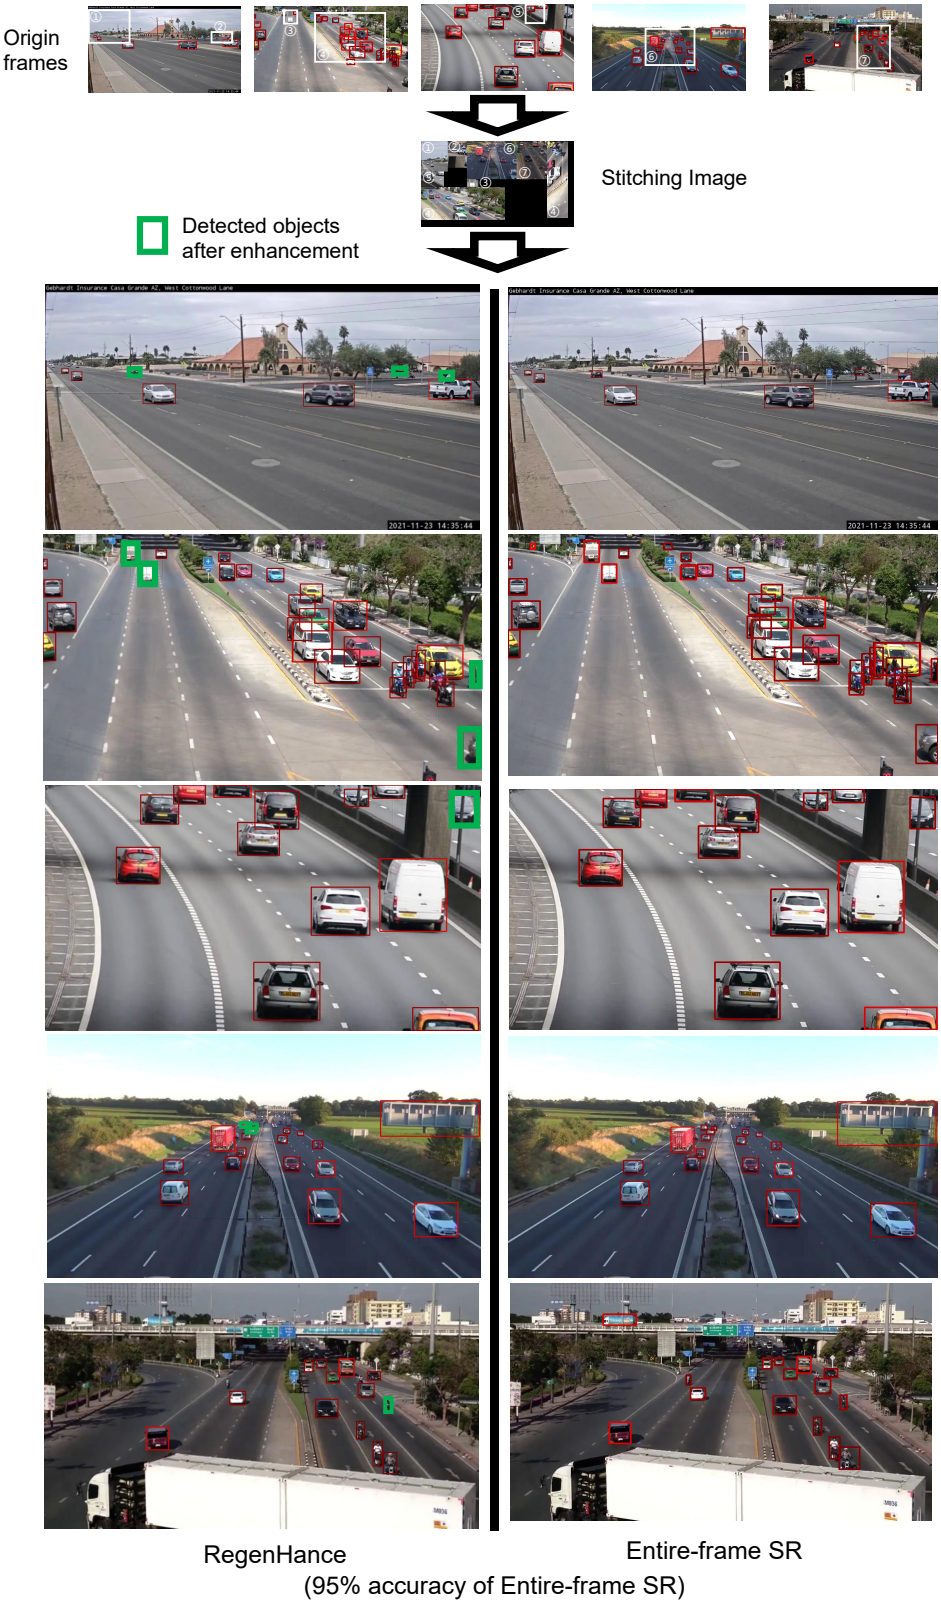

Figure 34: Examples of running super-resolution on stitched regions and their inference results compared to entire-frame enhancement.

Figure 35: Representative mask*.

Tooth: Toward Optimal Balance of Video QoE and Redundancy Cost by Fine-Grained FEC in Cloud Gaming Streaming

Abstract

Despite the rapid rise of cloud gaming, real-world evaluations of its quality of experience (QoE) remain scarce. To fill this gap, we conduct a large-scale measurement campaign, analyzing over 60,000 sessions on an operational cloud gaming platform. We find that current cloud gaming streaming suffers from substantial bandwidth wastage and severe interaction stalls simultaneously. In-depth investigation reveals the underlying reason, *i.e.*, existing streaming adopts coarse-grained Forward Error Correction (FEC) encoding, without considering the adverse impact of frame length variation, which results in over-protection of large frames (*i.e.*, bandwidth waste) and under-protection of smaller ones (*i.e.*, interaction stalls). To remedy the problem, we propose Tooth, a per-frame adaptive FEC that aims to achieve the optimal balance between satisfactory QoE and efficient bandwidth usage. To build Tooth, we design a dual-module FEC encoding strategy, which takes full consideration of both frame length variation and network dynamics, and hence determines an appropriate FEC redundancy rate for each frame. Moreover, we also circumvent the formidable per-frame FEC computational overhead by designing a lightweight Tooth, so as to meet the rigid latency bound of real-time cloud gaming. We implement, deploy, and evaluate Tooth in the operational cloud gaming system. Extensive field tests demonstrate that Tooth significantly outperforms existing state-of-the-art FEC methods, reducing stall rates by 40.2% to 85.2%, enhancing video bitrates by 11.4% to 29.2%, and lowering bandwidth costs by 54.9% to 75.0%.

1 Introduction

Cloud gaming, as an increasingly embraced application, involves high-quality video streaming from remote servers to diverse devices, thereby obviating the need for advanced local hardware and enabling pervasive gameplay across all connected devices, particularly mobile devices with limited computation and storage capacity. In recent years, several gaming platforms have launched acclaimed cloud-based versions of games, such as Cloud Genshin Impact [12] and Tower of Fantasy [13]. Market analyses reveal that the global cloud gaming market, which stood at US$ 1,905.6 million in 2023, is projected to reach US$ 48,552.2 million by 2032, demonstrating a compound annual growth rate of 42% [5].

To ensure a satisfactory interaction QoE, cloud gaming requires consistently ultra-low latency from player request to game response, typically less than 100 milliseconds [29]. To better understand the real-world QoE of cloud gaming, we conduct a comprehensive field measurement involving 66,128 players across 22 cities worldwide, as detailed in Table 1. Our measurements reveal that the downlink delivery of game video content (*i.e.*, from the remote server to the end devices) is the primary bottleneck impacting interactive QoE. To mitigate this, besides usual retransmission mechanisms [21,36], cloud gaming commonly adopts Forward Error Correction (FEC) from the current video streaming works [18, 20, 31, 33, 42] to recover lost data packets. However, our analysis indicates that existing FEC algorithms significantly increase bandwidth usage, adding an additional 0.26× to 1.0× redundancy than the original data streaming. We further conduct an in-depth exploration of existing FEC schemes and identified their two primary limitations.

- *Frame length affects the redundancy rate for recovering a frame.* Specifically, FEC can recover the lost packets within a frame when the redundancy rate can cover the Loss Rate In Frame (LRIF). However, we observe that the video frame length (number of packets) in cloud gaming varies largely, *i.e.*, spanning from 2 packets to over 80 packets, and frame LRIF is a random variable that follows a binomial-like distribution with a function of the frame length. Especially, the LRIF of a small frame is as high as 30+% and that of a large frame is as low as 2%, differing by over 10× and requiring completely different redundancy rates (§2.3).
- *Existing FEC algorithms are coarse-grained, ignoring frame LRIF differences but applying a uniform redundancy rate across almost all video frames.* As a result, they tend to over-protect large frames by adding significantly more redundancy than necessary, with median values ranging from 5.2× to 9.2×. Worse still, they under-protect small frames, failing to recover their lost packets and resulting in frequent interaction stalls, occurring more than once per minute. Furthermore, our findings indicate that coarse-grained FECs exacerbate stall frequency in operational cloud gaming systems due to excessive redundancy, which leads to increased network congestion bursts. This, in turn, elevates the LRIF for video frames, particularly for smaller frames, making them more difficult to recover.

In this paper, we aim to address a key problem: *How to follow frame LRIF to ensure successful recovery in small frames meanwhile avoiding wasting redundant bandwidth in*

large frames, so as to propel cost-effective cloud gaming in the real world? To accomplish this, we propose Tooth, a novel fine-grained FEC tailored for cloud gaming at the frame level. It precisely determines the delivery probability of each frame through the frame length distribution, and adaptively applies the per-frame redundancy rates for different frames to align the delivery probability. Although conceptually simple, building Tooth in practice introduces two significant challenges.

Firstly, the realistic LRIF pattern is more complicated than the binomial distribution, and identifying the critical factors that influence the binomial distribution of per-frame LRIF is essential for enabling precise FEC. Our field measurements reveal that both the application-layer frame length and the transport-layer network loss patterns significantly impact LRIF. In particular, the frame length can be readily acquired from the video encoder, while inferring the network loss pattern is a non-trivial task. Traditionally, loss patterns are simply characterized by the loss rate [18,20,27,31,38]. However, our evaluations show that this metric does not accurately depict the distribution of network loss events on a per-video-frame basis. To address this deficiency, we introduce a novel metric–network loss aggregation, which quantifies whether network packet loss events are more dispersed across multiple video frames or concentrated within a few frames, thereby aligning more effectively with fine-grained FEC encoding strategies.

Secondly, effectively mapping LRIF-related factors to per-frame redundancy rate, while ensuring Tooth lightweight enough for practical deployment. In particular, the relationship between per-frame redundancy rate and LRIF-related factors is non-linear. Straightforward mapping methods like linear function or neural network models, cannot guarantee the video QoE and running cost simultaneously (as will be validated in §5.3). Furthermore, the key factors we investigated, such as network loss rate and loss aggregation, are highly volatile due to network dynamics, *i.e.*, only historical network loss pattern cannot reliably reflect future conditions. Therefore, we design a dual-module FEC encoding for Tooth, which consists of *(i)* a *slow-module*, which learns network volatility to estimate the future network loss pattern (loss rate lr and loss aggregation la) based on historical loss patterns and packet-by-packet reception. It utilizes a compressed neural network model to improve prediction accuracy and operates with lower frequency, *i.e.*, once for each network RTCP feedback cycle. *(ii)* a *fast-module*, which formulates the non-linear and discontinuous mapping between LRIF-related factors and redundancy of each frame as a regression problem, and then uses a lightweight random forest method to model the relationship. The *fast-module* runs every time a video frame is encoded, thus ensuring that redundancy is immediately determined and applied to each newly generated video frame. As a result, the above decoupled dual modules avoid implementing frame-level FEC through heavy neural network models and also reduce the execution frequency, which allows Tooth agile enough to operate in real-world scenarios.

We have implemented Tooth in a commercial cloud gaming system, one of the popular cloud gaming platforms (anonymized as Company W), and deployed it in its production environments, involving about 2,300 sessions and lasting 6 weeks in total. Compared to state-of-the-art FEC solutions such as RL-AFEC [18] and RTC-FEC [9,28], Tooth achieves an ideal balance between optimized video QoE and efficient redundancy cost. For instance, it significantly reduces stall frequency by 40.2%-85.2%, increases perceptual video bitrate by 11.4%-29.2%, and reduces bandwidth costs by 54.9%-75.0%. Moreover, we also evaluate Tooth's effectiveness in different *(i)* network types like WiFi, 4G, and 5G; *(ii)* game types like 2D games and 3D games; *(iii)* Internet Service Providers (ISP); *(iv)* distances of game server to end devices, *i.e.*, cross-city sessions and intra-city sessions. The above extensive experiments (§5.2) validate that Tooth can achieve excellent QoE consistently in real-world cloud gaming scenarios. We also conduct a series of ablation studies to verify the key design modules of Tooth.

To summarize, our main contributions are:

- We conduct a large-scale measurement on an operational cloud gaming system and uncover underlying reasons for the inefficiencies of existing loss recovery solutions (§2).
- We propose Tooth, a lightweight dual-module approach that can map the application-layer frame length and transmission-layer network loss pattern to per-frame redundancy in real-time, thus achieving a fine-grained FEC for enhancing cloud gaming streaming (§3).
- We implement and deploy Tooth in the operational cloud gaming system and conduct real-world evaluation, which outperforms state-of-the-art solutions significantly and consistently across environment variation (§5).

2 Background and Motivation

2.1 Background

2.1.1 Packet Loss Recovery

In conventional real-time applications such as video conferencing, playback delays of 200 to 500 milliseconds are typically tolerable [28, 43, 47]. However, in cloud gaming scenarios, stronger interactivity is critical, with significantly stricter latency constraints, *i.e.*, the application-layer interaction latency must consistently remain below 100 milliseconds to ensure optimal user QoE [22–24]. Here we clarify that the application-layer interaction latency refers to the duration between a user's operation input (*e.g.*, run and hit) in the game client and the moment the user receives the corresponding screen feedback. It contains the system processing delay and data round-trip network delay, the measurement method is given in Appendix A. Given the stringent latency requirements of cloud gaming, it significantly influences the design considerations for packet loss recovery. In particular, there are typically two loss recovery mechanisms, which are usually adopted jointly in cloud gaming:

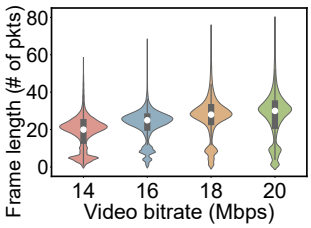

Figure 1: Frame length details at different video bitrates.

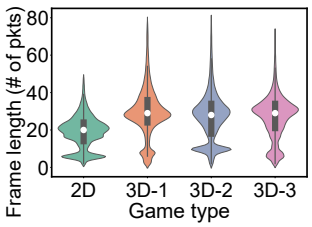

Figure 2: Frame length details in 2D and 3D games.

Table 1: Datasets statistics of our large-scale measurements on an operational cloud gaming system, compared with other existing measurement efforts.

- *Forward Error Correction (FEC)* [18, 20, 31, 42], which proactively supplements original data with additional encoded data as redundancy before each transmission. In this case, the lost original data packets will very likely be recovered by the receiver. FEC reduces the delay by not requiring retransmission but increases the bandwidth cost since future packet losses are uncertain.
- *Retransmission* [21, 36]. There are also recent proposals that call for the revitalization of retransmission due to the reduction of RTT. When the packet is lost and detected, the sender will transmit the lost data packets again. This will introduce additional RTT delays to the data delivery, but will only consume the bandwidth of the lost packets.

2.1.2 Variation in Frame Length

A key observation in this paper is the variation of frame length in cloud gaming, for the following two reasons:

- *Rate adaptation.* The available network bandwidth is highly dynamic, sometimes dropping by a factor of 50× in wireless real-time communications [35], so the encoding bitrate will also change accordingly. This is determined by the rate adaptation algorithms such as GCC [17]. Such an adaptive bitrate will result in the variation in frame length (number of packets). We emphasize that the frame length variation here is different from the segment length variation reported in [45], which has a far loose latency requirement.
- *Variable bitrate (VBR).* Meanwhile, due to the internal design of video codecs, even if the bitrate is fixed, the frame length can also vary due to the VBR encoding. For example, under the same video bitrate, the frame length of a static scene will be shorter than that of a dynamic scene.

We conduct a measurement campaign over our operational cloud gaming system (later described in §2.2), and the statistics are shown in Table 1. The video codec we use is NVENC [1, 8] following H.265 [7] and it adopt infinite GOP encoding manner to meet the low-latency transmission characteristics of cloud gaming. Unlike the traditional finite GOP manner sets a fixed GOP length, such as 30 in RL-AFEC [18], infinite GOP disables the server to send I frames periodically, to reduce latency surges, more explanations in Appendix B. The congestion control algorithm is GCC [17]. We present the distribution of frame lengths when the encoding bitrates are fixed to different levels in Fig. 1, and this length difference exists in both 2D and 3D cloud games, as shown in Fig. 2.

2.2 Inefficacy of Existing Solutions

Unfortunately, when deploying FEC and retransmission into production-scale systems, we find that existing solutions suffer from a fundamental trade-off between bandwidth cost and interaction latency.

Measurement Setup. We conduct a large-scale measurement campaign over our operational cloud gaming system. The measurement covers 22 cities across China and 4 ISPs, with other statistics shown in Table 1. It is worth noting that the dataset we collect is the largest dataset in the field of cloud gaming to the best of our knowledge.

FEC algorithms often over-protect data packets with drastically high bandwidth costs. An interesting observation is that many existing FEC solutions often add much more redundant packets than necessary. For example, when there are 5 packet losses out of 25 data packets, ideally only 5 additional redundant packets will protect the data packets. However, existing solutions [18, 36, 42] often add much more than 5 packets. This reason is quite intuitive – more redundancy is added to get prepared for unforeseen packet losses, however, which leads to drastic bandwidth waste. Especially considering that bandwidth cost is the major contributor to the operational expenses for streaming applications such as cloud gaming, this will directly lead to a revenue loss [2, 3, 42].

We validate the observation by deploying two representative FECs in our cloud gaming platform:

- *RTC-FEC* [28], the de-facto rule-based solution in WebRTC [9] based on the current video bitrate and network loss rate.
- *RL-AFEC* [18], a reinforcement learning driven FEC solution. It defines the first I frame and the following K-1 P frame of one GOP (length is N) as the K "critical" frames[1], and the remaining N-K P frames as "non-critical" frames. RL-AFEC finds that non-recoverable critical frames have a more serious negative impact on video quality, so it sets different redundancy rates[2] for the critical frames of each

[1] In *RL-AFEC* [18], there are 6 candidate values for K, *i.e.*, 5, 10, 15, 20, 25, and 30. Here we use the recommended optimal value, *i.e.*, K = 15.

[2] Here we set 10 candidate redundancy rates for RL-AFEC, *i.e.*, 10%, 20%,...100%, completely consistent with [18].

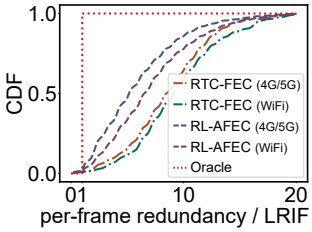

Figure 3: CDF of the ratio of per-frame redundancy rate to LRIF for coarse-grained FEC.

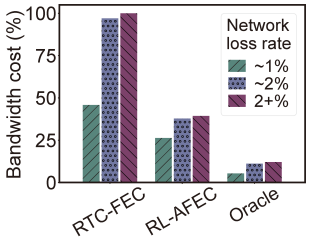

Figure 4: Bandwidth costs of the representative FECs and the ideal Oracle solution.

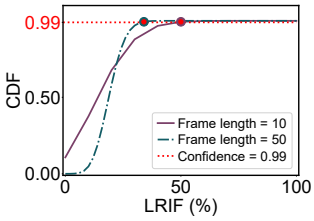

Figure 5: The CDF of video frame LRIF binomial distributions with different numbers of trials.

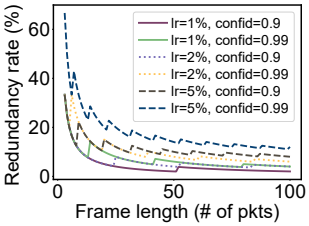

Figure 6: Lines: when the loss rate (lr) is 1%, 2%, and 5%. Y-axis: the redundancy rate. X-axis: the frame length.

GOP. As for the remaining non-critical frames, it still uses the same uniform redundancy rate.

As shown in Fig. 3, both algorithms add much more redundant packets to frames than necessary, with a median number of 5.2×-8.6× in 4G/5G networks and 6.6×-9.2× in WiFi networks, resulting in serious bandwidth waste. In Fig. 4, we show the overall redundancy bandwidth costs of two representative FECs, both are very high, *i.e.*, 45.9%-100% and 26.3%-39.4% respectively. To show the potential optimization space, we compare the existing FECs with an "Oracle" approach, *i.e.*, we count the actual data loss rates of all video frames as the ideal bandwidth cost. As shown in Fig. 4, only 5.4%-12.1% redundancy is required.

Retransmission-oriented solutions still suffer from severe stalls. Including the recent effort, Hairpin [36], there has been an understanding that since the RTT is low enough, merely relying on retransmission might be sufficient to recover the lost packets. However, our experiments show the contrary:

- The network RTT measured in our cloud gaming system is 23 ms for WiFi users and 35 ms for 4G/5G users. This is because as the scale of the product expands, the users with worse network conditions are naturally included.
- The detection of packet loss also takes time in the commonly used negative acknowledgement (NACK) methods. For example, in WebRTC, it will take the receiver up to 20 ms before sending NACK through RTCP protocol.
- Affected by the congestion control and pacing rate of the sender, the transmission duration of video frame data packets often exceeds 10 ms.

Therefore, considering the stringent deadline requirement of around 100 ms [22–24, 36, 37, 48], it is still insufficient to rely on retransmission to recover the lost packets, and the stall frequency even reaches 41.9 times per minute. We will provide the detailed experimental results in §5.2.

2.3 Observation – Frame length matters

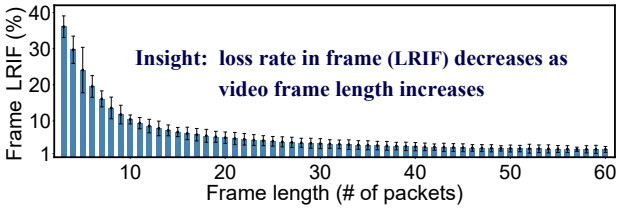
In Fig. 3, we have shown that existing FEC algorithms often over-protect many video frames while under-protecting some others (the ratio < 1), leading to both bandwidth waste and interaction stalls. In this subsection, we will show that the root cause of this inefficiency is the neglect of the frame length in the FEC algorithms. For the sake of clarity, we first denote the loss rate in each frame as LRIF, which is defined as $\frac{\#\ of\ lost\ packets\ in\ frame}{\#\ of\ all\ packets\ in\ frame}$. We later have the following findings:

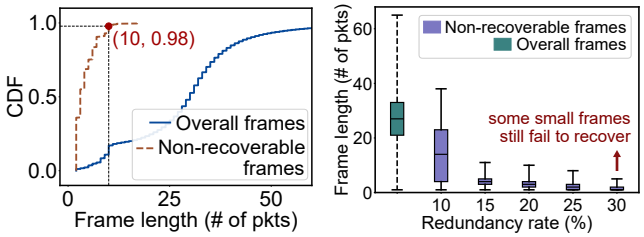
Finding 1: The distribution of video LRIFs vary significantly with the frame length. As we all know, network loss events are random and bursty [33, 36, 42]. Now let's begin with a simple probability question: assume that the loss rate of each packet is 10% and they are independent from each other, if we want to protect the delivery of the frame with the confidence of 99%, how many redundant packets do we need to add when (a) the frame has 10 data packets; and (b) the frame has 50 data packets? In this case, we need to calculate the per-frame LRIF as it is the necessary redundancy rate to be set. The LRIF in this example follows the Binomial Distribution [11], with the probability of each trial being 0.9, and we want the minimum number of trials such as $P(X \geq framelength) \geq 0.99$. The answer is: when the frame length is 10 packets, we need to add 4 redundant packets; when the frame length is 50 packets, we need to add 12 redundant packets. The redundancy rate for smaller frames (40%) is much higher than that for the larger frames (24%)[3].

The reason behind this phenomenon is a basic law in probability theory – the law of large numbers. As shown in Fig. 5, when the number of trials (in our case, frame length) increases, it requires a lower redundancy rate to successfully recover 99% of all frames. Therefore, the redundancy rate needed to protect the frame will decrease as the frame length increases. Here we clarify that a lower redundancy rate does not directly represent adding fewer redundant packets. For a video frame, the ideal redundancy rate is its LRIF and the ideal number of the redundant packets is $framelength \times LRIF$. Next, we further simulate the necessary redundancy rates with different confidence levels and frame lengths, and the results are shown in Fig. 6. This phenomenon is general – the redundancy rate for small frames is much higher than that for large frames.

Finding 2: Existing FEC algorithms ignore the LRIF variation caused by frame length, either over-protect large frames or under-protect small frames. We delve anew into existing FEC algorithms and find the underlying

[3] One can validate the result at https://stattrek.com/online-calculator/binomial.aspx. The parameters we use are (0.9, 14, 10) and (0.9, 62, 50).





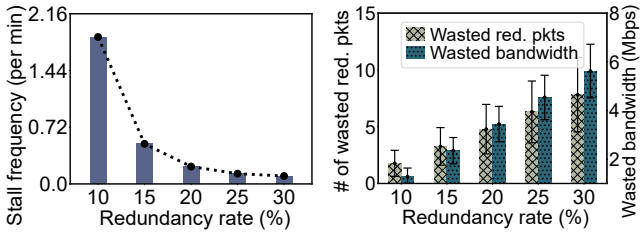


Figure 7: Relationship between video frame length and LRIF. The statistical results come from video frames that suffered packet loss in our commercial cloud gaming platform. Only these frames can reflect the optimal redundancy rate to protect each video frame, more explanations in Appendix D.

(a) Recovery of video frames when redundancy rate is 20%.

(b) Recovery of video frames under different redundancy rates.

(c) Stall frequency under different redundancy rates.

(d) Wasted redundancy (original streams are average 19.3Mbps).

Figure 8: Video frame recovery and wasted bandwidth under coarse-grained redundancy rates. The results are obtained from the controlled analysis to FEC. We replay real-world stream traces in the simulator and don't consider the damage to network condition caused by excessive data transmission.

reason: most of them are coarse-grained, ignoring the impact of frame length, and set a uniform redundancy rate r (defined as $\frac{redundant\ data}{original\ data}$) for all frames based on network conditions. While RL-AFEC [18] proposes setting varying redundancy rates for each of the first K critical frames in one GOP, it overlooks the remaining N-K non-critical frames. This is especially unsuitable in the context of cloud gaming, where N-K non-critical frames can comprise up to 99.9% of all frames in one GOP (details in Appendix B). Thus the vast majority of frames will still be set the uniform redundancy rate, even though these frames behave with significant LRIF variations. Therefore, all existing FEC methods tend to set a higher redundancy rate, as we presented above. Unfortunately, even if the redundancy rate is high enough for most frames, it might still be insufficient for small frames. For example, in the line of (lr=10%, conf=99%) in Fig. 5, when setting the redundancy rate to 40% (4× the average loss rate), frames

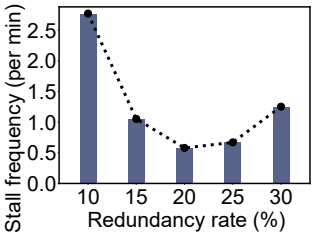

Figure 9: As redundant rate increases, the over-sent redundancy even exacerbates interaction stalls.

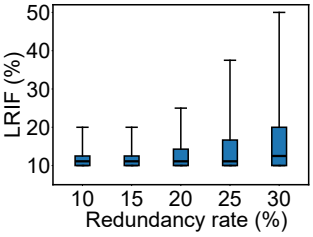

Figure 10: As redundant rate increases, the over-sent redundancy exacerbates small frames' LRIF.

smaller than 10 packets are still likely to fail to recover even though for frames larger than 10 packets the redundancy will be significantly wasted. We further validate this observation by our online measurements as well. As shown in Fig. 7, as the frame length increases, the LRIF mean of the frames that suffered packet loss decreases significantly. This indicates that large frames will easily be over-protected while small frames will be under-protected by the coarse-grained FECs.

The adverse impact of coarse-grained FECs on operational cloud gaming systems. Here we demonstrate how existing coarse-grained FECs impact the performance of cloud gaming in practice, for which we use all traces as listed in Table 1. Firstly, we apply a uniform redundancy rate of 20% to each gaming stream and observe the frame recovery. As shown in Fig. 8a, the non-recoverable frames are relatively small, *i.e.*, 98% of them are small frames (length ≤10). Furthermore, we also apply other 4 redundancy rates to each video stream in turn, *i.e.*, 10%, 15%, 25%, 30%. Fig. 8b plots the recovery results under all five redundancy rates. We can observe that: increasing the redundancy rate can indeed recover more video frames, but some small frames still fail to be recovered, which requires a higher redundancy rate, exceeding 30%. To examine the impact on QoE, we present the interaction stall frequency in Fig. 8c and the wasted redundancy in Fig. 8d. Obviously, the stall frequency decreases along with the increase of redundancy rate, but the marginal effect diminishes very fast, *e.g.*, we barely have extra gain when the redundancy rate rises from 25% to 30% but the wasted bandwidth keeps increasing substantially, from 4.5 Mbps to 5.6 Mbps.

More importantly, in the real world, *our measurement results show the counter-intuitive fact: more redundancy instead exacerbates cloud gaming's interaction stall*. Specifically, we measure the interaction gains of FEC under different redundancy rates of 10%, 15%, 20%, 25%, 30%. As shown in Fig. 9, when the redundancy rate is relatively low, *i.e.*, 10%, 15%, 20%, FEC can continuously reduce the interaction stall frequency. However, as redundancy rate keeps increasing, FEC fails to further optimize and even worsens the stall performance. We investigate the traces and find the root reason: adding too much redundancy will lead to more bursting network congestion, thus the LRIF of a video frame especially a small frame will be even higher, as shown in Fig. 10.

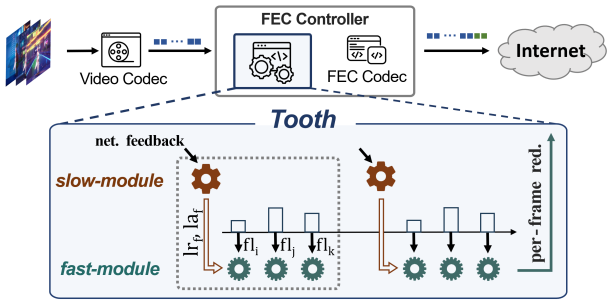

Figure 11: Design overview of Tooth.

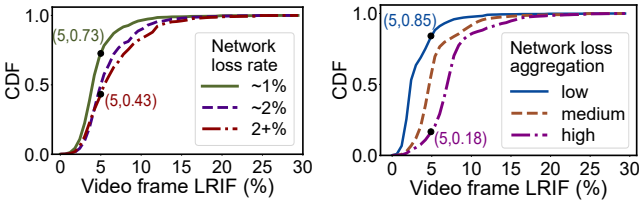
To sum up, existing FEC algorithms are commonly coarse-grained and ignore the LRIF differences across video frames. Hence they are trapped in the dilemma of improving frame recovery and avoiding bandwidth waste. Nowadays, cloud gaming applications are becoming more bandwidth-demanding (with higher image quality), it is more imperative to break the dilemma with a novel FEC design.



2.4 Design Challenges

Although we have revealed the significant impact of frame length on per-frame redundancy rate, adapting it to achieve fine-grained FEC is non-trivial, which faces 3 key challenges: *(i)* Besides frame length, LRIF also intertwines with the transport-layer network loss pattern. Identifying the critical factors that influence the per-frame redundancy rate is essential for enabling precise FEC at the fine-grained level. *(ii)* The relationship between per-frame redundancy rate and the related factors is non-linear and discontinuous, making it difficult to represent using a straightforward mapping function. Meanwhile, network loss pattern fluctuates, meaning the historical observations cannot reliably reflect the future network conditions. *(iii)* Fine-grained FEC necessitates immediate determining and executing redundancy rate upon generating a new video frame (*e.g.*, 16.7 ms at FPS=60). The high frequency and stringent time constraints make existing learning-driven approaches impractical.

3 Design

3.1 Design Overview of Tooth

We first perform the field measurements to identify critical factors influencing the per-frame redundancy rate, including application-layer frame length and transmission-layer network loss pattern. Notably, in addition to the loss rate introduced in the conventional approaches [16], we based on the FEC operation to supplement loss pattern with loss aggregation, which further describes the temporal distribution of network packet loss events (§3.2). Then, we design Tooth as a decoupled dual-module architecture (Fig. 11), which can map the LRIF-related factors to per-frame redundancy rate and meanwhile minimize computational and inference time overheads. It consists of a *slow-module* and a *fast-module*, which circumvents the need for bulky large neural networks but

(a) Network loss rate *lr*. (b) Network loss aggregation *la*.

Figure 12: Other related factors affecting video frame LRIF. Fig. 12b is obtained by analyzing the data with a network loss rate of ~1% in Fig. 12a. The network loss rate is analyzed from the RTCP feedback (every 100ms in our system).

also lowers the execution frequency, effectively tackling the computational complexities and inference time constraints in real-world environments. Specifically,

- *Slow-module* utilizes a compressed neural network model to discern network fluctuations and estimate future loss pattern. It does not need to execute frame by frame but is activated only upon receiving new RTCP network feedback to avoid unnecessary computational overhead (§3.3).
- *Fast-module* incorporates an exceedingly lightweight machine learning model to determine per-frame redundancy based on the frame length and future network loss patterns obtained from the *slow-module* (§3.4).

3.2 Investigating the Impact Factors of LRIF and Evaluating Strawman Solutions

We make an in-depth analysis of the large-scale measurement dataset in §2.2, and find that *besides the frame length, transport-layer network loss rate (lr) and loss aggregation (la) also significantly influence over video frame LRIF.* Next, we give more analysis: *(i)* in Fig. 12a, we plot the CDF of the video frame LRIFs related to network loss rate *lr*. The result clearly demonstrates a trend where frames experience increasing LRIF as the network loss rate escalates. For instance, when *lr* is 1%, 73% of the frames have LRIFs below 5%. However, when *lr* increases to 2% or higher, only 43% of the frames maintain LRIFs below 5%, marking a significant difference of 30%. *(ii)* Previous study [42] has noted that continuous packet loss severely impacts video frame recovery. However, we argue that for advanced FEC methods like Reed-Solomon codes [41], there is no distinction between losing n packets continuously or discretely within a single frame. Therefore, we introduce a novel metric, *i.e.*, network loss aggregation *la*, to reflect whether packet loss events will be more dispersed in many frames or concentrated in a few frames. *la* can be represented as follows,

$$la = \begin{cases} 0 & n \le 1 \\ \dfrac{n}{\sum^{n} |t_n - centroid| + \alpha} & n > 1 \end{cases} \quad (1)$$

Here n represents the number of packets lost within a network feedback period, and t_n denotes the ideal arrival time of the n^{th} lost packet, measured in milliseconds. We define the timing

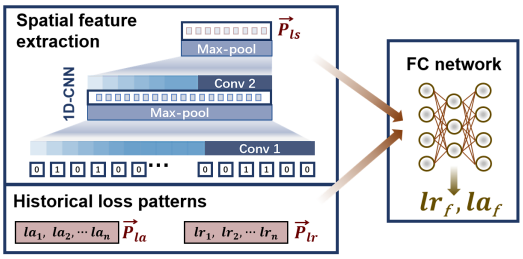


Figure 13: *Slow-module*'s model design.

centroid of all lost packets as $\frac{\sum^n l_n}{n}$, and α is set to 0.5 to avoid $\sum^n |t_n - centroid|$ being 0, which means packets are lost within 1ms. To intuitively illustrate the impact of la on LRIF, we briefly divide all la values into 3 levels according to the numerical distribution (*i.e.*, low: 0-1, medium: 1-5, high: 5-max) and categorize the video LRIFs. As shown in Fig. 12b, elevated la will increase the video frame LRIF. For instance, when la is low, 15% of frame LRIFs exceed 5%, but when la is high, this jumps to 82% of frame LRIFs exceed 5%.

Strawman solutions for fine-grained FEC. To assess the impact of video frame length (fl), network loss rate (lr), and loss aggregation (la) on per-frame redundancy rate, one preliminary approach is to manually establish the mapping relationship. However, this task proves to be non-trivial due to several challenges: *(i)* The relationships among the three factors and per-frame redundancy are not straightforwardly linear. Instead, they are implicit and complex, making manual modeling difficult. *(ii)* Both lr and la are subject to continual changes due to network fluctuations. Notably, there is also a dependent relationship where an increase in lr can sometimes lead to a higher la, though not invariably. Thus, it is imperative for Tooth to accurately determine per-frame redundancy amid varying network conditions.

Another strawman idea is to leverage powerful neural network models [18–20, 31]. Existing approaches generally operate at a coarser granularity, typically making decisions every 100 ms or longer [32, 42], which is inadequate for Tooth's fine-grained frame-by-frame optimization. On one hand, Tooth necessitates frequent redundancy execution within the tight frame encoding period of 16.7 ms at a frame rate of 60 FPS. On the other hand, Tooth must maintain exceptionally low overheads in both computation and inference time to enable feasible deployment in production environments. However, even neural network models with optimized architectures and parameters, such as pruning, often fail to satisfy these stringent overhead requirements, which will be validated in §5.3.

3.3 *Slow-module*: Estimating Future Network Loss Pattern

Slow-module is tasked with learning network fluctuations to estimate future network loss rate lr_f and loss aggregation la_f, and update them to the *fast-module*. Obviously, estimating la is very challenging since it is potentially affected by lr in addition to its own intrinsic characteristics. Existing simple methods, like arithmetic average of the heuristic observations, will bring serious deviations to the judgment of per-frame redundancy, as verified in §5.3. Thus, we introduce a NN model to build *slow-module*, and we provide more details next.

Input and output. As illustrated in Fig. 13, *slow-module*'s input is the historical network loss pattern vectors: the network loss rate sequence in the past n RTCP feedback, *i.e.*, $\vec{P_{lr}} = (lr_1, lr_2, ..., lr_n)$, the loss aggregation sequence ($\vec{P_{la}} = la_1, la_2, ..., la_n$), and the spatial distribution features $\vec{P_{ls}}$ of historical packet loss events. $\vec{P_{ls}}$ is extracted from the packet loss events in the past n network feedback periods. In particular, we encode the arrivals of all N packets in the past n RTCP feedback periods into a 0, 1 vector $\vec{ls}$, *i.e.*:

$$\vec{ls} = (x_1, x_2, ..., x_N), \quad x_i = \begin{cases} 1 & \text{packet lost} \\ 0 & \text{packet received,} \end{cases} \tag{2}$$

Here we build a 1D-CNN block to process $\vec{ls}$, which consists of two cascaded one-dimensional convolution layers with kernel sizes of 100 and 4, respectively. Each convolution layer in the 1D-CNN module uses *ReLU* activation and a pooling layer with a kernel size of 2 to extract the spatial features $\vec{P_{ls}}$.

The output of Tooth's *slow-module* is the future network loss rate (lr_f) and loss aggregation (la_f).

Neural network model. We pass the concatenated sequences of $\vec{P_{lr}}$ (10×1), $\vec{P_{la}}$ (10×1), and $\vec{P_{ls}}$ (12×1) to the *slow-module*'s cascaded FC networks, with 64, 32 and 16 units respectively. For the loss function, we emphasize that the overestimated lr_f and la_f will guide Tooth add excessive redundancy, increasing bandwidth cost. But the underestimated future lr_f and la_f may lead to insufficient redundancy, thus incurring stalls, more unacceptable than wasting bandwidth. Therefore, we set a larger loss for the underestimated case and the final loss function $\mathcal{L}_S$ is defined as follows:

$$\mathcal{L}_S = \frac{(lr_f - \hat{lr})^2 + (la_f - \hat{la})^2}{2} \times \left(\frac{e^{(\hat{lr} - lr_f) + (\hat{la} - la_f)}}{|\hat{lr} - lr_f + \hat{la} - la_f| + \beta}\right), \tag{3}$$

where $\hat{lr}$ and $\hat{la}$ are the true values of network loss rate and loss aggregation. The first part calculates the difference between the estimated lr_f, la_f and the true $\hat{lr}$, $\hat{la}$. For the second part, if lr_f, la_f are larger than $\hat{lr}$, $\hat{la}$, the loss can be appropriately reduced and when lr_f and la_f are smaller than $\hat{lr}$, $\hat{la}$, the loss will be enlarged. β is a constant and is set to 1 to avoid $|\hat{lr} - lr_f + \hat{la} - la_f|$ being 0.

3.4 *Fast-module*: Determining Per-frame Redundancy

Fast-module takes the future network loss rate lr_f, loss aggregation la_f, frame (to be encoded) length fl as inputs, and outputs the per-frame redundancy decision. In crafting *fast-module*, we gather lr, la, fl, and *LRIF* from historical frames as label to build sample dataset. Next, we incorporate a machine learning approach different from complex NN models to reduce the computation complexity.

Incorporating Random Forest model. We clarify *fast-*

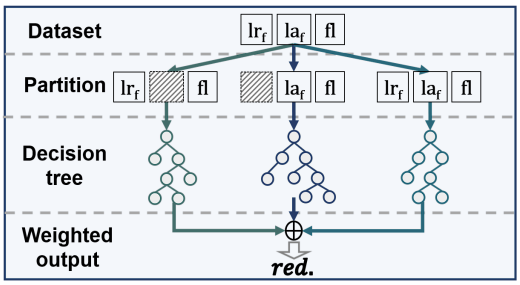

Figure 14: *Fast-module*'s model design.

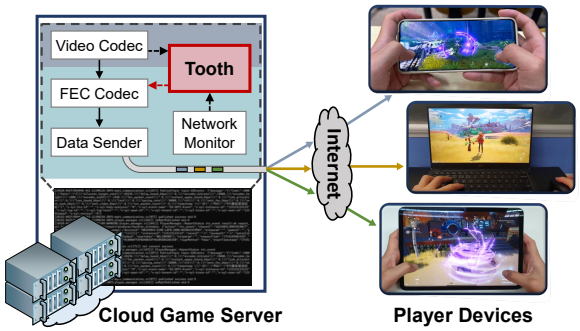

Figure 15: The implementation of Tooth.

module's inputs (lr, la, fl) exhibit the following characteristics: *(i)* High cardinality, especially lr and la boast hundreds of non-continuous potential values, while fl may also have dozens, thus rendering the feature space inherently variable and intricate. *(ii)* These features exert distinct and non-linear impacts on per-frame redundancy. For instance, a marginal 1% increase in lr may result in the loss of several more packets within a frame, whereas a similar increase in fl may not yield a substantial damage. In light of these issues, we leverage Random Forest (RF) model to construct *fast-module* as multiple LRIF decision trees. On one hand, RF model can effectively handle high-cardinality samples. Each redundancy decision tree of RF model will be built by randomly selecting training samples, ensuring strong generalization ability. On the other hand, each redundancy decision tree will split its nodes based on different input features during the establishment process, enabling to learn the degree to which each feature affects the per-frame redundancy. As shown in Fig. 14, we first partition the dataset based on lr,la, and fl, while ensuring that the elements in each dataset are evenly distributed to avoid situations where a large amount of data is concentrated near a certain value. Subsequently, we adjust the features carried by each subset, and the explicit features carried by each subset are divided into (lr, fl), (la, fl), and (lr,la, fl). This strategy prevents the decision trees from overly relying on a certain feature. Moreover, we choose MSE (Mean Squared Error) as the *criteria* of RF model to train the *fast-module*.

The final redundancy decision of the RF model is taken as the average of all decision trees' outputs. We emphasize that *(i)* the combination of multiple decision trees can help *fast-module* learn the non-linear relationship between lr, la, fl, and per-frame redundancy. *(ii)* Each tree examines distinct features and autonomously assesses the significance of each input feature, culminating in the integration of multiple decision trees' outputs. This can significantly enhance *fast-module*'s ability to generalize across varied network conditions and gaming environments, as validated in §5.2.

4 Implementation

Tooth's implementation workflow. As the workflow illustrated in Fig. 15, Tooth serves as a pivotal control module of the game server, positioned between Video Codec and FEC Codec. For each gaming session, Tooth acquires the receipt information of past data packets from Network Monitor and the frame length from Video Codec, subsequently controlling FEC Codec to add redundancy for each newly generated frame. In terms of data flow, the server generates the real-time game content, which is encoded by Video Codec and FEC Codec. Then, Data Sender transmits the data packets to players' devices (*e.g.*, smartphone, laptop, iPad) via the Internet.

Tooth's dual-module training methodology. In §2, we have collected extensive cloud gaming traces from the production environment, which records *(i)* transmission and reception details of transport-layer RTP packets. From which, we count the network loss rate and aggregation at a granularity of 100ms to construct the network loss pattern dataset; *(ii)* Each packet's sequence number and the associated video frame ID, locations of all lost packets. For each frame, we count its length, number of lost packets, and integrate its current network loss pattern to construct the video frame LRIF dataset. Based on these two datasets, we complete the training of Tooth.

System implementation details. *(i) Tooth's integration.* Our commercial cloud gaming system has been running online for nearly two years and has more than 100,000 players. It follows the RTP protocol stack [44] and is implemented based on WebRTC [9, 10]. On game server, there is a real-time streaming service (RTSS) module, responsible for handling the game video content and streaming it to the client. Tooth is integrated as an RTSS sub-module, embedded into RTSS's media and network stack to *1)* obtain the frame information and network information *2)* return to RTSS main process the redundancy rate decision. *(ii) Redundancy encoding method.* We leverage the Reed-Solomon (RS) codes [41] to build FEC Codec. Through our engineering refinement, it empowers an FEC block to handle up to 256 packets and the encoding time consistently remains below merely 1 ms. Also, we use WebRTC's FlexFEC codec to support existing FEC solutions. For protection of uplink client-to-server data flow, see Appendix C. *(iii) Network Monitor* discerns the RTP packets' arrival via the client's RTCP feedback (per 100 ms) then provides it for Tooth as the basis for FEC decision-making. Moreover, it calculates the frame LRIFs and archives comprehensive network metrics (*e.g.*, RTT, throughput) into the trace database based on the MQTT protocol [4]. These massive network traces facilitate continuously optimizing Tooth in the offline environment.

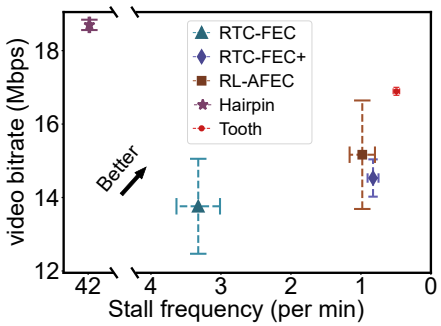

Figure 16: Interaction QoEs of all baseline methods. Tooth exhibits the optimized performance in stall frequency and video bitrate.

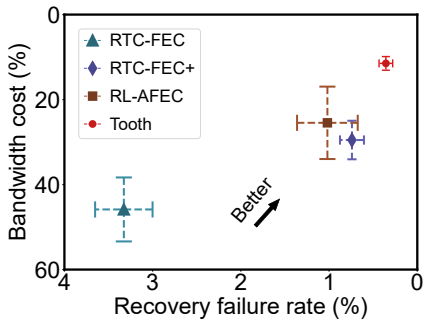

Figure 17: Redundancy rate and recovery failure rate of different FEC methods. Tooth recovers more frames with less redundancy.

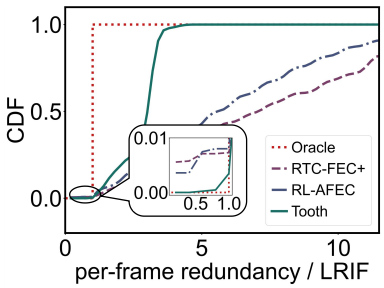

Figure 18: CDF of the ratio of per-frame redundancy rate to LRIF. A ratio of 1 means FEC adds the most appropriate redundancy to a frame.

5 Evaluation

5.1 Experimental Methodology

Comparison baselines. Here we compare Tooth with four state-of-the-art loss recovery baselines:

- *RL-AFEC* [18], which we have already introduced in detail in §2.2. Here we maintain its K as the recommended optimal value of 15 in [18] and provide the further ablation experimental results for other K values in the Appendix E.
- *RTC-FEC* [28], as the default FEC solution of WebRTC framework [9], is widely used in the industry. We integrate the m119 release from Chromium [10] in 2023 into our cloud gaming system.
- *RTC-FEC+*, which replaces *RTC-FEC*'s FlexFEC codec with more powerful RS codec [41]. We also tune *RTC-FEC+*'s redundancy table to suit the RS codec.
- *Hairpin* [36], which is the latest effort in interactive video streaming. It noticed that the loss of retransmission packets will bring multiple RTT overheads and ultimately incur stalls. So it adds redundancy to retransmission packets.

Evaluation metrics. For each cloud gaming session, we log the following metrics to conduct a comprehensive evaluation.

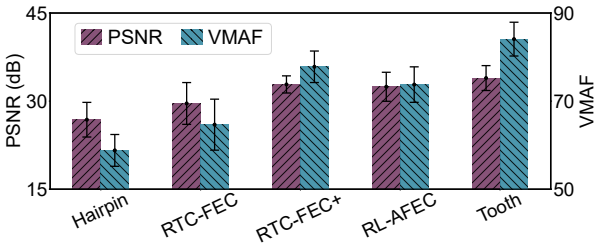
- Our direct optimization goals, *i.e.*, FEC performance, including *1)* bandwidth cost from FEC redundancy; *2)* recovery failure rate, which is the percentage of video frames that fail to recover when suffering packet loss. We clarify that adding redundancy will lower the video bitrate because production systems often have a bitrate cap (20 Mbps in our case) to control overall bandwidth costs, which is a common industry practice. Moreover, when FEC fails to recover a video frame, retransmission is used to ensure the data integrity of non-recoverable frames (whether I frame or P frame). Otherwise, the subsequent video frames won't play normally, leading to interaction stalls.
- Player interaction QoEs, including *3)* stall frequency, *i.e.*, how many times a player experiences stall per minute. We consider an interaction latency of more than 100ms as a stall, for which players will feel that the game is laggy; *4)* video bitrate, which does not include redundancy, represents better picture quality when it is higher; *5)* video PSNR and VMAF, which are close to the user-perceived feedback and have been widely adopted in the community and industry [18, 19, 31, 48].

To avoid the impact of differences in gaming session duration, we calculate these metrics at a one-minute granularity.

Field deployments. We deploy Tooth and baseline solutions to a production server, and conduct rigorous A/B tests in the real world. To ensure fair comparisons, we randomly apply an FEC solution to a gaming session instead of relying on manual allocation, and all solutions operate within the consistent system environment. The evaluation spans a duration of 6 weeks, and the players are in various activity scenarios (*e.g.*, library, office, cafe, home, park) with various wireless network conditions (*i.e.*, WiFi, 4G, 5G). We remove the first minute of each gaming session, during which the game is in the initial animation phase with no user interaction, and the system only monitors the user's network loss conditions.

5.2 System-level Evaluation

Tooth significantly enhances interaction QoE. Here we first focus on the two key application-layer QoE metrics, *i.e.*, stall frequency and video bitrate, to explore Tooth's QoE gains. As shown in Fig. 16, Tooth achieves the lowest stall frequency, *i.e.*, only 0.49 times per minute, reducing that of baseline FECs by 40.2%-85.2%. Furthermore, Tooth achieves the highest video bitrate, *i.e.*, 17.8 Mbps, which is 11.4%-29.2% higher than the baseline FECs. As a result, Tooth can enhance the state-of-the-art FECs' QoE in terms of both stall frequency and video bitrate. Next, we delve into all FECs' bandwidth costs and frame recovery results to further elucidate. As depicted in Fig. 17, Tooth can surpass existing FECs in reducing their bandwidth costs by 54.9%-75.0% while reducing the recovery failure rate by 51.9%-89.3%. This is attributed to Tooth sets higher redundancy rates for small frames to prevent recovery failures and lower redundancy rates for large frames to reduce unnecessary bandwidth costs. Since there are fewer small frames, the redundancy saved by large frames far exceeds the redundancy increased by small frames.



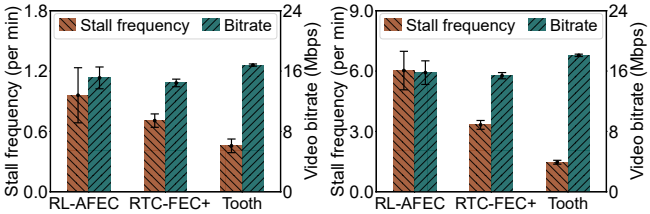


Figure 19: Video PSNR and VMAF results of different loss recovery methods.

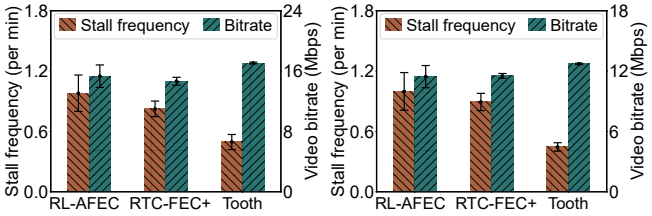
(a) WiFi networks. (b) 4G/5G networks.

Figure 20: Interaction QoE under different network types. Tooth can decrease stall frequency more in 4G/5G networks.

To further clarify this, we calculate the ratio of per-frame redundancy rate and LRIF, where a ratio of 1 means that FEC adds the most appropriate redundancy to a frame. As shown in Fig. 18, Tooth is closest to the Oracle solution.

Regarding other baselines: *(i)* RTC-FEC, constrained by FlexFEC codec (mentioned in §5.1), behaves with a 45.9% bandwidth cost and 3.3% frame recovery failure rate. Consequently, RTC-FEC demonstrates a QoE of 3.3× stall frequency and a video bitrate of only 13.8 Mbps, inferior to Tooth. *(ii)* RTC-FEC+, optimizes RTC-FEC's bandwidth cost and frame recovery failure rate by 35.6% and 77.8%, respectively, thus improving QoE. *(iii)* RL-AFEC achieves a 13.7% lower bandwidth cost than RTC-FEC+ via reinforcement learning, but with a 35.2% degradation in recovery failure rate. These two competent coarse-grained FECs, RTC-FEC+ and RL-AFEC, can only fall into the inherent trade-off between saving bandwidth cost and ensuring recovery. *(iv)* For the retransmission-based Hairpin, its stall frequency is as high as 41.9 times per minute due to the additional RTT delays, despite improving video bitrate. Although Hairpin aims to recover all lost packets with only one round of retransmission, even this brings an additional RTT delay, which in our system will cause the interaction latency to be noticed. In the following sections, we will not delve further into the codec-limited RTC-FEC and retransmission-based Hairpin because they fail to meet the bitrate or stall frequency demands.



Tooth exhibits better video PSNR and VMAF performance. Note that video PSNR and VMAF require frame-by-frame comparison between the server-side source video and the client-side received video, which is not yet feasible in our current commercial platform. Therefore, we recruit 20 volunteers across campus to conduct a small-scale evaluation [4]. Specifically, we first build a local testbed using our commercial cloud gaming system, and randomly select 20 network traces (one per volunteer) from our network dataset to simulate the real network environments. Then, every volunteer is asked to initiate 5 cloud gaming sessions, with each session lasting 10 minutes and using different packet loss recovery methods. Finally, we collect 100 groups of gaming session videos and use the FFmpeg tool [6] to calculate their PSNR and VMAF results. As shown in Fig. 19, Tooth outperforms the baseline methods, with a 3.3% higher video PSNR and an 11.9% higher video VMAF than the next best RTC-FEC+.

Tooth is more effective in 4G/5G networks. Players on our game platform come from two network types, *i.e.*, WiFi and cellular[5], which represent different network conditions. WiFi networks exhibit lower RTT than 4G/5G networks, *i.e.*, 22.9ms vs. 35.1ms in average, which means the retransmission packets are more likely to timeout to incur stalls if FEC fails to recover the frames. Moreover, WiFi's network loss rate is 1.15% and 4G/5G's is 0.76%, *i.e.*, fewer frames will suffer packet loss in 4G/5G networks. In Fig. 20, we give the QoE results under these two networks. We conclude that: *(i)* From WiFi to 4G/5G networks, all three FECs' stall frequencies increase obviously due to higher RTT. For example, Rl-AFEC's stall frequency increases from 1.02 to stunningly 6.03. But Tooth can achieve more QoE gains, from reducing the baseline FECs' stall frequency by 35.5%-52.4% on WiFi to 55.9%-75.6% on 4G/5G. *(ii)* Due to the lower loss rate, RL-AFEC and RTC-FEC+ tend to decrease the redundancy rate, with their video bitrates increasing by 4.6% and 6.7%. Tooth can achieve a more significant bitrate increase of 7.7%. As proved in Fig. 7, the LRIF of large frames gradually approaches the network loss rate. So when the network loss rate greatly reduces, there are more bandwidth can be saved in large frames for Tooth, but which is something that uniform redundancy rate of coarse-grained FECs cannot achieve.

Tooth can still achieve significant QoE gains in 2D games whose frame length differences are smaller. As mentioned in Fig. 2, the frame length difference of 2D games is smaller overall than that of 3D games, with the maximum and minimum values being 50 and 80 respectively. An intuitive worry is: does Tooth still have QoE gains in 2D games? We break down the interaction QoE results of 3D games and 2D games to clarify the issue, as shown in Fig. 21. For 3D games, Tooth can achieve 39.9%, 49.5% lower stall frequency and 11.4%, 16.4% higher video bitrate than RTC-FEC and RL-AFEC, respectively (Fig. 21a). More importantly, for 2D games, Tooth still shows significant QoE gains over the baselines (Fig. 21b). In details, RL-AFEC and RTC-FEC+ both show slightly worsened stall frequency due to more small frames in 2D games,

[4]For campus volunteers, we only collect their operation instructions and video content from the cloud game client. This data collection process doesn't involve any user privacy information and has received approval from the ethical review committee.

[5]Our game APP cannot obtain detailed 4G and 5G access information from player devices, so they are unified into cellular players. In addition, the number ratio of WiFi players to cellular players is almost 8.5:1.

(a) 3D games. (b) 2D games.

Figure 21: Tooth can not only benefit 3D game but also 2D games whose frame length differences are smaller.

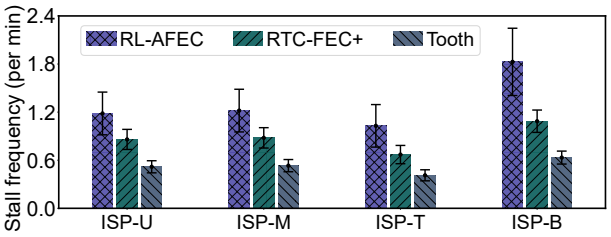


Figure 22: Tooth can achieve consistently lower stall frequency than baseline FECs under different ISP networks.

from 0.82 to 0.89 and from 0.97 to 0.99, respectively, while Tooth can further decrease the stall frequency from 0.49 to 0.44. In terms of video bitrate, Tooth still achieves considerable improvement, 10.4% and 11.1% higher than the baseline FECs. It can reduce the stall frequency by 76.2%, 77.8% and increases the video bitrate by 7.8%, 12.5% (Fig. 21b). Because in both 3D games and 2D games, frequent operations and dynamic game content will lead to inevitable variations in frame length. Thus, Tooth can exploit this difference to adaptively add appropriate redundancy to each frame.

Tooth exhibits exceptional stall performance in various ISP networks. Our cloud gaming platform encompasses players from all four major ISPs in China, *i.e.*, ISP-U (China Unicom), ISP-M (China Mobile), ISP-T (China Telecom), and ISP-B (China Broadnet), with player ratios of 1.1:3.1:1.8:0.01 respectively. Despite ISP variations, video bitrate gain remains largely unaffected, thanks to consistent CDN egress bandwidth set for each game stream (20Mbps in our system). Remarkably, there's a notable contrast in stall frequency. Illustrated in Fig. 22, players from ISP-T exhibit the lowest stall frequency, trailed by ISP-U and ISP-M, those from ISP-B encounter the highest stall frequency. Divergent stall performances stem from disparities in fundamental network performance and link load among ISPs: *(i)* ISP-B, in its nascent stage, is gradually enhancing its CDN links and base station infrastructure, showing relatively poor network RTT, average 28.0ms. *(ii)* The RTT conditions among ISP-M and ISP-U are comparable, 24.3ms and 23.8ms respectively, both are worse than ISP-T's 21.8ms. Fortunately, irrespective of the ISP networks, Tooth can achieve exceptional stall performance, reducing the stall frequency of the next best RTC-FEC+ by 1.63× to 1.72×.

Tooth can achieve consistent QoE gains in both intra-city and cross-city sessions. We divide gaming sessions into two

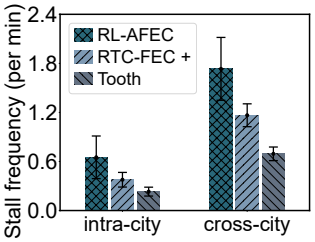

Figure 23: Stall frequency under different server distances.

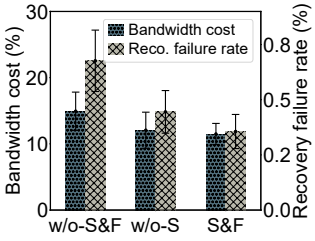

Figure 24: Ablation study of Tooth's two modules.

categories: intra-city sessions and cross-city sessions, contingent upon whether the player and game server are in the same city, accounting for 17.2% and 82.8% of sessions respectively. As illustrated in Fig. 23, Tooth can decrease the stall frequency of the baselines by 40.5% and 59.9% in cross-city sessions. More importantly, in cross-city sessions, Tooth's stall performance can even match that of RL-AFEC in intra-city sessions, and it demonstrates greater robustness (with smaller error bar). Additionally, for intra-city sessions boasting superior network conditions, Tooth shows noteworthy stall frequency gains, reducing by 38.6% and 64.5% compared to the baselines.

5.3 Micro-benchmark Comparisons

Ablation study of Tooth's two modules. Here we examine the separate utility of Tooth's two modules. For *slow-module*, we build its heuristic replica with the arithmetic average method, estimating network loss rate lr and loss aggregation la as the averages over the last three RTCP feedback periods. For *fast-module*'s heuristic replica, we look for a past RTCP feedback period where the network loss pattern is closest to lr and la, then use fl as the observation window to observe the maximum number N of lost packets in this period. The replica will add N redundant packets to the frame. Next, we develop three variants of Tooth: w/o-S&F, w/o-S, S&F, leveraging identical cloud gaming session traces in the simulator for a fair comparison. The results in Fig. 24 show that: *(i)* w/o-S&F can yield 34.3% lower recovery failure rate than w/o-S, and meanwhile reduce the bandwidth cost by 19.2%. The S&F, employing a Random Forest model, demonstrates significantly superior accuracy in determining per-frame redundancy compared to simple historical observations. *(ii)* Compared to w/o-S, *slow-module* provides a more precise estimation of network loss patterns through the NN model. This enhancement allows *slow-module* to further diminish the recovery failure rate from 0.41% in w/o-S to 0.32% in S&F, marking a noteworthy 22.0% improvement. Additionally, we also evaluate the inference accuracy of *slow-module*, more details in Appendix F.

Importance of LRIF-related factors. In §3.2, we expand the LRIF-related factors beyond just frame length (fl) to include network loss rate (lr) and loss aggregation (la). To justify this expansion, we evaluate various combinations of these factors as inputs to Tooth's *fast-module*, specifically A (fl, la), B (fl, lr), and C (fl, lr, la). We train the corresponding *fast-module* variants with these inputs, naming them *fast*-A,

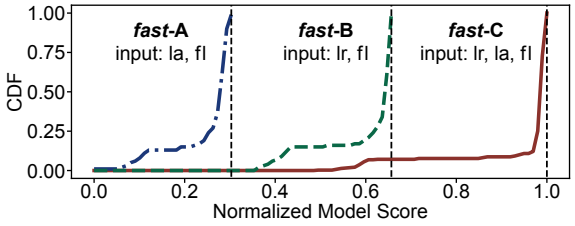

Figure 25: Importance of LRIF-related factors, *i.e.*, network loss rate (lr), loss aggregation (la), and frame length (fl).

Structure	GPU usage (%)	CPU usage (%)	Inference time (ms)	FEC encode time (ms)
Single-stage	7.9	7.1	3.6	0.5
Dual-module	1.4	1.8	0.7	0.5

Table 2: Computational and inference time overhead.

fast-B, and *fast*-C. To eliminate experimental contingency, each *fast-module* variant is trained with 400 different sets of model parameters, obtaining 1200 (3×400) Random Forest models. These models are then tested on the same dataset, with higher scores indicating more accurate LRIF judgment. Fig. 25 illustrates the CDF of model scores for each variant. It is evident that the maximum normalized scores of *fast*-A, *fast*-B, and *fast*-C are 0.30, 0.65, and 1.0 respectively. This highlights the importance of introducing lr and la as LRIF-related factors, especially la, which further emphasizes the subtle differences in network loss pattern that have not been considered by existing works [18, 20, 31, 49, 50].

Overhead comparison of Tooth's model structures. As discussed in §3.2, although it is feasible to directly use powerful neural networks to build Tooth as a single-stage structure, the high execution frequency (every 16.7ms) will inevitably lead to unacceptable computational and inference time overhead. Instead, the dual-module structure we designed decouples Tooth into two modules to reduce overhead. We test both structures on a game server (CPU: Xeon 8369HC; GPU: RTX 3060) and then present their detailed differences in Table 2. Obviously, by decoupling modules and reducing execution frequency, Tooth's dual-module structure can reduce GPU usage, CPU usage, and inference time by 5.6×, 3.9×, and 5.1× respectively. Both structures use RSFEC codec (mentioned in §4) and take 0.5ms for encoding the redundancy, which is a little lower than the decision-making time of Tooth's dual module, *i.e.*, 0.7ms. However, the single-stage decision-making time is 7.2× longer than the FEC encoding time, which obviously reduces its timeliness in commercial cloud gaming.

6 Related work

Network transmission optimization in cloud gaming. Traditional video streaming applications, such as video conferencing and live streaming [32, 34, 39, 46, 53], typically tolerate end-to-end network delays of several hundred milliseconds. In contrast, cloud gaming requires significantly lower latency, necessitating that the time from the player's action to the screen response consistently remains below 100 milliseconds [28, 43, 47]. Cloud gaming currently depends on congestion control algorithms [14, 15, 25, 26, 30, 52–54] to dynamically adjust the data transmission rate, aiming to minimize queuing delays of network packets. Our system employs a custom-optimized variant of GCC [17] for enhanced performance (see Appendix G). Despite these advanced measures, packet loss remains an inevitable challenge, consistently resulting in incomplete data delivery. To address this, cloud gaming systems have to implement effective loss recovery mechanisms, such as retransmission, represented by ART [33], Hairpin [36], and PTO [21]. However, retransmission mechanism commonly introduces additional delays—at least one RTT, and can lead to catastrophic interaction stalls (§5.2).

FEC-based loss recovery. FEC is initially employed to recover lost packets in audio transmissions [38, 40], and has recently been expanded to various video-related applications. For instance, CLOSET [50] and PATON [49] utilize FEC to reduce stalls during TCP-based video playback. DeepRS [20] and RL-AFEC [18] integrate FEC in real-time video communications to minimize end-to-end delays while optimizing FEC bandwidth costs. Additionally, R-FEC [31] and ABRF [19] combine FEC with congestion control to enhance the overall real-time video QoE. A recent advancement in video-conferencing, Tambur [42], introduces stream coding [27] to use multiple sequential frames to recover lost packets from earlier frames, but brings delay that spans multiple frame intervals. However, the above solutions all utilize coarse-grained redundancy mechanisms that do not satisfy the stringent interaction QoE requirements in cloud gaming scenarios (§5.2).

7 Conclusion

In this paper, we propose Tooth, an innovative fine-grained FEC method specifically designed for commercial cloud gaming. We highlight two main novelties: the first-of-its-kind large-scale measurements conducted in real-world environments to investigate the bottlenecks of existing loss recovery methods, and the design of fine-grained FEC encoding mechanisms to achieve an optimal balance between video QoE and redundancy bandwidth cost. Our online evaluations significantly demonstrate the advantages of Tooth. We believe that Tooth has the potential to benefit a wide range of latency-sensitive applications in the future.

Appendices

A Measurement Method for Application-layer Interaction Latency

We track user interaction delays frame by frame to identify whether a video frame is delayed and by how much. The interaction latency refers to the time it takes from when a user inputs an operation (*e.g.*, run and hit) into the game client to when the user receives the screen feedback. To measure this latency actually, we break down the cloud gaming application-layer latency into two parts:

(i) System processing delay, which involves tasks like capturing user input, video encoding, decoding, and playback on the game client and server. These contribute to a total average delay of 32ms, which is relatively stable.

(ii) Data round-trip network delay, which involves transmitting user operations to game server (uplink) and receiving all RTP packets of the responded video frame from the game server to the client (downlink) via the Internet. These delays depend on network transmission conditions, we record frame ID and the timestamps of all uplink and downlink packets to calculate them.

If the sum of these two parts of delays exceeds 100ms, we determine that the user interaction has timed out, in the same way, we can know how late the complete frame arrives.

B Applying Infinite GOP Video Encoding in Cloud Gaming

Traditional real-time video communication usually uses the finite GOP encoding manner and sets a fixed GOP length for the video codec, such as 30 set in RL-AFEC [18]. For cloud gaming, this ultra-low latency interactive video streaming application, a common practice in the industry is to adopt the infinite GOP video encoding [1, 8]. Infinite GOP video encoding disables the server to send I frames periodically, and the client is allowed to request a new I frame only for necessary error recovery, *e.g.*, the client frame buffer pool overflowed after multiple video frames suffering packet loss and failing to be decoded. As a result, our cloud gaming system sends an I frame every 4.7 minutes on average, which means our average GOP length is 16,920 and 564× higher than that of conventional video streaming in [18].

We explain that the P frame only needs to encode the difference between the current video frame and the previous one, while the I frame must encode the entire video frame. When encoding the next video frame, the size of a P frame will not exceed that of an I frame, even if the cloud gaming scene changes. Therefore, the infinite GOP encoding can avoid frequently sending high-load I frames and the accompanying latency surge, and is recommended by the popular NVENC video codec [1, 8] for low-latency cases, especially game-streaming, video conferencing, *etc*. We emphasize that multiple top gaming platforms, including our partner company W, adopt this encoding method to optimize the cloud gaming interaction latency. This is a common practice in industry although less frequently introduced in academic papers.

C Protection of uplink client-to-server data

The client-to-server data flow in cloud gaming, mainly discussing player operation data here, typically ranges from a few to several tens of Kbps, which is much smaller than the available network bandwidth. For such a small operation data flow, there are no multiple concurrent packets like server-to-client video flow. Therefore, the industry usually doesn't add redundancy using FEC rather than adopting some repeated delivery strategies (*i.e.*, sending data replicas) to ensure reliable transmission. Take our system as an instance, a single player operation amounts to no more than 10 bytes, and the total number of concurrent operations remains far below the maximum capacity of an RTP packet (MTU=1500). Thus, an operation RTP packet from the client will not only contain the latest player operations but also the previous n operations. Additionally, each operation RTP packet will be sent twice, with a 2ms interval, to further improve reliability.

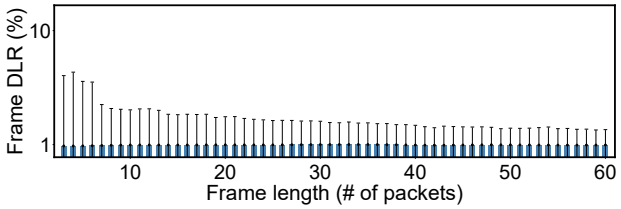

Figure 26: LRIF results of all video frames (including those experiencing no losses) observed in our commercial cloud gaming platform.

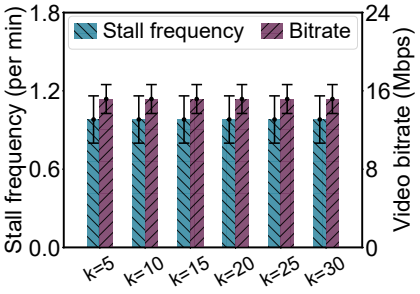

Figure 27: Ablation experiment results of the RL-AFEC model with different K values.

D A Deeper Dive into LRIF Results

We make the following explanations to clarify why in Fig. 7 we need analyze the LRIFs of frames that suffered packet loss rather than all GOP frames. *(i)* FEC in video streaming is more interested in higher percentiles of LRIF because only they can reflect how many redundant packets that FEC should add to protect all video frames as much as possible from network packet loss events; *(ii)* As shown in Fig.26, the average and standard deviation of all GOP frame LRIFs are actually consistent with the overall network loss rate (about 1%), but obviously, FEC should not adjust the redundancy rate based on this insight. So, in Fig. 7, we plot the LRIF average and std of video frames that suffered packet loss to reveal the relationship between non-zero LRIF and video frame length, which is more meaningful for guiding us in designing the fine-grained FEC in cloud gaming.

E Ablation Study of RL-AFEC Using Different K Values

For RL-AFEC [18], we further present ablation study experiments with the variation of K, *i.e.* setting K as 5, 10, 15, 20, 25, 30, consistent with [15]. As shown in Fig. 27, the six candidate values of K have little impact on the cloud gaming interaction QoE, which can be almost ignored. That's because the GOP length of cloud gaming streaming is very large, it is far from enough to optimize only a few K critical frames. We should set a fine-grained redundancy rate for each video frame.

More importantly, we emphasize that directly defining K to be GOP size N with RL-AFEC will not yield a similar outcome as Tooth. We elaborate on the key differences in the design principles of Tooth and RL-AFEC: *(i)* RL-AFEC is designed for common video call scenarios, where the length of the remaining P frames remains relatively uniform, apart from the initial I frame in each GOP. In other words, RL-AFEC does not account for significant frame length variations and the resulting huge LRIF differences in cloud gaming streaming. As a result, RL-AFEC may fall short of fully meeting the redundancy adaptation design required for specific cloud gaming scenarios. *(ii)* In RL-AFEC, the GOP length N is 30 and the authors conclude that the optimal K value is 15, the reason is that increasing K will cause its reinforcement learning model to explore huge action space, resulting in an obvious decrease in its model effectiveness. Especially considering that the GOP size N will be hundreds even thousands of times larger than K in cloud gaming scenarios, defining K to be N is even less feasible. Instead, Tooth, with its unique dual-module design, makes larger K or even infinite K feasible, and ultimately is fully capable of setting fine-grained redundancy rate for each frame.

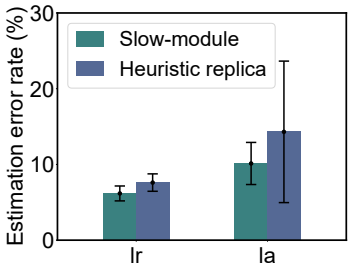

Figure 28: Estimation errors of network loss rate *lr* and loss aggregation *la*.

F Micro-benchmark Experiments on Tooth's Slow-module

To further evaluate Tooth's *slow-module*, we analyze Tooth online dataset to supplement the micro-benchmark experiment results, including the estimation errors (mean and std) of network loss rate *le* and loss aggregation *la*. Then, we calculate the mean and std of all estimation error rates. Moreover, we also replay these online traces in the simulator and evaluate *slow-module*'s heuristic replica (implementation details in §5.3) to compare their performance differences. As shown in Fig. 28, Tooth's *slow-module* behaves good inference accuracy, with an average error of 6.2% for *lr* and 10.1% for *la*, which are 18.8% and 29.2% lower than the heuristic replica, respectively.

G Fine-tuning of GCC's hyper-parameters in our system

The default GCC congestion control algorithm in WebRTC [10] isn't fully adapted for the streaming characteristics of cloud gaming. We follow the algorithm logic of GCC but

customize its hyper-parameters based on practical engineering experiments: (i) We increase GCC's upper bitrate limit to 20Mbps to meet the production streaming requirement of cloud gaming; (ii) We shorten the observation window length in GCC's trend-line estimator from 20 to 15, making the system more aware of delay increases; (iii) We slightly enlarge the rate increase factor in AIMD-based bitrate control from 1.08 to 1.11 for fast bitrate recovery after the delay stabilizes; (iv) We disable GCC's probe action during bitrate reduction since cloud gaming is more delay-sensitive than bandwidth-sensitive. Probing at this time can easily harm delay performance. (v) When the observed network loss rate is below 0.3%, we block GCC's loss-driven decision on reducing bitrate and rely solely on the delay-driven bitrate adjustments.

AsTree: An Audio Subscription Architecture Enabling Massive-Scale Multi-Party Conferencing

Operational Systems Track

Tong Meng Wenfeng Li Chao Yuan Changqing Yan Le Zhang
ByteDance Inc.

Abstract

While operating a multi-party video conferencing system (Lark) globally, we find that audio subscription alone may pose considerable challenges to the network, especially when scaling towards massive scales. Traditional strategy of subscribing to all remote participants suffers from issues such as signaling storm, excessive bandwidth and resource consumption on both server and client sides. Aimed at enhanced scalability, we share our design of AsTree, an audio subscription architecture. By a cascading tree topology and media plane-based audio selection, AsTree dramatically reduces the number of signaling messages and audio streams to forward. Practical deployment in Lark reduces audio and video stall ratios by more than 30% and 50%. We also receive 40% less negative client reviews, strongly proving the value of AsTree.

1 Introduction

Real-time multi-party video conferencing has been ubiquitous in our daily lives. Lark [1], as one of a rich set of heavily used services and products (*e.g.*, Zoom [2], Microsoft Teams [3], DingTalk [4]), serves tens of millions of users, and benefits vast many industries such as online education, international business, interactive social networking, *etc.*

Rather than focusing on simulcast-based video subscription like many existing literature [5, 6], we report our experiences of designing and deploying AsTree in Lark, an audio subscription architecture targeted at massive-scale conferences (*e.g.*, scaling up to hundreds and thousands of participants per room). Notably, there are several key differences between audio and video subscription, posing challenges to the architecture for the former correspondingly.

Whether to subscribe to a stream. Subscription and unsubscription to video streams can be the outcome of a subscriber's proactive operations, *e.g.*, when the subscriber scrolls through the participant list, or pins/unpins a specific publisher. In comparison, a subscriber mostly needs to be passively subscribed to an audio stream, as long as its publisher is actively speaking. That makes the audio subscription relations between conference participants unpredictable, because we cannot deterministically predict when and which participant will speak.

When to subscribe to a stream. Subscribing to a video stream requires 4 steps: (1) a publisher broadcasts a Publish signaling message when turning on camera, (2) a subscriber sends an Subscribe message (not necessarily closely follow previous step), (3) an overlay cascading path is established between the publisher and subscriber, (4) the video stream is cascaded and distributed. For an audio stream, however, the above steps cannot wait until a participant becomes unmuted. Considering that audio is generally more latency-sensitive than video, the signaling round trip and on-demand establishment of cascading path induce unwanted delay. What is worse, there would be loss of audible information if a participant starts talking right after clicking the unmute button.

How many streams to subscribe. Even if all participants open their cameras, each one subscribes to a bounded number of video streams, depending on the user interface layout. Yet when it comes to audio subscription, the number of audio streams for subscription may increase indefinitely, since every participant in a room may unmute. At a massive conference scale, subscribing to all unmuted participants may lead to considerable signaling overheads and bandwidth consumption.

In the early stage of our deployment, massive conferences where all participants are allowed to unmute themselves were uncommon. So we assumed audio consumes much lower bandwidth than video at that time, and employed a straightforward "subscribe-to-all" strategy for audio subscription (denoted as FullAud henceforth). To improve timeliness of audio signal, subscription to a participant is aggressively initiated when they joins a conference room, without waiting for them to unmute. Since most participants start muted by default, we expect the signaling round trip and cascading path establishment to finish before a participant actually starts talking. Along with that, each participant keeps publishing an audio stream while in the conference. When the microphone is muted, the audio stream simply contains a few Discontinuous Transmission (DTX) frames [7]. Then, the signaling message emitted from a participant clicking the mute/unmute button is used to toggle the displayed audio status seen by other participants. As far as we know, at least until the pandemic, many products also default to full audio subscription [8–10], though their realizations may differ.

Not surprisingly, as our DAU (daily active users) continuously grows and massive-scale conferences become increasingly frequent, FullAud starts to face scalability issues.

- **Signaling storm.** Influx of participants often happen at the start of a conference, inducing surging signaling messages for audio subscription. As a result, both audio and video are more likely to suffer from network and host congestion. Besides, the signaling broadcast generated every time a

participant mutes/unmutes the microphone interferes with cascading and distribution of media data to some extent.

- **Client-side resource overheads.** When a single participant has to fetch tens or hundreds of audio streams, the last-mile access link can be easily overwhelmed, increasing chances of choppy audio and video rebuffering. Meanwhile, CPU, memory, and battery power on user devices consistently operate under excessive loads, and thus, tend to cause performance issues such as overheating that eventually impair audio/video quality, as well.
- **Server-side resource overheads.** A room with N participants distributes $O(N^2)$ downlink audio streams at the edge. The quadratic scaling egress bandwidth makes FullAud substantially less affordable. In addition, the ever-expanding conference scale urges prohibitive investment in WAN bandwidth and media servers, considering that (1) individual media servers are more likely to be overloaded in densely populated regions, and (2) massive participants are more geographically dispersed and cascade more server clusters.

The AsTree architecture is designed to overcome the above issues. It is inspired by an empirical observation: at any time during a multi-party conference, almost all critical information comes from a small number of audio streams [10, 11]. Therefore, a majority of audio streams can be ignored from subscription. To effectively carry out that idea in a practical system, we should fulfill the following objectives.

- **Light-weight signaling.** For agile conference management, the selection of audio streams and notification to participants should not only avoid adding new signaling messages, but also significantly alleviate the existing signaling storm.
- **No single point of failure.** Audio stream selection needs to compare attributes of all audio streams. Gathering streams to a single server for that purpose should be avoided. Otherwise, that server becomes the computing and bandwidth bottleneck, whose failure impacts all participants in a room.
- **Compatibility with simulcast.** We want the new design for audio subscription to induce minimal changes to the already mature video simulcast architecture, and enable independent engineering development and modular upgrade.

As a large-scale system in a well-explored field, AsTree shares similarities with some existing works (*e.g.*, separation of media and control planes [5], cascaded media servers [12, 13]). Importantly, many conferencing service providers disclose limited information on how they scale the audio subscription architecture. To the best of our knowledge, we are the first to provide comprehensive experiences on that. Our main contributions are highlighted below.

- AsTree constructs a cascading tree between media servers for each conference room to lower WAN bandwidth consumption. It assigns a delegate server in each region connecting other intra-region media servers, and calculates an inter-region tree cascading region delegates.
- AsTree selects a subset of audio streams composed of dominant speakers at each media server, without control plane involvement. Effectively, a subscriber only subscribes to those audio streams containing valid vocal signal. Moreover, it eliminates the signaling broadcast when a participant mutes/unmutes the microphone.
- We present extensive results from benchmarking tests and practical deployment. AsTree is shown to significantly outperform FullAud. To be specific, negative reviews are reduced by 50%, audio stall is reduced by 30%, and video stall is reduced by 50%. Also, a media server can hold conferences with an order of magnitude more participants.

This work does not raise any ethical issues.

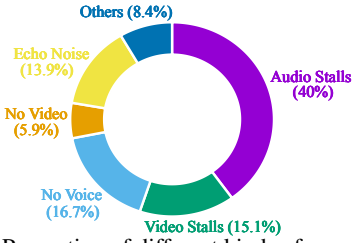

Figure 1: Proportion of different kinds of user complaints

2 Motivation

Thanks to the deployment of simulcast, Lark's video quality of experience (QoE) has been notably improved, making audio stall the most common category among millions of our user complaints (as in Figure 1, collected by post-call questionnaire with non-exclusive options). That confirms the importance of evolving the audio subscription architecture. To fully motivate AsTree and gain some insights, we explain the scalability issues of our early-stage FullAud implementation in more detail, and analyze the drawbacks of several strawman solutions.

2.1 Scalability Issues of FullAud

2.1.1 Local Signaling Overheads

A centralized signaling unit is both the gathering point of signaling reports and originating source of signaling broadcasts, *e.g.*, so as to maintain a full picture of the conference room and direct the establishment of cascading links, respectively. To alleviate its pressure, we deploy local signaling units co-located with media servers, and aggregate signaling messages between centralized and local signaling units into $O(1)$ per broadcast. However, each local signaling unit generates $O(N)$ messages while signaling its connected participants.

As an example, Figure 2 illustrates the signaling round trip for audio subscription. FullAud amortizes the signaling delay to the moment a participant joins a conference, and thus, merges the broadcast of Join and Publish. It also triggers a consequent ingestion of $O(N)$ Subscribe messages. Additionally, signaling broadcasts also happen when participants (1) click the mute/unmute button and (2) leave the room.

If combining all participants in a room, the volume of signaling messages borne by local signaling units is as high as

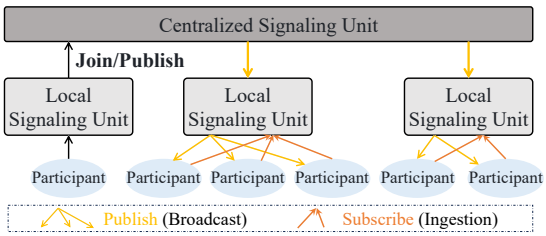

Figure 2: Signaling round trip for audio subscription in FullAud

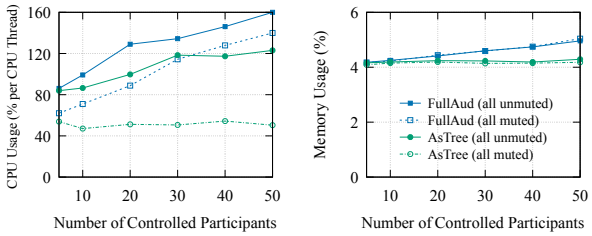
Video Stream	Focus Window	Thumbnail
	700 Kbps	120 Kbps
Audio Stream	Unmuted	Muted (DTX only)
	64 Kbps	1 Kbps

Table 1: Approximate bandwidth requirements of video and audio streams (video based on Lark's mobile app)

$O(N^2)$. Although each message does not exceed several tens of bytes, massive-scale conferences may still suffer from signaling storm and degraded user experience, especially when:

- A large number of participants join within a short time period, which is common at the starting phase of a conference.
- Highly concurrent conferences during peak hours already leave a high CPU usage on the edge nodes.
- Participants repeatedly unmute/mute for different purposes, including playing with the button aimlessly.



As will be demonstrated in §6.1, the signaling storm may consume even higher CPU than media processing. Regardless of the frequency of signaling storm, the possibility of its occurrence prevents us from scheduling many participants to the same media server. That limits the maximum number of participants a single media server can accommodate per room under FullAud, leading to inefficient utilization of server machine resources.

2.1.2 Client-Side Overheads

FullAud's client-side bandwidth consumption increases linearly with the room size. To intuitively compare it with video subscription, let us consider a simple scenario: a participant joins a conference using Lark Mobile on a smartphone. Assume speaker layout is used, with a 720p full-screen focus video and a 90p floating thumbnail. Referring to [14] and our internal configurations, bandwidth requirements of individual video and audio streams are approximated as in Table 1.

Each participant needs 0.82 Mbps to fetch the focus and thumbnail videos, regardless of the room size. When there are more than 12 unmuted participants at the same time, audio will consume more bandwidth than video. Even if all participants are muted, their DTX-based audio streams will require the same order of magnitude bandwidth as video with more than 100 participants. We should note that this is a conservative estimation, since we do not consider possible reduction in video resolution to resist weak networks, and needs for higher-quality audio for increased immersion.

In addition, we leverage the stress test system at Lark to demonstrate FullAud's hardware loads on user devices. We use a Redmi Note 13 smartphone to join setup conferences with different number of controlled participants, and monitor its CPU/memory usage (Figure 3). All controlled participants do not publish video streams to isolate the overheads of audio subscription. We test two extreme cases where controlled participants are either all unmuted or all muted.

(a) CPU Overheads **(b)** Memory Overheads

Figure 3: Client-side overheads induced by FullAud

As expected, FullAud's resource usage scales nearly linearly with the number of participants. Because the smartphone has to receive and process muted audio streams, when the number of muted controlled participants increases from 5 to 50, it occupies more than half an additional CPU core. It has almost the same memory usage in both cases. That means some low-end smartphones may not even have enough capabilities to join a conference with hundreds of participants. For comparison, we also depict AsTree in Figure 3. In AsTree, the smartphone subscribes to a limited number of audio streams, excluding any muted streams. Thus, its resource usage remains relatively stable with different number of muted participants. When there are 50 muted participants, AsTree's CPU and memory usage are 64% and 17% lower than FullAud, respectively. We note that all controlled participants use the same audio track, causing the selected dominant speakers to change frequently. That explains the increasing CPU usage of AsTree when there are more unmuted participants.

2.1.3 Server-Side Overheads

FullAud effectively creates an overlay mesh cascading every pair of media servers. As a result, a room that involves N participants and M media servers consumes $O(MN)$ and $O(N^2)$ bandwidth on inter-server WAN and egress links, respectively.

More importantly, a larger conference scale alone can raise server-side expenses, even with the same user population. Assume a media server instance has the CPU, memory and associated egress link bandwidth that are just enough to distribute 100 audio streams. Then, one such instance can hold 50 concurrent 2-party audio-only conferences, but we need 100 instances to have a single 100-party conference (*e.g.*, each instance serves a single participant). Moreover, the overall egress bandwidth consumption is 99×, and the same amount of WAN bandwidth is needed for cascading. Although ignoring the influence of many practical factors, such a comparison illustrates the possibly forbidding costs while scaling FullAud. Similar issue is mitigated by simulcast in video subscription, where the number of video streams distributed to an individual participant is capped by the user interface.

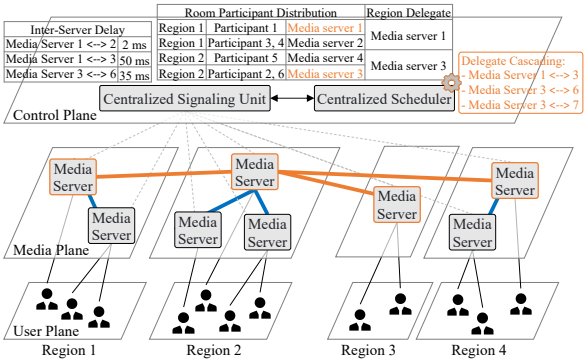


Figure 4: Overview of the AsTree architecture (local signaling units co-located with media servers are omitted)

2.2 Strawman Solution Analysis

Several strawman solutions can reduce the number of audio streams subscribed by each participant. Though seemingly simple, they come with various drawbacks.

(1) Restricted unmute privilege. The most straightforward way to enforce subscription to fewer audio streams is to set a hard limit on the maximum number of concurrent unmuted participants. Many online webinars adopt that solution. Therein, an audience member should request to unmute from a host, and be muted after finishing. That way, subscribing to all active speakers does not generate high overheads.

Drawbacks: Having to apply and compete for opportunities to speak induces inconvenient manual operations. One such interaction easily takes several seconds. Thus, the solution has a much narrower scope other than lecture-style conferences. It is not applicable in emerging scenarios requiring strong interactivity, such as online social and virtual karaoke.

(2) Signaling-based audio selection. While publishing to the local media server,[1] a participant also signals the attributes of their audio stream to the centralized signaling unit. Based on the collected audio attributes, the signaling unit leverages a controller to select a subset of audio streams to be forwarded. Each media server waits for instructions from the signaling unit to determine which ingested audio streams to cascade.

Drawbacks: This solution introduces new signaling messages for audio stream selection, which should be sent frequently to reflect dynamics in audio attributes (*e.g.*, fluctuating voice volume, *etc.*). That exacerbates the signaling storm issue. What is worse, user experience is more vulnerable due to the additional signaling round trip for a selected audio stream.

(3) Select before distribute A media server still pulls one audio stream from each participant, whether they are unmuted or not. Whereas in the downlink direction, a selection logic is added to each media server, such that only selective audio streams are distributed. Besides that, the publishing and cascading of audio streams are kept the same as in FullAud.

Drawbacks: Compared with the previous two solutions, this solution puts no limit to applicable use cases, and avoids complicated signaling interactions for audio selection. Yet it is still based on full audio subscription, and media servers are still cascaded by a mesh. An audio stream, whether selected or not, needs to be received and processed by all media servers involved in a conference. That provides limited help to control server-side costs on WAN bandwidth and media servers. In fact, that is an important reason why Jitsi had to temporarily disable mesh cascading during the COVID-19 pandemic [15].

[1] A local media server specific to a participant is the server to which the participant is directly connected. A local media server specific to an audio stream is the local media server of its publisher.

3 AsTree Design Overview

Figure 4 presents the high-level architecture of AsTree. Similar to [5], it is composed of user plane, media plane, and control plane. The user plane and media plane are divided into separate geographical regions, and the control plane is logically centralized.

AsTree is based on selective forwarding units (SFUs), which has been the dominating choice by modern multi-party conferencing providers [5, 6, 16, 17]. Participants connect to nearby local SFU media servers. Cascaded SFUs form overlay paths between participants, and forward media streams without decoding them. Furthermore, one or more SFUs involved in a conference room form an audio selection tree (hence the acronym AsTree[2], details in §4) as opposed to a mesh. Each region has a single media server as the region delegate. The other media servers are cascaded to their intra-region delegates. Then, all the delegate servers are connected by a spanning tree encompassing the corresponding regions. Such an AsTree topology is calculated by a centralized scheduler in the control plane. For that purpose, it synthesizes distribution of participants in the same room and latency between media servers, which are collected by the signaling unit.

Beyond that, the control plane does not participate in selection of audio streams. Instead, audio selection is conducted hop by hop at the media plane, *i.e.*, each media server only selects at most L loudest active speakers (details in §5). All participants, including those muted ones, still keep publishing audio streams to their local media servers, but muted audio streams will be excluded from audio selection. Thus, the number of audio streams forwarded on any cascading link and distributed to any participant is capped by a constant parameter. Moreover, no signaling broadcast is needed when a participant mutes/unmutes the microphone. The audio status of each participant displayed on user interface directly corresponds to the results of audio selection, *i.e.*, only those whose audio streams are selected are displayed as unmuted.

4 Calculation of Cascading Tree

In Lark's deployment, the division of regions is fairly static, depending on geo-planning of server clusters. The calculation of the AsTree topology focuses on the two hierarchies as outlined in §3, *i.e.*, intra-region and inter-region cascading.

[2] AsTree may stand for the audio subscription architecture or the cascading tree topology. The context where it is used can help avoid ambiguity.

4.1 Intra-Region Cascading

The core of intra-region cascading is the selection of region delegate. To lower the implementation complexity, we do not adopt complicated leader election algorithms (*e.g.*, [18, 19]) from the field of distributed systems. Instead, we take a "first comer elected" method. When a media server is the first in its region to join a conference room, it is configured to be the region delegate. Subsequent media servers joining the same room in the same region are cascaded to that delegate.

The above simple method is out of three considerations. First, the one-way latency between media servers in the same region is usually much lower than the industrial target for acceptable one-way latency (*e.g.*, above 200 ms between individual participants [20–22]). Changing the elected region delegate delivers similar audio QoE in most cases. Second, the interaction delay between intra-region participants is kept minimal, because their audio streams reach each other without leaving the region. Third, since each media server only forwards at most L audio streams, the region delegate will not face a high processing load. According to our experiences, the number of audio streams cascaded from non-delegate servers to a region delegate rarely exceeds two dozens, because many participants stay muted in a majority of time. That is far below the capacity of a single media server (§6.1).

A region delegate remains in the cascading tree, unless all participants in its region leave the room (details in §4.3).

4.2 Inter-Region Cascading

A spanning tree can connect a set of region delegates with the fewest cascading links. Each cascading link represents an overlay path, and the cascading links between a pair of delegates form a cascading path. The calculation of cascading spanning tree is formulated as follows.

$$
\begin{aligned}
\textit{Input}: \quad & \mathcal{R} = \{ R_1, R_2, \cdots, R_M \} \\
& \mathcal{N} = \{ N_1, N_2, \cdots, N_M \} \\
& \mathcal{D} = \{ d^L_{ij} \mid 1 \le i < j \le M \} \\
\textit{Output}: \quad & \mathcal{T} = \{ x_{ij} \mid 1 \le i < j \le M \} \\
\textit{Subject to}: \quad & x_{ij} \in \{ 0, 1 \}, \quad \forall\ 1 \le i < j \le M \\
& \sum_{j=i+1}^{M} x_{ij} + \sum_{k=1}^{i-1} x_{ki} > 0, \quad \forall\ 1 \le i \le M \\
& \sum_{i=1}^{M-1} \sum_{j=i+1}^{M} x_{ij} = M - 1
\end{aligned}
$$

We use $\mathcal{R}$, $\mathcal{N}$, and $\mathcal{D}$ to denote the set of M ($M \ge 2$) region delegates, the number of participants in each region, and the cascading link RTT between each pair of delegates, respectively. They are updated by the signaling messages triggered when a participant joins or leaves. The cascading link RTTs are measured passively via recent media flows, or proactively with infrequent probes. To lower complexity, d^L_{ij} is regarded as undirected, and takes the larger value between the RTT measured at R_i and at R_j.

The inter-region spanning tree should aim at objectives of practical importance. Therefore, classic minimum spanning tree (MST) algorithms that minimize the total RTT of involved cascading links are not suitable in this case, because it may lead to cascading paths with arbitrarily long RTTs (Figure 5d). We provide several alternatives to generate the inter-region spanning tree. Meanwhile, we illustrate using an example with 4 regions in Figure 5. The RTT statistics in the figure refer to public Azure network latency [23]. Again, we defer the discussion on updating the spanning tree along with changes in $\mathcal{R}$ and $\mathcal{N}$ to §4.3.

4.2.1 Minimized Longest Path RTT

In a spanning tree, the cascading path with the longest RTT largely determines the worst-case end-to-end audio latency. Minimizing the longest path RTT guarantees the lower bound of QoE for all participants in a room. Given the above problem formulation, the objective can be expressed as:

$$
\textit{Objective}: \quad \min \left(\arg\max_{1 \le i < j \le M} w_{ij} \cdot d^P_{ij} \right)
$$

where d^P_{ij} denotes the RTT of cascading path between R_i and R_j. In addition, we add a path weight w_{ij} to enable priority control among different regions. For example, we can assign a smaller value to w_{ki} and w_{ij} ($k < i < j$) than the other weights, if R_i is favored as the root of the spanning tree (*e.g.*, when the conference host is in the same region as R_i and we need to minimize the delay from the host to other participants).

As shown in Figure 5a, when all path weights equal 1, the spanning tree rooted at West US minimizes RTT of the longest cascading path, which is between West Europe and East Asia (299 ms). However, if the host locates in East Asia and the three cascading paths originating from there have a smaller weight of 0.5, the root of the optimal spanning tree will change to delegate server in East Asia (Figure 5b).

4.2.2 Minimized Weighted Average Path RTT

Sometimes it is commercially advantageous to enhance experience for a majority of participants. That leads to the objective of minimizing weighted average of cascading path RTTs, based on participant distribution between regions:

$$
\textit{Objective}: \quad \min \sum_{1 \le i < j \le M} w_{ij} \cdot d^P_{ij} \cdot (N_i + N_j)
$$

Compared with §4.2.1, the optimal cascading spanning tree under unity value path weights is now rooted at East Asia (Figure 5c), because 5× participants in East Asia can benefit from shorter cascading paths. However, if the weights of three cascading paths from West US is decreased to 0.5, the optimal root delegate will still be in West US. We omit that case in Figure 5 due to limited space.

4.2.3 One Single Master Delegate

Both objectives on above increase the calculation complexity compared with classic MST algorithms. For cost-effectiveness, we propose a simple heuristic instead of trying

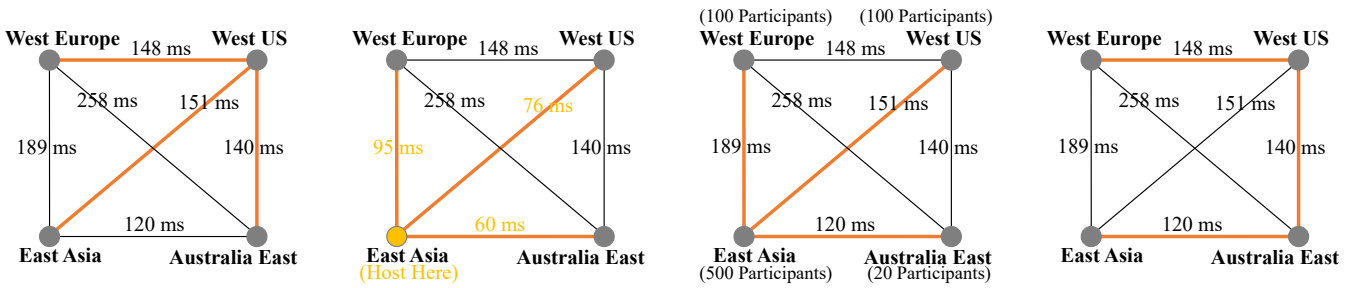

Figure 5: Illustrating example of inter-region cascading ((a), (c) and (d): all path weights equal 1; (b) path weights between East Asia and other regions equal 0.5, RTTs of three corresponding cascading paths are weight-adjusted and shown in yellow text)

to find the optimal solution to the optimization objectives. It enforces a cascading structure similar to that in the intra-region scenario: one of the region delegates acts as the master delegate, and directly cascades to other delegates. On that basis, the unweighted objective in §4.2.1 is adopted while selecting the master delegate. We postpone exploration on the necessity and effectiveness of tuning path weights to future work. By doing so, the needed computation is determined by the number of regions per room, which is usually a relatively small number in practice. We do not choose the objective in §4.2.2, because it is sensitive to fluctuations in $\mathcal{N}$.

In Figure 5, our heuristic actually generates the optimal spanning tree under the objective in §4.2.1 (Figure 5a&5b).

4.3 Reaction to Room Dynamics

To lower the workloads of engineering development and complexity of failover, our implementation tries to avoid disassembling established cascading links in reaction to dynamics in the involved regions. Next, we elaborate on how we handle participant joining and leaving, respectively.

4.3.1 Participant Joining

We focus on how to update inter-region cascading upon newly joined participants. The intra-region case has been covered in §4.1. The following is the process of constructing an AsTree from an initially empty room.

- There is no need for inter-region cascading, until a conference involves a second region. At that time, it suffices to cascade the only two delegates.
- When the third region is added, one of the existing two delegates is selected as the master delegate (§4.2.3). Then, the third region's delegate cascades to the master, without influencing the established cascading link.
- As more regions join, we stick to the same master delegate, unless the spanning tree cannot fulfill an empirical threshold of end-to-end audio latency.

We understand that starting from the third region, the selected master delegate may not be the optimal choice under the heuristic in §4.2.3 and the objective in §4.2.1 without changing established cascading links. Yet fortunately, in practical deployment, we find the need to change master delegate is rare, especially considering that most participants are from the same country as the first joiner in a majority cases [20], and the host tends to join in the beginning of a conference.

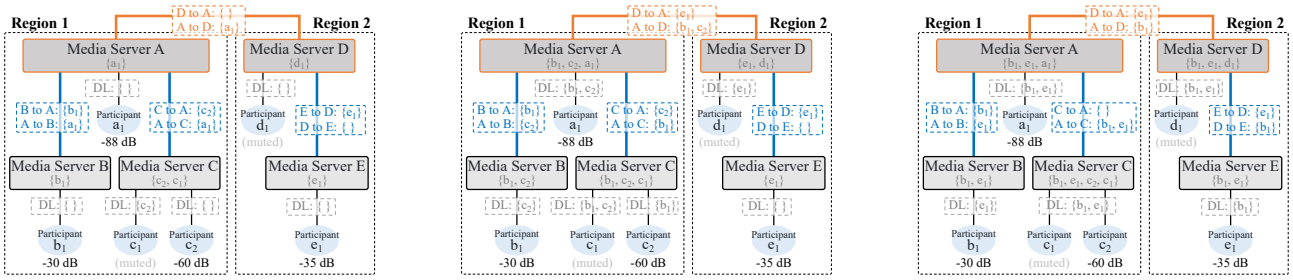
4.3.2 Participant Leaving

Ideally, if the last participant connected to a media server in a room goes offline, the media server can be removed from the corresponding AsTree. For brevity, we call such a media server an idle server specific to the AsTree topology.

It is safe to remove an idle server if it is a leaf node in the AsTree. That is the case if it is not the region delegate, or it is the only media server in its region but not the master delegate. Meanwhile, the intra-region or inter-region cascading connections on that idle server can as well be closed, if they do not carry other multiplexed traffic.

Otherwise, the idle server is a region delegate or the master delegate, and cascades other media server(s). In the former case, if we re-select the delegate, only participants under the new delegate will become closer to others by one intra-region cascading link. Provided the latency requirements of conferencing applications nowadays, we assess that such a benefit does not compensate for the complexity of tearing down and re-establishing cascading links. Therefore, we retain the role of the idle server as region or master delegate, since that does not worsen remaining participants' QoE anyway.

As more participants leave, those idle delegate servers can be removed from the AsTree topology when the media servers below them are all removed, making them the leaf nodes.



5 Select-Before-Forward Audio Selection

Different from strawman solution 3 in §2.2, AsTree expands audio selection to all cascading links. Intuitively, "select before distribute" is replaced by more generalized "select before forward". In this section, we illustrate the audio selection process, as well as how we implement dominant speaker identification and control signaling overheads.

5.1 Hop-by-Hop Audio Selection Process

All media servers adhere to a unified audio selection logic, irrespective of their roles in the cascading tree. They always select audio streams out of the following set:

- Those ingested from the connected participants.
- Those received from the cascading neighbors.

(a) Local Consensus **(b)** Intra-Region Consensus **(c)** Inter-Region Consensus

Figure 6: Illustrating the process of audio stream selection in AsTree

Then, when forwarding and distributing the selected audio streams, a media server does not send them back to where they are received. For example, a media server never sends an audio stream to its publisher again.

Another important characteristic of hop-by-hop audio selection is that it achieves asynchronous consensus on the selected active speakers among distributed media servers. Figure 6 exemplifies 3 possible states during the process (without being comprehensive). It depicts a scenario where participant a_1, b_1, c_2, and e_1 unmute together, and each media server only selects 2 audio streams for illustration.

- *Local consensus* (Figure 6a): At this phase, the unmuted audio streams are disseminated by their respective local media servers, but have not reached any cascading neighbors. So only participant c_1 hears its sibling speaker c_2.
- *Intra-region consensus* (Figure 6b): If the inter-region cascading link has much longer RTT, each region may agree on the selected intra-region active speakers, before receiving audio streams from other regions. Thus, participant c_2 is temporarily selected within region 1.
- *Inter-region consensus* (Figure 6c): In the end, every media server selects the same set of audio streams. Compared with Figure 6b, participant e_1 replaces c_2 as the second active speaker in region 1.

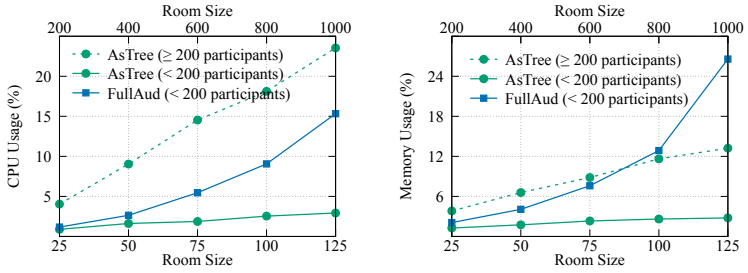
Figure 6 also shows that muted participants c_1 and d_1 also publish audio streams to their local media servers, which is the same as in FullAud. However, those muted audio streams are not considered in audio selection.

5.2 Dominant Speaker Identification

In Lark, RTP packets of an audio stream carry a header extension that indicates audio level [24]. It takes values from 0 to 127, representing $0 \sim -127$ dB. Media servers leverage that to select dominant active speakers, without processing raw audio. To avoid interference from non-vocal noise, we compare the weighted average audio level of each stream. It is computed from the most recent 15 audio packets (about 300 ms) of a stream, which are maintained in a per-stream ring buffer. To limit computation overheads, a media server computes a weighted average sample every 5 packets for each stream, and conducts audio selection every 50 ms (pseudo-code in Algorithm 1, with some engineering details omitted).

Instead of directly selecting L audio streams, we first pre-select at most L_i streams each time. If there are already L_i streams in the selected set S_A, a pre-selected audio stream is added to S_A only if it is louder than the least loud stream in S_A by an empirical margin (*extraCushion*). That limits the occurrence of frequent switching of selected streams. Once a stream is selected, it remains in S_A for at least a *smoothTime*. In our deployment, we set $L_i = 4$ and $L = 10$ by default.

Algorithm 1: Audio Selection



```
// S_A: set of selected audio streams
Pre-select at most L_i loudest audio streams as set S_t ;
foreach stream s ∈ S_A do
    if s ∈ S_t then
        s.lastSelected = now ;   S_t = S_t \ {s} ;
    else if now − s.lastSelected > smoothTime then
        S_A = S_A \ {s};
// louder stream has smaller audio level
foreach s ∈ S_t in order of increasing audio level do
    if |S_A| == L then break ;
    if |S_A| < L_i or s.audioLevel + extraCushion <
      GetMaxAudioLevel(S_A) then
        s.lastSelected = now ;   S_A = S_A ∪ {s} ;
```

As defined in [24], an audio level of 127 indicates a silent sample. Muted streams composed of silent samples are excluded from audio selection.

5.3 Signaling Overhead Mitigation

No Publish broadcast for audio. We do not broadcast Publish signaling messages specific to audio streams. The audio subscription process is initiated by media servers instead. Specifically, each media server caches the incoming SDP offers. Whenever a new active speaker is selected, it sends an updated SDP answer to cascaded media servers or connected participants. Immediately following that starts the transmission of audio RTP packets. Besides lowering signaling overheads, that avoids the subscription signaling round trip, and enables smooth change in the selected active speakers.

Aggregated Join. The Join message, unmerged from Publish, is solely used to notify the arrival of a new participant. When there are already a large number of participants in a room (*e.g.*, more than 50), it is both rare and hard for us to keep a close eye on every change to the participant list. Therefore, we do not necessarily need a Join broadcast specific to each newly joined participant. In that case, the local signaling unit aggregates

(a) CPU Usage **(b)** Memory Usage

Figure 7: Benchmark: AsTree uses less CPU and memory (Results of AsTree with ≥ 200 participants depicted in dashed line, refering to x2-axis on the top of the figures)

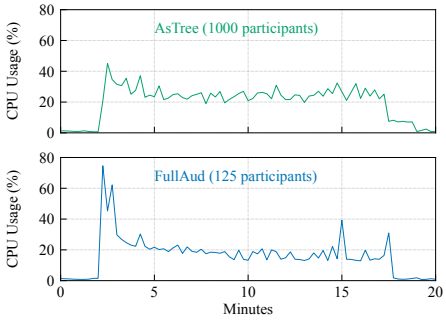


Figure 8: Example Benchmark Trials

Participant Type	Type Description
Type A	Active speakers that open both camera and microphone, and keep talking
Type B	Participants that leave their microphone unmuted but stay silent
Type C	Audience that close both the camera and the microphone

Table 2: Types of participants in benchmarking tests

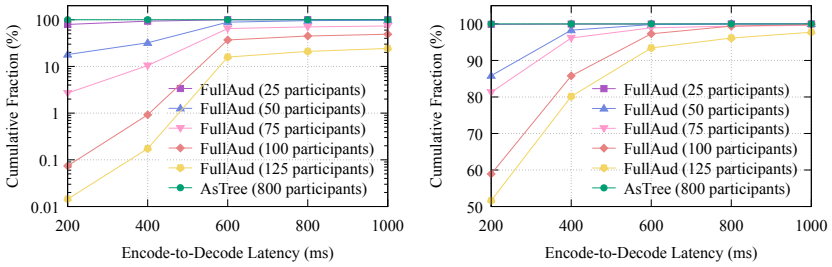
newly joined participants in a short interval (*e.g.*, every 1 second) into a single signaling message. The cancellation of audio Publish and aggregation of Join dramatically mitigate signaling storm in the beginning of conferences.[3]

No Mute/Unmute signaling. In FullAud, the displayed audio status on user interface is updated strictly according to the Mute/Unmute broadcast, which has to be triggered each time a participant clicks the mute/unmute button. AsTree totally eliminates that kind of signaling broadcast. A participant is displayed as unmuted if and only if the corresponding audio stream is selected. That said, an unmuted silent participant will not be displayed as unmuted. Such a mismatch is not a very important factor in terms of user experience. Indeed, we do not receive any negative reviews on that front.

6 Benchmark

FullAud has been fully replaced by AsTree in Lark's current deployment. To compare them from a micro-level perspective, we conduct benchmarking stress tests in our test environment. Media servers there are co-located with but isolated from our production environment servers, *i.e.*, test traffic does not interfere with real-world user traffic. Three types of participants are introduced as detailed in Table 2. Through command line parameters, we can initiate a controlled number of virtual participants for each type, and specify audio/video files as their microphone/camera output. Each virtual participant runs an instance of our Linux SDK on specialized server clusters in each region. Because we only focus on evaluation of the audio subscription architecture, we need to eliminate the influence of video simulcast. Thus, we use a single-resolution (360p) video to emulate the camera video of type-A participants. Also, we limit the number of type-A participants so that all participants in a room subscribes to the same set of all published video streams. Besides, we feed two separate recorded audio tracks to type-A and type-B participants, respectively.

Unless otherwise specified, we average results of 10 runs in each test setup, to avoid interference of other test traffic.



6.1 Media Server Capacity

AsTree forwards and distributes fewer audio streams and signaling messages than FullAud, and frees up considerable CPU and memory resources on media servers. To quantify that, we set up rooms with varying number of participants in a single region, all of which are forced to the same media server instance. Each conference lasts for 15 minutes, and involves 4 type-A participants, 4 type-B participants, and different number of type-C participants. In the beginning of each conference, we launch 50 participants per second, until reaching the target room size.

We first calculate average CPU and memory usage in the last 10 minutes of each trial (Figure 7). AsTree scales approximately linearly, and achieves increasingly significant gains over FullAud. That is because FullAud enforces quadratic subscriptions to all type-B and type-C participants, even though they mostly publish DTX frames. With 125 participants in a room, AsTree consumes 80.9% and 89.5% less CPU and memory than FullAud, corresponding to 5.2× conferences that can be held on a single server. Intuitively, the CPU busy time occupied by a 600-participant conference using AsTree is barely not enough for 125 participants under FullAud; the memory consumed by a 1000-participant AsTree-based conference can only support 100 participants under FullAud.

Figure 7 accounts for consumption of media processing in steady state. The capacity of a single media server also depends on the signaling overheads upon participants joining. We present the trend of CPU usage from a 125-participant conference under FullAud in Figure 8. Although it stabilizes at around 15% CPU usage, the initial peak is as high as 75% when many participants join together. In fact, given how we initiate a conference (*i.e.*, participants joining in bursts of 50), the media server instance crashes in the process of accommodating 150 participants using FullAud. That is why we only show FullAud's results with up to 125 participants in Figure 7. In comparison, the upper portion of Figure 8 exemplifies a 1000-participant room based on AsTree. The initial signaling peak is not obvious, despite having 8× participants.

[3] Leave/Unpublish in FullAud is replaced similarly.

(a) Audio **(b)** Video

Figure 9: Benchmark: AsTree reduces end-to-end latency

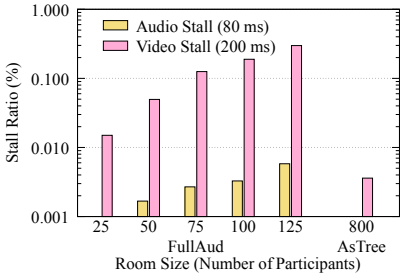


Figure 10: Benchmark: AsTree lowers stall ratio for both audio and video

Taking both media and signaling processing into consideration, AsTree can increase both the maximum conference scale and the number of concurrent rooms supported by a single server instance by as high as an order of magnitude, especially when it comes to massive-scale conferences.

6.2 User Experience

The decreased volume of traffic forwarded and distributed by AsTree mitigates cascading and last-mile congestion. That should eventually improve both audio and video QoE. To validate that, we test with a similar room setup as above, with 4 type-A participants, 4 type-B participants, and various type-C participants. This time, we load-balance participants to multiple media servers within the same region, instead of sticking to a designated media server.

We start with end-to-end latency (Figure 9), measured as the duration from when a media frame is encoded at publisher to when the same frame is decoded at subscriber. For AsTree, all audio and video frames are decoded within 200 ms. Yet due to interference from signaling storm and super-linear number of subscribed audio streams, the performance of FullAud deteriorates quickly as the room size grows. For instance, with 125 participants per room, merely 0.014% of audio frames are decoded within 200 ms, and the proportion is 51.6% for video frames. Even when we relax the latency target to 1000 ms, a 800-participant AsTree-based conference is 312% and 2.3% better than a 125-participant FullAud-based conference in terms of audio and video latency, respectively.

We note that the DTX frames from type-B and type-C participants, which have the lowest transmission and decoding priority, are also included in calculation. That leads to the extremely high audio latency by FullAud in Figure 9a. However, our test results still correctly reflect the performance trend of FullAud under different room sizes. That can be confirmed by the video latency in Figure 9b, as well.

Furthermore, lower end-to-end latency contributes to fewer stalls. In Figure 10, we plot the audio and video stall ratios, computed as the percentage of playback time in which the stall is longer than 80 ms and 200 ms, respectively. FullAud accomplishes zero audio stall only under a room size of 25 participants, while AsTree maintains zero audio stall with 800 participants. As for video stall, AsTree with 800 participants achieves a dramatic reduction of nearly two orders of magnitude, compared with FullAud with 125 participants.

Therefore, by optimizing the architecture of audio subscription, AsTree simultaneously delivers better audio and video experience at a larger conference scale.

7 Deployment

AsTree's initial deployment in Lark dates back to August 2021. It completely replaced FullAud in March 2022, and has been running at full scale since then for over two years. To demonstrate its effectiveness in improving user experience, we present the trend of three key indicators over 30 weeks ending in January 2022 in Figure 11. During that period, Lark served more than 100 million conferences. All data are normalized for confidentiality. We note that there were several parallel optimizations in Lark's audio codec starting late January 2022. We do not show results beyond that to isolate the gains by AsTree.

QoE Metrics. The audio and video stall ratios in Figure 11 account for stall duration longer than empirical thresholds of 80 ms and 200 ms, respectively. Over the presented period after AsTree was deployed, they were improved significantly at the same time: the median and 95th percentile audio stall ratios were reduced by more than 30% and 45%; corresponding reductions in video stall ratios both exceeded 50%. In practical deployment, an important factor contributing to such improvements is that AsTree alleviates congestion on participants' access links, which usually have more limited bandwidth than our test environment for stress tests (§6.2).

Additionally, we present the audio stall ratio partitioned in different range of room sizes in Figure 12. It is averaged from a recent month. We can see that a conference with more than 350 participants does not even double the audio stall ratio over a small-scale conference with only 3 to 5 participants. We regard that as acceptable for a global system like Lark, considering increasingly heterogeneous participant access bandwidth and geo-distributed regions under larger rooms.

User Satisfaction. Along with better QoE comes higher user satisfaction. We observed a reduction of around 40% in the ratio of negative reviews in Figure 11. The ratio of negative reviews complaining specifically about bad audio or video experience was also reduced by 40%, closely following the trend of overall negative reviews. That indicates the QoE gains by AsTree were the dominating reason that raised our

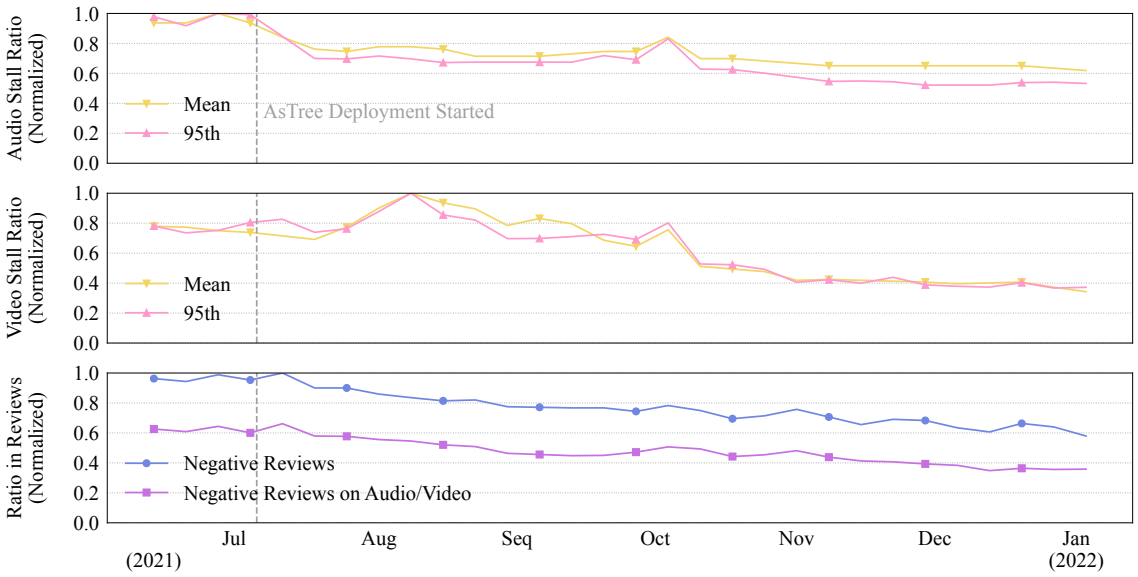

Figure 11: Trend of stall ratios, and negative review ratio after AsTree was deployed (median and 95th stall ratios are normalized independently)

user satisfaction. Moreover, if we look at the ratio of negative reviews under different room sizes (Figure 13, averaged from a month for both architectures), AsTree effectively narrows the gap of user experience under large and small conferences.

Cascading Complexity. A remaining concern on AsTree is whether it induces excessive cascading links and impacts user experience, *i.e.*, due to selection of region and master delegates. Enhanced user satisfaction shown above implies that does not occur to most participants. To confirm that more directly, we monitored the number of cascading links needed to forward and distribute a subscribed stream for two weeks earlier in 2024. On average, Lark only increases the number of cascading links per stream by 5.7% compared with other ByteDance RTC applications. Thus, the AsTree cascading topology has restricted adverse influence on QoE, indeed.

8 Discussion

In this section, we share some practical insights drawn from deployment experiences, and potential future work directions.

8.1 More Implementation Details

Participant aggregation. Because signaling storm is significantly mitigated, AsTree enables us to aggregate more participants on a single media server, so as to reduce the number of intra-region cascading links. Participant aggregation saves server-side costs on media servers and bandwidth, and lowers the complexity of participant migration upon failover. While achieving aggregation, we may need to redirect a joining participant to a different media server from the one retrieved through DNS. In that case, we notify the participant with a customized signaling message. Other approaches, such as DNS redirection as adopted by many CDN systems [12, 25], may also fulfill the same purpose. Meanwhile, to avoid overloading a single media server, we configure the upper limit of aggregation to 200 participants per room per server.

Cascading connection reuse. Before forwarding audio streams to and from a newly involved media server, we need to establish a cascading connection and accomplish SDP negotiation. To reduce latency and start media transmission as soon as possible, we try to reuse existing connections on the same cascading link. That means a cascading connection may carry audio streams of multiple conference rooms. Two corresponding configuration parameters are introduced. First, we restrict the maximum number of (RTP) streams allowed on a cascading connection, in case they impact the processing efficiency of the thread worker. Second, we set a timeout of several seconds before closing an idle cascading connection, during which it may be reused again.

Decoupled video and audio subscription. In the media plane, the AsTree cascading tree topology is independent of the routing and forwarding of video streams. In the control plane, the bandwidth reserved for audio streams before allocating to video streams of different bitrates is bounded and thus, more predictable. That ensures great flexibility for innovations in either video or audio subscription architecture. We do not need to worry about interfering video simulcast while implementing and deploying AsTree. As for the synchronization of video and audio streams of the same publisher, we rely on jitter buffer on client side. That fulfills the current latency requirements of multi-party conferencing.

Fault tolerance. Fault tolerance in AsTree is in essence the same as in video simulcast, *i.e.*, ensuring connectivity between each pair of participants. We mainly handle two types of failures, which are broken cadcading link and crashed server/cluster. The routing of each overlay cascading link is managed by our centralized SDN controller. When we observe abnormal RTT inflation and loss rate on a specific cascading link, we switch to a back-up path without awareness of conference participants and SFU media servers. If a

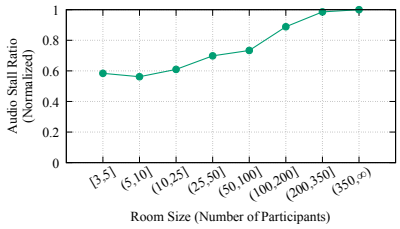

Figure 12: Audio stall ratio after AsTree is fully deployed

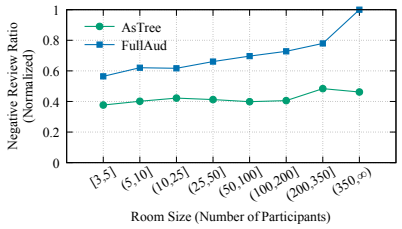

Figure 13: Negative review ratios before/after AsTree's deployment

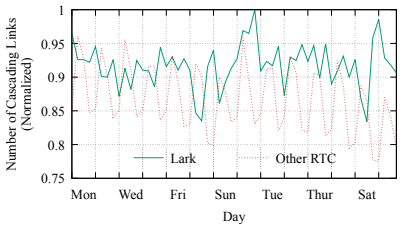

Figure 14: Number of cascading links per stream subscription

media server or a cluster crashes, participants already connected to a faulty server will go through a connection timeout, triggering a request to the control plane for a new SFU. The original faulty server is replaced by the new SFU in the AsTree topology, and overlay cascading paths are re-established. In that process, the faulty server(s) will be blacklisted by our scheduler until they recover from connection issues.

8.2 Other Implementation Options

Mesh *vs.* AsTree. The select-before-forward audio selection as detailed in §5 can also work when media servers are cascaded by a mesh. In that case, each media server selects audio streams from those injected from its connected participants, and forwards to all the other media servers. Compared with an AsTree, a mesh topology has shorter cascading paths on average, but induces more cascaded audio streams. For example, a conference room involving M media servers cascades at most $2L(M-1)$ audio streams with a cascading tree, which is no larger than $L \cdot M(M-1)$ when using a mesh. Considering that AsTree can satisfy the latency requirements of multi-party conferencing, we adopt it for lower deployment cost.

Audio stream SSRCs. Some existing service providers use a fixed set of negotiated RTP SSRCs [26] for the selected audio streams [27, 28]. Our web SDK also adopts similar solution, due to lower development workloads based on the WebRTC codebase. However, that requires the media server to make sure the participants receive consecutive sequence number and monotonous timestamp under each SSRC. To avoid such processing overheads, while implementing the native SDK of Lark application, we choose to let each media server generate a random SSRC each time an audio stream is selected, even if it is from a speaker that is previously selected. That said, different participants may observe different SSRCs for the same selected audio stream at the same moment; and the same participant may observe different SSRCs for the same speaker during a conference. The identity of each selected speaker is notified to participants through the updated SDP answer triggered by the media server (§5.3).

8.3 Effectiveness and Applicability

Benefits for all conference scales. Although designed to support massive-scale conferences, AsTree achieves significant gains in small-size conferences, as well. That is because a muted audio stream, although requiring lower bandwidth, consumes almost the same amount of memory and comparable CPU as an audio stream from an active speaker. Therefore, AsTree can serve as a general-purpose architecture that benefits a broad spectrum of cases, and we enable it by default.

Extended application scenarios. AsTree has been adapted to support more advanced use cases. An example is to provide simultaneous interpretation for foreign participants in international conferences. A channel attribute can be added to the original and interpretation audio streams. Participants can subscribe to the original channel, the interpretation channel, or both channels on demand from Lark user interface, and selection of audio streams at each media server can be conducted accordingly on a per-channel basis.

8.4 Future Directions

Joint video and audio optimization. Although audio and video subscription are decoupled in media plane, there may be QoE benefits to jointly optimize the cascading topology of video and audio streams in control plane. For example, in a typical conference where an invited speaker presents slides via screen sharing, the audio and screen video streams of the presenter may share a cascading tree rooted at the corresponding local media server, which also facilitate the synchronization of the speaker's audio and video signals.

Dynamic AsTree topology deformation. Given latency requirement of multi-party conferencing nowadays (*e.g.*, up to hundreds of milliseconds), we adopt a straightforward heuristic to select intra-region and master delegates, and rarely change the role of each media server (§4.3) during an ongoing conference. Yet doing so improves user experience in some cases. In the above example with an invited speaker, if we continue to the next speaker on the agenda who is in another region, it lowers the latency from the new speaker to the audience to switch the master delegate, as well. Such a deformation may even become inevitable as we keep pursuing more real-time interactivity. Therefore, we plan to work on a highly efficient deformation mechanism based on an established cascading topology. In the example of switching to a new speaker, it may be triggered by dynamically assigned cascading path weights. Besides, it can also be used for media server migration and failover.

Formulation of AsTree calculation. Similar cascading topology may also apply in other application scenarios such as live streaming. Our current objectives listed in §4.2 only optimize

the cascading path latency. When aiming at more latency-sensitive future-proof applications, we may need to refine the problem formulation and express the QoE target more accurately. For example, an additional term representing per-media server processing latency may be added, if that accounts for a fair proportion in the overall end-to-end latency. For compute-intensive applications (*e.g.*, cloud rendering [29, 30], artificial video generation [31]), the computing resource consumption may be explicitly captured, especially when leveraging limited computing power at the edge [32]. Furthermore, in extreme cases with multiple concurrent continuous publishers, a more complicated topology than a single tree may be needed.

9 Related Works

Dominant speaker identification (DSI). DSI is not a new problem in the context of multi-party conferencing. Volfin *et al.* identified the dominant speaker by computing per-participant immediate, medium-term, and long-term speech activity scores [11]. However, the computation was based on frequency representation of audio frames. That is not available on an SFU without decoding audio streams. Inspired by [11], Jitsi introduced LastN [10], and computed speech activity score directly from audio levels carried in RTP header [24]. Different from AsTree, LastN was used to make sure only dominant speakers' video streams are forwarded. It remained full subscription for audio streams. Similar DSI method is often utilized in video subscription to track and render the active speaker view [33, 34].

Audio selection. Full audio subscription was adopted by many service providers previously, some of which stick to that till now (*e.g.*, Twilio [8]). As the popular conference scale continues to grow, several service providers have started to support audio selection based on DSI in recent years. The audio mixer in early-stage WebRTC codebase mixed at most 3 audio sources [35], but it ran on client side. Google Meet and Google Duo forwarded the 3 loudest speakers with fixed SSRCs [27]. Jitsi introduced a "loudest" feature, which only forwards a configured number of loudest audio streams [36]. Agora allowed audio-strength stream selection based on audio volume [37]. Nevertheless, limited details are revealed about those schemes. Some providers such as Jitsi and Agora still disable audio selection in their default configuration. AsTree is the first to share the architecture and performance of audio selection from a large-scale practical deployment.

Conferencing architecture. For audio subscription, there are still a few services implementing Multipoint Control Unit (MCU) to get a single mixed audio streams [38, 39]. Yet for video subscription, SFU has been the choice by a majority of popular conferencing providers [6, 16, 17, 40], due to lower overheads on server side. Both simulcast and SVC can rely on the SFU architecture. In simulcast, each participant encodes multiple video streams in different bitrates, and the SFU determines which stream to forward to which participant. A representative example is GSO-Simulcast [5], where a centralized controller orchestrated the resolution and bitrate of video streams. SVC leverages scalable video codec [41] to include multiple layers in a single video stream, so that it can be adapted to multiple bitrates. Zoom is claimed to belong to this category [42]. AsTree is compatible with the SFU-based video subscription architecture.

In addition, focusing on routing in the media plane, existing works such as LiveNet [12] and VIA [43] constructed overlay cascading paths, enabling participants to access the service through the nearby edge. Aimed at resource provisioning for conferencing services, Switchboard [20] enforced peak-aware server allocation and capacity provisioning. Those works are complementary to AsTree.

Measurements of multi-party conferencing. Recognizing the importance of multi-party conferencing and the challenges it brings to the network, researchers conducted extensive measurements of popular applications on the market [6, 44–48]. On one hand, by analyzing their protocol encapsulation and session behaviors from collected traces, they confirmed the usage of simulcast by many conferencing applications, including Google Meet, Microsoft Teams, WebEx [44]. On the other hand, owing to lack of abundant resources of media servers, it is hard to capture the global picture under massive conference scales. For example, authors of [46] conducted small-scale experiments with only up to 6 participants.

10 Conclusion

In this paper, we present our design of AsTree, the architecture specifically for audio subscription aimed at massive-scale multi-party conferencing in Lark. AsTree evolved from our early-stage implementation of FullAud, which was based on full audio subscription. For each conference room, it constructs a two-hierarchy (intra-region and inter-region) cascading tree composed of all involved media servers, and enforces per-hop audio selection while forwarding audio streams. AsTree eliminates the signaling broadcasts triggered by participants' muting/unmuting operations.

After serving millions of conferences in several years of deployment, AsTree is proved to significantly improve the scalability of Lark. Thanks to dramatically mitigated signaling storm and fewer number of audio streams to forward, AsTree improves the capacity of media servers by nearly an order of magnitude compared with FullAud. Meanwhile, less congestion on last-mile and cascading links results in enhanced QoE. In our practical deployment, the median audio and video stall ratios are reduced by 30% and 50%, respectively. That comes with a 40% reduction in the ratio of negative reviews.

To fulfill even more stringent latency requirements, we envision more flexible and dynamic cascading topology calculated from more realistic QoE objectives in the future.

Abstract

The collective communication libraries are pivotal in optimizing the performance of distributed and parallel deep neural network (DNN) training. Most network optimizations are under the assumption that these libraries are well-tuned, ignoring their low-level parameter selection. In this paper, we present a novel automated tuning method AutoCCL that significantly improves communication performance without incurring additional costs. One of the primary challenges we tackle is the state explosion in searching for the optimal configuration. To overcome this, we decouple implementation-related parameters from those sensitive to the search space size and propose a divide-and-conquer algorithm, minimizing the requirement for exhaustive trials. We further propose an online tuning approach that accounts for communication-computation interference to enhance accuracy in finding optimal configurations, while hiding tuning overhead within early iterations of training jobs. We implement AutoCCL atop NCCL, a leading and widely-used communication library provided by NVIDIA. Our evaluation on both a 2-node cluster (16 A40 GPUs, intra-node NVLink, inter-node 2× 400Gbps InfiniBand) and a 4-node cluster (32 A40 GPUs, intra-node PCIe, inter-node 100Gbps InfiniBand) demonstrates that AutoCCL achieves 1.24-1.29× and 1.15-1.22× speedups on microbenchmarks compared to NCCL and another SOTA NCCL tuner, respectively, and up to 1.80× and 1.49× with concurrent computation. End-to-end evaluations on three large language models and one vision model show 1.07-1.32× improvements in per-iteration training time.

1 Introduction

Training contemporary DNN models often distributes computation over a cluster of GPUs and relies on collective communication primitives to frequently exchange model data in a group-wise manner. However, many studies have pointed out that communication is a well-known bottleneck that throttles training performance [14, 26, 27, 33, 34, 36].

Communication optimization has become a research hotspot, garnering growing interest including communication-computation overlapping [13, 19, 22, 23, 31, 43, 46, 50, 59, 60, 67], message compression [9, 53, 56, 62], and new collective algorithm design [10, 12, 15, 16, 27–29, 32, 35, 42, 47, 57]. These proposals assume the off-the-shelf communication libraries such as NCCL [5] to be already well-tuned. Some works [12, 47] have attempted to provide empirical guidance, but in Section 3.1, we have found that the guidance is not always correct in practice. Besides, our study highlights that collective communication tasks can be further improved, e.g., up to 35% higher bandwidth, by tuning low-level performance-sensitive parameters. Unfortunately, these libraries are often used as black boxes, and the potential for tuning them across different hardware and communication tasks is overlooked.

In this paper, we propose AutoCCL, a tool for automatically tuning collective communication with accelerated end-to-end training performance. Compared to existing communication optimizations, AutoCCL aims to provide *a free lunch* and transparently support upper-level training jobs, maintaining model accuracy without requiring additional hardware investment. However, AutoCCL's design faces the following challenges:

First, existing work lacks a comprehensive analysis of the mainstream collective communication libraries to identify key performance-sensitive parameters as tuning candidates, understand the joint impact of these parameters, and establish practical tuning guidelines. Second, computation and communication are executed concurrently during training. Therefore, tuning for communication also necessitates accounting for computational interference. This understanding needs to be further adapted to different hardware, as well as the dynamics in the concurrent combination of computation and communication due to runtime scheduling.

To address the above challenges, we propose the following innovations. First, we conduct a comprehensive tuning study (Section 2.3 and Section 3) to identify six low-level NCCL parameters that are performance-sensitive, forming a very large search space. Then, we experimentally analyze and theoretically model these parameters and the relationships among them and make some important and instructive

This research project began in June 2023.

observations. For example, the parameters can be classified into two categories, one defining the implementation method of communication primitives and the other determining the resource allocations. The former is a prerequisite for the latter, and the former has a small range of values while the latter has a large range of values. In addition, we analyze the resource parameters using the control variable method and find that their combination is characterized by a unimodal function on the communication bandwidth. These findings are far beyond a recent preliminary study [64].

Second, guided by the aforementioned analysis, we design an efficient tuning algorithm (Section 4) that avoids a brute-force search within the parameter space. This algorithm handles implementation parameters and resource parameters separately. Since the combinations of the former are relatively few and the analysis of resource parameters must begin with the determination of the communication task, the tuning algorithm first divides the implementation parameters into several subspaces, each representing an independent search task. Within any given subspace, we employ a coordinate descent method to search for the optimal combination of resource parameters. This approach is feasible because the characteristics of unimodal functions indicate that their combination to the communication bandwidth curve will initially increase, then reach a peak, and subsequently decrease gradually until reaching a steady state (at which point bandwidth becomes the bottleneck).

Finally, we propose an online tuning method (Section 5) that co-runs with training. We exploit the iterative nature of DNN training (where identical communication tasks are repeated throughout the training process) to integrate the tuning process into the initial training iterations. Once the optimal configuration is obtained, it is updated via atomic broadcast to all nodes participating in collective communication for consistent future usage. The advantage of this online approach is that we can directly capture the performance of communication primitives under the influence of computational interference and scheduling dynamics. After integrating this into the tuning algorithm, the performance analysis achieves higher accuracy, thus eliminating the need to model uncertain factors directly, such as hardware capabilities and the concurrency of tasks in the real training environment.

We implemented the tuning tool `AutoCCL` on top of NCCL, a leading and widely adopted collective communication library. `AutoCCL` maintains compatibility with the NCCL interface, allowing it to seamlessly integrate with training frameworks like PyTorch and transparently support any DNN model training task. We've made it open-source `AutoCCL` [2]. We conducted extensive testing on a 4-node cluster with 32 A40 GPUs and a 100Gbps network, as well as a 2-node cluster with 16 A40 GPUs and two 400Gbps links. Pure communication experiments with different communication primitives show that, compared to NCCL and AFNFA [64] (the most recent NCCL tuner), our communication bandwidth speedups are 1.24-1.29× and 1.15-1.22× higher, respectively. In microbenchmark experiments with computational interference, the results show that `AutoCCL` achieves even greater average gains, with improvements of 24.1% and 20.7%, respectively. Additionally, we conduct end-to-end training tests on three popular large-scale models and one computer vision model. Compared to NCCL and AFNFA, `AutoCCL` achieves average training speed improvements of 16.7% and 14.5%, respectively, with gains of up to 32% on some large models. Note that the training gains have taken tuning overhead into account, and since `AutoCCL` converges quickly, the tuning overhead is negligible.

In summary, we make the following contributions:

- A comprehensive study that uncovers the tuning guidelines of low-level performance parameters of collective communication primitives in NCCL, a leading communication library;
- An online tuning method that implements the parameter subspace division and intra-subspace coordinate descent search algorithms and leverages training iterativeness for accurately modeling the impacts of parameter assignment in the context of computational interference;
- The `AutoCCL` tuner that incorporates this tuning method and transparently supports training jobs;
- An in-depth evaluation of `AutoCCL` compared to NCCL and another state-of-the-art tuner on communication micro-benchmarks and representative training jobs.

2 Background

2.1 Distributed and Parallel DNN Training

It has been a common practice to distribute and parallelize DNN training jobs over a cluster of GPUs for fast model parameter updating [17, 20, 24, 25, 30, 37–39, 44, 45, 48, 49, 51, 55, 58, 66]. For instance, as shown in Table 1, when the model size does not exceed a single GPU's memory budget, *data parallelism* is often employed to let GPUs consume disjoint data partitions for collective model training. This requires GPUs to frequently synchronize gradients, with the transmission volume equal-sized with model parameters. When a model's memory consumption exceeds the GPU capacity, in addition to *data parallelism*, AI participants employ either *tensor parallelism* or *pipeline parallelism* to partition a model into smaller computational units, which are distributed across various GPUs. This results in more complex communication patterns among GPUs, which are often on the critical path of the training pipeline, compared to *data parallelism*. Recently, various studies have already proved that communication is the major bottleneck that limits the scalability of distributed and parallel DNN training [14, 26, 27, 33, 34, 36].

A wide range of optimizations aim to address communication bottlenecks, including scheduling [13, 19, 22, 23, 31,

Table 1: The parallelism and collective communication primitives used by training 4 DNN models on a cluster of 32 GPUs (four machines). *B* stands for billion model parameters. *TP*, *DP*, and *PP* stand for tensor parallelism [48], data parallelism [32], and pipeline parallelism [20], respectively. The numbers in parentheses following these parallelism approaches represent the corresponding number of GPU participants. For each collective communication primitive, its (*x_y_z*) value represents that an *x*-sized message is exchanged among a *y*-sized communication group for *z* times per training iteration.

Model	Phi-2-2B	Llama-3.1-8B	Yi-1.5-34B	VGG-19-0.14B
Parallelism[1]	TP (8) + DP (4)	TP (8) + DP (4)	TP (8) + PP (4)	DP (32)
AllGather	(80 MB_8_3,120)	(128 MB_8_6,240), (857 MB_4_1)	(56 MB_8_61,440)	—
ReduceScatter	(80 MB_8_2,064)	(128 MB_8_4,128), (1,710 MB_4_1)	(56 MB_8_93,184)	—
AllReduce	(632 MB_4_1)	—	—	(15-392 MB_32_6)

46, 50, 59, 60, 67], data compression [8, 9, 53, 56, 62, 63], sparsity exploration [10, 28], and topology-based algorithm design [12, 15, 16, 27, 29, 32, 35, 42, 42, 47, 57]. The vast majority of these approaches focus on improving communication performance based on the assumption that the underlying communication library is well-tuned and will effectively deliver their improvements. However, we have experimentally validated that the communication tuning matters a lot in Section 3 with significant bandwidth benefits.

2.2 Collective Communication

Distributed and parallel DNN training introduces a distinct class of communication patterns, known as *collective communication*, where data is aggregated or disseminated across multiple GPUs. The NVIDIA Collective Communication Library (NCCL) is designed to optimize multi-GPU and multi-node communication for NVIDIA GPUs and networking systems [5]. It offers high-performance primitives like *ReduceScatter*, *AllGather*, *AllReduce*, and so on. These APIs are optimized to provide high bandwidth and low latency communication over PCIe and NVLink interconnects within a single node, as well as over networks across multiple nodes. In addition, RCCL (ROCm Collective Communication Library) [1] is AMD's counterpart to NCCL. In this paper, we focus on NCCL since it is the most widely used and its design philosophy has influenced followers such as RCCL.

Table 1 summarizes the training parallelisms for the four deep neural network training tasks, including three large language models and a computer vision model, with typical message sizes and the collective communication primitives used. The detailed hardware and workload configurations can be found in Table 8. Of the four model training tasks, the VGG-19 model is the smallest, necessitating the use of only data parallelism. VGG-19 employs 32-way data parallelism, so every GPU needs to exchange its six bucketed gradients (15-392 MB in size) with any other GPU within the 32-GPU communication group via *AllReduce* in each iteration.

Unlike VGG-19, the other three large language models utilize a complex hybrid parallelism, combining 8-way tensor parallelism and 4-way data parallelism or 4-way pipeline parallelism. In such a configuration, for example, Yi-1.5-34B executes *AllGather* 61,440 times in a single training iteration, each time transferring 56 MB of activation data among eight GPUs within a single machine. It also executes *ReduceScatter* 93,184 times, each time passing 56MB of activation data between eight GPUs to each other within a single machine. Phi-2-2B and Llama-3.1-8B transfer more data each iteration, up to 1,710 MB, as it also requires transferring the model gradient along the data-parallel dimension between four GPU servers with *AllGather*, *ReduceScatter*, and *AllReduce*, respectively, due to their four-way data parallelism.

In summary, multiple types of collective communication primitives are frequently used in distributed DNN training, with message sizes ranging from tens of MB to a few GB, varying communication group sizes, and hardware setups. Therefore, it is crucial to efficiently execute communication tasks despite their complexity and variety.

Table 2: Primitive configuration parameters of NCCL

Parameter	Value Range
Algorithm (A)	Tree, Ring
Protocol (P)	LL, LL128, Simple
Transport (T)	peer-to-peer (P2P), shared memory (SHM)
Nchannel (NC)	$1 \le n \le 128, \quad n \in \mathbb{N}$
Nthread (NT)	$n = 32 \times i, \quad i \in \{1,2,3,\ldots,20\}$
Chunk size (C)	$n = 256 \times i, \quad i \in \{1,2,3,\ldots,8K\}$

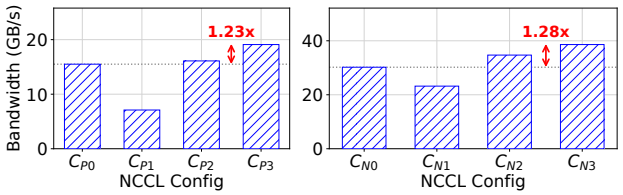
2.3 Low-Level Primitive Configurations

We conduct a systematic and comprehensive study of NCCL's parameter space, analyzing all 158 parameters, including 93 undocumented ones. Our findings reveal that NCCL has 28 performance-sensitive parameters, categorized as follows: 1 for *algorithm* (*A*), 3 for *protocol* (*P*), 3 for *transport* (*T*), 11 for *nchannel* (*NC*), 3 for *nthread* (*NT*), and 7 for *chunk size* (*C*). Other parameters will be discussed in Section 8. When users call a communication primitive, NCCL runtime will create a corresponding collective communication task, and assign it a *configuration* in the form of $< A, P, T, NC, NT, C >$. As shown in Table 2, the parameter *A* determines how data is distributed, combined, or aggregated across GPUs and has several possible values like ring or tree. Specifically, when a *ring* algorithm is used for the *allreduce* primitive, data is transferred sequentially between nodes in a ring-like fash-

Table 3: Various configurations of *AllGather* (80MB) on the 8-GPU node with intra-node **PCIe** w.r.t. varied NCCL configurations. C_{P0} refers to the default NCCL configuration.

Config	A	P	T	NC	NT	C
$C_{P0}{}^{*}$	Ring	Simple	SHM	2	256	2 MB
C_{P1}	Ring	Simple	P2P	2	96	32 KB
C_{P2}	Ring	Simple	P2P	8	256	32 KB
C_{P3}	Ring	Simple	P2P	8	96	32 KB

ion for both reduction and broadcast phases. *P* defines how data is moved across GPU memory hierarchies and managed within the GPUs, such as loading data into the GPU cores (SMs) and performing necessary operations (like reductions). Among its options, *LL* stands for the Low-Latency protocol, optimized for small message sizes to minimize latency. *T* refers to the mechanism used for physically transferring data between GPUs, either within the same machine or across different machines. For instance, its *P2P* (Peer-to-Peer) option defines a direct connection between GPUs bypassing CPU, typically using NVLink or PCIe. *SHM* refers to enabling data transmission between certain GPUs via shared memory.



The remaining three parameters correspond to the allocation of resources or the degree of parallelism during communication. First, for a large message, NCCL will decompose data into *NC* partitions, with each partition bonded to a threadblock for independent transmission and processing. Each threadblock consists of a certain number of threads, defined by *NT*. In addition, each data partition can be further decomposed into several chunks, with the size defined by *C*. Therefore, *NC* threadblocks are transmitted chunks concurrently, and each threadblock processes its chunks sequentially.

3 NCCL Tuning Opportunities

However, we find that the default configuration of NCCL is often not optimal, and tuning the parameter values of the configuration can have a huge impact on communication performance during the DNN model training. Therefore, here, we will show the improvement of communication performance, as well as the positive impact during training performance through several examples.

3.1 Stand-alone Communication

Here, we consider communication tasks running alone without any interference. First, we take the $< AllGather, 80M, 8-A40-PCIe >$ communication task from the Phi-2-2B model in Table 1, i.e., *AllGather* aggregates 80MB data among 8 A40 GPUs in a single machine. Table 3 lists four primitive configurations that are used in the test. Figure 1 reports the communication bandwidth (higher is better). The best configuration C_{P3} achieves 2.69× the bandwidth of the worst configuration C_{P1}. The difference is that C_{P3} splits the message into more data partitions (larger *NC*), which are split into smaller chunks (smaller *C*), while adjusting the number of threads (*NT*) to align with the transmission granularity (*C*).

(a) PCIe (b) NVLink

Figure 1: Bandwidth comparison of using various NCCL configurations for <AllGather, 80M, 8-A40-*>

Table 4: Various configurations of *AllGather* (80MB) on the 8-GPU node with intra-node **NVLink** w.r.t. varied NCCL configurations. C_{N0} refers to the default NCCL configuration.

Config	A	P	T	NC	NT	C
$C_{N0}{}^{*}$	Ring	Simple	P2P	8	512	2 MB
C_{N1}	Ring	Simple	P2P	64	512	108 KB
C_{N2}	Ring	Simple	SHM	8	512	108 KB
C_{N3}	Ring	Simple	SHM	64	512	108 KB

Table 5: Various configurations of *AllReduce* on the 8-GPU node with intra-node **PCIe**. Each task is shown in the format x, y, where x indicates the message size and y represents the communication group size. *P* and *T* are omitted as they are set to Simple and SHM, respectively, across all configurations. C_0 refers to the default NCCL configuration.

Task	Config	A	NC	NT	C	Bwd (GB/s)
64 MB, 16	$C_0{}^{*}$	Ring	2	256	512KB	4.0
64 MB, 16	C_1	Tree	2	256	512KB	5.4
64 MB, 16	C_2	Tree	8	160	59 KB	8.9
15 MB, 8	C_3	Tree	8	160	59 KB	8.1
15 MB, 8	C_4	Ring	10	128	27 KB	8.8

All these parameters are set to utilize the parallel computing power of GPUs and the network transmission bandwidth. Compared to C_{P3}, C_{P1} uses a smaller concurrency count *NC*, leading to significant performance degradation. The performance of C_{P2} is lower than C_{P3}, even with an increase in the number of threads. It is worth noting that C_{P0}, the NCCL default configuration determined by NCCL's built-in cost model, is not optimal; its bandwidth is only 81.2% of that of C_{P3}.

Second, we run the aforementioned *AllGather* task in a new hardware environment with GPUs interconnected via NVLink instead of PCIe. As shown in Table 4, we test 4 configurations, namely, C_{N0} to C_{N3}. Figure 1 shows that the best configuration C_{N3} reaches 1.28× the bandwidth of the worst configuration C_{N0}. By comparing C_{N0} (the default configuration selected by NCCL) with C_{N3}, we observe that *T* plays a significant role, as C_{N3} employs share-memory (SHM) communication with better performance. By comparing C_{N3} with the second best performing C_{N2}, using more channels leads to better parallel performance, consistent with our observation in the PCIe experiment. Also, comparing C_{N1}, C_{N0} and C_{N3}, we can find that increasing *NC* plays the exact opposite role when setting the *T* parameter as P2P.

Table 6: Bandwidth of *AllGather* (80MB) on the 8-**NVLink**-GPU node w.r.t. varied computational interference levels

Interference level	NCCL Bwd	Tuned Bwd
Communication-only	30.08 GB/s	38.62 GB/s
Light computation	26.21 GB/s	35.14 GB/s
Heavy computation	18.26 GB/s	32.44 GB/s

Finally, we investigate the joint effect of different communication tasks, different hardware environments, and different configuration parameter choices. To this end, we take the *AllReduce-64MB* and *AllReduce-15MB* communication tasks from the VGG19 model, as listed in Table 1, running on a single machine with 8 A40 GPUs and two machines with 16 A40 GPUs, with PCIe for intra-node network and 100 Gbps InfiniBand for inter-node network. We test five configurations, with performance shown in Table 5. Comparing C_0 and C_1, we find that the algorithm parameter A becomes the key factor to performance as NCCL's default algorithm misjudging that the Ring algorithm better fits current hardware, but Tree is better in practice. Besides, if applying the best configuration C_2 for task $< AllReduce, 64MB, 16 >$ to the task $< AllReduce, 15MB, 8 >$ as C_3, it will be approximately 10% lower than the performance reached by C_4, indicating that configuration rediscovery is needed, even for very similar tasks. Comparing C_3 and C_4, we find that Ring algorithm is a better choice, and increasing the degree of parallelism (*NC*) can indeed enhance performance. In addition, we need to shrink both the minimum granularity of the transmission C and the number of threads *NT*.

According to all the experiments above, we observe that the default configurations determined by NCCL are often not optimal, leaving significant performance potential to NCCL parameter tuning. Our experiments in Section 6 prove that this problem also exists in multiple nodes. For various tasks on the same hardware or even the same task on different hardware, different optimal configurations are also needed. Also, it is not clear whether there is a certain pattern in the selection of parameters and the interactions between those parameters. Therefore, one needs to add an auto-tuning function so that the training task running above NCCL freely enjoys the optimized fast communication.

3.2 Concurrent Computational Interference

Communication and computation tasks without data dependencies are usually executed concurrently, and it is infrequent for communication to occupy resources exclusively. The competition between computation and communication for GPU resources, especially SM, cache, and global bandwidth, will cause the performance of each to degrade. Therefore, to better study the configuration tuning of NCCL communication tasks, especially in the presence of resource contention caused by computation tasks, we design the following NCCL tuning experiments with computational interference.

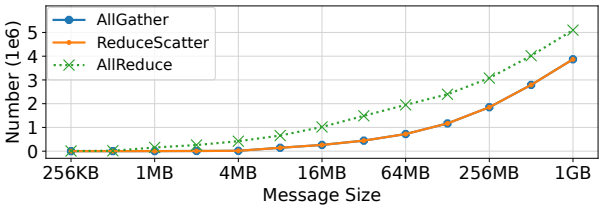


Figure 2: Combinations number of different communication

We introduce extra computational tasks over the *AllGather* communication task from Table 4, and take default configuration of NCCL as a baseline. The computational task we used is GEMM [4], which computes matrix multiplication A[m, k] $\times$ B[k, n] operation followed by a sigmoid [7] operation. Here, we choose different values of m, k, n in GEMM to represent the light and heavy computations. Table 6 shows that computational interference brings a significant communication performance degradation, even with light computation. For example, the *AllGather* bandwidth drops by 12.8% with interference by light computation and up to 39.3% by heavy computation. However, with carefully primitive configuration tuning, *AllGather*'s bandwidth has been improved by 34-78% for all settings. It's worth noting that, after configuration tuning, the cases with computational interference can be 7.8-16.8% faster than default NCCL without interference.

3.3 Challenges in NCCL Tuning

Tuning NCCL primitive configurations presents challenges that require addressing the following two questions.

How to quickly find the performant configuration in a large space? For specific communication types, message sizes, and communication group sizes, the configuration tuning space is huge. As shown in Figure 2, the number of possible combinations can reach up to millions. Traversing such a space and comparing the latencies and bandwidths of candidates is time-consuming. For example, testing all parameter combinations for *AllGather* with 80MB takes several hours on a single machine with 8 A40 GPUs connected by PCIe. With the increase of message size and communication group size, the time overhead expands significantly.

How to model computational interference w.r.t the training runtime dynamics? For parallel training tasks of a model, there are usually highly variable operators, dimensions of operator partitioning, and inputs to the operators, and consequently a diverse range of computational tasks are executed on the GPU. Modeling computational tasks and their impact on communication further increases the space of NCCL configuration. In addition, training frameworks add scheduling optimizations to the runtime, and introduce dynamics that can make the concurrent execution of computation and communication tasks unpredictable in advance. Exploring all potential combinations of these factors simultaneously results in an impractical search cost.

4 Communication Tuning Method

Next, we will design a unified, simple, and efficient configuration parameter tuning tool, `AutoCCL`, for collective communication primitives. We first consider communication modeling and tuning in an ideal state without computational interference. Recall that Table 2 presents six parameters that make up each configuration, and the selection of these parameter values forms a large search space. To address this challenge, we analyze NCCL's parameters and make several observations. First, we categorize the six parameters and apply different approaches to different types of parameters. We divide the parameters into two categories: those related to the implementation of primitives and those related to resource allocation, with a detailed analysis provided in Section 4.1.

Second, we find that resource allocation parameters are the primary cause of the large search space, and there are some patterns in the interactions between these parameters. By examining these interactions and their joint effects on performance, we propose a theoretical model to predict the performance of parameter combinations, thus avoiding exhaustive search in the vast parameter space (see Section 4.2). Finally, we integrate all these observations into a tuning algorithm, which is detailed in Section 4.3.

4.1 Parameter Division

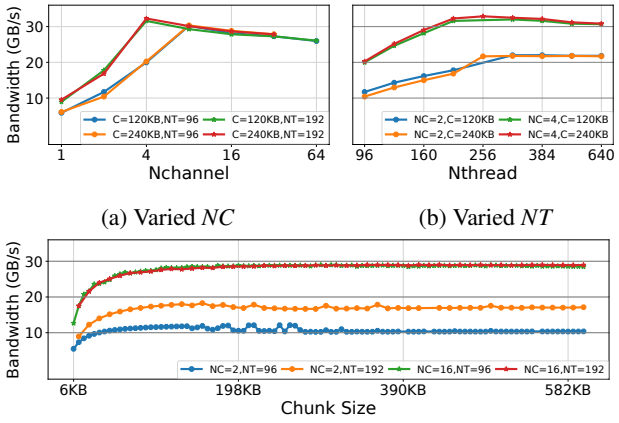
First, algorithm, protocol, and transport are implementation-related and together determine the topology of the algorithm execution logic, the method of data transmission, and the software stack calls required to complete the primitive semantics. These parameters are crucial, but the search space is relatively small. For example, there are only two options for *algorithm*, three for *protocol*, and two for *transport*.

Some prior works have provided useful guidelines for selecting these implementation parameters [12,16,47]. However, in practice, we find that these guidelines are not always reliable. For instance, some works assume that bandwidth and latency between GPUs are fixed, allowing the time cost for Tree and Ring topology to be estimated as $log_2 N$ and $2 \times (N-1)$, respectively. However, in reality, bandwidth is affected by many factors, such as message size, cluster topology, congestion, and concurrency, which makes the cost model inaccurate. As a direct consequence, in the experiment corresponding to Table 5, NCCL incorrectly selected the algorithm.

Second, the parameters *NC*, *NT*, and *C* correspond to resource allocation. It is well-known that communication tasks during model training require both data transmission over the network and GPU cores for operations like accumulation and averaging. These three parameters jointly determine how to utilize the network bandwidth and GPU computational power. The search space for these parameters is relatively large, with options such as 8,192 for *Chunk Size* and 128 for *Nchannel*. We further observe that analyzing their impact on performance must be based on a prior selection of the above three implementation parameters. In other words, the choice of the first three parameters provides the foundation for modeling the analysis of the latter three. Although the first three parameters can be explored exhaustively, it is practically infeasible to search through the combinations of the latter three exhaustively. Therefore, we must build a performance model for these resource-related parameters.

Table 7: Notation table

Notation	Description
M	Message size
α_i	Initialization cost of phase i
$\overline{\beta i}$	Peak bandwidth of phase i
β_i	Bandwidth of phase i
$\gamma(NC,NT,C)$	Congestion of all phases



In summary, based on the classification of these parameters, we propose a subspace-based tuning method. First, we divide the entire search space into different subspaces $< A,P,T >$, each of which corresponds to a specific combination of *algorithm*, *protocol*, and *transport*. Then, within each subspace, we use a unified performance model for *NC*, *NT*, and *C* to determine the optimal combination of these parameters for that subspace. Finally, we compare the optimal combinations from all subspaces to identify the global optimal configuration. This approach mitigates the search space explosion for resource parameters while eliminating reliance on heuristic rules for the implementation parameters.

4.2 Modeling Resource Parameters

Given a subspace, we need to model three additional resource parameters. The notations required for modeling are provided in the table 7. Here, we evaluate the impact of resource parameter choices on communication bandwidth, denoted by $\beta(NC,NT,C)$. We provide qualitative analysis while avoiding difficult-to-achieve quantitative modeling. The execution of a collective primitive can be divided into two phases. In phase 0, the transport step is responsible for reading data from other GPUs and transferring it to the local buffer. Then, in phase 1, the protocol loads the data from the buffer to the SM, performs the reduction, and stores it back to the buffer. The bandwidths of these two phases are denoted as β_0 and β_1, respectively. Since the execution of the transport and protocol stages has data dependencies and is serial, as shown in Equation 1, $\beta(NC,NT,C)$ is equal to the minimum of the transport and protocol bandwidths.

$$\beta(NC,NT,C) = \min(\beta_0(NC,C), \beta_1(NC,NT)) \tag{1}$$

Next, we introduce the derivation process for the transport bandwidth formula in phase 0. The performance of transport depends on chunk size *C* and the number of concurrent messages *NC*, but not on *NT* since the transport does not include computation. We first compute the time t_0 required to transfer a message of size *M* across GPUs, as shown in Equation 2. $\frac{M}{NC \times C}$ represents how many serial steps the message will be

(a) Varied NC (b) Varied NT

(c) Varied C

Figure 3: The trend of <AllGather, 80M, 8> bandwidth on a node with 8 A40 GPUs connected via NVLink

divided into, where each step consists of NC parallel transmission tasks, each of size C. The term in parentheses on the right side of the equation represents the time cost of one step. This cost consists of the initial latency α_0 and the transmission time for a step of size $NC \times C$, where $\overline{\beta_0} \times \gamma$ represents the bandwidth under the current congestion. γ is the congestion coefficient, which increases with the increase of NC, NT, and C. We only analyze it qualitatively here. Equation 3 defines bandwidth as the message size divided by the time. By solving Equations 2 and 3, we obtain the bandwidth formula for phase 0 as Equation 4.

Similar to the bandwidth derivation for phase 0, we can also obtain the estimated bandwidth formula for phase 1, as shown in Equation 5. The protocol already determines the data granularity and cache pattern, so processing performance is related to NC and NT, not to C. Due to space limitations, we omit the derivation process. According to the model, when any two parameters among NC, NT, and C are fixed and the third parameter is gradually increased, β_i will monotonically increase, approach its physical bandwidth upper limit $\overline{\beta_i}$, and then stabilize, or even fall, thereby affecting the overall bandwidth $\beta(NC,NT,C)$.

$$t_0(NC,C) = \frac{M}{NC \times C} \times (\alpha_0 + \frac{NC \times C}{\overline{\beta_0} \times \gamma}) \quad (2)$$

$$\beta_0(NC,C) = \frac{M}{t_0(NC,C)} \quad (3)$$

$$\beta_0(NC,C) = \frac{NC \times C}{\alpha_0 + \frac{NC \times C}{\overline{\beta_0} \times \gamma}} \quad (4)$$

$$\beta_1(NC,NT) = \frac{NC \times NT}{\alpha_1 + \frac{NC \times NT}{\overline{\beta_1} \times \gamma}} \quad (5)$$

To validate the aforementioned model and its characteristics, we designed a set of communication primitive experiments. By using a controlled variable method, we varied the values of different resource parameters and observed

Algorithm 1: Subspace-Directed Tuning

Input: Task (w).
1 optimum ← nil
2 **for** subspace s ∈ $[A \times P \times T]$ **do**
3 config ← CoordinateDescentSearch(s)
4 **if** config.BwDelta(optimum) > 0 **then**
5 optimum ← config
6 **return** optimum

the changes in bandwidth of $< AllGather, 80M, 8-A40-NVLink >$. As expected, as shown in Figure 3, when any two parameters are fixed, the bandwidth increases first, then decreases or stabilizes as the third parameter increases. Furthermore, when the first two parameters change, the bandwidth peak (sweet point) corresponding to the third parameter also shifts accordingly. Figure 3a depicts that the optimal values of NC are 4 and 16 when $C = 80KB, NT = 96$ and $C = 20KB, NT = 96$, respectively, since a larger C results in a higher congestion factor γ, reducing the number of NC values required to reach the optimal point. Similarly, as shown in Figure 3b, the optimal values of NT are 320 and 196 when $NC = 2, C = 120KB$ and $NC = 4, C = 120KB$, respectively, since increasing either NC or NT increases γ, and with a larger NC, the NT curve reaches the sweet point earlier. Similar patterns are observed again in Figure 3c.

In summary, we find that the joint impact of NC, NT, and C on performance is not monotonic but exhibits the characteristics of a unimodal function with a sweet point. Based on this feature, we can naturally use the coordinate descent method [3] to search the resource parameter combination space. By abstracting NC, NT, and C as the three dimensions of the coordinate descent method, we can find the maximum value by continuously moving in the ascending direction along each dimension (see Section 4.3 for details).

4.3 Tuning Algorithm

Based on the parameter classification, resource-related parameter modeling, and subspace search method described above, we design an NCCL parameter tuning approach, which consists of Algorithm 1 and Algorithm 2.

Subspace-directed Tuning. The algorithm 1 uses a divide-and-conquer strategy to separately search each subspace for every communication task w. Specifically, we iterate through all the subspaces (lines 2-5). In line 3, we invoke the coordinate descent search (Algorithm 2) for subspace s to obtain the optimal configuration within that subspace. If the optimal configuration of subspace s outperforms the current best configuration, we update the best configuration (lines 4-5).

Coordinate descent search. For the input subspace s, Algorithm 2 sets M as the total number of resource parameters, representing the dimensions of tunable parameters within the subspace s (line 1). In our case, M is 3. Next, a configuration p is randomly generated, where the implementation parameters of p are determined by subspace s, and the values of the

Algorithm 2: Coordinate Descent Search

Input: Subspace (s).

```

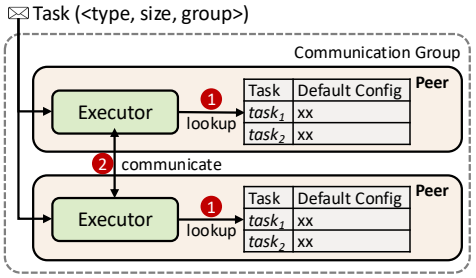
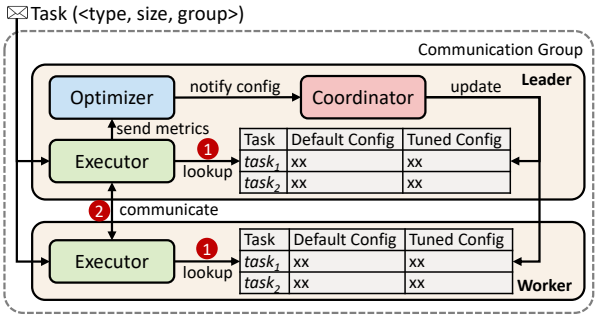
2  Randomly generate a config p from subspace s.
3  optimum ← p
4  dim, tuned_dim, lr ← 0, 0, 0.01
5  while tuned_dim ≤ M do
6      p.ProfileBw()
7      if p.BwDelta(optimum) > 0 then
8          lr ← p.BwDelta(optimum) / p.Bw()
9          optimum, tuned_dim ← p, 0
10     else
11         tuned_dim ← tuned_dim + 1
12         dim, lr ← dim + 1, 0.01
13     p ← optimum
14     p[dim] ← p[dim] + lr
15 return optimum
```



other resource parameters are randomly selected from their respective ranges (line 2). Line 4 initializes the index of the dimension to be tuned, the number of tuned dimensions, and the learning rate. Lines 5-14 execute a gradient descent search loop until all dimensions have been tuned (i.e., the number of tuned dimensions equals the total number of tunable dimensions). In line 6, configuration p is executed to profile its bandwidth. In line 7, the bandwidth of p is compared to the current *optimum*. Following this, two scenarios must be considered:

If p achieves higher bandwidth, then the configuration should be updated along the current tuning dimension. Line 8 calculates the percentage improvement in the bandwidth of p compared to the current *optimum*, using this percentage as the learning rate lr. Line 9 updates *optimum* to p and resets the tuned dimension counter, *tuned_dim*. If p does not improve bandwidth, then a new tuning dimension should be selected. Line 11 increments *tuned_dim*, and line 12 selects the next dimension to tune and resets the learning rate lr.



After analyzing p, lines 13 and 14 update the tuning dimension *dim* in the optimal configuration based on lr. If all dimensions have been tuned, line 15 returns the optimal configuration found within the subspace s.

5 AutoCCL: Design and Implementation

Next, we present the design and implementation details of the automated tuner, AutoCCL, focusing on how AutoCCL gathers the performance profiling data required for tuning from the training tasks and selects new configurations. To avoid the complexity of modeling computational interference and dynamic scheduling, we propose an online tuning approach. This approach leverages repetitive patterns of computation and communication cycles during the training process, using the tuning algorithm introduced in Section 4.3 for the same communication task until tuning is completed. It enables the collection of communication performance data affected by interference during the training process. This data is then incorporated into the tuning algorithm to capture accurately the impact of co-running computational tasks on communication. It could also amortise the cost of tuning over the early iterations.

(a) NCCL

(b) AutoCCL

Figure 4: The architecture of NCCL and AutoCCL

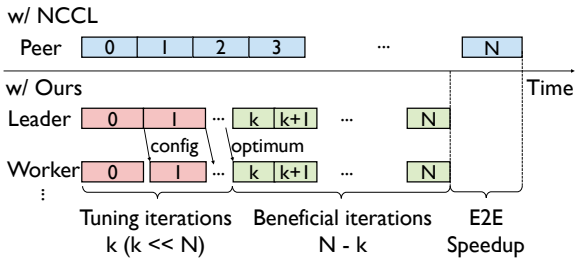


Figure 5: Online tuning workflow with AutoCCL (bottom). Rectangles with numbers represent training iterations.

5.1 Overall Architecture

Figure 4 illustrates the architecture of AutoCCL and its comparison with NCCL. Although AutoCCL evolved from NCCL, it exhibits significant differences from NCCL in several aspects. First, AutoCCL does not follow NCCL's peer-to-peer design. In NCCL, within each communication group executing a collective communication task, all GPUs are identical *Peers*, and each *Peer* independently generates a default configuration for the same communication task based on a deterministic cost model. Unlike this, in AutoCCL, one GPU is designated as the *Leader*, responsible for running the tuning algorithm, identifying the performant configuration, and updating the results to

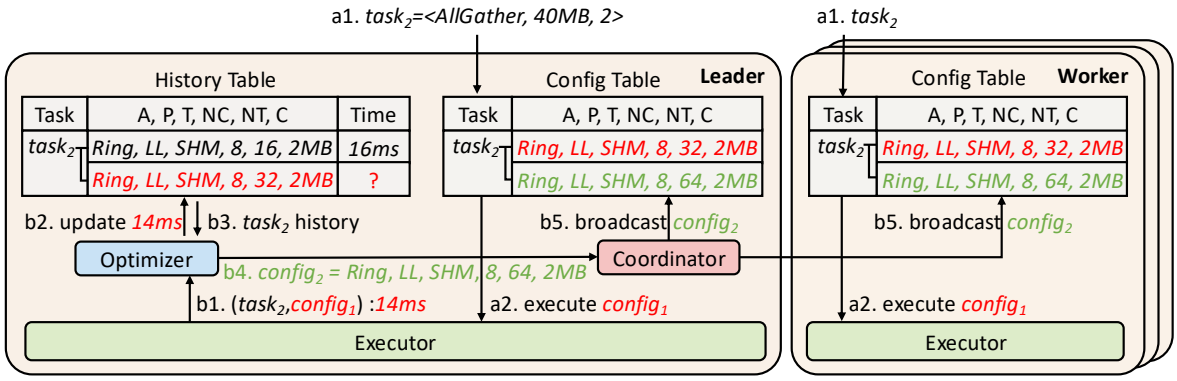

Figure 6: The online tuning workflow of AutoCCL. Colors distinguish different configurations.

the other GPUs, referred as *Workers*. Each AutoCCL *Worker* acts similarly as a *Peer* in NCCL, maintaining a configuration table. For any task, this table stores a default configuration (generated by NCCL's cost model) as well as a tuned configuration generated by the *Leader*. When a communication task is received, the *Worker*'s *Executor* checks the configuration table and selects the tuned configuration if available; otherwise, it uses the default configuration.

In contrast to the simple design of *Workers*, the logic of the *Leader* is more complex. The *Leader* introduces two additional system components: the *Optimizer* and the *Coordinator*. *Optimizer* collects performance profiling data from the *Executor*, determines whether tuning is necessary, and initiates the tuning process. Without requiring coordination with other nodes, it independently searches the performant configuration and decides whether to replace the current one. Notified by *Optimizer*, *Coordinator* then broadcasts the updated configuration to all nodes in the communication group, updating their tuned configuration. Upon success, all subsequent identical communication tasks will use the updated configuration.

5.2 Iterative Online Tuning

As shown in Figure 5, by placing the communication tuning process in the iterations of the pre-training period, we could cope with the diversity of workloads and hide tuning time cost.

We adapt the tuning algorithm for each subspace to the same communication task across the iterations. As shown in Table 1, due to the iterative nature of training and the use of microbatches, the same communication task is executed many times in each iteration. When performing a communication task, we run one step of the coordinate descent algorithm for the corresponding subspace. Upon completion, if the subspace has not reached its optimum, we save the corresponding state to facilitate the next search. Otherwise, we stop and switch to the next subspace. When the performant solution is found, the *Coordinator* broadcasts it to each node within the communication group, which guarantees the atomicity of the update and avoids the inconsistent state of the same communication task using different versions of the configuration.

Note that tuning introduces a slight overhead, which may extend the duration of each iteration. However, since the tuning process is highly efficient and the tuned iteration significantly improves performance, the end-to-end training acceleration remains substantial.

5.3 New Workflow

Here, we provide a walking-through example of the aforementioned online tuning method, illustrating the new workflow of AutoCCL, as shown in Figure 6. On the *Leader*, an additional *History Table* records the execution times of various tasks under different configurations, which the *Optimizer* uses to generate new configurations for tuning. Initially, the *Config Table* contains only the red *config_1* (<Ring, LL, SHM, 8, 32, 2MB>) for *task_2*, without green *config_2*, which will be generated during the tuning process of this example. *a*1 and *a*2 show the process of fetching and executing the current optimal configuration for the communication task, while *b*1 to *b*5 illustrate the online tuning and configuration update process.

Next, supposing both the *Leader* and *Worker* receive a new communication task with the same communication primitive, message size, and communication group members as the previously recorded *task_2*, the task is an *AllGather* operation with a message size of 40MB and a communication group size of 2. Both the *Leader* and *Worker* first need to query the *Config Table* for the target configuration (step *a*1). Since the *Config Table* is fully replicated between the *Leader* and *Worker*, both will retrieve the red *config_1* and submit *task_2* to the runtime for execution using *config_1* (step *a*2).

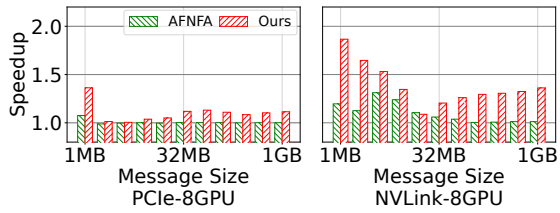
After a certain period, *task_2* completes execution, and the *Executor* on the *Leader* returns the execution time (14ms) to the *Optimizer* (step *b*1). The *Optimizer* updates the execution time in the *History Table* (step *b*2). The *Optimizer* then retrieves the historical execution times for *task_2* and initiates a new round of tuning (step *b*3). The *Optimizer* observes that increasing *NT* from 16 to 32 reduces the communication time from 16 ms to 14 ms. According to the coordinate

Table 8: DNN model statistics

Model	MBS	GBS	TP	PP	DP
Phi-2-2B	8	512	8	1	1-4
Llama-3.1-8B	2	256	8	1	1-4
Yi-1.5-34B	1	1,024	8	4	1
VGG-19-0.14B	32	32×[8,16,32]	1	1	8-32

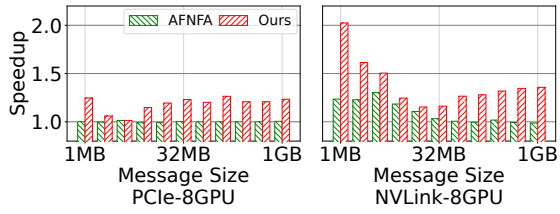
descent method, the next attempt will also increase NT. Therefore, it selects $NT = 64$, generating *config_2*, and notifies the co-existed *Coordinator* (step *b*4). The *Coordinator* uses a broadcast operation with synchronous semantics to update *config_2* in both the *Leader* and *Worker*'s *Config Table*, replacing the original *config_1* (step *b*5). Subsequent *task_2* executions will use *config_2*, and the online tuning process will continue until the optimal configuration is found.

5.4 Implementation Details



AutoCCL is implemented based on NCCL 2.18.3, with 9,176 lines of C++ code, supporting collective communication primitives such as *AllGather*, *Allreduce*, and *ReduceScatter*. We modified NCCL's configuration generation module and transport initialization module to allow more flexible use of various configurations. For any communication group, AutoCCL automatically launches an additional thread as the *Leader* on one node to perform communication task tuning. Due to the asynchronous execution characteristics of CUDA kernels, we start an additional thread to measure execution time.

AutoCCL is implemented based on the C++ standard library, the *Coordinator* is implemented based on Linux sockets, and no additional libraries are required. Thereby, users can seamlessly migrate from NCCL to AutoCCL by preloading the dynamic library without requiring any code modification. Since AutoCCL and NCCL share identical interfaces, training frameworks such as PyTorch [41] and MegatronLM [51] can directly integrate AutoCCL without modification, and training tasks running on these frameworks are unaware of the underlying switch. Our code is open-sourced at [2].



6 Evaluation

6.1 Experimental Setup

Cluster setup. We use two clusters to demonstrate the generality of our tuner. Cluster A has 2 nodes, interconnected via 2 pairs of 400 Gbps InfiniBand-PCIe 5.0 NIC. Each node has 8 NVIDIA Ampere A40 GPUs (48 GB GDDR6, PCIe 4.0), an AMD EPYC 9654 CPU, and 64GB of host memory. The 8 GPUs within a single node are divided into 4 pairs, with each pair of GPUs connected via 400 Gbps NVLink interconnects. Cluster B contains 4 machines in a single rack, connected via a 100 Gbps InfiniBand network. Each machine has 8 NVIDIA Ampere A40 GPUs (the intra-node GPUs are connected via PCIe 4.0), an Intel Xeon Gold 5320 CPU, and 504 GB of host memory. In Cluster B, due to hardware limitations, peer-to-peer communication is not available between some GPUs. Both clusters operate under the same environment with CUDA

(b) *ReduceScatter*

Figure 7: Bandwidth speedups for the *AllGather* and *ReduceScatter* communication of different A40 clusters

v12.1 and NVIDIA driver v470.63.01.

DNN training jobs. We evaluate four models from different application scenarios, including Phi-2-2B [21], Llama-3.1-8B [54], Yi-1.5-34B [65], and VGG-19 [52] shown in Table 8, where three are large language models with up to 32 billion parameters and one computer vision model. Model training is conducted using PyTorch version 2.1.0. Various parallelisms are managed by MegatronLM. Due to limited GPU memory, Llama-3.1-8B combines *distributed optimizer* [45] along with data parallelism. We set the micro-batch size as large as possible under the GPU memory limitation for better hardware utilization. The global batch size follows the setting of the GPT series with a similar model scale [11].

Baseline systems. We compare against NCCL v2.18.3-1, almost the latest version provided by NVIDIA, and internally performing tuning to some extent. We always enable its tuning function. We also include an academic collective communication tuning system, AFNFA [64]. We use the random forest algorithm to train 1% of the offline sampled data and use environment variables to set the configuration for different communication to reproduce the results of AFNFA. All data represent the average results from multiple experiments.

6.2 Communication Micro-Benchmarks

We explore how AutoCCL improves different collective communication primitives, considering various hardware setups and message transmission sizes. We first evaluate the communication performance without computational interference, followed by experiments with interference.

Communication without computational interference. We first consider *AllGather* and *ReduceScatter* primitives, which are heavily used in *Tensor Parallelism*. We test them with 8 GPUs within a single machine, connected via PCIe 4.0 or NVLink. Figure 7 summarizes the bandwidth speedups of AutoCCL and AFNFA over the native NCCL.

For A40-PCIe, AFNFA's results are almost identical

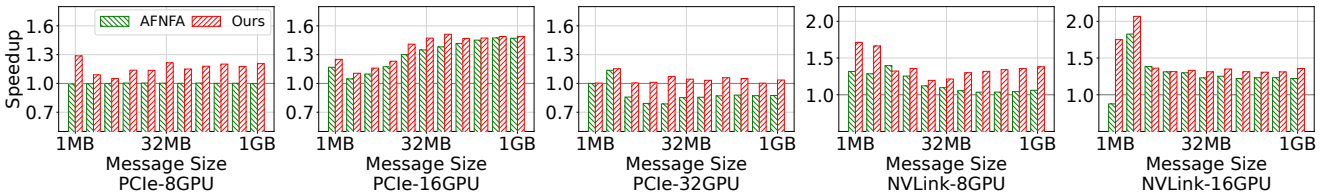

Figure 8: Bandwidth speedups for the *AllReduce* communication of A40 clusters with different setups

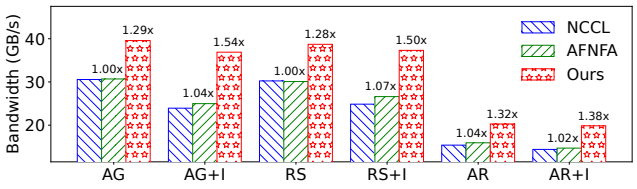

Figure 9: Comparison of bandwidth with and without computation **interference** for different communication. The message size is 128 MB. '+I' refers to the communication that interfered with computation. The speedup numbers are annotated in the figure. *AG*, *RS* and *AR* stand for *AllGather*, *ReduceScatter* and *AllReduce* respectively.

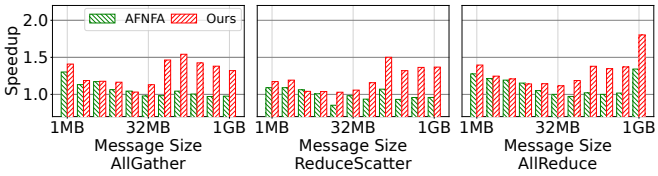

Figure 10: Bandwidth speedups with increasing message sizes and computation **interference** for different communication types of a cluster with 8 A40 connected with NVLink

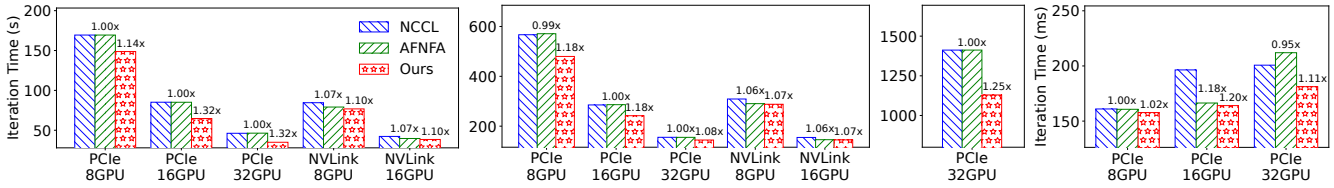
to NCCL, offering little optimization. However, AutoCCL achieved an average bandwidth improvement of 22.66% and 27.52% for *AllGather* and *ReduceScatter*, respectively, compared to NCCL. This is especially evident for larger message sizes, where AutoCCL outperforms both baselines.

It is widely acknowledged that NVLink is highly efficient, and NCCL has been heavily optimized for it. Despite this, AutoCCL demonstrates even greater advantages on NVLink compared to PCIe. For instance, for various message sizes, the average bandwidth speedups are 1.38× and 1.39×, respectively. In contrast, AFNFA shows far fewer benefits, particularly for large message sizes, where its tuning results still align with those of NCCL since it uses global configuration and cannot adapt to different message sizes.

We observe that in a few cases, AutoCCL's tuning results align with those of NCCL. This occurs because, for these particular message sizes, NCCL's configuration is already optimal. In other words, its standard α-β network model can accurately predict performance at these points, although this model does not generalize to all cases.

Next, we analyze *AllReduce*, which is commonly used in data parallelism to exchange gradient information. As shown in Figure 8, similar to the results above, AutoCCL achieved average bandwidth speedups of 1.28× and 1.15× compared to NCCL and AFNFA, respectively. In the PCIe-32GPU cluster, where AFNFA even results in negative optimization, AutoCCL slightly outperforms NCCL since the default configuration of NCCL is effective. However, NCCL becomes less suitable under computational interference.

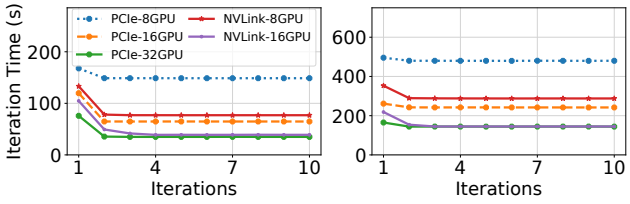
Communication with computational interference. We test the behavior of AutoCCL when communication and computation are co-executed. We evaluate the above three primitives with a GEMM operation running concurrently alongside each primitive. The matrices of GEMM are A[m, k] and B[k, n], where m, k, and n are 3,456, 128, and 3,456. Figure 9 compares the bandwidth of these primitives with and without computational interference for a fixed message size.



Similar to previous studies, the bandwidth of the three primitives decreases significantly under computational interference. With AutoCCL tuning, the bandwidth speedups compared to NCCL are 1.29×, 1.50×, and 1.38×, respectively. In contrast, AFNFA demonstrates poor performance, showing no improvements for *AllGather* and *ReduceScatter* and merely a 1.02× improvement for *AllReduce*. Interestingly, after AutoCCL tuning, the optimal bandwidth under interference closely approximates the optimal bandwidth without interference. This indicates that AutoCCL can accurately predict performance even with interference.

Figure 10 differs from Figure 9 by increasing the message size for primitives while simultaneously scaling up the corresponding co-executed GEMM to simulate varying degrees of resource sharing and interference.

For *AllGather* and *AllReduce*, AFNFA only shows tuning benefits for message sizes below 16 MB, compared to NCCL. In contrast, AutoCCL not only matches or slightly outperforms AFNFA for small message sizes, but also achieves significant bandwidth improvements of 1.11-1.76× and 1.16-1.39× for larger message sizes (e.g., those exceeding 32 MB) compared to NCCL, respectively. For *ReduceScatter*, AFNFA either performs on par with NCCL or results in negative optimization. This indicates that in more competitive scenarios, both NCCL and AFNFA fail to deliver satisfactory performance, as their modeling approaches are insufficient to handle complex environments and dynamic changes. In contrast, AutoCCL shows a distinct performance advantage in these situations.



6.3 End-to-End Performance

To show how AutoCCL accelerates the training progress for real-world models, we conduct experiments to train models

(a) Phi-2-2B (b) Llama-3.1-8B (c) Yi-1.5-34B (d) VGG-19-0.14B

Figure 11: Training iteration time for different models between NCCL, AFNFA, and AutoCCL, with speedup annotated

(a) Phi-2-2B (b) Llama-3.1-8B

Figure 12: Rapid convergence of AutoCCL tuning at early iterations of end-to-end LLM training

on different communication systems under various hardware setups. Figure 11 shows the training iteration time of different models. Among all the hardware setups, AutoCCL outperforms both NCCL and AFNFA in training these models, while AFNFA is slower than NCCL in some cases as its offline-tuned configurations degrade performance under computational interference. On the PCIe machine, we observed a greater performance improvement compared to microbenchmark results because our online tuner exhibits stronger resilience to such interference than NCCL and AFNFA, whose performances are significantly degraded. The end-to-end gains on NVLink machines are modest because in scenarios where communication overlaps with computation and computation is dominant, excessive optimization of communication can slow down computation and reduce overall performance. For best cases, AutoCCL can improve the training iteration time by more than 32% compared to both NCCL and AFNFA.

6.4 Efficiency of Iterative Online Tuning

To show the efficiency of the AutoCCL to find the performant configuration with iterative online tuning, we measure how the iteration time changes when training the models, as shown in Figure 12. As noted in Table 1, because of the repetition of layers in the model and the large number of repeated micro batch sizes in each global batch size, the Transformer models like Llama-3.1-8B, Phi-2-2B, and Yi-1.5-34B can generate thousands to tens of thousands of repetitive communication operations per iteration. For these models, only several iterations are required for AutoCCL to find the performant configurations. For smaller models like VGG-19, although less repetitive communication operations are involved in each iteration, the time consumed per iteration is relatively short, e.g., 150-200 ms per iteration for VGG-19 in Figure 11d, which is around 1,000 times shorter than that of Llama-3.1-8B. In our evaluation, it only takes no more than 10 minutes for AutoCCL to find the performant configuration in VGG-19. In summary, for these four models of different areas, AutoCCL can rapidly identify a sufficiently performant configuration within just a few iterations or minutes through online tuning, highlighting its ability to adapt quickly to new environments, which is infeasible for offline tuning strategies.

7 Related Work

Computation-communication scheduling. At the application level, many studies [13, 19, 22, 23, 31, 46, 50, 59, 60, 67] aim to reduce communication overhead by overlapping computation and communication, thereby enhancing training efficiency. For example, Horovod [46] overlaps all-reduce communication with backward computation to improve performance. AutoCCL complements these methods by additionally considering the interference between computation and communication during the tuning process, making it more effective for tasks with specific scheduling requirements.

Communication compression. Other approaches [8, 9, 53, 56, 62, 63] improve communication efficiency by exploiting data sparsity. HiPress [9] introduces a framework to efficiently compress gradient data in *AllReduce*, reducing latency. ZeRO++ [56] combines quantization with collectives of *AllReduce* and *AllGather* in the ZeRO optimization to improve efficiency. AutoCCL is complementary to them, as it can be used to further enhance the performance of underlying communication collectives for these compression algorithms.

Collective algorithm generation. At the algorithm level, several studies focus on developing topology-aware [12, 15, 16, 27, 29, 32, 35, 42, 42, 47, 57] or sparse-aware [10, 28] communication algorithms. For instance, Swing [16] proposes a new *AllReduce* algorithm to minimize hops in torus networks, while MCCLang [15] offers a domain-specific programming interface and efficient compiler for easier algorithm customization. Unlike these works, AutoCCL does not introduce new algorithms but treats the algorithm choice as a tunable parameter. In the future, AutoCCL can be integrated with these approaches to further enhance runtime performance.

Network tuning. At the hardware level, to achieve higher network communication bandwidth, NCCL [5] uses the Alpha-Beta model to predict communication efficiency based on hardware topology and bandwidth. AFNFA [64] improves this prediction using machine learning with offline profiling.

However, all these approaches share a global configuration (i.e., through NCCL environment variables [6]) and do not consider computational interference in real-world workloads. In contrast, AutoCCL employs online profiling to capture the interference effects and dynamically selects a performant configuration for each collective communication operation, improving performance across diverse workloads.

8 Discussion

8.1 Parameter Selection and Extensibility

Once the implementation-wise parameter T is determined, NCCL allows further optimization of transport-specific parameters, including *Ethernet*, *IB*, *COLL_SHARP*, *NVLS*, *SHM*, and *P2P*. AFNFA considers *NCCL_SOCKET_NTHREADS* for Ethernet transport and *NCCL_NET_GDR_LEVEL* for IB transport. However, our study does not include these parameters, as they introduce a risk of failures while providing limited performance gains (Section 8.2). AFNFA attempts to optimize NCCL including *NCCL_ALGO* for *A*, *NCCL_SHM_DISABLE* and *NCCL_P2P_LEVEL* for *T*, NCCL_MAX/MIN_NCHANNEL for *NC*, and *NCCL_BUFFSIZE* for *C*. These tunable combinations are incorporated into our search space. Our search space also includes P and NT, whose importance is demonstrated in Section 3.1.

The subspace coordinate descent method is inherently scalable, allowing users to optimize transport-specific parameters. Introducing transport-specific parameters only increases the number of implementation-wise parameter combinations, effectively subdividing the existing subspaces into finer-grained subspaces. The scalability of the subspace coordinate descent method enables users to further optimize transport-specific parameters as needed.

Our findings suggest that using default or fixed values for transport-specific parameters already yields robust performance. For example, we attempted to optimize IB-specific parameters and found that the default values of *NCCL_IB_SPLIT_DATA_ON_QPS* and *NCCL_IB_QPS_PER_CONNECTION* are already optimal. Similarly, the optimal value for *NCCL_NET_GDR_LEVEL* is typically determined based on the NIC and GPU topology, making it effective across different communication workloads. Since the optimal values for transport-specific parameters are often hardware-dependent, further exploration of their optimization is left for future work.

8.2 Task Failures and Valid Configurations

Tuning NCCL parameters can potentially lead to training task failures. This issue has been reported in related studies [40, 64] and confirmed by our experiments. As previously mentioned, once an implement-wise parameter such as T is determined, collective communication will employ a specific transport mechanism, such as P2P transport. NCCL allows further optimizations for specific transport mechanisms—for instance, enabling *P2P_USE_CUDA_MEMCPY* for P2P transport can improve bandwidth. However, in end-to-end training tasks, this setting may result in deadlocks. Additionally, we observed another type of failure: for resource-allocation parameters such as *NC*, *NT*, and *C*, excessively large values can lead to resource saturation, ultimately causing program crashes.

Nevertheless, failures induced by tuning have minimal impact on our system for two reasons. First, transport-specific optimizations are beyond our scope; therefore, we inherently avoid failures associated with them. In the future, we may explore further optimizations under failure recovery support. Second, for *NC*, *NT*, and *C*, due to the unimodal nature of the performance function, excessively large values do not yield performance gains. Therefore, we can impose upper bounds on resource usage without sacrificing performance, effectively preventing failures.

Besides, if a failure occurs, online tuning introduces additional overhead for loading checkpoints compared to offline tuning. However, given the numerous recent optimizations in checkpointing [18, 26, 61], this overhead has been significantly reduced and is negligible. The dominant cost of failure recovery remains container rebooting, which is required for both offline and online tuning.

Finally, failure handling and recovery are orthogonal to tuning. We can explore this topic in future work.

9 Conclusion

AutoCCL is an automated tuning tool that optimizes low-level NCCL parameter selection. By decoupling implementation-related parameters from those that inflate the search space, our divide-and-conquer approach reduces the necessity for extensive trial runs. Furthermore, its online tuning strategy efficiently handles communication-computation interference. Evaluation across multiple clusters and models demonstrates that AutoCCL significantly enhances both communication and end-to-end training performance compared to NCCL and another SOTA tuner.

Abstract

We present OPTIREDUCE, a new collective-communication system for the cloud with bounded, predictable completion times for deep-learning jobs in the presence of varying computation (stragglers) and communication (congestion and gradient drops) variabilities. OPTIREDUCE exploits the inherent resiliency and the stochastic nature of distributed deep-learning (DDL) training and fine-tuning to work with approximated (or lost) gradients—providing an efficient balance between tail performance and the resulting accuracy of the trained models.

Exploiting this domain-specific characteristic of DDL, OPTIREDUCE introduces (1) mechanisms (e.g., unreliable bounded transport with adaptive timeout) to improve the DDL jobs' tail execution time, and (2) strategies (e.g., Transpose AllReduce and Hadamard Transform) to mitigate the impact of dropped gradient entries on model accuracy. Our evaluation shows that OPTIREDUCE achieves 70% and 30% faster time-to-accuracy (TTA), on average, when operating in shared, cloud environments (e.g., CloudLab) compared to Gloo and NCCL, respectively.

1 Introduction

Synchronous distributed data-parallel training [175] is now the de-facto standard for training and fine-tuning large-scale deep-learning models (comprising billions or even trillions of parameters) and datasets (comprising terabytes of data) that form the backbone of many mainstream enterprise applications, including computer vision [64, 74, 96, 161], natural-language processing and large-language models [53, 63, 110, 167], recommendation and prediction systems [70, 71, 84, 86, 130], and healthcare [93, 112, 125, 169]. Under this scheme, the training occurs in rounds (or epochs). Workers locally train a copy of the model on a fragment of data and then share the model updates (i.e., gradients) among themselves over the network to compute an aggregated result. The aggregate is then used to update the model locally for the next round of training. Distributed deep-learning (DDL) is, therefore, inherently a computation- and communication-intensive workload and is becoming even more so with the growing model sizes (e.g., Bart [101], GPT-2/3 [53, 126], LLaMA [65, 146]), and datasets [38, 135, 143].

To train and fine-tune such large models, extensive efforts are underway in reducing both the computation and communication time of DDL jobs, albeit in isolation. On the one hand, we have GPUs [141] and emerging hardware accelerators, like Tensor Processing Units (TPUs) [90], that are drastically bringing down the computation time—reducing it by 62× over the last decade [136]. While, on the other hand, we have recent proposals based on programmable switches [157] that aim at reducing the communication time by 2–5× (via in-network aggregation) [136]. Yet, when seen together, both these efforts mainly help in improving the average completion time of a deep-learning job (either by accelerating computation or communication). The vast array of system-level variabilities (e.g., device failures, OS and hypervisor scheduling, and resource contention) and network-level delays (e.g., congestion and retransmissions) still lead to long tails; hence, resulting in poor overall performance for these training jobs—with tail reaching as high as 4× the mean latency in shared environments (e.g., public cloud providers)[1] [72, 77, 99, 106, 118, 153, 166].

In this paper, we make the case for OPTIREDUCE, a collective-communication system for the cloud tenants that ensures bounded, predictable completion times for deep-learning jobs in the presence of myriad computation and communication variabilities. Public clouds are becoming increasingly appealing for training, and more specifically fine-tuning, large foundation models [50], for enterprises and individuals lacking resources to set their own in-house distributed training clusters [14, 16, 17, 20, 21, 28, 33, 36, 37]. OPTIREDUCE exploits the inherent resiliency and the stochastic nature of deep-learning systems to work with approximated or lost gradients and provides an efficient balance between tail performance and the resulting accuracy of the trained models. Others are already utilizing this characteristic of deep learning to optimize DDL hardware design (e.g., chip area [134, 171]), minimize traffic overhead [68, 103, 109, 154], or offload certain DDL tasks to the network switches [99, 136, 153, 157, 160]. For instance, to reduce communication time, ATP [99] and SwitchML [136] leverage fixed-point arithmetic for gradient aggregation in programmable switches with acceptable approximation loss, whereas MLT [153] prioritizes and drops packets inside switches based on model layers and gradient magnitudes to limit loss in accuracy. Various gradient-compression schemes [68, 103, 109, 154] employ lossy compression to reduce network traffic over-

[1] Cloud providers typically do not offer preferential treatment to small tenants, but even large tenants with dedicated racks face long tails when communicating across racks in the provider's network. Private communication with a hyperscaler.

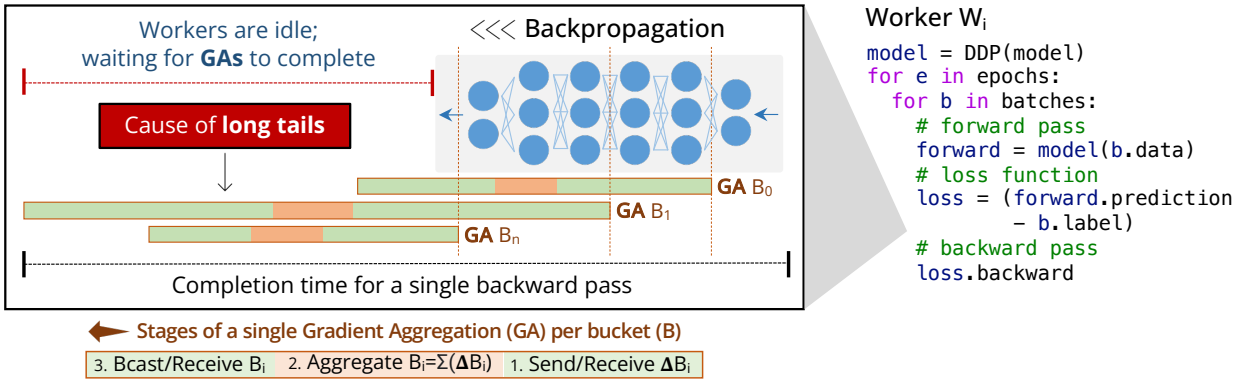

Figure 1: A backpropagation pass in distributed data-parallel (DDP) training. Multiple gradient aggregation (GA) runs share a bucket (B_i) worth of gradient entries among worker nodes (W_n), in parallel. The two send(bcast)/receive stages (1, 3) in GA incur the most time—contributing to the tail latency and stalling workers.

head (e.g., total bytes transferred) while limiting deviation from the achievable model accuracy. Similarly, hardware designers are incorporating approximate operations (e.g., approx. multipliers [134, 171]) in their architectures to minimize resource and energy usage—to scale to ever-increasing DDL models. However, these solutions are still susceptible to tail effects (e.g., slow workers and network variabilities) [47, 61, 78, 108, 127, 140, 153, 170, 173], and are not optimized for cloud environments, often times requiring direct access to the provider's network infrastructure.

In OPTIREDUCE, we exploit this resiliency and replace the (tail-prone) deterministic, run-to-completion stages of an AllReduce collective in DDL, with best-effort, *time-bounded* implementations.

- OPTIREDUCE introduces a *Transpose-Allreduce Collective (TAR)* to reduce the impact of lost gradient entries by establishing direct peer-to-peer communication among nodes in each round, rather than propagating the entries through all nodes as in Ring [121].
- It also implements an *Unreliable Bounded Transport (UBT)* to maximize the number of gradient entries received during each window. UBT introduces the notion of *adaptive timeout* to restrict the time a deep-learning job spends doing computation (aggregation) and communication (gradient sharing). Furthermore, it adds support for *dynamic incast* to dynamically adjust the number of concurrent senders per receiver in each round, thus optimizing communication by reducing the total rounds required for gradient aggregation.
- Lastly, to minimize the impact of missed or dropped gradient entries, OPTIREDUCE employs the *Hadamard Transform (HT)* [124] to ensure, for any drop pattern (e.g., tail drops), a receiver still obtains an unbiased estimate of the model's gradients resulting in a minimal loss in accuracy.

We implement OPTIREDUCE as a new AllReduce scheme inside Gloo [13],[2] a popular collective-communication library. Doing so makes OPTIREDUCE immediately compatible with existing DDL frameworks (e.g., PyTorch) without modifications. We run our experiments on various popular large deep-learning models (including BART [101], OpenAI's GPT-2 [126], and Meta's Llama 3.2) and evaluate OPTIREDUCE on CloudLab [66]—a public cloud facility for researchers—as well as under different shared environment settings using a local virtualized cluster, with varying tail-to-median latency ratios. We have made our complete OPTIREDUCE prototype [29] publicly available at https://optireduce.github.io.

Our evaluation demonstrates that OPTIREDUCE achieves, on average, 57% and 25% faster time-to-accuracy (TTA) on CloudLab compared to Gloo [13] and NCCL [87], respectively. These performance gains are even more pronounced in environments with larger tail-to-median latency differences, where OPTIREDUCE outperforms Gloo by 91% and NCCL by 35% (§5). We observe that it is the latency of the gradient aggregation (GA) step (Figure 1) that inflates three folds when operating under tail-heavy environments (e.g., public clouds), hence strengthening the need for a new collective like OPTIREDUCE. We also perform a deeper analysis of the various components of OPTIREDUCE. For example, in our evaluation, enabling Hadamard Transform mitigates the impact of tail-drops and improves TTA by 1.8× even when up to 10% of gradient entries are lost.

We begin with a background on distributed deep-learning (DDL) training—more specifically, distributed data-parallel (DDP) training—and the impact of stragglers on performance (§2). We then make a case for and present a design (§3) and implementation (§4) of a new communication-collective system, OPTIREDUCE, and evaluate how it exploits DDL's resiliency against gradient loss to improve performance (§5).

2 Background & Motivation

2.1 Distributed Deep Learning & Stragglers

Distributed deep learning (DDL) helps scale (and speedup) model training by utilizing an increasing number of hardware

[2]We pick Gloo for its ability to use both GPUs and CPUs (more suitable for a cloud environment), but OPTIREDUCE can operate with other libraries as well (e.g., NCCL [87] or MSCCL [24]).

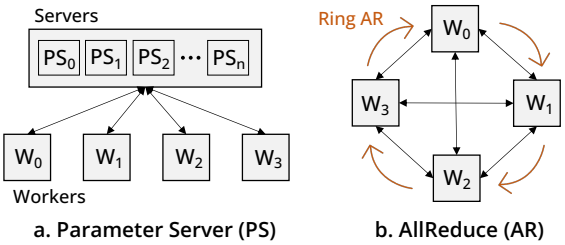

Figure 2: Architectures for gradient aggregation: Parameter Server (PS) and AllReduce (AR).

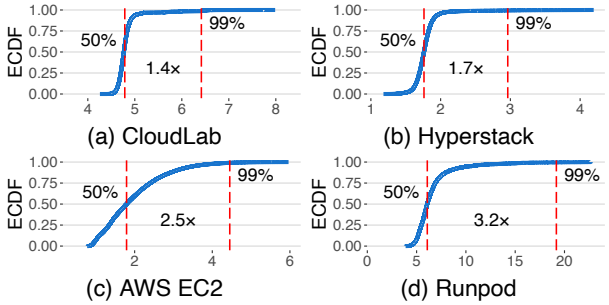

Figure 3: The latency ECDF (in milliseconds) showing tail-to-median ratio ($P_{99/50}$) observed across leading AI cloud platforms.

accelerators, e.g., GPUs [141] and TPUs [90], across server nodes [39, 55, 116]. To do so, it employs two approaches: *(i)* distributed data parallelism (DDP) [175] to run batches[3] on multiple accelerators in parallel, and *(ii)* distributed model parallelism (DMP) [91] to deploy larger models that fail to fit on a single accelerator. These approaches are orthogonal and can be used in conjunction. We focus on DDP in this paper to highlight our contributions (§3).

In distributed data parallelism (DDP), multiple worker nodes run the same deep-learning model on their portion of a training dataset, distributed evenly across nodes. Each portion is further subdivided into batches, which are processed sequentially (i.e., forward pass, loss function, and backward pass) in each epoch, Figure 1. During the forward pass, the model (e.g., a neural network) operates on a batch and generates a prediction, which is then compared with the ground truth (e.g., label) to calculate the model's loss. Next, the backward pass computes gradients using a loss function, which is used by an optimization algorithm (e.g., Stochastic Gradient Descent, SGD [52, 94]) to update the model parameters. Finally, to ensure all workers learn from what others have learned from their portion of the dataset, these gradients are averaged (reduced) and shared across all nodes, after each backward pass.

The process of accumulating, reducing, and sharing gradients back with worker nodes is referred to as *gradient aggregation* (or reduction) [62]. Originally, reduction used to happen strictly after the backward pass; however, more recently, to hide communication latency, modern frameworks (like PyTorch [106]) overlap it with the backward pass (Figure 1). As soon as a bucket (B) worth of gradient entries becomes available on a node, it is sent for reduction.[4]

Two common architectures for gradient aggregation are: Parameter Server (PS) [105] and AllReduce (AR) [59]. In the PS architecture (Figure 2a), a central server (or group of servers) receives (gathers) gradients from participating workers, aggregates (reduces) them, and broadcasts them back to all nodes. In AR (Figure 2b), instead of having separate servers, we distribute the aggregation task across workers, each reducing a subset of gradients and distributing them among themselves (e.g., Ring [121]). Both these architectures have their pros and cons. PS operates well in environments with less powerful worker machines but is bandwidth hungry—increasing linearly with the number of worker nodes. AR, especially Ring, is bandwidth-optimal but leads to longer execution delays that inflate with the number of worker nodes.

Impact of Stragglers on Performance. As shown in Figure 1, during each backward pass, all DDP worker nodes wait for the gradient aggregation (GA) operations to complete before processing the next batch of data. The forward and backward passes computation mostly takes place on a machine-learning (ML) accelerator (e.g., GPU or TPU)—a highly parallel and pipelined architecture with predictable and bounded execution time [69, 156]. Therefore, it is typically the GA operations that lead to long tails and GPU stalls (taking as much as 50% of the overall DDP processing time) [136, 137]. Our measurements across major AI cloud platforms—including AWS EC2 [3], Hyperstack [17], CloudLab [8], and RunPod AI [34]—quantify network tail latencies in a distributed training environment. Using the Gloo benchmark [12] with 2K gradients on eight nodes, we observe tail-to-median ($P_{99/50}$) latency ratios reaching up to 3.2× (Figure 3).

Various factors can contribute to this slowdown in gradient aggregation, including slow workers, transmission delays, incast effects, packet loss and retransmissions, network congestion, and more. For example, even in the PS architecture, each node sends a complete set of gradients to the parameter server, which can result in excessive drops and retransmissions, due to high incast at the ToR switch [104, 172]—hence, increasing the time to process gradients. Similarly, in Ring, a single slow worker (or a buggy link) can cause significant delays, because all nodes participate in the aggregation operation in the form of a ring.

2.2 Straggler Mitigation & Gradient Loss

Mitigating stragglers in distributed systems (as well as distributed deep learning) is an active area of research [48, 54, 60, 61, 81, 92, 132, 145, 158, 164]. One direction focuses on treating stragglers as black boxes and employs schemes, such as redundant task execution [73, 159] or skipping slow workers [57, 67, 164], to mitigate the delays due to network congestion or heterogeneous hardware, for example. They either employ backup workers and select the output of the fastest ones,

[3] A batch is a set of training data used in a given forward/backward pass.
[4] PyTorch limits these simultaneous reduction operations to two [106].

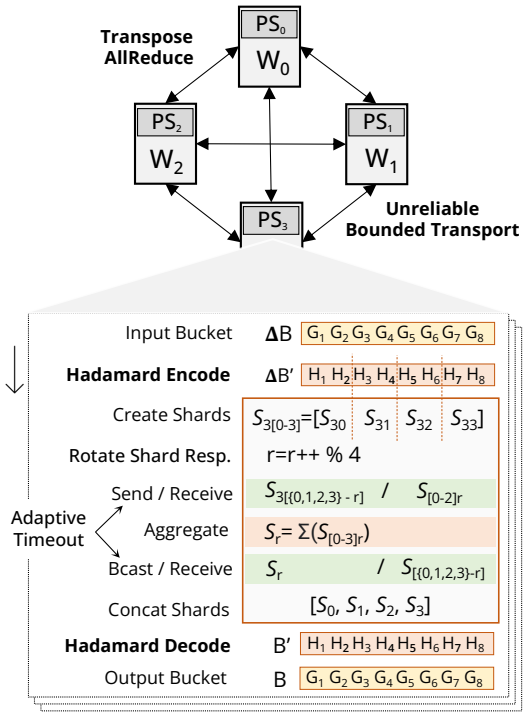

Figure 4: The OPTIREDUCE design: Transpose AllReduce with colocated parameter servers, Unreliable Bounded Transport, and Hadamard Transform.

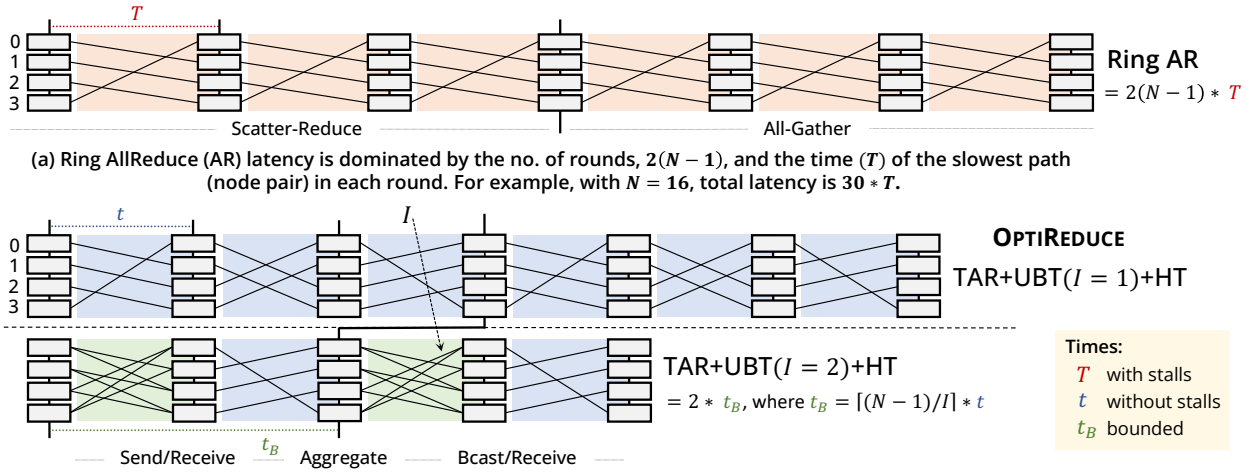
or simply skip the slow workers altogether. However, the former can significantly increase the operational expense (in dollars). For example, training a GPT-3 model consisting of 175 billion parameters over 355 GPU-years (on a V100) [5, 53] can cost an additional $1 Million ($5.6 Million total) on the AWS instance, `p3.16xlarge`, [27] with only 16% backup nodes (i.e., 2 backups for every 10 worker nodes). This cost can further inflate by about 10× when using more powerful GPUs (e.g., A100 and H100) [6, 7], higher link speeds (e.g., 40/100 Gbps), and RDMA-enabled NICs [4]. Whereas ignoring worker nodes entirely, in the latter case, can lead to slower convergence rates and poor accuracies [57, 164]. The other direction is to replace commodity servers with specialized hardware (e.g., powerful machines with predictable performance [163, 174]) and dedicated (lossless) communication fabric [47, 95, 123]. Despite their success in HPC-like environments [117, 120, 122, 162], these solutions are not applicable in a cloud environment with myriads of tenants, all sharing the resources of the underlying data centers.

Instead of treating them as black boxes or specialized devices, we argue to replace the (tail-prone) deterministic, run-to-completion workers with their best-effort, *time-bounded* implementations. The idea is to restrict the processing time of a slow worker and utilize its partial output (gradients) in the next training phase, rather than skipping it entirely.

Resilience to Gradient Loss vs. Performance and Accuracy. Unlike traditional distributed systems (e.g., file sharing and web serving), the stochastic nature of distributed deep-learning systems provides an interesting trade-off between gradient loss (approximation or drops), performance, and accuracy. These systems (based on SGD-based optimization) [52] are shown to be resilient against estimation inaccuracies in stochastic gradients under different settings [79, 153]. For example, various gradient sparsification [68, 131, 154] and quantization [44, 109, 155] schemes employ this fact to reduce network traffic overhead. ATP [99] and SwitchML [136] utilize fixed-point arithmetic to execute gradient aggregation in programmable switches with acceptable approximation loss. Hardware designers incorporate approximate operations (e.g., approx. multipliers [134, 171]) to minimize chip area and energy usage. More recently, MLT [153] demonstrated that these deep-learning models (e.g., CNNs and LMs) are also resilient to a certain degree of gradient drops—sustaining high accuracy up to 1% of gradient loss. Additionally, the impact of gradient loss further diminishes as the number of worker nodes increases [168].



3 Design of OPTIREDUCE

We present OPTIREDUCE, a robust AllReduce communication collective system optimized to mitigate tail-latency by exploiting the unique characteristics of distributed-deep learning (DDL)—i.e., resiliency to gradient loss—to quickly reach the convergence accuracies of traditional architectures (e.g., PS and Ring) while mitigating the impact of stragglers and network variabilities.

Overview. Figure 4 shows the various components of OPTIREDUCE. *Transpose AllReduce (TAR)* (§3.1) implements a peer-to-peer collective-communication fabric, where each node also serves as a parameter server (PS)—a colocated PS architecture [68, 88]. *Unreliable Bounded Transport (UBT)* (§3.2) allows these nodes to connect with each other in a best-effort but controlled manner, and bounds the time spent by the two send(bcast)/receive stages during the AllReduce phase. The PS nodes encode (and decode) gradients in the input bucket (B), using *Hadamard Transform (HT)* (§3.3) to disperse the effect of gradient loss, before creating shards (S_{ij}) of gradients to be sent to other nodes for reduction. They iteratively *rotate shard responsibility* among themselves by maintaining a global index (r). Finally, OPTIREDUCE employs mechanisms (i.e., snapshots and selective skipping) to protect against excessive gradient loss due to transient errors or failures (§3.4); these safeguards ensure robustness and help maintain accuracy under unstable conditions. All these components operate in tandem to optimize for three competing objectives in OPTIREDUCE: maximizing performance, minimizing gradient drops, and sustaining accuracy.

3.1 Transpose AllReduce (TAR)

We begin with Transpose AllReduce (TAR), which implements a hierarchical peer-to-peer gradient-sharing strategy to limit the impact of lost gradient entries when applying the other design optimizations, discussed later. TAR operates by

(a) Ring AllReduce (AR) latency is dominated by the no. of rounds, $2(N-1)$, and the time (T) of the slowest path (node pair) in each round. For example, with $N = 16$, total latency is $30 * T$.

(b) OPTIREDUCE improves latency by reducing the no. of rounds to $2\left\lceil\frac{N-1}{I}\right\rceil$ with incast parameter (I) and bounds the path delay to t_B using Transpose AllReduce (TAR), Unreliable Bounded Transport (UBT), and Hadamard Transform (HT). For example, with $N = 16, I = 2$, the total latency is within $2 * t_B = 16 * t$, where $t \ll T$.

Figure 5: A comparison of Ring versus OPTIREDUCE.

having each node send its gradient entries directly to all other nodes during an AllReduce phase for aggregation; hence, a lost entry would only impact the aggregated results of a given node-pair in that phase. Whereas, in Ring [121], the impact is accumulated and propagated through a ring until it reaches the intended destination nodes. For instance, in our micro-benchmarks (§5.3), the Mean Squared Error (MSE) between the expected gradients and those of Ring in the presence of loss is 6× that of TAR.

3.1.1 TAR Algorithm: A Colocated PS-inspired Collective. TAR combines the key features of traditional AllReduce (i.e., P2P communication) [59, 102] and Ring (i.e., minimizing bandwidth using shards and avoiding incast via rounds) [121].

In TAR, each node acts as a worker as well as a parameter server (PS), connected together over a P2P collective-communication fabric (Figure 4). The i^{th} PS node (PS_i) receives a bucket of gradient entries (ΔB) as input from the worker process (W_i) and divides it into N shards ($S_{i[0...N-1]}$), equal to the number of nodes. Keeping the r^{th} shard it is responsible for aggregating (S_{ir}), the node PS_i sends the remaining shards ($S_{i[\{0...N-1\}-r]}$) to the neighboring nodes. At the same time, PS_i waits for its shards ($S_{[\{0...N-1\}-i]r}$) and aggregates (i.e., averages) them with S_{ir} into a single shard S_r. Next, PS_i broadcasts S_r to all nodes and receives the aggregated shards from them, $S_{[\{0...N-1\}-r]}$. Finally, these shards are concatenated into a bucket (B) and forwarded to the worker (W_i) to process the next batch of data. When $r = i$, the whole operation appears like a row-wise sum of the transpose of the shard matrix S, as shown in Figure 6; hence, the name *Transpose* AllReduce.

In P2P, each PS node communicates directly with the other nodes (instead of forming a ring). When sharing gradients, they all interact with each other twice: once sending/receiving shards to the other node and then broadcasting/receiving aggregated shards, hence limiting the impact of accumulated

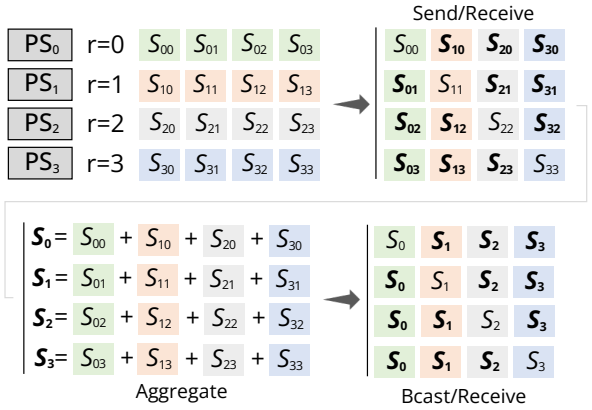


Figure 6: Transpose AllReduce algorithm: PS nodes send/receive shards S_{ij}, aggregate them, and bcast/receive to other nodes (all acquiring the same copy).

gradient loss. Sharding also alleviates the load on the PS nodes, where each node only aggregates a bucket (B) worth of gradients (rather than $N * B$).[5] Moreover, TAR utilizes the same bandwidth as Ring by sending $B * (N-1)$ bytes over the network during the two send(bcast)/receive stages. Lastly, to mitigate incast, TAR splits the communication between PS nodes over multiple rounds, where—unlike Ring with fixed node-pairs (Figure 5a)—nodes communicate with each other using a round-robin strategy, ensuring a given node-pair never repeats across rounds (Figure 5b).

3.1.2 Hierarchical 2D TAR: Scaling to Larger Node Clusters. TAR scales efficiently using a hierarchical design similar to the 2D Ring [22, 147]. By grouping nodes, it first performs intra-group communication, in parallel, to locally aggregate gradients, followed by inter-group communication for global aggregation. Doing so reduces the number of rounds from $2(N-1)$ in traditional TAR to $2(N/G-1)+(G-1)$, where

[5] PyTorch and TesnorFlow typically use a bucket size of 25 MB [106, 133].

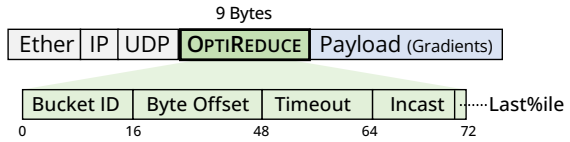

Figure 7: OptiReduce's header format

N is the total number of nodes and G is the number of groups. For example, with $N = 64$ and $G = 16$, traditional TAR requires an order of magnitude more rounds than 2D TAR—126 compared to just 21. We provide more details in Appendix A.

Summary: TAR functions similarly to Ring, yet it *reduces the impact of lost gradients* by establishing P2P communication among all nodes in each round, avoiding the propagation of losses via aggregation through intermediate nodes.

3.2 Unreliable Bounded Transport (UBT)

One of the primary causes affecting tail latency in DDL is the variability in the network behavior due to congestion [61, 153]. Current transport protocols (like TCP) further exacerbate these effects by demanding reliable, in-order delivery of packets (gradients) between training nodes—if packets are dropped or received out-of-order, TCP will stall until all gradients are received over the affected path.

However, simply replacing TCP with message-based protocols (like UDP) would not work. While UDP is faster, as it avoids packet retransmission and reordering, it lacks congestion control, which can lead to network congestion collapse. Moreover, UDP sends data at full link speed (e.g., 100 Gbps), causing excessive drops (loss of gradients) beyond what DDL models can tolerate.

To address this, we enhance UDP with adaptive timeouts, dynamic incast, and minimal rate control to create a new Unreliable Bounded Transport (UBT) protocol, which limits its computation and communication time while maximizing gradient delivery in each round. It adds a new 9-byte header, `OptiReduce` (Figure 7), to commit arriving packets (with gradients) to the right bucket and offset using the header fields, `Bucket ID` and `Byte Offset`, respectively. These fields ensure that gradients reach the correct bucket, irrespective of the ordering of the incoming packets when multiple GA operations are running in parallel (Figure 1).

3.2.1 Adaptive Timeout. UBT implements adaptive timeouts to bound the tail communication time of the send(bcast)/receive stages of the GA operations to t_B (Figure 5b). By restricting the time to t_B, we can control the worst-case execution of these stages—allowing GA operations to finish within a bounded time.

However, there are a couple of challenges with this approach. (1) How to select the value of t_B? Too small will lead to undue loss, and too high will cause unnecessary delays. Moreover, the value will vary with environmental settings (e.g., GPU type, CPU clock, vCPUs, and interface speed) and parameters (e.g., no. of nodes, bucket sizes, and incast). (2) A single lost packet, which is likely in UBT, would cause the

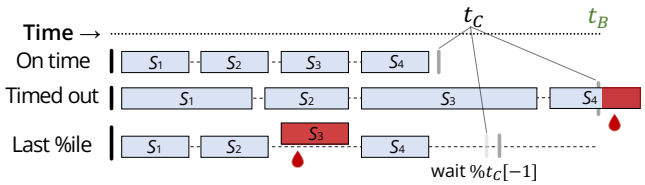

Figure 8: Different timeout strategies in OptiReduce.

GA operation to always take t_B (worst-case) time to finish. TCP, on the other hand, can perform better in some instances where communication may finish faster than waiting for the full timeout (t_B), even with retransmissions.

Selecting the Timeout Value (t_B). As shown in Figure 1, during backpropagation, multiple GA operations execute in parallel on buckets of varying sizes. For selecting t_B, during the initialization phase, we run GA with TAR and TCP, using the largest bucket, for a couple of iterations to collect completion times for both send(bcast)/receive stages. PS nodes share these values with each other using the `Timeout` field in the OptiReduce header (Figure 7).

We then form a list of these times and set t_B to the 95th %ile of that list. In §5, we show that using 20 iterations and the 95th %ile value allows OptiReduce to sustain full model accuracies while finishing up to 2× faster.

Progressing Quickly via Early Timeout. To avoid approaching t_B every time a loss happens, we introduce an early timeout scheme, which causes GA's receive stages to expire whenever there are no remaining gradient entries to read (i.e., the buffer is empty). For each bucket, we track a moving average (t_C) of completion times; we keep separate averages for both the receive stages in GA (Figure 5). The sender PS node tags the last 99th %ile packets by setting the `Last%ile` field in the header. When the buffer is empty, the receiver node checks if some of the last %ile packets have been received from all nodes. If so, it waits for an x% of t_C time before expiring (Figure 8).

The value of x% is dynamically adjusted based on the percentage of gradient entries dropped from the previous round. Starting at 10%, the goal is to maintain gradient losses between 0.01% and 0.1%. If losses exceed this range, x% is doubled until they return within the limit. If losses drop below 0.01%, x% is decreased by 1 until the desired range is reached. (The maximum x% is capped at 50%.) If gradient losses exceed 2% at any point, we activate Hadamard Transform (§3.3) to mitigate the effects of dropped gradients on convergence accuracy. [6]

We calculate t_C in the following steps. First, we compute the (expected) completion time of a given receive stage: (1) if on time, then we set t_C to the current time spent, (2) if timed out, then $t_C = t_B$, and (3) if last %ile received, then t_C is set to the expected time needed to receive all data (e.g., t_C = current time spent × total / received data). Next, we pick the median

[6] The 2% threshold is set based on prior work [153] and our evaluations §5.3.

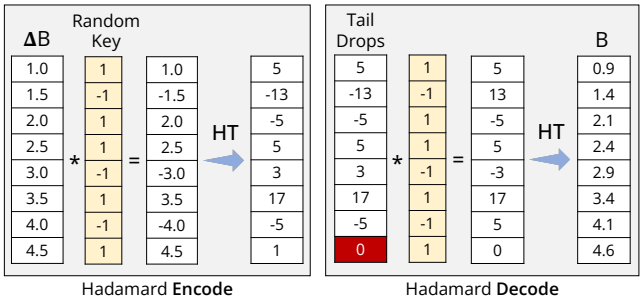

Figure 9: Dispersing the effect of lost gradients (e.g., due to tail drops) using Hadamard Transform (HT).

t_C from the values computed by the N PS nodes (shared over the `Timeout` field in the header). Finally, we calculate the moving average: $t_C = \alpha * t_C + (1-\alpha) * t_C[-1]$.

3.2.2 Dynamic Incast. UBT further introduces a notion of dynamic incast (Figure 5b). The TAR's P2P communication model lets OptiReduce alter the number of senders (I) a PS node can receive gradients from in a given round. For example, setting $I = 1$ (a single sender) would cause TAR to take the same number of rounds as Ring, $2(N-1)$; however, increasing $I = 2$ would quickly reduce these rounds by about half, $2\lceil (N-1)/2 \rceil$; and so on.

The incast parameter (I) can be configured either statically at boot time, based on the available network and node capacity (e.g., modern datacenters can handle hundreds of thousands of incast packets without degrading performance [80, 115]), or dynamically adjusted based on runtime metrics (like throughput, latency, or loss rate). In UBT, receivers dynamically modify the incast factor in response to current loss and timeout events. If the loss rate increases, the factor is reduced to alleviate congestion; conversely, if the loss rate remains low (indicating timely packet reception with no timeouts), the incast factor is increased. Receivers communicate their incast factor, I, by updating the `Incast` field in the OptiReduce header (Figure 7), and the sender then selects the smallest reported value of I for that round.

3.2.3 Minimal Rate Control. Since OptiReduce is resilient to loss, we only require a minimal scheme for rate control to prevent congestion collapse. For that, UBT employs a basic TIMELY-like rate-control mechanism [114], where the sender adjusts flow rates based on RTT feedback derived from timestamps returned by the receiver at regular intervals (every 10th packet) over a separate control channel. If the RTT (or its gradient) is below T_{low}, the sender increases the rate by α, and if the RTT exceeds T_{high}, the rate is reduced by $(1-\beta \cdot (1-T_{high}/\text{RTT}))$. In our experiments, we set $T_{low} = 25\mu$s, $T_{high} = 250\mu$s, $\alpha = 50$ Mbps, and $\beta = 0.5$, when running in a shared environment [114, 153].

Summary: UBT, in conjunction with TAR, *improves tail latency* by minimizing the impact of network congestion; adaptive timeouts bound the latency of the send(bcast)/receive stages, while dynamic incast reduces the number of communication rounds.

3.3 Dispersing Gradient Loss

Finally, to make OptiReduce resilient against drop patterns (e.g., tail drop) in the network, we employ *randomized* Hadamard Transform (HT) [144, 148, 149], which spreads the effect of a dropped gradient over the entire bucket. For example, in Figure 9, HT encodes a bucket (ΔB) and sends it over the network. Upon reception, the last gradient (in red) was lost; however, HT preserves the lost information by slightly perturbing the values of other gradients in the decoded bucket (B). The Mean Squared Error (MSE) between the decoded and received (without HT) bucket, compared to the original one, is 0.01 and 2.53, respectively. That is why, when combined with rotating shard responsibility between nodes (Figure 4), HT lets OptiReduce be more aggressive with the timeout value (t_B) while still reaching high model convergence accuracies (§5).

Summary: HT, together with TAR+UBT, *limits the effect of dropped gradients* by spreading it across the entire bucket, thus preserving the lost information. Additionally, it allows OptiReduce to operate faster, with stringent t_B values, without affecting convergence accuracies (§5).

3.4 Safeguards against Excessive Loss

OptiReduce continuously monitors gradient loss during each AllReduce phase, and if the loss exceeds a predefined threshold, it can either skip the gradient update for that round or automatically halt the training, prompting user intervention. Skipping an update helps minimize potential harm to the overall training process by discarding transient high-loss updates without impacting long-term model accuracy or completion time. This mechanism helps prevent major disruptions in the training process, ensuring users are notified of any accuracy concerns and can make necessary adjustments. Similar techniques are routinely integrated into modern deep-learning pipelines to monitor, track, and recover model accuracy [1, 2, 32, 119].

4 Implementation

We develop OptiReduce as a new collective-communication scheme inside the Gloo library (v0.5.0) [13] and integrate it with PyTorch Distributed (v1.12) [106], a widely used deep-learning framework—allowing OptiReduce to work without modification with a large body of deep-learning models (e.g., CNNs [82, 98, 138], RNNs [56, 85, 113], and Transformers [53, 63, 150]). We pick Gloo due to its simpler design and our familiarity with the codebase; however, we expect OptiReduce will yield similar benefits when operating with other popular libraries (e.g., NCCL [87] or MSCCL [24]).

We extend the C++ implementation of Gloo to support our Transpose AllReduce (TAR) collective and provide support for both reliable transport (over TCP) and our best-effort transport (over UBT). We prototype UBT as a userspace transport

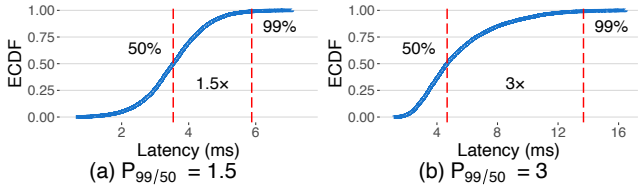

Figure 10: Our local cluster with tail-to-median latency ratio ($P_{99/50}$) of 1.5 (a) and 3 (b).

layered on UDP, including rate control, using Nvidia DPDK API (v20.11) [11].

We further add support for communication hiding in OptiReduce, i.e., running two AllReduce operations in parallel with backpropagation.[7] The sender maintains separate layer-3 port numbers to tag gradients for the two parallel AllReduce operations. On the receive side, two PMD threads poll incoming traffic (gradients) in their local receive queues. An Nvidia Connectx-6 NIC routes traffic to the respective queues based on the port numbers; we install rules in the NIC using DPDK's `rte_flow` API [10]. We also install rules to route non-OptiReduce traffic to the kernel using DPDK's Flow Bifurcation mechanism [9].[8] Doing so ensures that Gloo's kernel stack remains unaffected and other network operations, e.g., rendezvous in PyTorch DDP [106], continue uninterrupted.

To include support for adaptive timeouts, we use C++ STL library's `wait_for()` function [89], which is a blocking call that returns either when a given condition is met (such as received all gradients) or a timeout occurs. For the timeout, we pair the `wait_for()` function with Chrono library's `high_resolution_clock()` [89] to operate at nanosecond clock granularity. For Hadamard Transform, we apply a widely-used C++/CUDA implementation by HazyResearch [15], which uses GPUs to perform this operation. We use PyTorch DDP's communication hook [31] to register Hadamard's encode/decode callbacks for processing gradient buckets before and after reduction, respectively.

5 Evaluation

In this section, we provide an end-to-end comparison of OptiReduce with state-of-the-art solutions (§5.2), and microbenchmark the utility of its design components (§5.3).

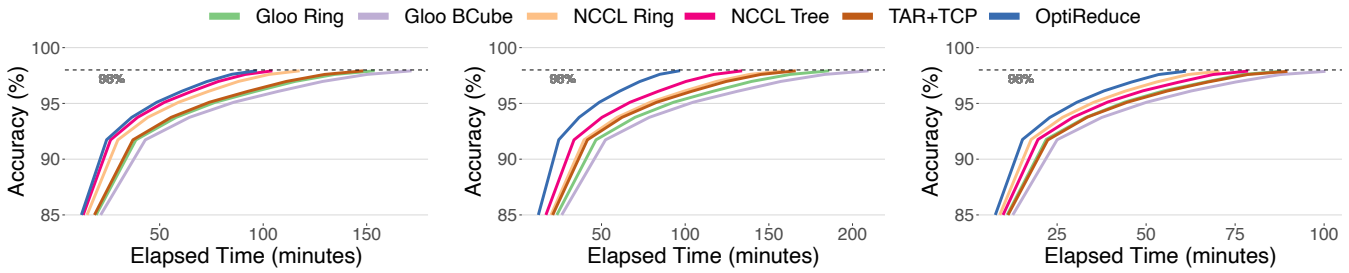
5.1 Experimental Setup

5.1.1 Test Environments. We evaluate OptiReduce in both our local virtualized cluster and a real-world environment using CloudLab [66].

a) Local Virtualized Cluster. Our local testbed is a collection of four servers configured as a virtualized cluster [30]. Each machine has a 32-core AMD EPYC 7542 CPU @ 2.90 GHz, 512 GB RAM, two Nvidia Tesla V100 GPUs, and a ConnectX-5 dual-port NIC. In total, there are eight V100 GPUs, one per VM in the cluster. The VMs communicate over the network using a dedicated NIC port with Nvidia's OFED device drivers (v24.04). Both GPU and NIC interfaces are exposed to the VMs via Intel's VT-d PCIe passthrough technology [41]—allowing direct (dedicated) access to the physical functions. A programmable switch (Tofino1 [18]) connects the servers and VMs over a 25 Gbps network. Additionally, it facilitates in-network aggregation for SwitchML benchmarks (§5.3).

Recent studies from Microsoft [137], Amazon [91], and Google [61, 62] show that the tail-to-median ratio ($P_{99/50}$) for distributed workloads, including deep-learning training, ranges from 1.5× to 4× in large cloud data centers [40, 61, 106].[9] To emulate these environments and their tail characteristics in our testbed, we follow the approach of previous studies [42,45,46,151,165] by running background workloads on random nodes and links. Varying the number of concurrent workloads allows us to adjust the tail-to-median latency ratio within the network. We validate the fidelity of our scheme using the Gloo benchmark utility [12] with 2K gradients. As shown in Figure 10, our method accurately preserves the expected latency distributions, maintaining the $P_{99/50} = 1.5, 3$ ratios.

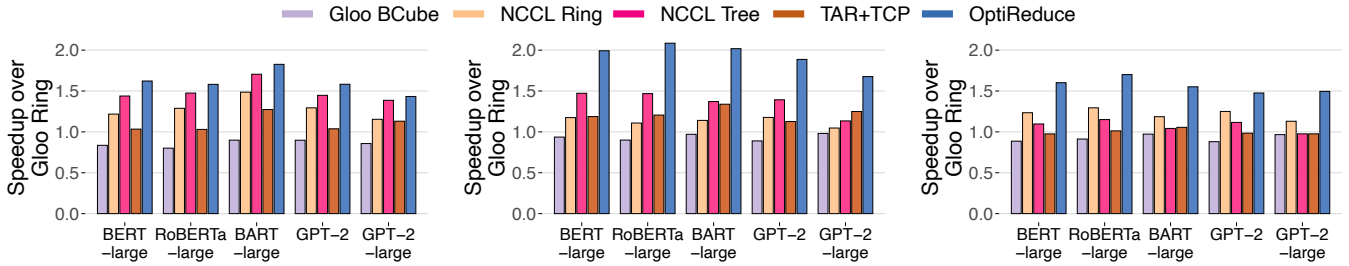
b) Public Cloud: CloudLab. We configured our real environment on CloudLab [66], a public research cloud widely shared by researchers and academics for computing and distributed systems experimentation. We provisioned eight `d7525` instances [8], each equipped with an Nvidia Ampere A30 GPU and a ConnectX-6 DX dual-port NIC, all connected via a 10 Gbps network.



5.1.2 Baselines, Workloads, and Parameter Settings. We evaluate OptiReduce against the following baseline systems: Gloo (Ring [121] and BCube [76]), NCCL (Ring [121] and Tree [22]) with TCP, as well as a reliable version of our Transpose AllReduce (TAR) with TCP (TAR+TCP). Additionally, we evaluate BytePS and three popular compression algorithms: Top-K [142], TernGrad [155], and THC [103]. To provide further insights, we also microbenchmark OptiReduce against in-network systems such as SwitchML [136], despite their reliance on switch-level access within the provider's network, which makes them inapplicable for cloud environments.

We train a variety of language models (LMs), including BERT-base/large [63] and RoBERTa-base/large [111] on the SQuAD 2.0 dataset [129], as well as BART-base/large [101] and OpenAI GPT-2-base/large [126] on the GLUE benchmark [152] for the SST2 (Stanford Sentiment Treebank) task [139]. We further evaluate OptiReduce on additional models and tasks, which we discuss in Appendix B and C. Specifically, we train the Llama-3.2 1B model [65] on three

[7] This is consistent with existing parallelism approaches that allow for two concurrent AllReduce operations (e.g., PyTorch [106]).



[8] Flow Bifurcation is a mechanism that lets hardware-capable NICs forward traffic directly to the userspace (DPDK thread) or the Linux kernel.

[9] Even CloudLab, a relatively small-scale cloud compared to commercial ones, exhibits a $P_{99/50}$ ratio of around 1.45.

(a) Local Cluster: $P_{99/50} = 1.5$ **(b)** Local Cluster: $P_{99/50} = 3$ **(c)** CloudLab

Figure 11: Time-to-accuracy (TTA) comparison for the OpenAI GPT-2 model with eight worker nodes.

(a) Local Cluster: $P_{99/50} = 1.5$ **(b)** Local Cluster: $P_{99/50} = 3$ **(c)** CloudLab

Figure 12: Training throughput comparison for large language models (LLMs) with eight worker nodes.

standard downstream tasks: SQuAD (extractive question answering) [129], ARC (science reasoning) [58], and MATH (symbolic mathematics) [83] (Appendix B). Additionally, we evaluate and microbenchmark OptiReduce on network-intensive models (VGG-16/19) [138] using the CIFAR-100 dataset [97] and compute-intensive models (ResNet-50/101/152) [82] with the ImageNet dataset [135] (Appendix C).

We compute the OptiReduce's timeout value (t_B) for each model using 20 iterations; we set $\alpha = 0.95$ when calculating the moving average (t_C). We use the incast parameter of $I = 1$, unless stated otherwise.

5.2 End-to-End Evaluation

We conduct end-to-end evaluations in two environments: (1) our local virtualized cluster, with tail-to-median ratios $P_{99/50} = 1.5$ (low variability) and 3 (high variability), and (2) a real public cloud, CloudLab. We compare OptiReduce against the baseline systems Gloo (Ring and BCube), NCCL (Ring and Tree), and TAR+TCP; and measure time-to-accuracy (TTA), throughput, gradient drop percentage (in bytes), and the achieved training accuracy.

Our results show that OptiReduce consistently outperforms the baselines. On our local cluster, we observe time-to-accuracy (TTA) reductions of up to (82%, 98%) compared to Gloo (Ring, BCube), and (44%, 25%) compared to NCCL (Ring, Tree), respectively. These improvements extend to CloudLab, where we see average TTA reductions of up to (47%, 67%) over Gloo (Ring, BCube), and (18%, 32%) over NCCL (Ring, Tree). Furthermore, OptiReduce achieves the same convergence accuracy as the baselines while limiting gradient entry losses to less than 0.1% of the total traffic.

• **TTA and Throughput.** Figure 11 illustrates how TTA for the five baselines and OptiReduce varies under different environments—Local cluster ($P_{99/50}$ = 1.5 and 3) and CloudLab—for the OpenAI GPT-2 model. Across all runs, OptiReduce maintains a lower TTA from the onset.[10] For example, on our local cluster with $P_{99/50} = 1.5$ (Figure 11a), OptiReduce converges in 96 minutes, while NCCL Tree takes 105 minutes, and the next best, NCCL Ring, taking 118 minutes. With $P_{99/50} = 3$, the TTA differences become more pronounced (Figure 11b). OptiReduce remains unaffected by the increased variability, maintaining its lead in TTA with a 98% accuracy and finishing in about 97 minutes. In contrast, the baselines experience significant slowdowns, with their TTA inflating by 1.41–2.18× compared to OptiReduce.

We see the same trend on CloudLab (Figure 11c), OptiReduce reaches the convergence accuracy in 60 minutes, whereas it is 71 minutes for NCCL Ring. Other baselines continue to trail behind OptiReduce, with NCCL Tree having the next-best TTA of 79 minutes.

We observe similar speedups for OptiReduce when training other models, including BERT-large, RoBERTa-large, BART-large, and GPT-2-large (Figure 12).

• **Gradient Drops and Convergence Time.** We further evaluate the drops in gradient entries and their impact on convergence time (Table 1). In our local cluster with $P_{99/50} = 1.5$, a small percentage of gradient entries is lost (i.e., 0.07%) due to OptiReduce's adaptive timeouts in UBT, causing the system to progress without waiting on stragglers. These timeouts manifest as dropped gradients in OptiReduce; whereas

[10] We observe that under ideal conditions, with $P_{99/50} = 1$ (no variability), all systems perform similarly (not shown).

Test Environment	Gloo		NCCL		TAR+TCP	OptiReduce:	*Dropped Gradients (%Entries)*
	Ring	*BCube*	*Ring*	*Tree*			
Local Cluster: $P_{99/50} = 1.5$	154	172	118	105	148	96	0.07
Local Cluster: $P_{99/50} = 3.0$	186	210	159	135	166	97	0.18
CloudLab	88	100	71	79	90	60	0.05

Table 1: Comparing the end-to-end convergence time (in minutes) of baseline systems vs. OptiReduce for OpenAI GPT-2 (total gradients, 40 TB). TAR+UDP suffers excessive drops, losing up to 30% of gradients, and fails to converge.

baseline systems stall on these stragglers. Still, OptiReduce achieves the same convergence accuracy (98% for GPT-2) as the baselines but in under 96 minutes, compared to 105 minutes for the next best, NCCL Tree. When $P_{99/50}$ increases to 3, increased congestion in the network and stragglers cause more gradient entries to be lost, but only slightly (0.18%), and does not impact OptiReduce's training accuracy and convergence time, whereas it inflates NCCL Tree's time to 135 minutes.

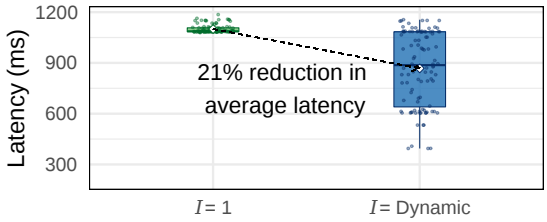
Similarly, in CloudLab, OptiReduce sees a 0.05% drop in gradient entries, which allows it to reach the convergence accuracy in 60 minutes, compared to its next best, NCCL Ring, taking 18% longer.

5.3 Microbenchmarks

We now evaluate the effectiveness of the individual design components in OptiReduce. We run the VGG-19 model on the CIFAR-100 dataset for these measurements using our local cluster.

• **OptiReduce's TAR topology leads to minimum dropped gradients when using a best-effort transport.** We compare the number of gradients lost across different AllReduce topologies using our Unreliable Bounded Transport (UBT). We measure Mean Squared Error (MSE) to gauge the difference between the original gradients and those received over these topologies for three different schemes on our local cluster with $P_{99/50} = 1.5$: Ring topology in Ring-AllReduce, P2P in PS, and P2P with rounds in TAR, using a 500 M tensor. Ring-AllReduce has the worst MSE (14.55)—an order of magnitude greater than TAR (2.47). The presence of fixed node pairs in Ring-AllReduce (§3.1) propagates losses, resulting in a higher deviation from the original gradients. PS also has a high MSE (9.92) due to excessive incast when all nodes send gradients to the parameter server (PS) simultaneously. In contrast, TAR avoids this by distributing P2P communication over multiple rounds.

• **UBT's dynamic incast improves OptiReduce's latency without overloading the receiver nodes.** We measure the effects of UBT's dynamic incast feature on OptiReduce's training latency. Figure 13 compares two configurations: one where we fix $I = 1$, and the other with dynamically managed incast. The results show that OptiReduce's senders can leverage buffer occupancy at receivers to increase I, thus reducing average latency by about 21% compared to always



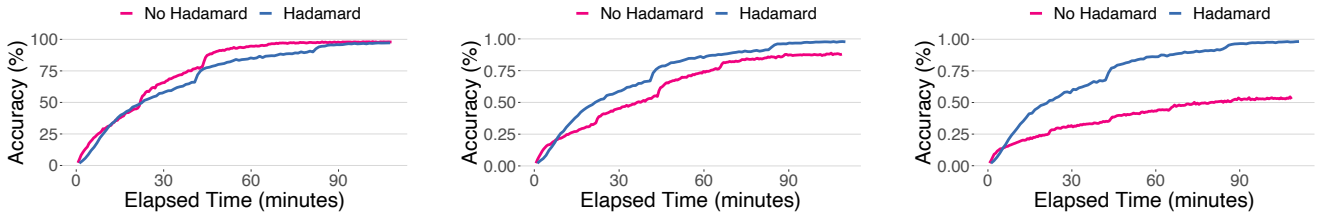


Figure 13: Latency distribution of OptiReduce with static ($I = 1$) vs. dynamic incast feature in UBT, using a synthetic 500 M-gradient AllReduce workload.

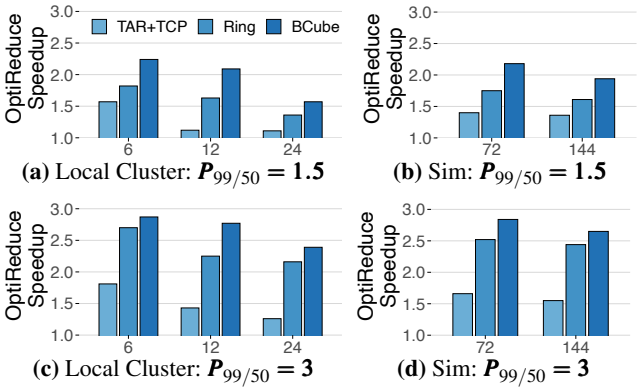
sending to a single receiver. This ability to dynamically control the incast parameter (I) allows OptiReduce to adapt itself based on the capacity of the receivers' resources, which is not the case with PS (all workers send to parameter server) or Ring-AllReduce (a receiver interacts with a single sender).



• **OptiReduce's early timeout strategy enables faster progress towards TTA.** We evaluate the effectiveness of the early timeout strategy (t_C) in OptiReduce. We disable t_C and only keep the timeout value t_B and measure its effect on training accuracy, time, and dropped gradients. We find that when training VGG-19 with $P_{99/50} = 1.5$, OptiReduce takes 130 minutes to reach convergence accuracy in 200 epochs while incurring 0.02% of gradient drops. Enabling early timeout brings this training time down by about 16% (to 112 minutes) with a similar drop rate (0.02%). By adapting t_C, OptiReduce sustains the same drop rate and finishes quickly, rather than waiting for the higher t_B value each time. We notice that with early timeout enabled, OptiReduce triggers t_C 95% more often than t_B; hence, resulting in faster TTAs.

• **OptiReduce's Hadamard Transform (HT) allows it to reach convergence accuracies even under higher percentages of dropped gradients.** Figure 14 shows the training accuracy of VGG-19 model with and without Hadamard enabled. When considering TTA, we see that Hadamard introduces some computational overhead when operating with only 1% of dropped gradient entries (Figure 14a). It takes Hadamard more time to reach convergence accuracies (around 97 minutes) compared to when it is disabled (90 minutes). However, as drops increase (5% or more), it starts to outperform the non-Hadamard instance with much faster TTAs (Figure 14b,c). Looking closely, we notice that across all dropped percentages, Hadamard is able to sustain the same TTA ($\approx$ 97 minutes)—showing its resilience to drops. In contrast, the non-Hadamard case quickly degrades and fails to achieve

(a) 1% gradient drops **(b)** 5% gradient drops **(c)** 10% gradient drops

Figure 14: Training accuracy of VGG-19 with/without Hadamard Transform (HT) in OPTIREDUCE.

(a) Local Cluster: $P_{99/50} = 1.5$ **(b)** Sim: $P_{99/50} = 1.5$

(c) Local Cluster: $P_{99/50} = 3$ **(d)** Sim: $P_{99/50} = 3$

Figure 15: OPTIREDUCE speedup over baseline systems (TAR+TCP, Ring, BCube) with increasing #workers using a synthetic 500 M-gradient AllReduce workload.

convergence accuracy even under 10% drops. The percentage drops include both drops incurred due to network variabilities (e.g., congestion and retransmissions) and gradients that a slow worker could not send due to timeouts.

• **OPTIREDUCE scales with increasing number of worker nodes, consistently maintaining high speedups.** To demonstrate OPTIREDUCE's performance at scale, we first run tests using CPU-based worker nodes on our local cluster. We compare OPTIREDUCE with TAR+TCP and Gloo (Ring and BCube) on a synthetic AllReduce workload, aggregating 500 M gradient entries across 6–24 nodes (Figure 15a, c).[11] Next, we conduct simulations with larger clusters (72 and 144 nodes), similar in sizes to prior works [43, 100, 107, 153]—using latencies sampled from the local cluster and scaled for higher node counts (Figure 15b, d). Across all tests, OPTIREDUCE consistently delivers high speedups, achieving 2× improvements over Ring and BCube in high-tail environments, $P_{99/50} = 3$ (Figure 15c, d).

• **Unlike OPTIREDUCE, lossy/compression schemes are vulnerable to tail effects in shared environments.** Though OPTIREDUCE is orthogonal to sparsification and quantization techniques, our comparison (Figure 16) shows that lossy/compression schemes (e.g., Top-K, TernGrad, and THC) fail to effectively address tail effects. While these schemes reduce the volume of gradient entries shared, they rely on a static evaluation of how much data to compress (or drop) a priori before transmission. In contrast, OPTIREDUCE handles loss

[11] We exclude NCCL from this comparison as it relies on GPUs.

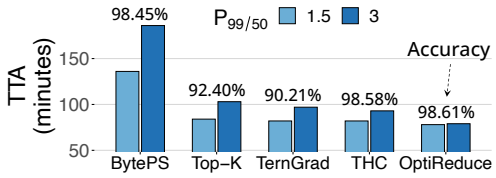


Figure 16: OPTIREDUCE comparison with lossy/compression schemes (BytePS, Top-K, TernGrad, & THC), showing TTA and their convergence accuracy.

in real-time, dynamically adapting to network conditions and minimizing tail latency. For instance, THC matches OPTIREDUCE in convergence accuracy but takes 4% and 18% longer to complete under $P_{99/50} = 1.5$ and 3, respectively. Other schemes perform even worse, either requiring 2× more time to converge or stalling at lower accuracies due to their lossy compression, failing to improve end-to-end TTA even with additional training epochs [103, 153].

• **In-network aggregation (INA) approaches struggle with tail effects, while OPTIREDUCE remains unaffected.** In-network aggregation (INA) methods, such as SwitchML [136], reduce network latency through hardware-accelerated aggregation within the network. However, they remain vulnerable to tail effects—significantly inflating their completion times as the tail-to-median ratio increases. For instance, in a low-tail environment ($P_{99/50} = 1.5$), SwitchML performs 52% faster than OPTIREDUCE. However, as the tail-to-median ratio increases from $P_{99/50} = 1.5$ to 3, its completion time rises by about 2.1×, even surpassing OPTIREDUCE by 28%. In contrast, OPTIREDUCE remains unaffected by this change while reaching convergence. By bypassing stragglers and proceeding without waiting for all gradients, OPTIREDUCE is better suited for shared and high-tail environments. Moreover, OPTIREDUCE's design can be extended to incorporate INA, potentially achieving similar speedups in low-tail environments—an avenue we plan to explore in future work.

6 Limitations & Future Work

In the current AllReduce design, there are two primary bottlenecks: (a) in the computation (or reduction) phase and (b) in the communication phase. We explore potential solutions for both bottlenecks in the subsequent sections.

a) Accelerators for Reduction. In OPTIREDUCE, we primarily focus on bounding the execution time of the two send/receive stages in AllReduce (Figure 1). The reduction stage, i.e.,

the process of averaging gradients together, still happens on CPUs. However, as models grow and gradient sizes increase, the reduction stage can become a bottleneck. Rather than opting for the most extreme case of offloading all of AllReduce to network switches [99,136], we can instead consider offloading the reduction operation on the end-host server (similar to how we accelerate GEMMs using GPUs) [141]. Modern SmartNICs [19,25,26], with onboard FPGAs and ML accelerators, can present a promising opportunity for accelerating reduction. But, doing so requires rethinking and redesigning the application interface (API) between OptiReduce and SmartNICs. We hope OptiReduce to serve as a stepping stone for research in this direction.

b) Accelerators for Network Transport. As with reduction, network transport can also become a bottleneck with link/interface speeds reaching 400 Gbps+. Existing offloads, like RDMA [77], provide high-bandwidth communication between nodes by moving data to/from the main memory and the network without engaging the host CPU. However, these implementations are still susceptible to tail effects in the network (e.g., packet drops and retransmissions). We hope OptiReduce's transport design can offer guidance in building new offloads for network transport, particularly with support for unreliable bounded protocols. As a next step, we could explore offloading OptiReduce's transport onto hardware using RDMA's Unreliable Connected (UC) or Unreliable Datagram (UD) queue pairs [49]. However, these implementations currently suffer from excessive packet drops when packets arrive out of order [23]. We plan to address these challenges in future work.

7 Related Work

Lossy Architectures for Accelerating Allreduce Collectives. THC [103] presents compression-aware gradient synchronization architectures for DNN training, introducing homomorphic compression to reduce bandwidth through quantization. OmniReduce [68] introduces the concept of a streaming aggregation, which exploits parameter sparsity to maximize effective bandwidth use by sending only non-zero data blocks. MLT [153] configures network switches to prioritize and drop packets based on model layers and gradient magnitudes, leveraging inter-packet order-independency to balance load. In contrast, OptiReduce exploits DDL's resiliency to gradient drops in mitigating tail effects while sustaining convergence accuracies in the cloud without requiring access to the provider's network. It could apply techniques like OmniReduce to reduce network usage for models with sparse gradients or use quantization methods similar to THC.

Accelerating Deep Learning using In-Network Computing. SHArP [75] is a hierarchical aggregation protocol and architecture in Nvidia Switches (e.g., IB-2 [35]), which builds an overlay reduction tree for aggregating data flowing through the switch. SwitchML [136] accelerates distributed training by using a programmable data-plane device (e.g., Intel Tofino [18,51]) to aggregate the model updates from multiple workers in the network. To overcome the switch memory and computational constraints, they co-design the in-switch processing with end-host protocols (e.g., sliding window of parameters) for handling drops. ATP [99] is an in-network aggregation solution similar to SwitchML, but for deep learning, and is designed to provide a dynamic, best-effort in-network aggregation service for multi-tenant multi-switch clusters. Unlike these solutions, OptiReduce does not require specialized hardware or access to the provider's network.

Optimizing Deep Learning for Enterprise and HPC Environments. Cassini [128] is a network-aware job scheduler for ML clusters in HPC environments that optimizes network resource usage by interleaving communication patterns of ML jobs, reducing congestion and improving cluster performance. Meta's recent paper [72] presents a custom backend for distributed deep-learning training targeting enterprise data centers. It optimizes network topology, job scheduling, placement, and data transport to improve training performance, efficiency, and scalability. On the other hand, OptiReduce offers a resilient and tail-optimal solution for deep-learning training in the cloud.

8 Conclusion

OptiReduce leverages distributed-deep learning's (DDL) resiliency to lost gradients and achieves speedups of up to (70%, 30%), on average, over existing frameworks (Gloo, NCCL), in shared environments (e.g., public clouds). OptiReduce implements a domain-specific Transpose Allreduce collective algorithm with unreliable bounded transport (UBT) featuring adaptive timeouts, while mitigating the impact of gradient loss using Hadamard Transform. It delivers higher tail performance (e.g., TTA and training throughput) while preserving DDL models' convergence accuracy and limiting gradient drops to under 0.1%. Looking forward, we hope OptiReduce inspires further exploration of the tradeoff between tail performance and training accuracy in processing contemporary deep-learning models.

Acknowledgements

We sincerely appreciate the guidance of our shepherd, Changhoon Kim, as well as Ashwin Murthy, Roop Mukherjee, Leo Liu, Minlan Yu, Tushar Krishna, Ajay Brahmakshatriya, and the anonymous reviewers for their valuable feedback in strengthening this paper. We also thank Roop Mukherjee, Leo Liu, Ali Imran, and Ali Aqdas for helping with the artifact and initial background studies on tail behavior in distributed training environments, conducted on Nvidia's internal shared clusters and AWS EC2 instances. This work was supported in part by ACE, one of the seven centers in JUMP 2.0, a Semiconductor Research Corporation (SRC) program sponsored by DARPA; by NSF awards CAREER-2338034 and CNS-2211381; and through a Google Research Scholar Award. Support also came in part via a generous gift from Nvidia.

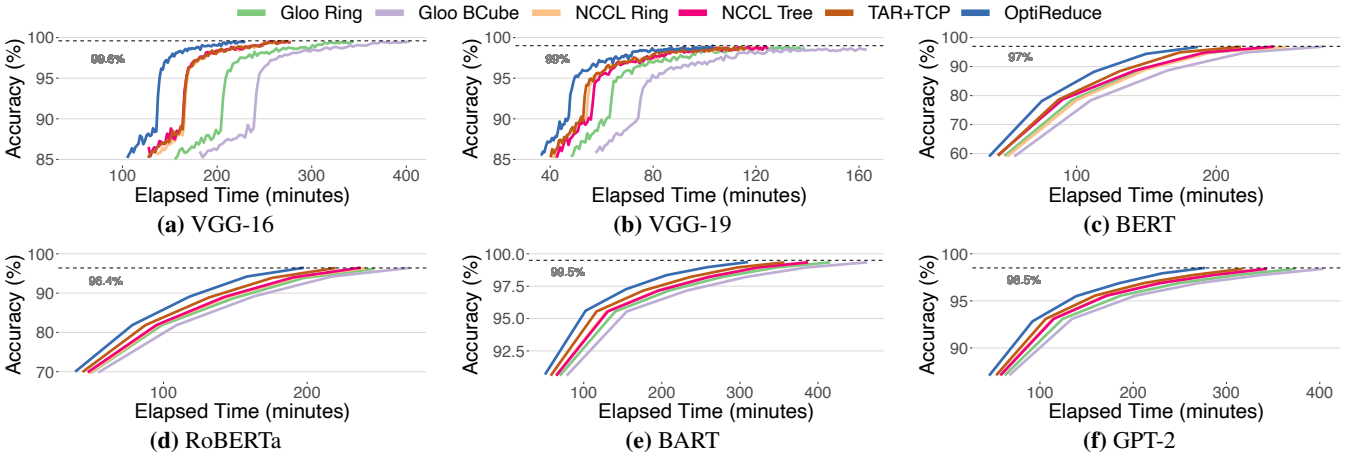
A Hierarchical 2D TAR Algorithm: Scaling to Larger Node Clusters

In the hierarchical TAR design (Figure 17), nodes are grouped to optimize both intra-group and inter-group communication, reducing the total number of rounds and connections required for AllReduce. For example, with $N = 64$ total nodes divided into $G = 16$ groups, each node communicates only with its corresponding rank across the groups. The number of rounds reduces from $2(N-1) = 126$ in traditional TAR to $2(N/G-1)+(G-1) = 21$ rounds. The algorithm works in three steps:

- **Intra-group Communication:** Nodes within each group perform send/receive operations followed by aggregation, in parallel, resulting in the *locally* aggregated shard for their rank—taking $(N/G-1)$ rounds.
- **Inter-group Communication:** Corresponding ranks across groups then perform send/receive operations, followed by aggregation, to get the *globally* aggregated shard for their rank—adding another $(G-1)$ rounds.
- **Broadcast Phase:** Finally, nodes within the group broadcast their aggregated shards, which are concatenated to form the globally aggregated gradient bucket—an additional $(N/G-1)$ rounds.

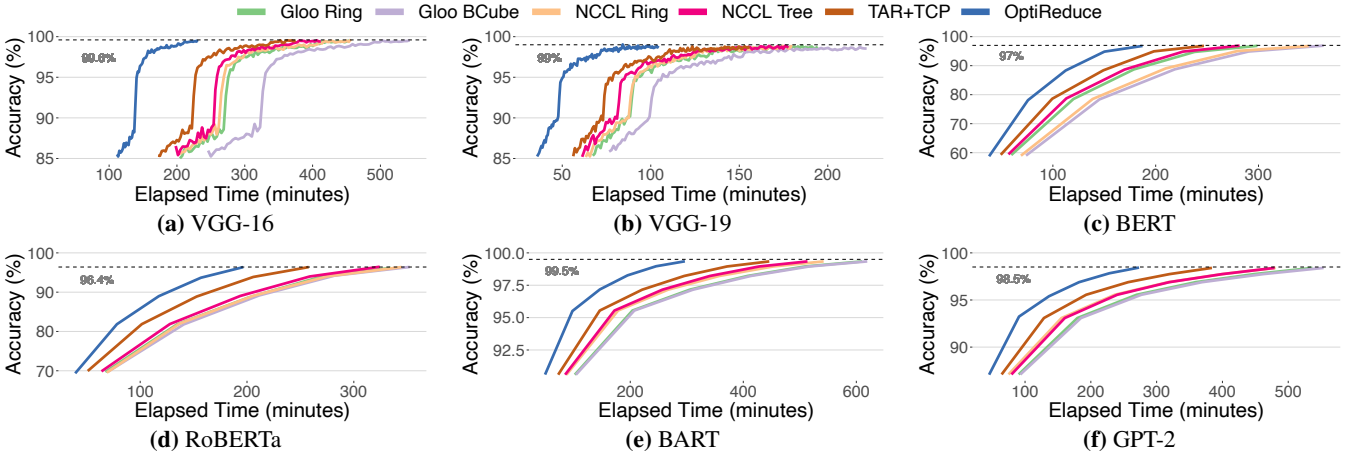


This hierarchical design significantly reduces communication overhead, improving scalability and efficiency for large-scale distributed training.

B Benchmarking Llama-3.2 1B Model

Using our local testbed (§5.1), we evaluate OptiReduce with the Llama-3.2 1B model [65] on three well-known downstream tasks: SQuAD (extractive question answering) [129], ARC (science reasoning) [58], and MATH (symbolic mathematics) [83], across both low-tail ($P_{99/50} = 1.5$) and high-tail ($P_{99/50} = 3.0$) environments. Table 2 provides a detailed comparison of training times across all schemes. OptiReduce consistently demonstrates performance improvements across all tasks. Compared to NCCL, it achieves speedups of 1.35× on MATH, 1.25× on ARC, and 1.08× on SQuAD, averaging a 1.24× improvement. The gains are even more pronounced against Gloo, with speedups of 1.73×, 1.61×, and 1.49× respectively, averaging 1.61×. These improvements scale further under high-tail conditions, reaching speedups of up to 2.1× while preserving baseline model convergence and test accuracies.

C Network and Compute Intensive Models & Base LMs



In this section, we present time-to-accuracy (TTA) plots for additional models, including computer vision models (ResNet-50/101/152, VGG-16/19) and base LMs (BERT, RoBERTa, BART, and GPT-2). The experiments use the same local testbed setup described in §5.1, but with six worker nodes (VMs). We compare results across two environment configurations, characterized by tail-to-median ratios ($P_{99/50}$) of 1.5

(a) VGG-16 (b) VGG-19 (c) BERT

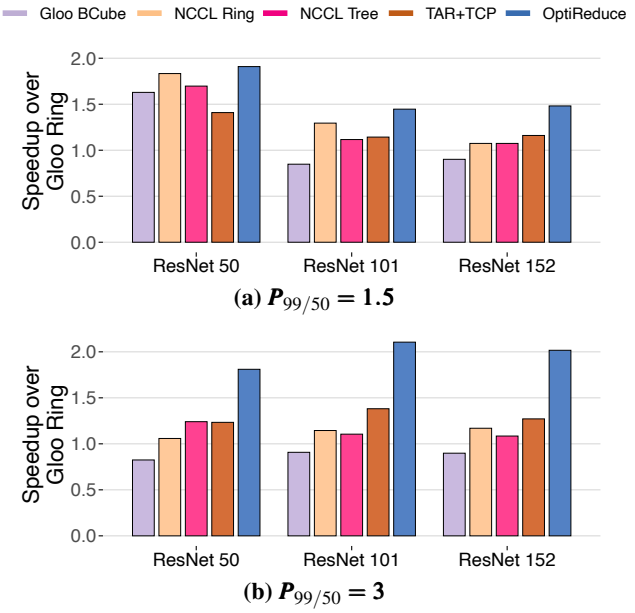
(d) RoBERTa (e) BART (f) GPT-2

Figure 18: Time-to-accuracy (TTA) of baseline systems vs OptiReduce with tail-to-median ratio: $P_{99/50} = 1.5$.

(a) VGG-16 (b) VGG-19 (c) BERT

(d) RoBERTa (e) BART (f) GPT-2

Figure 19: Time-to-accuracy (TTA) of baseline systems vs OptiReduce with tail-to-median ratio: $P_{99/50} = 3$.



(low variability) and 3 (high variability).

C.1 Time-to-accuracy (TTA)

We observe similar gains for these network-intensive models (VGG-16/19) and base LMs, with up to (66%, 75%) and (50%, 51%) reductions in TTA, on average, compared to Gloo (Ring, BCube) and NCCL (Ring, Tree), respectively—Figure 18 ($P_{99/50} = 1.5$) and Figure 19 ($P_{99/50} = 3$). OptiReduce achieves the same convergence accuracy as the baselines while limiting lost gradients to less than 1.5%, on average, of the communicated traffic.

C.2 Training Throughput (Speedup)

While compute-intensive models like ResNets [82] typically do not gain significant advantages from optimized communication [103, 153], their performance can be impacted in shared environments (such as public clouds) due to long-tail latencies. Our evaluations reflect this, where OptiReduce demonstrates notable improvements over baseline systems, achieving average speedups of 22% over NCCL and 53% over Gloo for three ResNet models (50/101/152) across both environment configurations (Figure 20).

(a) $P_{99/50} = 1.5$

(b) $P_{99/50} = 3$

Abstract

We consider the problem of distilling efficient network topologies for collective communications. We provide an algorithmic framework for constructing direct-connect topologies optimized for the latency vs. bandwidth trade-off associated with the workload. Our approach synthesizes many different topologies and communication schedules for a given cluster size and degree, then identifies the best option for a given workload. Our algorithms start from small, optimal base topologies and associated schedules, using techniques that can be iteratively applied to derive much larger topologies and schedules. Additionally, we incorporate well-studied large-scale graph topologies into our algorithmic framework by producing efficient communication schedules for them using a novel polynomial-time algorithm. Our evaluation uses multiple testbeds and large-scale simulations to demonstrate significant performance benefits from our derived topologies and schedules.

1 Introduction

Collective communication operations involve concurrently aggregating and distributing data on a cluster of nodes and are used in both machine learning (ML) and high-performance computing (HPC). With the improved computational capabilities of accelerators, collective operations are a significant overhead in large-scale distributed ML training [20,44,64,76].

An emerging approach to address these challenges has been to employ various forms of optical circuit switching to achieve higher bandwidth at reasonable capital expenditure and energy costs [29,30,40,43,73,77,81]. Hosts communicate using a limited number of optical circuits that can be reconfigured at timescales appropriate for the hardware, thus exposing network topology as a configurable component. We refer to this setting as *direct-connect* with circuits configured and fixed for an appropriate duration.

Existing optical-circuit-based ML systems [30,43,73,81] fit this direct-connect model but do not exploit the flexibility topology reconfiguration offers. Collective operations such as allreduce are still limited to a few well-known algorithms that can fit the degree constraints of the optical fabric (e.g., rings, multi-rings, tori) and accept the consequent performance tradeoffs. For example, ring allreduce, while bandwidth-efficient, has a high graph diameter, causing high total-hop latency. A double binary tree, on the other hand, has a logarithmic diameter but suffers from load imbalances and bandwidth inefficiencies. Conversely, the broader spectrum of well-known collective algorithms that achieve desired latency and bandwidth (e.g., recursive-doubling, Bruck algorithm) [72,79] use dynamic communication patterns ideal for switch networks but are ill-suited for degree-constrained direct-connect networks.

To fill this gap, we seek to identify new custom-built topologies and communication schedules for direct-connect networks. We pose the following question: *How to efficiently construct high-performance direct-connect topologies and communication schedules for collectives given the network's performance characteristics and degree constraints?*

This question poses several challenges. First, jointly optimizing *both* the network topology and the corresponding communication schedule is intractable at a large scale. Prior efforts reduce the search cost by optimizing only one or the other (e.g., schedules for a given topology [10,65,76] or topology permutations while retaining a ring schedule [77]). The combination of topological structure and communication schedule as degrees of freedom explodes the search space, making this a seemingly intractable problem. Second, the optimization must carefully consider the workload and the network's performance characteristics when distilling a topology and schedule. For example, minimizing the topology's diameter is ideal not only for latency-sensitive allreduce at small data sizes but also for all-to-all throughput; however, this could come at the cost of load imbalance across links in bandwidth-sensitive allreduce at large data sizes. Finally, lowering the synthesized schedules to the underlying hardware and runtimes [26,49] in an efficient way requires careful scheduling to achieve the desired performance in practice.

Our work addresses these issues by developing an algorithmic toolchain for quickly synthesizing efficient topologies and schedules for collective communications.

1. We devise a range of **expansion techniques** for synthesizing custom large-scale network topologies and schedules. The expansions start with small, optimal topologies and communication schedules and expand them to achieve near-optimal large-scale topologies and schedules.

2. We devise a **polynomial-time schedule generation algorithm** to produce optimal collective communication schedules for large-scale topologies with specific symmetry properties. This exposes many well-known topologies as options for the direct-connect network fabric.

*Distribution Statement "A" (Approved for Public Release, Distribution Unlimited).

3. We devise a **topology enumeration and search algorithm** to identify the best option for a target cluster and workload by exploring the *Pareto-efficient* options that provide different tradeoffs for bandwidth efficiency, total-hop latency, and also all-to-all throughput.
4. We develop **compilers** to realize our optimized schedules. We offer efficient implementations for both GPUs and CPUs, integrating with ML frameworks (e.g., PyTorch) through the MSCCL [49] and oneCCL [26] runtimes.

We evaluate our approach using two testbeds: a 12-node GPU cluster capable of topology reconfiguration and torus clusters on Frontera [69] supercomputer with up to 54 CPU nodes. Our techniques reduce collective communication times by $>30\%$ for DNN training on the GPU testbed and up to $3.1\times$ in supercomputing settings. Simulations for large-scale DNN training show up to an order of magnitude reduction in total communication time from topology and schedule optimization. Our schedule generation algorithm is orders of magnitude faster than the state-of-the-art (e.g., SCCL [10] and TACCL [65]), capable of producing schedules for topologies with thousands of nodes in a minute.

2 Background & Related Work

2.1 Network Fabric

Our work identifies topologies and schedules helpful for a broad range of settings, such as *switchless physical circuits*, *patch-panel optical circuits*, and *optical circuit switches*. While these options differ in cost and reconfigurability [77], they are all significantly cheaper than packet-switch solution [29, 40, 77] and can benefit from our work.

Switchless physical circuits require the least amount of fabric hardware. However, the topology must remain reasonably static for long periods, as the reconfiguration is manual. *Patch-panel optical circuits* provide a higher degree of reconfigurability by using a mechanical solution (e.g., robotic arms) to perform physical reconfigurations through a patch panel. The reconfigurations occur on the scale of minutes, but the patch panel itself can scale to a large number of duplex ports and is reasonably cheap (e.g., 1008 ports at $100 per port [70]). Both options can benefit from a carefully curated topology optimized for the workload, but they require it to remain static for a job given the reconfiguration time.

Commercial *optical circuit switches (OCS)* can perform reconfigurations in $\approx$10ms, are more expensive than patch panels, and scale to fewer ports (e.g., Polatis 3D-MEMS switch has 384 ports at $520 per port). Though OCSes support faster reconfigurations, the delays are still too high to support the rewiring of the circuits *during* a typical collective operation.[1] Thus, they cannot take advantage of algorithms designed for full-bisection switches, such as recursive halving/doubling [72, 79], that exploit high logical degree over time to provide both latency and bandwidth optimality. Thus, OCSes can also benefit from the custom-built and low-degree topologies synthesized by our approach.

All of these optical technologies allow for a shared cluster to be split into multiple subclusters for running separate jobs [29], so each job can be configured with its own topology. Further, unidirectional topologies are technically feasible on optical testbeds. Unidirectionality gives greater freedom in topology design and can enable lower-diameter networks.

Evaluation Target: In this paper, we use a reconfigurable optical patch panel to configure and evaluate different topologies. Given the high reconfiguration costs for the patch panel, we identify an efficient topology that will remain static for the duration of a job. Nevertheless, our techniques could be used to derive topologies for finer reconfiguration timescales if the hardware can efficiently support frequent reconfigurations.

2.2 Related Work

Several existing optical-circuit-based ML systems [30, 43, 73, 77, 81] fit the direct-connect model; however, they rely on existing implementations of collectives. Typically, communication libraries for ML training [20, 56, 64] offer either ring collective for high-latency bandwidth-optimal transfers or tree collective, which has logarithmic latency but suffers from load-imbalances across links. Other topologies such as mesh, tori, hypercubes, etc., have also been explored in HPC systems [3, 8, 11, 12, 18, 23, 58], but their bandwidth-latency tradeoff choices are limited as well. Bandwidth and latency optimal collectives for switch networks such as recursive-doubling, Bruck algorithm [72, 79], BlueConnect [13], etc., are unsuitable for direct-connect networks, because their one-to-one communication patterns fail to utilize all available links, and they assume a fully connected network.

Our work uniquely considers joint optimization of *both* the network topology and the corresponding collective communication schedule at a large scale, while prior work either optimizes one or the other. For instance, TopoOpt [77] generates customized shifted-ring topologies to optimize concurrent collective and non-collective communications for hybrid data-parallel [15, 37, 38] and model-parallel [28, 52, 67] DNN training, respectively. The collective communications in TopoOpt still use existing ring collectives. Consequently, when data parallelism, for example, dominates the workload, TopoOpt's performance suffers from similar latency issues present in existing ring collectives. Our effort is complementary as it synthesizes new topologies and schedules for collectives that span the entire cluster, but we do not optimize sub-cluster communications for hybrid parallelism. Extending our work to jointly optimize topologies and schedules for hybrid parallelism is future work.

Recent work like Blink [76], SCCL [10], and TACCL [65] also focus on generating a collective schedule for a given

[1] Research prototypes [1, 48] support μs to ns reconfigurations using overlay-hop relays and Valiant load balancing (VLB). While this is valuable for generic workloads, collectives have structured communication patterns, and it would be ideal to realize them without incurring the VLB overheads.

M	total data size	α	single-hop latency

Table 1: Summary of Important Notations

topology. However, they all involve NP-hard optimizations that severely limit their scalability. SCCL is capable of generating optimal schedules, but it fails to generate a schedule in a reasonable time when the topology size is beyond 30 nodes. TACCL improves the scalability of SCCL by using communication sketches and also handles switch networks, but it sacrifices schedule performance and is still limited in scalability. In our approach, we either synthesize the schedule along with the topology or rely on a polynomial-time schedule generation technique that is provably optimal for networks with certain symmetry properties.

Generic large-scale topologies are typically not optimized for collective communications but for general datacenter traffic [6, 31, 33, 68, 75, 80]. Our framework can incorporate any degree-constrained regular topology (e.g., low-diameter expander graphs [25, 61]) and generate candidate schedules.

2.3 All-to-All Throughput

While we optimize allreduce, reduce-scatter, and allgather, the performance of all-to-all communication is also crucial for training DNN models like Mixture of Experts (MoE) [19, 34, 36, 60] and Deep Learning Recommendation Model (DLRM) [45, 53, 54]. Unlike other collectives, the scheduling of all-to-all can be easily formulated and efficiently solved as a multi-commodity flow (MCF) problem [4, 21, 32, 75, 78]. However, the graph diameter of the underlying topology is critical for all-to-all throughput [4, 41, 42, 48, 77]. The intuition is that if the nodes are far from each other, then all-to-all flows cost more *bandwidth tax* [47, 77] (i.e., the bandwidth of the flow multiplied by the length of the flow). With a fixed *network capacity* (i.e., the total number of links times link bandwidth), longer flows reduce the available bandwidth for each flow, thus decreasing all-to-all throughput. In this work, we construct topologies and associated schedules that are high-performance in both allreduce-type collectives and all-to-all by **deriving efficient allreduce-type schedules on existing or our synthesized low-diameter topologies**.

3 Formal Model of Collective Communications

We provide a formal model of ***reduce-scatter***, ***allgather***, and ***allreduce*** collectives. In each operation, there are N nodes operating on a vector of data of total size M. The data can be divided into N **shards**. In *reduce-scatter*, each node i reduces the i-th shard from all other nodes; in *allgather*, each node i broadcasts the i-th shard to all other nodes; in *allreduce*, each node i ends up with the fully reduced vector of data.

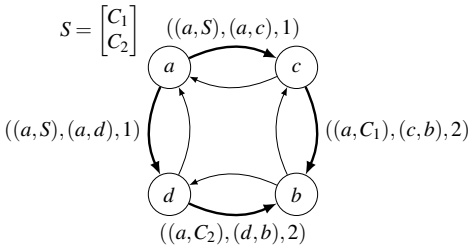

Figure 1: The allgather schedule of complete bipartite graph $K_{2,2}$. Shard S is divided into two half chunks C_1 and C_2. From a, at the 1st comm step, a sends the entire shard S to both c and d. At the 2nd comm step, c and d send the two half chunks C_1 and C_2, respectively, to b. Thus, every node receives the full shard from a. By applying similar broadcast from c, b, d in parallel, we have a complete BW-optimal *allgather* schedule with $T_L = 2\alpha, T_B = \frac{M}{B} \cdot \frac{3}{4}$.

Throughout the paper, we elaborate only on *allgather* schedule construction because the other two collectives are direct transformations. Since *allgather* and *reduce-scatter* are, respectively, simultaneous broadcasts and reductions for each node, we can **construct *reduce-scatter* schedules** in bidirectional topologies by simply reversing the communications in *allgather* schedules [11]. In unidirectional topologies, we utilize graph transposition to achieve a similar transformation (Appendix B).[2] **To construct an *allreduce* schedule,** we concatenate *reduce-scatter* and *allgather*.

3.1 Communication Topology & Schedule

The network topology is modeled as a directed graph (digraph) $G = (V, E)$, where V denotes the set of nodes ($\lvert V\rvert = N$) and E denotes the set of directed links/edges. The direct-connect network imposes a constraint that all nodes have degree d, which is the number of connection ports on each host and is typically low and independent of N.

A communication **algorithm** (G, A) uses the communication **schedule** A on topology G. Schedule A can be specified as what chunk C is communicated over which link in which **communication (comm) step** t. We define **chunk** C as a subset of shard S. Both C and S are specified as *index sets* of elements. Typically, S is interval $[0, 1]$ representing the whole shard, and C is some subinterval. We denote v's chunk C as (v, C), which is a subset of v's starting shard (v, S). Let $((v, C), (u, w), t)$ denote that v's chunk C is sent by node u to its neighbor w at comm step t. Schedule A then is specified as a list of tuples $((v, C), (u, w), t)$. Figure 1 gives an example of an allgather schedule in such a tuple notation. Within a schedule, chunks can be different-sized subsets of S. Appendix B gives formal definitions of reduce-scatter/allgather schedules.

3.2 Cost Model

We use the well-known α-β cost model [24]. The cost of sending a message of size H over a link is $\alpha + \beta H$. This cost comprises two components: the constant single-hop latency α and a bandwidth component β, which is the inverse of link

[2] The main text of this paper focuses on high-level ideas of various techniques. We provide detailed mathematical analyses in the appendix.

bandwidth, i.e., $\beta = \frac{1}{b}$. This simple model has been shown to be appropriate for GPU interconnects [10, 35, 65]. In our analysis, we use node bandwidth B with $B = db$. In this paper, we focus on homogeneous networks, although some techniques also support heterogeneous ones (Appendix E.3).

The runtime of a schedule A can be broken down into a total-hop latency component and a bandwidth component. The **total-hop latency** component $T_L(A) = t_{\max}\alpha$, where $t_{\max}$ is the number of comm steps. $T_L(A)$ represents the cost of performing schedule A on an infinitesimal amount of data. The bandwidth component $T_B(A)$, or **bandwidth (BW) runtime**, is the sum of the BW runtime of each comm step, i.e., $\sum_t T_B(A_t)$. The BW runtime of comm step t is the max amount of data transmitted by a link within the comm step, divided by link bandwidth $b = B/d$. For N-node d-regular graphs, the optimal runtime of both *reduce-scatter* and *allgather* is approximately $\alpha \log_d N + \frac{1}{B} \cdot \frac{M(N-1)}{N}$. The 1st term represents the total-hop latency required for communicating across the diameter of a topology, while the 2nd term represents the transmission time for any node to send/recv $N-1$ shards in reduce-scatter/allgather. **One should not confuse total-hop latency with overall latency,** which is the sum of total-hop latency and BW runtime. We omit the computational time of reduction and discuss this in Appendix C.4.

We analyze the optimality of total-hop latency and BW runtime separately. An algorithm (G, A) is optimal in one component if no (G', A') with the same N, d can perform better. For BW runtime, an algorithm is **bandwidth (BW) optimal** iff its T_B equals $T_B^*(N) := \frac{M}{B} \cdot \frac{N-1}{N}$. For total-hop latency, given G, the lowest T_L achievable is $\alpha \cdot D(G)$, where $D(G)$ is the graph diameter of G. Thus, the optimal total-hop latency equals the smallest diameter of any N-node d-regular graph, which remains an open question in graph theory [50]. Therefore, we define *Moore optimality* based on *Moore bound*, which provides a lower bound for diameter given N, d and thus a well-defined $T_L^*(N, d)$. An algorithm is **Moore optimal** iff $T_L = T_L^*(N, d)$. Moore optimal topologies have the lowest diameters, which is also ideal for all-to-all throughput. Appendix C gives formal definitions of optimalities.

Ring allreduce has a total-hop latency that is linear in N, while the BW runtime is optimal. *Double binary trees* (DBT), on the other hand, offer the advantage of logarithmic total-hop latency but have suboptimal BW performance. Our work offers a range of topologies that are Pareto-efficient in total-hop latency and BW performance.

4 Overview of Our Approach

Direct-connect topologies can typically be categorized as either **low-hop** topologies, which have low diameters (e.g., expander graphs) suited for all-to-all throughput and small-data allgather/reduce-scatter/allreduce, or **load-balanced** topologies, which have simplistic structure (e.g., ring, torus) with easy load-balanced schedule for large-data allgather/reduce-scatter/allreduce (see Table 2). We seek to jointly identify network topologies and schedules that achieve high performance in both categories to the extent possible. Specifically, this entails the challenging task of constructing load-balanced allgather[3] schedules for low-hop topologies.

Topology Type	Small-Data Allreduce (Total-Hop Latency T_L)	Large-Data Allreduce (BW Perf T_B)	All-to-All Throughput
Low-Hop	✓	–	✓
Load-Balanced	–	✓	–

Table 2: The tradeoffs of low-hop topology vs. load-balanced topology. Reduce-scatter and allgather perform similarly to allreduce.

At a small scale, one could handpick a topology such as the complete bipartite graph $K_{2,2}$ defined at $N = 4, d = 2$. $K_{2,2}$ is both low-hop and load-balanced that a Moore- and BW-optimal allgather could be manually constructed (Figure 1). But how do we scale the topology and the schedule to larger sizes? Our work approaches this problem with two tools: *expansion techniques* (§5) and *BFB schedule generation* (§6).

Expansion Techniques: Given a base topology and its schedule, expansion techniques can expand them into a larger topology and associated schedule with minimal loss in performance. We call the resulting topologies **synthesized topologies**. The base topologies are small in scale, such as $K_{2,2}$ in Figure 1, for which straightforward schedules exist or an exhaustive search for the schedule is feasible. The line graph expansion, for example, can then expand $K_{2,2}$ and its schedule in Figure 1 to an allgather for $N = 4 \cdot 2^n$, for arbitrarily large n, while retaining a node degree of 2. Multiple expansion techniques can be composed to achieve the desired N and d.

Breadth-First-Broadcast (BFB) Schedule Generation: Besides synthesized topologies, we can use known topologies from graph theory (e.g., twisted torus, expander graphs). We call them **generative topologies** as they can be instantiated at various Ns and ds. Generative topologies are often low-hop, beneficial for total-hop latency and all-to-all throughput. The problem, though, is that efficient load-balanced collective schedules are not known for many of these topologies, and existing schedule generation methods [10, 65] are intractable even at moderate scales. Our work offers BFB, a polynomial-time schedule generation that can yield efficient schedules for large-scale topologies. For allgather, it performs a breadth-first broadcast from each node and uses linear programs to balance the workload on links. Although not always optimal, BFB schedules are provably optimal for many topologies exhibiting certain symmetries. For instance, BFB can generate a schedule with the lowest total-hop latency and BW optimality on any torus, including those with *unequal dimensions*.

With expansion techniques and BFB schedules, our *topology finder* (§5.4) assembles a large pool of topologies and schedules, identify *Pareto-efficient* ones from a low-hop vs. load-balanced perspective, and select from them for a given workload. When two options are Pareto-efficient, one must be better than the other in either low-hop (i.e., total-hop latency) or load-balanced (i.e., BW performance) but not in both. We

[3] We construct allreduce and reduce-scatter from allgather schedules.

choose low-hop options for workloads requiring all-to-all throughput and small-data allgather/reduce-scatter/allreduce, and load-balanced options for large-data allgather/reduce-scatter/allreduce. Finally, the *compiler* (§7) lowers the chosen topology and schedule to the runtime and hardware.

5 Expansion Techniques

We present three techniques that can be applied to construct near-optimal large-scale *synthesized topologies* and schedules by expanding small-scale topologies and associated schedules. The three techniques provide different options for increasing the size of the topology and the per-node degree while preserving either total-hop latency or BW optimality of the base graph and schedule (Table 3). While we describe the techniques in the context of allgather, corollary 1.2 in §B implies equivalent constructions for reduce-scatter and allreduce.

5.1 Line Graph Expansion

We borrow the line graph transformation from graph theory [22], which transforms an input graph G into a larger graph $L(G)$ as follows: every edge in G becomes a node in $L(G)$, and two nodes in $L(G)$ are adjacent if the corresponding edges are adjacent in G (Definition 12).

Intuition: Line graph expands an N-node degree-d topology into a dN-node topology. The degree d remains the same, which is crucial since the degree is often limited by hardware constraints like the number of available ports. While the number of nodes grows by d-fold, the diameter of the topology only increases by one, which is also optimal for total-hop latency and all-to-all performance. In addition, the paths in the base topology are mapped into the expanded topology, allowing the communication schedule for the base to be expanded as well. Line graph expansion can be applied repeatedly to scale the topology and schedule to arbitrarily large sizes.

Figure 2 gives an example of the line graph expansion of the complete bipartite graph $K_{2,2}$. Any (shortest) path $w_0 \to w_1 \to \ldots \to w_n$ in $K_{2,2}$ can be mapped to a (shortest) path $w_{-1}w_0 \to w_0w_1 \to \ldots \to w_{n-1}w_n \to w_nw_{n+1}$ in $L(K_{2,2})$ from $w_{-1}w_0$ to w_nw_{n+1}, for any w_{-1}, w_{n+1} provided that $w_{-1}w_0 \neq w_nw_{n+1}$.

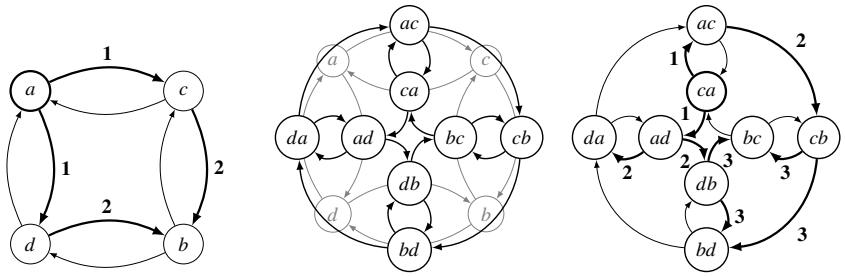
Given an allgather schedule A_G for G, we construct schedule $A_{L(G)}$ for $L(G)$. Pick any node $v'v$ in $L(G)$. It needs to broadcast its shard to every other node in $L(G)$. Pick any other node, say, uu'. For each element x of $v'v$'s shard, we want to send x to uu'. Since v broadcasts x to every other node in A_G, there is a path $v \to w_1 \to \ldots \to w_{n-1} \to u$ in G along which x is sent to u in A_G. Thus, the path $v'v \to vw_1 \to w_1w_2 \to \ldots \to w_{n-1}u \to uu'$ can be utilized to send x from $v'v$ to uu' in $L(G)$.

Definition 1 (Schedule of Line Graph)**.** *Given an allgather schedule A_G for topology G, let $A_{L(G)}$ be the schedule for line graph $L(G)$ containing:*

1. $((v'v, S), (v'v, vu), 1)$ *for each edge* $(v'v, vu) \in E_{L(G)}$ *with* $v'v \neq vu$. **[Insert the 1st comm step in $A_{L(G)}$.]**
2. $((v'v, C), (uw, ww'), t+1)$ *for each* $((v, C), (u, w), t) \in A_G$ *and* $v'v \neq ww'$. **[Adapt A_G to form $A_{L(G)}$.]**

At the 1st comm step, x is broadcasted by $v'v$ to every neighbor, including vw_1. Then, for every $((v, C), (w_i, w_{i+1}), t)$ in A_G with $x \in C$, there is $((v'v, C), (w_iw_{i+1}, w_{i+1}w_{i+2}), t+1)$ in $A_{L(G)}$ that takes x from w_iw_{i+1} to $w_{i+1}w_{i+2}$ and, eventually, to uu' ($v = w_0, u = w_n$). Since x and uu' are picked arbitrarily, $v'v$ broadcasts every element of its shard to all nodes in $L(G)$. Figure 2c shows an example of schedule construction.

As for the performance of $A_{L(G)}$, we leave the mathematical details in Appendix D.1. In practice, one can apply line graph expansion repeatedly to scale the topology and schedule indefinitely. The more optimal the base topology and schedule are, the more optimal the expanded topology and schedule will be. Figure 3 shows how the performance evolves as we continuously apply line graph expansion to several Moore and BW optimal base graphs. The total-hop latency always remains Moore optimal. The BW performance deviates from optimality T_B^* but remains a constant factor away asymptotically. A key observation in Figure 3 is that the larger the size of the base graph is, the closer the expanded schedule is to BW optimality. Line graph expansion is notable for its ability to construct indefinitely large-scale topologies without increasing degree d. The expansion also maintains low-hop, making it ideal for synthesizing all-to-all topologies as well.



5.2 Degree Expansion

Intuition: While line graph expansion expands the number of nodes, degree expansion additionally expands the topology degree. Taking a base topology G, we make n copies of it and connect two nodes in different copies if they are adjacent in G. This process forms an expanded topology $G * n$, which multiplies both the number of nodes and the degree of G by n. Because the connections in $G * n$ are derived from G, similar to line graph expansion, we can map paths from G to $G * n$ to expand the communication schedule of G as well.

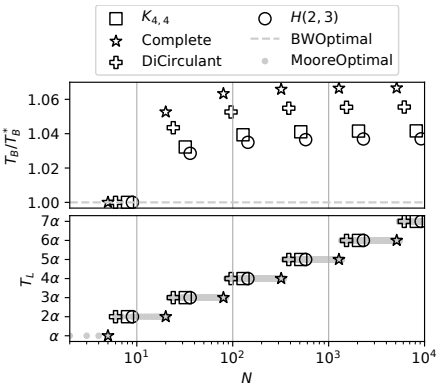
Figure 4 gives an example of expanding a 4-node unidirectional ring into an 8-node degree-2 topology (see formal definition of degree expanded topology in Definition 13). Based on the input schedule A_G for G, we construct a schedule A_{G*n} for $G * n$. For any data traveling along $v \to w^{(1)} \to \ldots \to w^{(m)} \to u$ in A_G, A_{G*n} has the data travel along $v_i \to w_i^{(1)} \to \ldots \to w_i^{(m)} \to u_j$ for all i, j. That is, data is transmitted within the i-th copy of G, except at the last step. With this construction, any node u_i has broadcasted the data to all other nodes except its own copies u_js. We add an additional comm step for u_j to collect the data from its in-neighbors (see Figure 4c).

Definition 2 (Degree Expanded Schedule)**.** *Given an allgather schedule A_G for G, construct A_{G*n} for $G * n$:*

1. *For all i, j including $i = j$ and for each $((v, C), (u, w), t) \in A_G$, add $((v_j, C), (u_j, w_i), t)$ to A_{G*n};*
2. *Divide shard S into equal-sized chunks $C_1, \ldots, C_{nd}$. Given $u_i, u_j \in V_{G*n}$ with $i \neq j$, add $((u_i, C_\alpha), (v_\alpha, u_j), t_{\max} + 1)$ to A_{G*n} for each $(v_1, u_j), \ldots, (v_{nd}, u_j) \in E_{G*n}$, where $t_{\max}$ is the max comm step in A_G.*

(a) $K_{2,2}$ $(N=4,d=2)$ (b) $L(K_{2,2})$ $(N=8,d=2)$ (c) Broadcast from ca

Figure 2: The complete bipartite topology $K_{2,2}$ with its line graph $L(K_{2,2})$. Figure (a) shows the base topology and broadcast paths from a to c,b,d in $A_{K_{2,2}}$ (see Figure 1). The number next to edge shows the comm step using the edge. Figure (b) shows the expanded topology. Observe that every edge in $K_{2,2}$ becomes a vertex in $L(K_{2,2})$, and two vertices are connected if the corresponding edges in $K_{2,2}$ have one's head node being the other's tail node. Figure (c) shows the broadcast paths of node ca, transformed from the broadcast paths of a in figure (a). At the 1st comm step, by step 1 of Def 1, ca broadcasts its shard to all its neighbors: $((ca,S),(ca,ac),1)$, $((ca,S),(ca,ad),1)$. The rest of the broadcast paths are transformed from $A_{K_{2,2}}$ by step 2 of Def 1, e.g. $((a,C_1),(c,b),2) \mapsto \{((ca,C_1),(cb,bc),3),((ca,C_1),(cb,bd),3)\}$. Each of the nodes bc and bd receives C_1,C_2 from its two in-neighbors, just like b does in $A_{K_{2,2}}$.



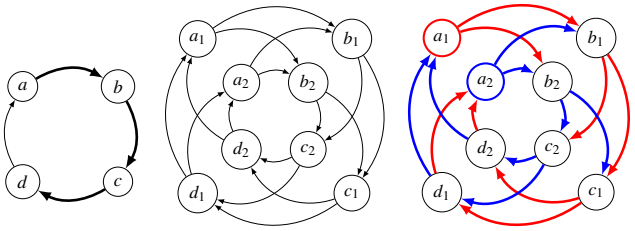


Figure 3: Line graph expansion on Moore and BW optimal degree-4 base graphs: complete bipartite graph $K_{4,4}$, complete graph, directed circulant graph, and Hamming graph $H(2,3)$. $T_B^* = \frac{M}{B} \cdot \frac{N-1}{N}$ is the optimal BW runtime.

(a) $G(N=4,d=1)$ (b) $G*2$ $(N=8,d=2)$ (c) Broadcasts from a_1,a_2

Figure 4: 4-node unidirectional ring and its degree expansion to $d=2$. Figure (a) shows the base topology and broadcast path from a to b,c,d. Figure (b) shows the expanded topology. Figure (c) shows the broadcast paths from a_1 and a_2 to other nodes marked in red and blue, respectively. For any $u \neq a$, the path from a_i to u_j stays in i until the very last step when it jumps to u_j, e.g., $a_1 \to b_1 \to c_2$ and $a_2 \to b_2 \to c_2 \to d_1$. For a_i to a_j, each in-neighbor of a_j sends an equal portion of a_i's shard to a_j in the end; for example, d_1 and d_2 each send half of a_1's shard to a_2 and half of a_2's shard to a_1. The red and blue broadcast paths are disjoint, resulting in BW optimality.

Unlike line graph expansion, degree expansion preserves BW optimality. This is because the expanded broadcast paths from copies of an original node are totally disjoint from each other (Figure 4c). However, degree expansion does not preserve Moore optimality. While line graph expansion does not change degree, degree expansion increases it, reducing the number of comm steps required for Moore optimality.

5.3 Cartesian Product Expansion

The Cartesian product of two graphs G_1,G_2 is an expanded graph $G_1 \Box G_2$ with size and degree equal to the product of G_1,G_2's sizes and the sum of their degrees, respectively.

Definition 3 (Cartesian Product)**.** *The Cartesian product digraph $G_1 \Box G_2$ of digraphs G_1 and G_2 has vertex set $V_{G_1} \times V_{G_2}$ with vertex $\mathbf{u} = (u_1,u_2)$ connected to $\mathbf{v} = (v_1,v_2)$ iff either $(u_1,v_1) \in E_{G_1}$ and $u_2 = v_2$; or $u_1 = v_1$ and $(u_2,v_2) \in E_{G_2}$.*

This definition generalizes to the Cartesian product of n digraphs: $G_1 \Box G_2 \Box \ldots \Box G_n$. When $G_1 = \ldots = G_n = G$, the product is denoted as Cartesian power $G^{\Box n}$. We use Cartesian power and product in our topology and schedule expansion.

Intuition: The Cartesian product $G_1 \Box G_2 \Box \ldots \Box G_n$ consists of n dimensions, with connections in dimension i identical to G_i. Taking the schedules of $G_1,G_2,\ldots,G_n$, we can balance the amount of traffic going through each dimension to achieve high BW performance. Cartesian product expansion greatly expands the set of topologies we construct by enabling the combination of existing topologies to form a new product topology with an efficient schedule.

Cartesian Power Expansion: Given a d-regular G and schedule A_G, we can construct a schedule $A_{G^{\Box n}}$ for $G^{\Box n}$, which is nd-regular and has $|V_G|^n$ nodes. This technique helps generate efficient topologies, including some well-known ones like hypercube and Hamming graph. We describe how to construct allgather schedules for Cartesian power graphs by using $\ell \times \ell$ torus (ℓ-ring$^{\Box 2}$) as an example. A typical allgather schedule on an $\ell \times \ell$ torus is to perform the ℓ-ring allgather along rings in one dimension first and then the other dimension, as in hierarchical ring allreduce [74]. Consider two schedules: $A^{(1)}$ performs allgather on vertical rings first and then horizontal ones; $A^{(2)}$ performs allgather in the opposite order. $A^{(1)},A^{(2)}$ use disjoint set of links at any comm step. Thus, we divide each data shard in $\ell \times \ell$ torus into two halves and let them be allgathered by $A^{(1)},A^{(2)}$ separately. The combined schedule, where $A^{(1)}$ and $A^{(2)}$ are performed in parallel, is BW-optimal, with a total-hop latency of $2T_L(A)$.

The above torus schedule has appeared in previous literature [62]. It can be generalized to generate schedules for Cartesian power of arbitrary topologies (see Appendix D.3).

Cartesian Product Expansion: One can also construct a schedule for the Cartesian product of distinct topologies. For example, an $a \times b \times c$ 3D torus is the Cartesian product of three rings with lengths a,b,c. Constructing this schedule requires BFB schedule generation technique, which we introduce in §6. If individual topologies have BW-optimal BFB schedules, as in the case of any torus, then the schedule generated for the Cartesian product is BW-optimal (Table 3).

Expansion Techniques	# of Nodes	Deg	Moore	BW	Perf
Line Graph Exp $L^n(G)$	d^nN	d	✓	×	Thm 7.1
Degree Exp $G*n$	nN	nd	×	✓	Thm 11
Cartesian Power $G^{\square n}$	N^n	nd	×	✓	Thm 12
Cartesian Prod $G_1\square\ldots\square G_n$	$\prod_i N_i$	$\sum_i d_i$	×	✓	Thm 13

Table 3: Summary of expansion techniques. The table shows the characteristics of the resulting topology and schedule after applying expansion techniques to an N-node degree-d base topology. "✓, ×" show whether the expansion preserves Moore/BW optimality. The last column refers to the theorems that give the exact performance of expanded schedules. Appendix D presents more formal definitions and analyses of expansion techniques.

Topology	T_L	T_B	$2(T_L+T_B)$	$D(G)$	All-to-All
$\Pi_{4,1024}$	5α	$1.332M/B$	323.5us	5	409.1us
$L^3(C(16,\{3,4\}))$	6α	$1.020M/B$	291.0us	6	403.5us
$L^2(\text{Diamond}^{\square 2})$	8α	$1.004M/B$	328.4us	8	446.6us
$L(\text{DBJMod}(2,4)^{\square 2})$	11α	$1.000M/B$	387.8us	9	529.9us
$(\text{UniRing}(1,4)\square\text{UniRing}(1,8))^{\square 2}$	20α	$0.999M/B$	567.6us	20	1174.4us
Theoretical Bound	**5α**	$\mathbf{0.999}M/B$	**267.6us**	**5**	**382.3us**

Table 4: Pareto-efficient topologies at $N=1024$, $d=4$. The $2(T_L+T_B)$ column shows the allreduce runtimes for $\alpha=10$us and $M/B=1$MB/100Gbps. We multiply T_L+T_B by 2 because allreduce is performed by combining reduce-scatter and allgather. The all-to-all time is computed via multi-commodity flow (Appendix A.5) with each node having 1MB of data to send (i.e., sending $1/N$ MB to each node). For comparison, the baselines Shifted Ring and Double Binary Tree (§8.2) have allreduce times of 20640us and 1434us, and all-to-all times of 10738us and 21475us, respectively. Table 9 shows the details of the base topologies.

5.4 Topology Finder

The goal of Topology Finder is to produce the best topologies and schedules for a target N and d. If we aim for asymptotic performance ($N\to\infty$ with fixed d), we want **the base topology to be as large as possible and the base schedule to be as optimal as possible** (Theorem 9). However, for a target N and d, only base topologies with certain sizes (e.g., divisors of N) and degrees can be expanded to the target. Thus, we keep a collection of known base topologies and their schedules (Table 9). These topologies and schedules are highly optimized and cover a wide range of N and d.

Given base topologies, we perform a bottom-up search for the combinations of expansion techniques to reach the target N and d. We iteratively apply expansions to candidates. At intermediate sizes, we prune candidates with inferior performance and keep the best ones for further expansion. Because each expansion multiplies the topology size (Table 3), the number of expansions that can be applied before the size gets too large—and hence the number of possible combinations—is limited, making the search feasible.

While we expand the topologies, proved theorems (Table 3) allow us to predict the performance of expanded topologies. This is vital for the search because it is intractable to construct schedules for every topology and compare their performance. Using a simple formula for prediction enables us to quickly compare different topologies and prune inferior ones. We keep a Pareto frontier of topologies for each given N and d. A topology is inferior to another only if it is worse in both total-hop latency and BW runtime. Ultimately, the search finds all Pareto-efficient topologies for the target N and d. Depending on the testbed, we may convert unidirectional topologies to bidirectional ones (Appendix A.6). Then, we determine the best-performing topology for a given workload.

Table 4 shows the result for $N=1024$ and $d=4$. From top to bottom, the Pareto frontier exhibits an increasing T_L and a decreasing T_B, with the top and bottom being Moore and BW optimal, respectively. On the all-to-all side, the diameters of the topologies also follow the same trend as T_L because of $T_L\geq\alpha\cdot D(G)$ (Theorem 3). Table 4 also shows the allreduce and all-to-all times calculated based on specific α, M, B. Notably, the line graph of circulant graph $L^3(C(16,\{3,4\}))$ has both the lowest allreduce and all-to-all times, within 9% and 6% of the theoretical bounds. Table 7 in appendix contains more results for $N=32,64,\ldots,1024$.

While low-hop/diameter indicates high all-to-all throughput, other metrics like the average distance between nodes [41, 42] also play a role. Thus, despite having a lower diameter, $\Pi_{4,1024}$ underperforms $L^3(C(16,\{3,4\}))$. Including other metrics makes the search process more complex and computationally expensive. In practice, T_L and $D(G)$ are feasible and accurate enough for predicting all-to-all throughput.

In DNN training experiments, we use one topology for the entire training due to the high reconfiguration latency of our target patch panel platform. We select the best option based on the distribution of collective sizes Ms, which depends on the communication strategy of the training framework [38]. With faster reconfiguration, one could change topology to optimize for different collective runs during training.

Our implementation runs under a minute for all $d=2,4,8,16$ and N up to 2000. While this can be sped up, we find it acceptable for now, given that the search is performed once for all Ns and ds, and results can be saved for future use.

6 Breadth-First-Broadcast (BFB) Schedule

We now present a scalable algorithm for generating schedules for *generative topologies*, which are directly borrowed from graph theory, as well as for topologies obtained through Cartesian Product expansion—the only expansion technique that does not yield a schedule. State-of-the-art schedule generations (e.g., Blink [76], SCCL [10], and TACCL [65]) can scale only to a modest number of nodes because they involve NP-hard optimization. To ensure polynomial-time generation, we impose a *breadth-first* broadcast order from each node such that (1) data always travels along the shortest paths between source and destination nodes; (2) the schedule is structured as a series of comm steps, where each comm step is responsible for eagerly transmitting data to a set of nodes that is one additional hop away. Our BFB schedule generation technique does not guarantee optimality in an arbitrary topology, given these constraints prohibit the use of longer paths or delayed (non-eager) transmissions along paths, but these constraints enable polynomial-time generation.

Despite these constraints, BFB schedules guarantee the following: (1) The schedules have the lowest total-hop latency as all data is eagerly communicated over the shortest paths.

(2) For Cartesian product topologies, BFB schedule generation yields a BW-optimal solution if the underlying product components admit BW-optimal BFB schedules (thus yielding optimal schedules for networks such as torus with arbitrary dimensions). (3) BFB schedules are also provably BW-optimal for many generative topologies with certain symmetries.

6.1 BFB Schedule Generation Linear Program

Intuition: Allgather is a simultaneous broadcast from every node in the topology. A BFB allgather schedule, as the name suggests, performs a *breadth-first* broadcast from every node. At each comm step, a node typically has the option to receive a chunk from multiple in-neighbors on the previous breadth-first frontier. To optimize BW performance, BFB uses a linear program to balance the traffic across the ingress links.

At each comm step t, a BFB schedule requires that for every node v, all nodes at a distance t from v, i.e., $N_t^+(v)$, receive v's data shard within the comm step. To achieve this, all nodes at distance $t-1$, i.e. $N_{t-1}^+(v)$, need to collectively multicast the data shard to nodes $N_t^+(v)$ in comm step t.

Given any v and $u \in N_t^+(v)$, u may have multiple in-neighbor ws in $N_{t-1}^+(v)$. All of them can provide v's data shard because they have received it in comm step $t-1$. Since the BW runtime of a comm step equals the transmission time of the most congested link, a question is **how to allocate the amount of data u receives from each w to balance the workload on links?** Figure 5 shows an example. Here, u_1 needs to get v_1's shard from w_1, w_2 and v_2's shard from w_2. The solution is simple: since u_1 can only get v_2's shard from w_2, we let w_1 send v_1's shard and w_2 send v_2's shard, achieving a perfectly balanced workload. For u_2, it is more complicated. We formulate such a problem as a linear program:

$$\begin{aligned} \text{minimize} \quad & U_{u,t} \\ \text{subject to} \quad & \sum_v x_{v,(w,u),t} \le U_{u,t}, && \forall w \in N^-(u) = N_1^-(u) \\ & \sum_w x_{v,(w,u),t} = 1, && \forall v \in N_t^-(u) \\ & 0 \le x_{v,(w,u),t} \le 1. && \forall w, v \end{aligned} \tag{1}$$

$x_{v,(w,u),t}$ is the proportion of v's shard that is sent from w to u and is defined for every v, w such that $w \in N^-(u)$ and $d(v,u) = d(v,w)+1 = t$. $U_{u,t}$ is the max workload among links to u, i.e., $(w_1,u_2),(w_2,u_2),(w_3,u_2)$ in the case of u_2. Minimizing $U_{u,t}$ is equivalent to minimizing $\frac{M/N}{B/d} \cdot U_{u,t}$, the max transmission time among links to u at comm step t. The 1st and 2nd constraints ensure correct max workload and u receiving all data shards, respectively. Appendix E gives the specific LP for u_2, and the solution is shown in blue in Figure 5. The workload is also balanced with each link sending $2/3$ shard and hence BW runtime $\frac{M/N}{B/d} \cdot \frac{2}{3}$.

SCCL [10] and TACCL [65] use NP-hard optimizations with discrete variables used to ensure each chunk is received before being sent. In contrast, we do not need discrete variables. A key observation from Figure 5 is that because w_1, w_2, w_3 all receive the entire shard of v_1 at comm step $t-1$,

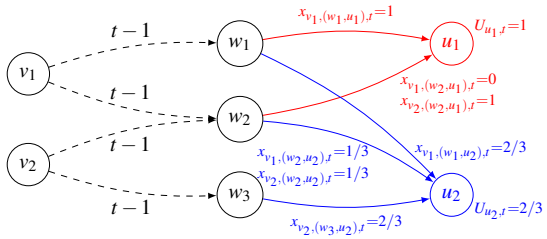

Figure 5: Example of BFB allgather schedule at comm step t. Here, $w_1, w_2 \in N_{t-1}^+(v_1)$ and $w_2, w_3 \in N_{t-1}^+(v_2)$. u_1, u_2 are at distance t from both v_1, v_2, so they both need to receive the data shards of v_1, v_2 in comm step t. Note that u_1 cannot get v_2's shard from w_3 because w_3 is not an in-neighbor of u_1. The figure also shows the solutions to LPs (1). The red and blue are independent LPs optimizing $U_{u_1,t}$ and $U_{u_2,t}$ respectively.

the $x_{v_1,(w_1,u_2),t} = 2/3$ and $x_{v_1,(w_2,u_2),t} = 1/3$ in the solution can be any portions of the data shard, as long as their union is the entire shard. Assuming $[0,1]$ is the entire shard of v_1, no matter the $2/3$ sent by w_1 to u_2 is $[0, \frac{2}{3}]$ or $[\frac{1}{3}, 1]$, the $1/3$ sent by w_2 can simply be $[\frac{2}{3}, 1]$ or $[0, \frac{1}{3}]$ accordingly. Thus, **we only need to decide the amount of data sent on each link, which are continuous variables**, enabling polynomial-time schedule generation. To obtain a complete schedule, one needs to solve an LP (1) for each $u \in V_G$ and $t \in \{1, \ldots, D(G)\}$. The BW runtime of the generated schedule is

$$T_B = \frac{M/N}{B/d} \sum_{t=1}^{D(G)} \max_{u \in V_G} U_{u,t}. \tag{2}$$

One could create an LP incorporating all $U_{u,t}$s and minimize T_B (2) *"globally"*. However, the result is equivalent to individually solving small LPs (1) for each u and t. This is because the LPs are independent of each other, e.g., the decisions made to minimize $U_{u_2,t}$ in Figure 5 do not affect $U_{u_1,t}$, and vice versa. The advantage of small LPs is that they can be solved in parallel. Due to the breadth-first nature of BFB, data always follows the shortest paths between source and destination. Thus, the number of comm steps of the BFB schedule always equals the graph diameter, i.e., $T_L = \alpha \cdot D(G)$, the lowest possible T_L given G.

Appendix E analyzes the BFB schedule and includes modifications to generate **discrete chunked schedules** (§E.2) and schedules for **heterogeneous link bandwidths** (§E.3). Corollary 1.1 implies how to generate **reduce-scatter** schedules.

6.2 Generative Topologies

Generative topologies, unlike synthesized ones, are large graphs directly borrowed from graph theory. They are too large for manual or NP-hard schedule generation. Thus, we use the BFB linear program to generate schedules. Since a BFB schedule always has the lowest T_L for a topology, if it is also BW-optimal, then it is *the optimal schedule* for that topology. Generative topologies often have symmetries that allow us to prove optimality mathematically. Their low diameters are also ideal for all-to-all throughput.

Torus is a widely used topology in parallel computing systems. Our torus schedule generated by BFB is theoretically

optimal and represents a significant improvement over traditional torus schedules [62]. Given a $d_1 \times d_2 \times \ldots \times d_n$ torus, the traditional schedule, which performs parallel ring collectives on dimensions, only works (or is efficient) when dimensions are equal, i.e., $d_1 = d_2 = \ldots = d_n$, and has $T_L = \sum_i (d_i - 1)\alpha$. BFB torus schedule, however, is BW-optimal with any d_is and $T_L = \sum_i \lfloor d_i/2 \rfloor \alpha$. The BW optimality is due to torus being the *Cartesian product* of rings, each of which has a BW-optimal BFB schedule. BFB torus opens up many more construction possibilities since d_is can be any combination.

Generalized Kautz Graph (§F.2) and **Circulant Graph** (§F.4) are a pair of versatile graphs in our toolbox. The former can be constructed for any N and d, while the latter can be constructed for any N and even-value d. Furthermore, the BFB schedule of the former is at most one α away from Moore optimality, making it the topology with the lowest T_L, while the latter always has a BW-optimal BFB schedule. Thus, they can fill gaps in N and d that expansion techniques fail to cover (e.g., prime N) or provide good candidates.

Besides the aforementioned ones, the following graphs also have optimal schedules by BFB. **Distance-Regular Graph** (§F.3) is a family of large highly-symmetric graphs that are both BW-optimal and low-hop at the same time. The **Twisted Torus** [14] used by TPU v4 [29] is also computationally verified to be BW-optimal for at least $N \leq 10^4$. A **BFB Ring Schedule** with half the T_L of traditional one is shown in §F.1.

7 Schedule Compilation

We implemented two compilers for lowering communication schedules to both GPU and CPU clusters, given the significance of collective communication for both ML and HPC workloads. We lowered over 1K schedules for various topologies and configurations. The compilers enable us to evaluate the performance of our topologies and schedules on hardware and to validate our mathematical model.

For GPUs, our compiler lowers a mathematically defined schedule to an XML file that can be executed by the MSCCL runtime [49]. MSCCL is an open-source collective communication library that extends NCCL [56] with an interpreter providing the ability to program custom schedules. Communication schedules are defined in XML as instructions (send/receive/reduce/copy) for each GPU threadblock. Our compiler also performs certain optimizations, such as consolidating non-contiguous sends using a scratch buffer and evenly distributing the computational workload across threadblocks.

For CPU-based supercomputers, we use Intel oneCCL [26] + libfabric [39] to execute schedules. We extended oneCCL with an interpreter that executes XMLs. The mathematical schedules are lowered into instructions (send/recv/reduce/copy/sync) for CPUs in an XML file and then executed.

8 Evaluation

We present performance evaluation results on a 12-node direct-connect optical GPU testbed and a supercomputing CPU torus cluster with up to 54 nodes. We also present analytical and simulation results at larger scales.

Collective Communication: On the 12-node testbed, our topologies consistently outperform baselines in allreduce, reduce-scatter, and allgather (§8.3, Fig 6, Fig 12). Analytical model shows order-of-magnitude improvements in allreduce and all-to-all performance at larger scales (Fig 7).

DNN Training: In data-parallel training experiments, our topologies achieve the best performance for both small models and GPT-2 [59] (§8.4, Fig 8). In simulated large-scale training, our topologies demonstrate order-of-magnitude improvements in all-to-all involved expert-parallel training (Fig 9).

Schedule Generation: While generating optimal schedules, BFB is orders of magnitude faster and more scalable than SCCL [10] and TACCL [65] (§8.5.1, Tab 6 & Fig 10). On supercomputing torus clusters, BFB schedules outperform traditional scheduling [62], SCCL, and TACCL (§8.5.2, Fig 11).

Finally, we also conducted experiments on our testbed to compare BFB against widely adopted solutions for switch networks (e.g., NCCL and recursive halving & doubling) (§A.1) and to validate the α-β cost model (§A.2).

8.1 Direct-Connect Optical Testbed

Our testbed consists of 12 servers, each with an NVIDIA A100-PCIe-40GB GPU [55] and an HPE Ethernet Adapter, configured as 4x25Gbps breakout interfaces. The NICs are directly connected via a Telescent optical patch panel [70]. Our testbed can realize topologies by reconfiguring the patch panel. We limit our evaluation to bidirectional topologies due to limitations in our testbed (discussed in Appendix A.6).

8.2 Experiment Setup

Baselines: We evaluate against the two baselines at $d = 4$: (1) *ShiftedRing*, which improves upon NCCL ring [56], is used by TopoOpt [77] for data-parallel training. The topology is a superposition of two bidirectional rings, each allreducing half of the data. (2) *Double Binary Tree* (DBT), implemented in NCCL [27], uses the topology and schedule from [63].

Methodology: We use the MSCCL runtime [49] to evaluate the topologies and schedules. We sweep through runtime parameters, such as the protocol (Simple or LL), number of channels (1, 2, 4, or 8), degrees of pipelining for the DBT baseline, etc., and choose the best-performing schedule for each data size. For DNN training, we run our schedules in PyTorch through MSCCL as the backend.

8.3 Collective Communication Evaluation

Figure 6 shows allreduce results for varying topology sizes N and data sizes M. Table 5 shows the topologies generated by our topology finder (§5.4). We also add *ShiftedBFBRing*, which is ShiftedRing topology but with our BFB generated schedule. We observe that in the small data regime ($M =$ 1KB), our topology beats ShiftedRing by a significant margin ($\sim$75% at $N = 12$) and also outperforms DBT ($\sim$20% at $N = 8, 10, 12$). Our ShiftedBFBRing beats ShiftedRing ($\sim$40%

N	Topology	T_L
5	Complete Graph: K_5	2α
6	Degree Expansion of Complete graph: $K_3 * 2$	4α
7	Circulant Graph: $C(7,\{2,3\})$	4α
8	Complete Bipartite Graph: $K_{4,4}$	4α
9	Hamming Graph: $H(2,3)$	4α
10	Degree Expansion of BFB augmented Bidirectional Ring: BiRing$(2,5) * 2$	4α
11	Circulant Graph: $C(11,\{2,3\})$	4α
12	Circulant Graph: $C(12,\{2,3\})$	4α

Table 5: OurBestTopo at $d=4$ generated by topology finder (§5.4). All topologies listed above are BW-optimal.

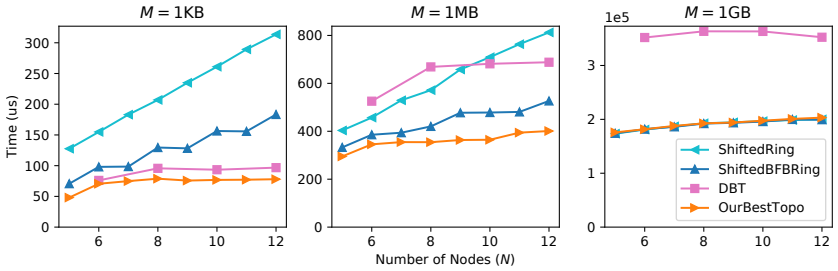

Figure 6: Allreduce experiment results on testbed at $M=1\text{KB}, 1\text{MB}, 1\text{GB}$. "OurBestTopo" topologies are listed in Table 5. Reduce-scatter and allgather results are in Appendix Figure 12.

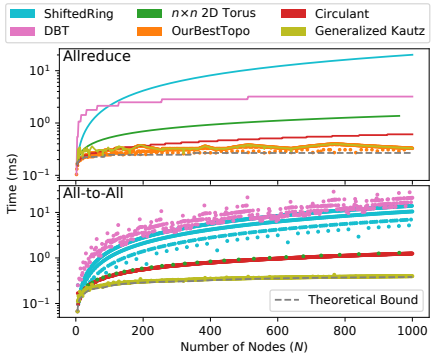

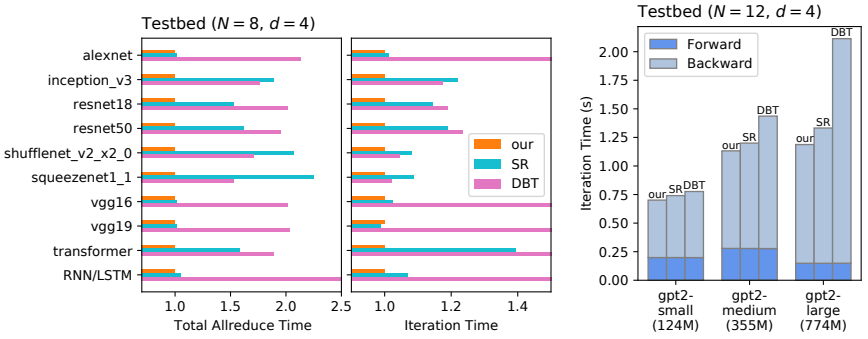

Figure 7: Comparing theoretical allreduce and all-to-all runtimes analytically at large N for $d=4$, $\alpha=10$us, and $M/B=1\text{MB}/100\text{Gbps}$. The all-to-all times are computed via multi-commodity flow (Appendix A.5) with each node having 1MB of data to send (i.e., sending $1/N$ MB to each node).

(a) Small Model testbed training results (normalized by our $K_{4,4}$)

(b) GPT2 testbed training results

Figure 8: Testbed data-parallel training results with different topologies. We compare our topologies (Table 5) against ShiftedRings (SR) and double binary trees (DBT) at 8- and 12-node scale. (a) shows results of training small models on 8 A100 GPUs of our testbed, all using batch size 64. The total allreduce time is the sum of the allreduce times for all layers in the model. (b) shows results of training GPT-2 with 12 A100 GPUs. The per-GPU batch sizes are selected to max out the 40GB GPU memory, with the small, medium, and large models having per-GPU batch sizes of 8, 4, and 1, respectively.

at $N=12$) despite using the same topology. At small data sizes, the runtime is dominated by total-hop latency T_L, and hence, we can significantly outperform ShiftedRing, which has linear instead of logarithmic T_L growth with respect to N.

In the large data regime ($M=1\text{GB}$), our topology beats DBT by a significant margin (~50% lower at $N=8,10,12$) and matches the performance of ShiftedRing. At large data sizes, the runtime is dominated by BW runtime T_B. Since the ShiftedRing is BW-optimal, we can only match its performance. Due to the influence of both total-hop latency and BW runtime at intermediate data sizes ($M=1\text{MB}$), our topology outperforms ShiftedRing (~50% at $N=12$) and DBT (~45% at $N=8,10,12$) in this regime. Our ShiftedBFBRing also outperforms ShiftedRing (~35% at $N=12$). Note that although our gains over ShiftedRing diminish as M grows, future increases in hardware bandwidth will enhance gains at large M due to T_L playing a more significant role. Appendix Figure 12 shows the reduce-scatter and allgather results, which demonstrate trends and conclusions similar to those in Figure 6.

Figure 7 shows the allreduce and all-to-all runtime comparison for large N based on our analytical model. Topologies generated by our topology finder perform orders of magnitude faster in both allreduce and all-to-all. In allreduce, our best topologies outperform ShiftedRing and DBT by 56× and 10×, respectively, near $N=1000$, due to the former's linear growth in T_L and the latter's poor BW performance. When compared against 2D torus, our topologies also achieve 4× better allreduce performance near $N=1000$ (see §A.3 for a detailed analysis of our topologies at large N for different $\alpha, M/B$). As for all-to-all, we compare baseline topologies against our lowest-diameter topology, generalized Kautz, and our highest-diameter topology, circulant, from our Pareto-frontier for any N and d. These two represent our best and worst all-to-all topologies, respectively, while also serving as the worst and best BW-efficient allreduce topologies. Nevertheless, circulant still outperforms all baselines in all-to-all: 9× and 14× better than ShiftdRing and DBT, respectively, on average from $N=900$ to 1000. It is barely matched by the 2D torus, which is limited to the square number Ns. Our lowest-diameter topology, generalized Kautz, outperforms ShiftedRing and DBT by 28× and 42×, respectively, and is within 5.2% of the theoretical bound from $N=900$ to 1000.

8.4 DNN Training Evaluation

We compare our topologies against ShiftedRings and double binary trees in DNN training. On our small-scale testbed, we demonstrate improvements in data-parallel training across various small models and also GPT-2 [59]. For full-scale LLM training involving up to 1024 nodes and all-to-all com-

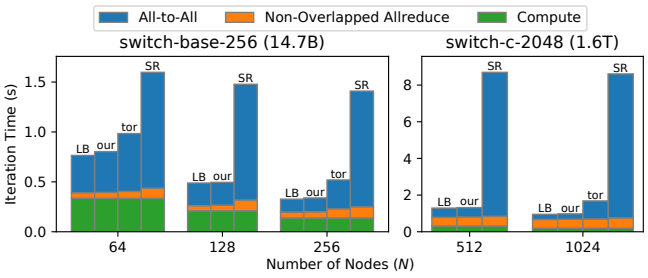

Figure 9: Simulated expert-parallel training of Switch Transformers across various topologies of different sizes. The simulation is conducted assuming $\alpha = 10$us, $B = 100$Gbps. All-to-all time is computed via multi-commodity flow (Appendix A.5). We detailed our setup in Appendix A.4.

munications, we simulate expert-parallel training of a Mixture of Experts (MoE) model to show our improvements at scale.

Testbed Training: We run PyTorch Distributed Data Parallel (DDP) [38] training experiments on our testbed. Figure 8 shows the results of training both small DNN models and GPT-2. We compare our topologies (from Table 5) against ShiftedRings and DBT. In training small models (Figure 8a), our topology improves total allreduce time by 30% and 50% on average against ShiftedRing and DBT, respectively. With optimizations such as compute-communication overlap, our topology still secures a 10% and 25% average improvement in iteration time over the baselines. In GPT-2 training (Figure 8b), despite the limited scale of our testbed, our topology enhances iteration time by 7% and 25% on average compared to ShiftedRing and DBT, respectively.

Large-Scale Simulation: While improvements over ShiftedRing and DBT have been shown in testbed training, full-scale LLM training is performed on much larger clusters. In Figure 9, we simulate expert-parallel training of Switch Transformers [19] on a much larger scale with parameter sizes up to 1.6 trillion. We collect execution timestamps from one A100 GPU to derive the compute times for each layer. Communication times are then added to simulate training, ensuring compute-communication overlap/dependency. Appendix §A.4 provides further details of the simulation.

Expert-parallel training involves not only data-parallel allreduce for non-expert layers but also all-to-all communications to transfer tokens to and from the routed experts, which are in the critical path of compute [19, 34, 36, 60]. In Figure 9, we break down the iteration time into compute time, non-overlapped allreduce time, and all-to-all time for a better understanding of performance. As previously analyzed in Figure 7, ShiftedRings (SR) exhibit all-to-all performance that is order-of-magnitude worse than our topologies. At 256-node training of 14.7B MoE model, ShiftedRing has 8× greater total all-to-all time, resulting in 4× longer iteration time compared to our topology. We also include 2D torus (tor) for comparison due to its relatively better all-to-all performance. However, it still has all-to-all and iteration times that are 2× and 1.5× greater, respectively, than our topology. The disparity is even larger at 1024-node training of 1.6T MoE model, where ShiftedRing and 2D torus show all-to-all times that are 27× and 3.3× greater, and iteration times that are 9× and 1.7× longer, respectively. At this scale, ShiftedRing and 2D torus spend 91% and 58% of iteration time on all-to-all communications, while our topology only spends 30%. We omit DBT in Figure 9 due to its significantly worse performance (∼2× of ShiftedRing). Due to high performance in both allreduce and all-to-all, our topologies consistently remain within 5% of the theoretical lower bound (LB) for iteration time.

Since large models involve large allreduce sizes and both torus and ShiftedRing are BW-optimal, the allreduce performance is similar across these topologies. For a broader spectrum of all-to-all efficient low-hop topologies like expander graphs, the lack of efficient allreduce schedules prior to our work has prevented their use in allreduce-involved training.

8.5 BFB Schedule Evaluation

We evaluate schedule generation from two aspects: schedule generation runtime and the performance of generated schedules. In §8.5.1, we compare BFB with state-of-the-art schedule generations: SCCL [10] and TACCL [65], in both generation runtime and theoretical schedule performance. In §8.5.2, we compare, on supercomputing torus clusters, the performance of torus schedules generated by BFB, traditional torus scheduling [62], SCCL, and TACCL.

8.5.1 Schedule Generation

In schedule generation, SCCL and TACCL are the closest in spirit to BFB schedule generation. Table 6 shows the runtime comparison between SCCL, TACCL, and BFB when generating allgather schedules for hypercube and 2D torus. Both SCCL and TACCL use NP-hard optimization to generate schedules. SCCL, which uses an SMT solver, fails to generate a schedule within 10^4 seconds beyond $N = 30$. TACCL formulates the scheduling problem as a mixed integer linear program (MILP). It sets an 1800s time limit for its MILP solver, after which it will return the best solution found up to that point. However, for larger topologies, TACCL's solver fails to find a solution within the time limit, resulting in an error. In comparison, BFB schedule generation is faster by orders of magnitude due to its polynomial-time generation.

In terms of theoretical schedule performance, Figure 10 compares the total-hop latency and BW runtime of generated schedules. Given a topology, SCCL and TACCL need to perform a sweep across parameters such as the number of chunks and symmetry. They have to generate schedules for different parameter sets to identify the high-performance ones, unlike BFB, which requires no parameter. In Figure 10, the schedules of SCCL and BFB can both achieve exact optimality, but TACCL's have significantly worse performance, especially at large Ns. SCCL is uniquely capable of generating all Pareto-efficient schedules. However, due to the prohibitive runtime of parameter sweep, SCCL can only do so for very small Ns.

N	SCCL				TACCL w/o Symmetry				TACCL w/ Symmetry				BFB
	$c=1$	$c=2$	$c=3$	$c=4$	$c=1$	$c=2$	$c=3$	$c=4$	$c=1$	$c=2$	$c=3$	$c=4$

Table 6: Comparing allgather schedule generation runtimes (in seconds) of SCCL, TACCL, and BFB. The setup of SCCL is to generate schedules with the least number of comm steps. Both SCCL and TACCL were run with chunks=1,2,3,4 (number of chunks per shard), and TACCL was run w/ and w/o manually set topology symmetry. "n/a" indicates where TACCL reports an error due to failure to generate a solution within its 1800s time limit for MILP solver.

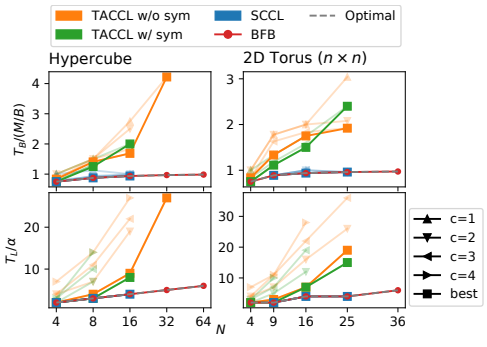

Figure 10: Comparing theoretical performances of schedules from Table 6. We show both T_L and T_B of the schedules, along with the theoretical optimal. For SCCL and TACCL, the solid lines show the best results from parameter sweeps. The inferior ones are dimmed.

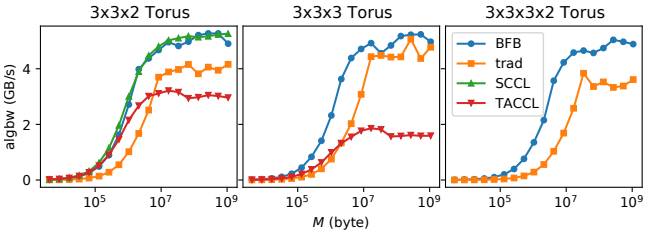

Figure 11: Comparing allreduce performances of torus schedules generated by BFB, traditional torus scheduling [62], SCCL, and TACCL on Frontera [69] supercomputer. The y-axis is algorithmic bandwidth (algbw), computed as M divided by end-to-end runtime. SCCL fails to generate a schedule for 3×3×3 and 3×3×3×2 tori, and TACCL fails to generate a schedule for 3×3×3×2 torus within the time limits.

8.5.2 Supercomputing Allreduce Experiments

In the supercomputing setting, we run torus schedules generated by BFB, traditional torus scheduling [62], SCCL, and TACCL on Frontera [69] supercomputer at the Texas Advanced Computing Center (TACC) [71]. The cluster consists of 396 nodes in a 6D torus direct-connect topology. Each node is equipped with an Intel Xeon Platinum 8280 CPU and a Rockport NC1225 network card, capable of delivering 25 Gbps per link, with degree 12. However, the total BW of a single node may be bottlenecked by the 100 Gbps host BW of PCIe Gen3 x16. Finally, the schedules are lowered and run using Intel oneCCL [26] + libfabric [39].

We run schedules on two types of sub-torus within the cluster: equal-dimension (3×3×3) and unequal-dimension (3×3×2 & 3×3×3×2). As shown in Figure 11, BFB schedules achieve the highest performance in all settings. As mentioned in §6.2, the traditional torus schedule can only achieve high BW performance in tori with equal dimensions. At large M, it matches BFB's performance in 3×3×3 torus but significantly underperforms in 3×3×2 and 3×3×3×2, where BFB has 29% and 42% higher algbw on average for $M \geq 100$MB. At small to intermediate M (< 100MB), BFB outperforms traditional schedules by 3.1× on average in all settings due to its 2× lower in total-hop latency and higher BW performance.

As for SCCL and TACCL, we adhere to the same time limits and parameter sweeps as in §8.5.1 and select the best result at each M from all parameter sets. In 3×3×2 torus, SCCL is able to generate an optimal schedule, matching BFB's performance across all M. However, it fails to generate a schedule within 10^4 seconds for other larger tori. TACCL can only generate schedules in 3×3×2 and 3×3×3, and its schedules underperform BFB's by a large margin. One additional observation is that the algbw of BFB at large M hardly changes from 18-node (3×3×2) to 54-node (3×3×3×2) torus. This can be explained by the fact that BFB schedules have theoretically achieved allreduce BW optimality ($\frac{2M}{B} \cdot \frac{N-1}{N}$), which remains nearly constant as N increases.

9 Concluding Remarks

Collective communications are critical to both ML training and HPC workloads. Current solutions often rely solely on existing topologies and schedules, resulting in high total-hop latency, bandwidth inefficiency, or low all-to-all throughput. We presented a general, highly scalable, and automated algorithmic framework for optimizing topology and schedule generation for collectives by leveraging scalable graph-theoretic approaches. Our evaluation demonstrates significant performance gains across multiple testbeds and large-scale simulations in both standalone collective communications and end-to-end ML training.

Appendix

In this appendix, we give additional evaluation results, along with formal mathematical definitions and analyses of the various techniques and concepts discussed in the main text:

- §A provides supplementary materials to evaluation section.
- §B gives formal definitions of reduce-scatter/allgather schedule and how one can be transformed into another.
- §C gives formal definitions of total-hop latency and bandwidth optimality, along with discussions on optimal allreduce schedule and computational cost of reduction.
- §D provides formal definitions of expansion techniques and optimality analysis of their expanded schedules.
- §E provides optimality analysis of BFB schedule generation and discusses variant formulations that support generating schedules for a fixed number of chunks and for heterogeneous network topology.
- §F discusses various generative topologies and the performance of their generated BFB schedules.
- §G provides proofs of all theorems in this paper.
- §H contains supplementary tables and figures. In particular, Table 9 gives a summary of topologies in this paper.

A Evaluation Appendix

- §A.1 presents experiment results that compare BFB schedule generation with communication solutions for switch networks: NCCL [56] and recursive halving & doubling.
- §A.2 shows experiment results to validate α-β cost model.
- §A.3 gives an analysis of Pareto-efficient topologies/schedules under different hardware and workload specifications.
- §A.4 details setup of simulated DNN training and the topologies generated by our topology finder.
- §A.5 provides the multi-commodity flow (MCF) formulation used to compute all-to-all throughput.
- §A.6 shows how to convert unidirectional topologies/schedules into bidirectional ones.

A.1 Comparison Against Switch Solutions

NCCL [56] and recursive halving & doubling (RH&D) are widely adopted collective communication solutions on switch networks. We assess the schedule performance of BFB against these solutions over two direct-connect 8-node topologies: hypercube and twisted hypercube [17]. Hypercube is widely used in HPC settings, and its connections perfectly match the communication pattern of RH&D. Twisted hypercube is a variant of hypercube with a lower diameter.

Figure 13 compares the baselines against our BFB schedule when run over either hypercube or twisted hypercube with $N=8$, $d=3$ on the testbed. At small M, all schedules and topologies perform roughly the same, except BFB can take advantage of the lower diameter of twisted hypercube and

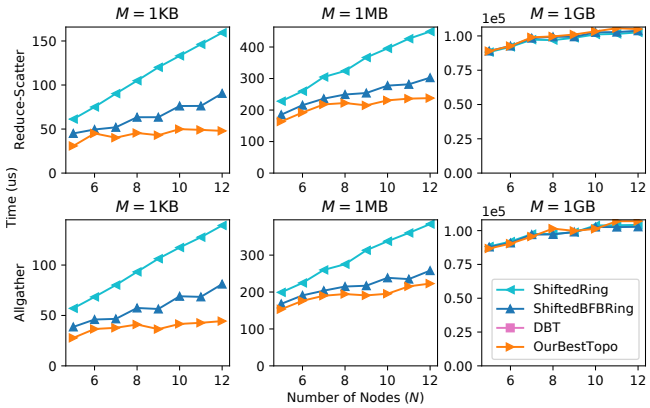

Figure 12: Comparing reduce-scatter and allgather runtimes of topologies. This figure shows the corresponding reduce-scatter and allgather results of Figure 6.

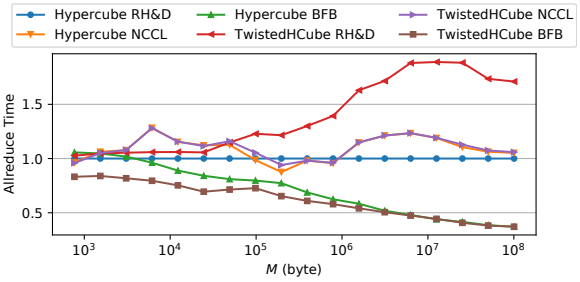

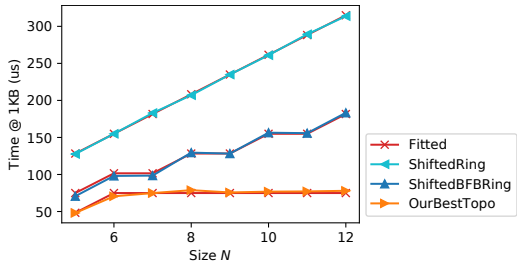

Figure 13: Comparing switch allreduce solutions (recursive halving & doubling (RH&D), NCCL) against BFB schedule on hypercube and twisted hypercube on $N=8, d=3$ testbed. The runtimes are normalized by the runtime of recursive halving & doubling on hypercube.

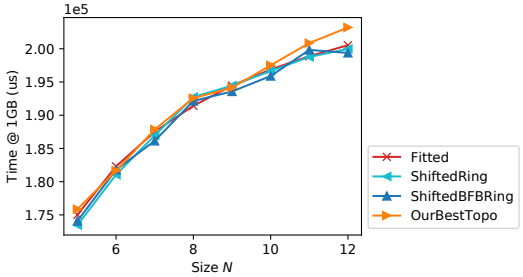
achieve ∼20% lower runtime. At large M, because BFB achieves BW optimality on both topologies, it performs even better with 60% lower runtime. RH&D and NCCL perform poorly as M grows because they cannot utilize all $d=3$ links simultaneously. At every comm step of RH&D, a node only communicates with one of the three neighbors, utilizing at most $1/3$ of the total bandwidth (similarly with NCCL). Also, because the schedule is not matched to the twisted hypercube, some nodes communicate with nodes multiple hops away, occupying more links and causing congestion.



A.2 Cost Model Validation

Despite the wide acceptance of α-β cost model by previous literature [10, 11, 24, 63, 65], we also conducted a linear regression analysis to validate the cost model on our testbed. In particular, we want to verify that (1) total-hop latency follows $T_L = \alpha \cdot x + \varepsilon$ and (2) BW runtime follows $T_B = \frac{M}{B} \cdot y$, where x and y are the number of comm steps and bandwidth factor respectively ($y = 2 \cdot \frac{N-1}{N}$ if BW-optimal). ε is the constant latency[4] including time costs such as GPU kernel launching. Here, we use linear regression to derive the values of α, ε, and $1/B$, and compute the relative errors between the observed

[4]This part of latency is a fixed constant for all topologies and schedules, so it is omitted earlier.

(a) Total-Hop Latency T_L (Relative error: avg 1.71%, max 6.21%)

(b) BW Runtime T_B (Relative error: avg 0.47%, max 1.32%)

Figure 14: Linear regression results.

runtimes and expected runtimes. We fit the allreduce runtimes at 1KB to the total-hop latency, since BW runtime is negligible at such a small M. Similarly, we fit the runtimes at 1GB to the BW runtime, since total-hop latency is negligible at such a large M.

Figure 14 shows our results of linear regression analysis to verify our cost model. For total-hop latency, we obtain estimates $\alpha \approx 13.33$us and $\varepsilon \approx 21.60$us with low errors (average and maximum relative errors of 1.71% and 6.21% respectively). As one can see from Figure 14a, ShiftedRing and ShiftedBFBRing have a straight and a stair-step shape of runtime growth respectively, which match the expected numbers of comm steps $2(N-1)$ and $2\lfloor N/2 \rfloor$ respectively. For BW runtime, we get an estimate $1/B \approx 1.018 \times 10^{-4}$us/byte or $B \approx 79$Gbps with low errors (average and maximum relative errors of 0.47% and 1.32% respectively). As one can see from Figure 14b, all three topologies follow the fitted curve $2\frac{1\text{GB}}{B} \cdot \frac{N-1}{N} = 2T_B^*(N)$ since they are all BW-optimal. However, there is a gap between $B \approx 79$Gbps and the hardware theoretical bandwidth 4x25Gbps=100Gbps. Besides inevitable loss of bandwidth in actual communication, the gap can also be explained by the fact that computational cost of reduction also accounts for part of $1/B$ as discussed in §C.4.

A.3 Pareto-Efficiency Analysis

There could exist multiple Pareto-efficient topologies at given N and d. For different α and M/B, the Pareto-efficient topology with minimum allreduce runtime is also different. To see how N affects the best choice of topologies, we use topology finder (§5.4) to generate Pareto-efficient topologies at $d=4$ for N up to 2000 and pick the best one based on specific values of α and M/B.

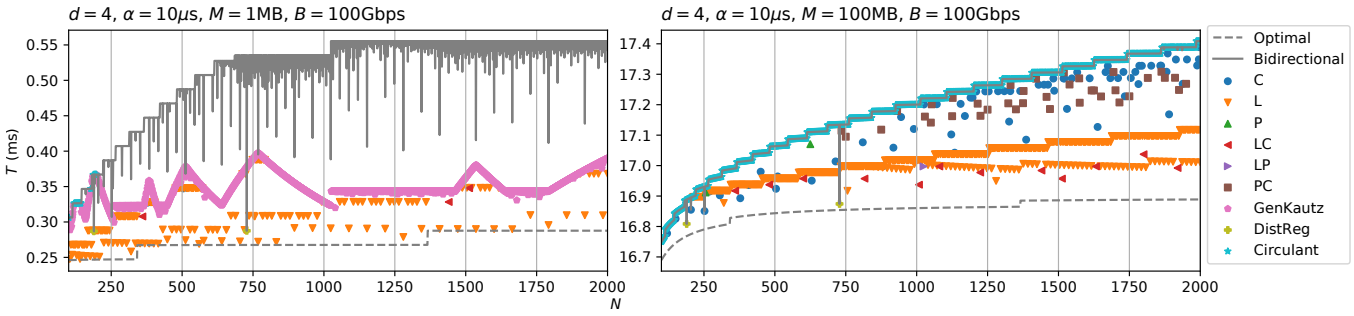


Figure 15: The minimum allreduce runtimes at different N for $d = 4$, $\alpha = 10$us, and $M/B = 1$MB/100Gbps, 100MB/100Gbps. "L", "P", and "C" stand for line graph, Cartesian power, and Cartesian product (of different graphs) respectively. For example, "LC" means the runtime is achieved by a topology whose construction involves line graph expansion and Cartesian product. "GenKautz", "DistReg", and "Circulant" stand for generalized Kautz graph (§F.2), distance regular graph (§F.3), and circulant graph (§F.4) respectively. The figures also show the best bidirectional topology known at different Ns. Degree expansion does not show up due to target $d = 4$ being relatively small.

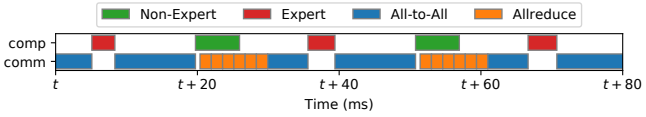

Figure 16: Example of a training timeline for Switch Transformers.

Figure 15 shows two examples of such analysis. At $M =$ 1MB, total-hop latency is more important than BW runtime. Thus, we see that generalized Kautz graph is the most popular one, being the best topology at many Ns. On the contrary, at $M = 100$MB, BW performance becomes the dominant factor, and thus circulant graph becomes the most popular one. Line graphs are also popular in both settings; however, line graph expansion requires target N to be divisible by some power of d, so it does not work for any N.

A.4 Details of Simulated Distributed Training

We simulate distributed ML training by first collecting actual compute times for model layers, running the models on an NVIDIA A100-SXM-80GB GPU, and then adding communication times according to the specific parallelism, e.g., data or expert parallelism. The communication time is calculated using α-β model for allreduce (§A.2) and multi-commodity flow for all-to-all (§A.5), assuming $\alpha = 10$us, $B = 100$Gbps over $d = 4$. Our simulation is designed to match the compute-communication overlap pattern of PyTorch Distributed Data Parallel [38]. As in PyTorch DDP, we bucket gradients that are ready for allreduce during backward propagation. Once the gradient volume reaches a predefined bucket capacity, an allreduce is performed. While a large bucket size results in less latency overhead, a small bucket size enhances compute-communication overlap. We choose the best bucket size by comparing the iteration times of bucket sizes {1MB, 10MB, 100MB, 1GB}. To ensure overlap, computation and communication are handled as independent streams, with the communication stream executing one collective at a time.

For the simulated training of Mixture-of-Experts (MoE) models, we follow the standard practice of expert parallelism [19, 34, 36, 60], where experts are sharded across all nodes while non-expert layers are replicated. All-to-all communications are needed before the expert layers to route tokens to the nodes of the assigned experts, and afterward to return tokens to the original nodes for the continuation of the forward/backward pass, thus blocking the computation stream. Furthermore, all-to-all and allreduce are not allowed to be overlapped as they occupy the same network bandwidth [36]. Figure 16 shows a timeline example of the simulated expert-parallel training. For simplicity, we assume a uniform token distribution among the experts, as MoE models are trained to balance expert load [19, 66, 82]. Consequently, the all-to-all communication is uniform across the nodes. We use the multi-commodity flow formulation (3) to compute the all-to-all communication time.

All hyperparameters, including sequence lengths and global batch sizes, are chosen according to the original paper of Switch Transformers [19]. The topology degree is fixed at 4, and the topology sizes are chosen such that the local batch size at each node is ≥ 1 and not so large as to run out of GPU memory. Table 7 includes all the Pareto-efficient topologies used in the simulation. For each model and topology size, we choose the topology that results in the smallest iteration time.

A.5 All-to-All Throughput

The problem of deriving the throughput of all-to-all communication on a topology can be nicely formulated as a multi-commodity flow (MCF) problem [4, 21, 32, 75, 78]. In an all-to-all MCF, each pair of nodes $(s,t) \in V_G^2$ acts as the source and sink of a commodity. The objective is to simultaneously route f units of flows from each s to t such that f is maximized, with flow allocation subject to flow conservation and edge capacities. In [4], the authors have devised an efficient LP formulation to compute the optimal f:

$$\begin{aligned} \text{maximize} \quad & f \\ \text{subject to} \quad & \sum_s y_{s,(u,v)} \leq 1, && \forall u,v \\ & f + \sum_v y_{s,(u,v)} \leq \sum_w y_{s,(w,u)}, && \forall s,u : s \neq u \\ & y_{s,(u,v)} \geq 0. && \forall s,u,v \end{aligned} \tag{3}$$

In LP (3), we assume the capacity/bandwidth of each link is 1 unit. Therefore, if the bandwidth of each link is B/d,

Table 7: Pareto-efficient topologies at $N\in\{32,64,128,256,512,1024\}$, $d=4$. The results are generated from the topology finder (§5.4). For notations of the topologies, see Table 3 and 9. For distance regular graphs (DistReg), see Table 8. The MCF values are computed using LP (3).

then fB/d represents the rate at which every node can send to every other node simultaneously.

A.6 Unidirectional to Bidirectional

Unidirectional topologies are technically feasible on optical testbeds. The optical cable contains two fibers, one for each direction, and the fabric can link them to two distinct end-hosts, thus enabling unidirectional topologies at no additional hardware cost.

However, in our evaluation, we only use bidirectional topologies. While unidirectional topologies can be realized by configuring the patch panel in simplex mode, the requisite overlay routing for the reverse path traffic (acks, etc.) is currently only supported using routing rules performed by the host kernel as opposed to the NIC, leading to unpredictable RTTs. Therefore, we can functionally validate unidirectional topologies on our testbed, but we cannot accurately evaluate their performance. Note that newer NICs [9, 57] do support hardware offloading for these rules, which we will examine in future work.

While this paper considers unidirectional topologies a lot, many of the techniques can be conveniently applied to bidirectional topologies as well. For example, BFB schedule generation, degree expansion, and Cartesian product can all be used on bidirectional topologies by replacing each bidirectional edge with two opposite unidirectional edges. The resulting degree expanded and Cartesian product topologies still have unidirectional edges in opposite pairs. Although line graph expansion only works within unidirectional topologies, there is a way to convert unidirectional topology and schedule to bidirectional ones with zero performance sacrifice. In this section, we will show how to convert a reverse-symmetric (see Definition 6) d-regular unidirectional topology G and its allgather schedule A to a $2d$-regular bidirectional topology G' and its schedule A' such that $T_L(A)=T_L(A')$ and $T_B(A)=T_B(A')$.

Let $g:V_G\to V_{G^T}$ be the isomorphism from G to G^T, then it is trivial to see that $g(A)$ (see Definition 7) is an allgather schedule for G^T. Observe that $G'=G\cup G^T$ is a $2d$-regular bidirectional topology. Consider both A and $g(A)$ as allgather schedules for bidirectional topology G'. Schedules A and $g(A)$ use disjoint sets of edges, because they use opposite directions. Thus, we can divide each shard into two halves. Let one half follow schedule A and the other half follow $g(A)$. Let such a schedule be A'.

It is trivial to see that $T_L(A)=T_L(A')$. As for $T_B(A)=T_B(A')$, it follows the fact that the total data size is halved for each of A and $g(A)$, but the bandwidth per edge is also halved due to the doubling of degree. Note that if A is BW-optimal, then A' is BW-optimal; however, A' is not necessarily Moore optimal if A is Moore optimal.

B Reduce-Scatter & Allgather

We use tuple $((v,C),(u,w),t)$ to denote that u sends v's chunk C to w at comm step t. Node v is the source and destination node of chunk C in allgather and reduce-scatter respectively. A communication schedule is thus a collection of tuples.

Definition 4 (Allgather)**.** *An algorithm (G,A) is an allgather algorithm if for arbitrary $x\in S$ and distinct $u,v\in V_G$, there exists a sequence in A:*

$$((v,C_1),(w_0,w_1),t_1),((v,C_2),(w_1,w_2),t_2),\ldots ((v,C_n),(w_{n-1},w_n),t_n),$$

where $w_0=v$, $w_n=u$, $t_1<t_2<\ldots<t_n$, and $x\in C_1\cap C_2\cap\cdots\cap C_n$.

This sequence serves to broadcast x from v to u. A reduce-scatter algorithm has the same definition except $w_0=u$, $w_n=v$. In reduce-scatter, we assume any chunk received by a node is immediately reduced with the node's local chunk.

In this paper, many of the techniques are discussed under allgather only. We will show that anything holds in either reduce-scatter or allgather has an equivalent version for the other collective operation. To do so, we use the concept of *transpose graph* from graph theory and define *reverse schedule*. We say a schedule A is *for* topology G if every $((v,C),(u,w),t)\in A$ satisfies $u,v,w\in V_G$ and $(u,w)\in E_G$.

Definition 5 (Reverse Schedule)**.** *Suppose A is a schedule for G. A reverse schedule A^T of A is a schedule for trans-*

pose graph G^T such that $((v,C),(u,w),t_{\max}-t+1) \in A^T$ iff $((v,C),(w,u),t) \in A$, where $t_{\max}$ is the max comm step in A.

It is trivial to see that $T_L(A) = T_L(A^T)$ and $T_B(A) = T_B(A^T)$. Note that $(u,w) \in E_{G^T}$ if and only if $(w,u) \in E_G$ by definition of transpose graph.

Theorem 1. *If A is a reduce-scatter/allgather schedule for G, then A^T is an allgather/reduce-scatter schedule for G^T.*

Theorem 1 has the following two corollaries:

Corollary 1.1. *Suppose $G \mapsto f(G)$ is a function to construct reduce-scatter/allgather schedule given graph G, then $G \mapsto f(G^T)^T$ is a function to construct allgather/reduce-scatter schedule given graph G.*

Corollary 1.2. *Suppose $(G,A) \mapsto (f(G), f(A))$ is a mapping within reduce-scatter/allgather algorithms, then $(G,A) \mapsto (f(G^T)^T, f(A^T)^T)$ is a mapping within allgather/reduce-scatter algorithms.*

For example, the line graph expansion in §5.1 can be seen as a mapping within allgather, and the BFB linear program (1) can be seen as a function to construct allgather schedule. Thus, Corollary 1.1 and 1.2 have shown that they both have equivalent versions in reduce-scatter.

In undirected topology, it is well-known that reduce-scatter and allgather are a pair of dual operations such that one can be transformed into another by reversing the communication in schedule [11]. It is similar for directed topology but with extra requirement and more complicated transformation. We define the following property for directed graphs:

Definition 6 (Reverse-Symmetry)**.** *A digraph G is reverse-symmetric if it is isomorphic to its own transpose graph G^T.*

In graph theory, there is a similar concept called *skew-symmetric graph*. Reverse-symmetry is a weaker condition than skew-symmetry.

We define a way to transform the schedule for G into a schedule for G^T based on graph isomorphism:

Definition 7 (Schedule Isomorphism)**.** *Suppose G and G' are isomorphic. Let $f : V_G \to V_{G'}$ be the graph isomorphism and A be a schedule for G, then $f(A)$ is a schedule for G' that $((f(v),C),(f(u),f(w)),t) \in f(A)$ iff $((v,C),(u,w),t) \in A$.*

Theorem 2. *Suppose G is reverse-symmetric. Let G^T be the transpose graph, and let $f : V_{G^T} \to V_G$ be the isomorphism from G^T to G. If (G,A) is a reduce-scatter/allgather algorithm, then $(G, f(A^T))$ is an allgather/reduce-scatter algorithm with $T_L(f(A^T)) = T_L(A)$ and $T_B(f(A^T)) = T_B(A)$.*

Theorem 2 establishes that given any reverse-symmetric topology, if we have either reduce-scatter or allgather, then we can construct both reduce-scatter and allgather. Since allreduce can be achieved by applying a reduce-scatter followed by an allgather, we only need one of reduce-scatter and allgather to construct a complete allreduce algorithm. Furthermore, if the reduce-scatter or allgather algorithm has runtime T, then the resulting allreduce algorithm has runtime $2T$.

Most of our base topologies are reverse-symmetric (Table 9). In addition, all of our expansion techniques also preserve reverse-symmetry. Thus, one can almost always use Theorem 2 to derive reduce-scatter and allreduce schedules from allgather schedule on our synthesized topologies. For non-reverse-symmetric topologies like generalized Kautz graph, one can apply Corollary 1.1 or 1.2 to construct reduce-scatter and allgather separately.

C Topology-Schedule Optimality

Because our cost model is only concerned with total-hop latency and BW runtime, the optimality of reduce-scatter/allgather algorithm is only related to total-hop latency optimality and BW optimality in this paper. Note that we also consider topology as a dimension that can be optimized, so optimality is discussed in the space of all topology-schedule combinations, i.e., *algorithms* by our definition.

C.1 Total-Hop Latency Optimality

Definition 8 (Total-Hop Latency Optimal)**.** *Given an N-node degree-d reduce-scatter/allgather algorithm (G,A), if any other N-node degree-d reduce-scatter/allgather algorithm (G',A') satisfies $T_L(A') \geq T_L(A)$, then (G,A) is total-hop latency optimal.*

Because in reduce-scatter/allgather, every node needs to send a shard of data to every other node, the number of comm steps is lower bounded by the graph diameter:

Theorem 3. *Every reduce-scatter/allgather algorithm (G,A) satisfies $T_L(A) \geq \alpha \cdot D(G)$, where $D(G)$ is the diameter of G.*

Because we can always construct a BFB schedule A for topology G with $T_L(A) = \alpha \cdot D(G)$, it follows the corollary:

Corollary 3.1. *An N-node degree-d reduce-scatter/allgather algorithm (G,A) is total-hop latency optimal if and only if $T_L(A) = \alpha \cdot D(G) = \alpha \cdot \min\{D(G') : |V_{G'}| = N, \deg(G') = d\}$.*

The minimum diameter of a directed graph given a number of vertices and degree is still an open question. One can check *degree/diameter problem* [50] for more information. However, as a close upper bound of number of vertices given degree and diameter, the *Moore bound* for digraph is sufficient to tell the total-hop latency optimality in most cases.

Definition 9 (Moore Bound)**.** *Let G be any degree-d digraph of diameter k. The Moore bound is an upper bound on the number of vertices in G:*

$$M_{d,k} = \sum_{i=0}^{k} d^i = \frac{d^{k+1}-1}{d-1}.$$

Definition 10 (Moore Optimal)**.** *Let (G,A) be an N-node degree-d reduce-scatter/allgather algorithm with $T_L(A) = k\alpha$, then (G,A) is Moore optimal if $N > M_{d,k-1}$.*

Because for any degree-d digraph G, $D(G) \geq k$ must be true as long as $|V_G| > M_{d,k-1}$, Moore optimality is a stronger condition than total-hop latency optimality. We define a function T_L^* such that $T_L^*(N,d)$ equals the Moore optimal total-hop latency of N-node degree-d reduce-scatter/allgather algorithms.

C.2 Bandwidth Optimality

Definition 11 (Bandwidth Optimal)**.** *Given an N-node degree-d reduce-scatter/allgather algorithm (G,A), if any other N-node degree-d reduce-scatter/allgather algorithm (G',A') satisfies $T_B(A') \geq T_B(A)$, then (G,A) is BW-optimal.*

In reduce-scatter/allgather, each node needs to send/receive at least $M \cdot \frac{N-1}{N}$ amount of data. Thus, the following holds:

Theorem 4. *$\frac{M}{B} \cdot \frac{N-1}{N}$ is a lower bound of $T_B(A)$ for any N-node reduce-scatter/allgather algorithm (G,A).*

Note that one can always construct a ring of degree d by sending d parallel edges from one node to the next node. The trivial ring reduce-scatter/allgather schedule has $\frac{M}{B} \cdot \frac{N-1}{N}$ BW runtime. Therefore, we have:

Corollary 4.1. *An N-node reduce-scatter/allgather algorithm (G,A) is BW-optimal if and only if $T_B(A) = \frac{M}{B} \cdot \frac{N-1}{N}$.*

We define a function T_B^* such that $T_B^*(N) = \frac{M}{B} \cdot \frac{N-1}{N}$ is the optimal BW runtime of N-node reduce-scatter/allgather algorithms. From Corollary 4.1, we have the following necessary and sufficient condition for BW optimality:

Theorem 5. *An allgather algorithm (G,A) is BW-optimal if and only if:*

1. *$\frac{1}{B/d}\sum_{((v,C),(u,w))\in A_t}|C| = T_B(A_t)$ for all $(u,v)\in E_G$ and $t \in \{1,\ldots,t_{\max}\}$. A_t is the subschedule of A at comm step t.*
2. *Pick any distinct $u,v \in V_G$. For each $x \in S$, there exists a unique $((v,C),(w,u),t) \in A$ such that $x \in C$.*

Condition 1 ensures that at each comm step, every link of topology G has equal workload, so no link finishes early and results in waste of bandwidth. Condition 2 ensures that no piece of data is received twice by some node, so no duplicated send exists.

C.3 Allreduce Optimality

In this paper, we construct an allreduce algorithm through a reduce-scatter followed by allgather. In such construction, the lower bound of allreduce algorithm is $2(T_L^*(N,d)+T_B^*(N))$. To compare this with the lower bound of any allreduce construction, in [58], the authors have proved that $2T_B^*(N)$ is indeed the lower bound of BW runtime of any allreduce algorithm. As for total-hop latency, a reduce-scatter followed by allgather has at least $2D(G)$ number of comm steps, so $2T_L^*(N,d)$ is the lower bound of total-hop latency. Although one can use all-to-all to construct an allreduce with number of comm steps equal to one diameter $D(G)$ (lower bound being $T_L^*(N,d)$ instead of $2T_L^*(N,d)$), the lower bound of BW runtime for all-to-all is $\frac{M}{B} \cdot (N-1) = N \cdot T_B^*(N)$, which is much worse than $2T_B^*(N)$.

There is also another way of constructing allreduce: reduce followed by broadcast. In such an approach, the number of comm steps can be twice the radius of G instead of twice the diameter. However, the Moore bound for graph diameter also applies to graph radius, so $2T_L^*(N,d)$ is still a lower bound of allreduce via reduce+broadcast. By Theorem 16, the total-hop latency optimal allreduce via reduce+broadcast is at most 2α lower than the total-hop latency of generalized Kautz graph can do with reduce-scatter plus allgather. Furthermore, reduce+broadcast is usually poor in BW performance.

C.4 Computational Cost

In this paper, we omit the computational cost of reduction operation in performance analysis. While this approach is commonly adopted in previous literature [10, 63, 65, 76], we give a formal reasoning why this approach is legitimate. It is not only because computational cost is generally orders of magnitude lower than network cost, but also because computational cost can be incorporated into network cost.

Assume a cost model where computation and network communication do not overlap at each node.[5] In particular, at each comm step of reduce-scatter, the computation to reduce chunks happens immediately after the node receives all chunks and before the node starts to send out chunks for the next comm step. We adopt notations from [11], where γ denotes the computational time cost per size of data. Like total-hop latency and BW runtime, we also let $T_C(A)$ be the total time spent on computation by schedule A. As argued in [11], a lower bound of computational cost is $T_C \geq M \cdot \gamma \cdot \frac{N-1}{N}$ for both reduce-scatter and allreduce, which is identical to the BW optimality of reduce-scatter and half of that of allreduce. The following theorem shows that BW runtime of a schedule can act as an upper bound for the computational time.

Theorem 6. *Given a reduce-scatter algorithm (G,A), suppose $T_B(A) = \frac{M}{B} \cdot y$, then $T_C(A) \leq M \cdot \gamma \cdot y$.*

The rationale behind Theorem 6 is that the amount of computation for any node at a given comm step equals the amount of data the node receives during that comm step. Thus, **as we balance network transmission, it naturally leads to a more balanced computation.** With Theorem 6, if the BW runtime of some allreduce schedule A is $T_B(A) = 2\frac{M}{B} \cdot y$, then $T_B(A) + T_C(A) \leq M \cdot (\frac{2}{B} + \gamma) \cdot y$. We can thus simply define $B' = (\frac{1}{B} + \frac{\gamma}{2})^{-1}$, and then $2\frac{M}{B'} \cdot y$ can represent the sum of BW runtime and computational runtime altogether. The value of y is all that matters. The following corollary shows that if an algorithm is BW-optimal, then such representation is exact.

Corollary 6.1. *If allreduce algorithm (G,A) is BW-optimal, i.e., $T_B(A) = 2\frac{M}{B} \cdot \frac{N-1}{N}$, then $T_C(A) = M \cdot \gamma \cdot \frac{N-1}{N}$ and $T_B(A) + T_C(A) = 2M \cdot (\frac{1}{B} + \frac{\gamma}{2}) \cdot \frac{N-1}{N}$.*

When profiling a testbed, one can simply derive the value of $\frac{1}{B} + \frac{\gamma}{2}$ using BW-optimal topologies and use it as the new $1/B$ to apply the results of this paper. While it is still possible for two schedules with the same BW runtime to have different computational runtimes, such difference is bounded by the aforementioned theorems and orders of magnitude smaller than BW runtime.

[5] Otherwise, the computational cost would be even more negligible.

D Optimality of Expansion Techniques

In this section, we provide formal definitions and detailed performance analysis of expansion techniques.

D.1 Line Graph Expansion

Definition 12 (Line Graph)**.** *Given a directed graph (or digraph) G, each edge $(u,v) \in E_G$ corresponds to a vertex uv in the line graph $L(G)$. For every uv, vw pair in $V_{L(G)}$, there exists an edge $(uv, vw) \in E_{L(G)}$.*

In the case of multiedges between u and v, the line graph also contains multiple vertex uv.

Definition 1 (Schedule of Line Graph)**.** *Given an allgather schedule A_G for topology G, let $A_{L(G)}$ be the schedule for line graph $L(G)$ containing:*

1. *$((v'v, S), (v'v, vu), 1)$ for each edge $(v'v, vu) \in E_{L(G)}$ with $v'v \neq vu$.* **[Insert the 1st comm step in $A_{L(G)}$.]**
2. *$((v'v, C), (uw, ww'), t+1)$ for each $((v,C),(u,w),t) \in A_G$ and $v'v \neq ww'$.* **[Adapt A_G to form $A_{L(G)}$.]**

The following theorem gives the performance of the expanded schedule:

Theorem 7. *Given a d-regular topology G, if (G, A_G) is an N-node allgather algorithm, then $(L(G), A_{L(G)})$ is a dN-node allgather algorithm satisfying:*

$$T_L(A_{L(G)}) = T_L(A_G) + \alpha, \tag{4}$$

$$T_B(A_{L(G)}) \leq T_B(A_G) + \frac{M}{B} \cdot \frac{1}{N}. \tag{5}$$

From Theorem 7, one can see that the performance of the expanded schedule depends on that of the base schedule. Note that T_B also depends on M and B. For simplicity, we write $T_B(A_G)$ instead of $T_B(A_G, M, B)$ when there is no ambiguity. Theorem 7 makes an implicit assumption that $T_B(A_G, M, B) = \tau(M/B)$ for some constant τ. This assumption, suggesting that T_B scales linearly with data size and inversely with bandwidth, should hold for any reasonably designed schedule.

Consequently, if we apply line graph expansion n times, the performance of the expanded schedule is:

Corollary 7.1. *Given a d-regular topology G, if (G, A_G) is an N-node allgather algorithm with $T_B(A_G, M, B) = \tau(M/B)$ for some constant τ, then $(L^n(G), A_{L^n(G)})$ is a $d^n N$-node allgather algorithm satisfying:*

$$T_L(A_{L^n(G)}) = T_L(A_G) + n\alpha, \tag{6}$$

$$T_B(A_{L^n(G)}) \leq T_B(A_G) + \frac{M}{B} \cdot \frac{d}{d-1} \left(\frac{1}{N} - \frac{1}{d^n N} \right). \tag{7}$$

In terms of the optimality of line graph expansion:

Theorem 8. *$(L^n(G), A_{L^n(G)})$ is Moore optimal if and only if (G, A_G) is Moore optimal.*

Theorem 9. *If (G, A_G) is BW-optimal with N nodes, then $T_B(A_{L^n(G)}) / T_B^*(d^n N) \leq 1 + [(d-1)N]^{-1}$ for all n.*

As mentioned in the main text, by Theorem 9, the key metric for the quality of base graph is how large it is while achieving both Moore and BW optimality. Currently, our largest such base graph that works for any even degree is Hamming graph $H(2, 1+d/2)$, which has $(1+d/2)^2 = \Theta(d^2)$ number of nodes. The corresponding line graph expanded topology is always Moore optimal and at most $O(1/d^3)$ away from BW optimality by Theorem 9.

Line graph expansion is closely related to BFB schedule for two reasons: (1) most of our base topologies like complete bipartite graph and Hamming graph use BFB schedule as the base schedule, and (2) the line graph expansion of BFB schedule is still a BFB schedule. To see the performance bound in Theorem 7 is tight, we have the following results in the context of BFB schedule:

Theorem 10. *Let A_G be a BFB allgather schedule for d-regular topology G with $|N^+(u)| > 1$ for all $u \in V_G$, then the expanded schedule $A_{L(G)}$ is a BFB allgather schedule for $L(G)$. In particular, if A_G is the optimal BFB schedule for G, then $A_{L(G)}$ is the optimal BFB schedule for $L(G)$ satisfying:*

$$T_B(A_{L(G)}) = T_B(A_G) + \frac{M}{B} \cdot \frac{1}{N}. \tag{8}$$

Corollary 10.1. *Let A_G be a BFB allgather schedule for d-regular topology G with $|N^+(u)| > 1$ for all $u \in V_G$, then the expanded schedule $A_{L^n(G)}$ is a BFB allgather schedule for $L^n(G)$. In particular, if A_G is the optimal BFB schedule for G, then $A_{L^n(G)}$ is the optimal BFB schedule for $L^n(G)$ satisfying:*

$$T_B(A_{L^n(G)}) = T_B(A_G) + \frac{M}{B} \cdot \frac{d}{d-1} \left(\frac{1}{N} - \frac{1}{d^n N} \right).$$

D.2 Degree Expansion

Definition 13 (Degree Expanded Topology)**.** *Given an N-node d-regular topology G without self-loops, construct the degree expanded nN-node nd-regular topology $G * n$:*

1. *For each vertex $v \in V_G$, add $v_1, \ldots, v_n$ to V_{G*n},*
2. *For each edge $(u,v) \in E_G$, add (u_i, v_j) to E_{G*n} for all i, j including $i = j$.*

Definition 2 (Degree Expanded Schedule)**.** *Given an allgather schedule A_G for G, construct A_{G*n} for $G * n$:*

1. *For all i, j including $i = j$ and for each $((v,C),(u,w),t) \in A_G$, add $((v_j, C), (u_j, w_i), t)$ to A_{G*n};*
2. *Divide shard S into equal-sized chunks $C_1, \ldots, C_{nd}$. Given $u_i, u_j \in V_{G*n}$ with $i \neq j$, add $((u_i, C_\alpha), (v_\alpha, u_j), t_{\max} + 1)$ to A_{G*n} for each $(v_1, u_j), \ldots, (v_{nd}, u_j) \in E_{G*n}$, where $t_{\max}$ is the max comm step in A_G.*

Theorem 11. *Given a d-regular topology G without self loops, if (G, A_G) is an N-node allgather algorithm with $T_B(A_G, M, B) = \tau(M/B)$ for some constant τ, then $(G * n, A_{G*n})$ is an nN-node allgather algorithm satisfying:*

$$T_L(A_{G*n}) = T_L(A_G) + \alpha, \tag{9}$$

$$T_B(A_{G*n}) = T_B(A_G) + \frac{M}{B} \cdot \frac{n-1}{nN}. \tag{10}$$

Corollary 11.1. *If (G, A_G) is BW-optimal and $T_B(A_G, M, B) = \tau(M/B)$ for some τ, then $(G * n, A_{G*n})$ is BW-optimal.*

Degree expansion preserves BW optimality. As for total-hop latency of degree expanded topology, observe that $T_L^*(N,d) = \Theta(\log_d N)$ and $\log_{nd} nN < \log_d N$, so T_L^* decreases as we apply degree expansion. Since T_L increases in degree expansion, Moore optimality is not preserved.

D.3 Cartesian Product Expansion

Definition 3 (Cartesian Product)**.** *The Cartesian product digraph $G_1 \Box G_2$ of digraphs G_1 and G_2 has vertex set $V_{G_1} \times V_{G_2}$ with vertex $\mathbf{u} = (u_1, u_2)$ connected to $\mathbf{v} = (v_1, v_2)$ iff either $(u_1, v_1) \in E_{G_1}$ and $u_2 = v_2$; or $u_1 = v_1$ and $(u_2, v_2) \in E_{G_2}$.*

Definition 3 generalizes to Cartesian product of multiple digraphs: $G_1 \Box G_2 \Box G_3 = (G_1 \Box G_2) \Box G_3$. The Cartesian product of n identical digraphs is denoted as Cartesian power $G^{\Box n}$.

Definition 14 (Schedule of Cartesian Power)**.** *Given an allgather schedule A_G for topology G and $n \in \mathbb{N}$, construct the schedule $A_{G^{\Box n}}$ for $G^{\Box n}$:*

1. *Construct the schedule $A^{(1)}$ as follows:*
2. *For $j = 1, \ldots, n$, for each $((w,C),(u,v),t) \in A_G$, add $(((\mathbf{x},w,\mathbf{z}),C),((\mathbf{y},u,\mathbf{z}),(\mathbf{y},v,\mathbf{z})),t+(j-1)t_{\max})$ to $A^{(1)}$ for all $\mathbf{x},\mathbf{y} \in V_G^{j-1}$ and $\mathbf{z} \in V_G^{n-j}$. $t_{\max}$ is the max comm step in A_G.*
3. *Similarly, construct $A^{(i)}$ for $i = 2, \ldots, n$ that each vertex $\mathbf{v}$ in $A^{(1)}$ is shifted by $i-1$ to $(\mathbf{v}[n-i+2:n], \mathbf{v}[1:n-i+1])$.*
4. *Divide each shard into n equal-sized subshards. Construct schedule $A_{G^{\Box n}}$ such that $A^{(i)}$ performs allgather over the i-th subshards of all nodes.*

Theorem 12. *Given a d-regular topology G, if (G, A_G) is an N-node allgather algorithm with $T_B(A_G, M, B) = \tau(M/B)$ for some constant τ, then $G^{\Box n}$ is an nd-regular topology, and $(G^{\Box n}, A_{G^{\Box n}})$ is an N^n-node allgather algorithm satisfying:*

$$T_L(A_{G^{\Box n}}) = n \cdot T_L(A_G), \tag{11}$$

$$T_B(A_{G^{\Box n}}) = T_B(A_G) \cdot \frac{N}{N-1} \cdot \frac{N^n - 1}{N^n}. \tag{12}$$

We then have the following corollary:

Corollary 12.1. *If (G, A_G) is BW-optimal and $T_B(A_G, M, B) = \tau(M/B)$ for some τ, then $(G^{\Box n}, A_{G^{\Box n}})$ is BW-optimal.*

Like degree expansion, Cartesian power expansion does not preserve Moore optimality.

We use BFB schedule generation when dealing with Cartesian product of distinct topologies:

Theorem 13. *Let $G_1, G_2, \ldots, G_n$ be topologies that*

1. *$G_1, \ldots, G_n$ are nontrivial simple digraphs;*
2. *Every G_i has BW-optimal BFB allgather schedule.*

Then, the optimal BFB allgather schedule, i.e. the schedule generated by BFB LP (1), for $G_1 \Box \ldots \Box G_n$ is also BW-optimal. The total-hop latency of the schedule equals $\alpha \cdot D(G_1 \Box \ldots \Box G_n) = \alpha \cdot \sum_i D(G_i)$.

The BFB schedule generation can also be used when individual topologies do not have BW-optimal BFB schedules; however, in such a case, we do not have performance bound for the schedule of the Cartesian product.

E BFB Schedule Generation

The LP formulation for u_2 in Figure 5 is:

$$\begin{aligned}
\text{minimize} \quad & U_{u_2,t} \\
\text{subject to} \quad & x_{v_1,(w_1,u_2),t} \le U_{u_2,t}, \\
& x_{v_1,(w_2,u_2),t} + x_{v_2,(w_2,u_2),t} \le U_{u_2,t}, \\
& x_{v_2,(w_3,u_2),t} \le U_{u_2,t}, \\
& x_{v_1,(w_1,u_2),t} + x_{v_1,(w_2,u_2),t} = 1, \\
& x_{v_2,(w_2,u_2),t} + x_{v_2,(w_3,u_2),t} = 1, \\
& 0 \le x_{v,(w,u_2),t} \le 1. \qquad \forall v, w
\end{aligned}$$

Definition 15 (BFB schedule)**.** *An allgather schedule A for G is a BFB schedule if A satisfies: $((v,C),(w,u),t) \in A$ only if $d(v,u) = d(v,w) + 1 = t$.*

Theorem 14. *A schedule A for G is a BFB allgather schedule if and only if the following are satisfied:*

1. *If $((v,C),(w,u),t) \in A$, then $d(v,u) = d(v,w) + 1 = t$;*
2. *For any distinct $u, v \in V_G$, the collection of chunks $\mathcal{C}_v = \{C \mid ((v,C),(w,u),t) \in A\}$ satisfies $S = \bigcup_{C \in \mathcal{C}_v} C$.*

Condition 1 ensures the schedule follows the breadth-first broadcast order. Condition 2 ensures every node receives the entire shard from every other node and thus a valid allgather.

E.1 Optimality

Theorem 15. *If A is a BFB schedule for G, then the total-hop latency $T_L(A) = \alpha \cdot D(G)$.*

There may exist many BFB schedules for a given topology G. They all have the same T_L but may have different T_Bs. Thus, the optimal BFB schedule is the one with the lowest T_B. Since every BFB schedule can be expressed as a solution to linear program (1), we have the following result:

Theorem 16. *Given any topology G, linear program (1) gives the optimal BFB schedule of G.*

An important implication of Theorem 16 is that **if we can show a BW-optimal BFB schedule exists for a topology G, then linear program (1) is guaranteed to generate one.** This has become an important tool for us to prove that BFB schedule generation can always generate BW-optimal schedules for some families of topologies (see §F). For the rest of this section, we show conditions that, if met by a topology, ensure it has a BW-optimal BFB schedule.

The following theorem shows the necessary and sufficient conditions for a BFB allgather schedule to be BW-optimal:

Theorem 17. *Suppose (G,A) is a BFB allgather schedule. (G,A) is BW-optimal if and only if:*

1. *There exists a sequence $N_1^-, N_2^-, \ldots, N_{D(G)}^- \in \mathbb{N}$ such that for any $x \in \mathbb{N}$ and $u \in V_G$, $|N_x^-(u)| = N_x^-$.*
2. *For any $(w,u) \in E_G$, $\sum_{((v,C),(w,u)) \in A_t} |C| = \frac{M}{N} |N_t^-(u)| / d = \frac{M}{N} N_t^- / d$.*

We assume G is d-regular. Condition 1 and 2 together ensure that at each comm step, all links have perfectly balanced workloads. In Theorem 13, we have already proven that *a Cartesian product graph has BW-optimal BFB schedule if it is the product of graphs that each have a BW-optimal BFB schedule.* Here, Theorem 17 also leads to the following sufficient condition for a bidirectional topology to have a BW-optimal BFB schedule:

Theorem 18. *There exists a BW-optimal BFB schedule for undirected graph G if for every distance x, two of the following constants exist:*

1. $N_x = |N_x(u)|$ *for any* $u \in V_G$;
2. $a_x = |N_x(u) \cap N_{x-1}(w)|$ *for any* $u \in V_G$ *and* $w \in N(u)$;
3. $b_x = |N(u) \cap N_{x-1}(v)|$ *for any* $u \in V_G$ *and* $v \in N_x(u)$.

Moreover, if two of N_x, a_x, b_x *exist, then the third one must also exist with* $N_x = da_x/b_x$.

Note that in undirected graphs, we have $N_x^+(u) = N_x^-(u) = N_x(u)$. To understand these constants, N_x is the number of data shards u needs to receive at comm step x; a_x is the number of data shards that can be transmitted by each link (w,u) at comm step x; b_x is the number of link (w,u)s that each data shard can use to transmit the data to u at comm step x. These three constants collectively ensure that links are perfectly balanced with each link transmitting $\frac{M}{N}N_x/d = \frac{M}{N}a_x/b_x$ amount of data at comm step x.

Now, we give a *necessary and sufficient condition* for any topology to have a BW-optimal BFB schedule. The condition is derived based on the observation that the BFB optimization problem is equivalent to a job scheduling problem. In each comm step t, for each node u, we have a set of jobs $\{j_1, j_2, \ldots, j_m\}$ (data from the source nodes $v \in N_t^-(u)$) and a set of processors $\{p_1, p_2, \ldots, p_d\}$ (links from in-neighbors $w \in N^-(u)$). There exists a map f from any job to a set of processors that j_i can only be scheduled to the processors in $f(j_i)$ (in-neighbor ws satisfying $d(v,u) = d(v,w) + 1 = t$). Assuming jobs can be arbitrarily divided into subjobs for parallel execution on multiple processors, the problem is how to schedule these jobs to processors so that workloads are balanced across all processors. We have the following result:

Theorem 19. *The workloads can be balanced if and only if there exists no subset* $J \subseteq \{j_1, j_2, \ldots, j_m\}$ *such that*

$$\frac{|J|}{\left|\bigcup_{j \in J} f(j)\right|} > \frac{m}{d}.$$

Note that there is an independent scheduling problem for each comm step t and node u. Therefore, topology G has a BW-optimal BFB schedule if and only if:

1. At each comm step t, $|N_t^-(u)|$ is the same for all $u \in V_G$.
2. The scheduling problem w.r.t. each t and u satisfies the condition in Theorem 19.

E.2 Discrete Chunked BFB Schedule

The BFB LP (1) makes an assumption that shards can be divided arbitrarily and infinitesimally. However, to compile the schedule into an executable form, one may need a *discrete chunked schedule*, where each shard is divided into a fixed number of equal-sized chunks. In practice, $x_{v,(w,u),t}$s are usually solved to be rational numbers. We can divide each shard into a number of chunks equal to the LCM of $x_{v,(w,u),t}$s' denominators so that each $x_{v,(w,u),t}$ represents some integer number of chunks. This approach has worked for us in evaluations. However, there exists the case where each shard of the data can only be divided into P equal chunks (i.e., the whole data M can only be divided into PN equal chunks). In such a case, we show that *we can approximate the optimal discrete chunked BFB schedule in polynomial time*.

Consider the following integer program given u, t:

$$\begin{aligned} \min \quad & W_{u,t} \\ \text{s.t.} \quad & \sum_v y_{v,(w,u),t} \le W_{u,t}, && \forall w \in N^-(u) \\ & \sum_w y_{v,(w,u),t} = P, && \forall v \in N_t^-(u) \\ & y_{v,(w,u),t} \in \{0, 1, \ldots, P\}, && \forall w, v. \end{aligned} \tag{13}$$

Compared with (1), one can easily see that the optimal solution of (13) gives the optimal BFB allgather schedule when each shard of the data can only be divided into P chunks. One can also easily solve the LP relaxation of (13) in polynomial time. Let T_B^{OPT} be the optimal BW runtime of the schedule obtained by directly solving integer program (13). Suppose the LP relaxation gives a schedule with BW runtime T_B^{LP}, then it holds that $T_B^{\text{LP}} \le T_B^{\text{OPT}}$.

Let $y_{v,(w,u),t}^{\text{LP}}$s be the solution to the LP relaxation of (13). We can obtain an integer solution $y_{v,(w,u),t}$s of (13) by rounding $y_{v,(w,u),t}^{\text{LP}}$s up or down to integers. For each v, we have

$$\sum_w \left\lfloor y_{v,(w,u),t}^{\text{LP}} \right\rfloor \le P \le \sum_w \left\lceil y_{v,(w,u),t}^{\text{LP}} \right\rceil.$$

Thus, it is trivial to round $y_{v,(w,u),t}^{\text{LP}}$s to integer $y_{v,(w,u),t}$s that $\sum_w y_{v,(w,u),t} = P$ and $y_{v,(w,u),t} < y_{v,(w,u),t}^{\text{LP}} + 1$. We give the following approximation bound for the resulting schedule:

Theorem 20. *Rounding LP gives a solution with BW runtime* $T_B \le T_B^{OPT} + \frac{M}{B} \cdot \frac{d(d^{D(G)}-1)}{(d-1)PN}$. *In addition, if topology G is Moore optimal, then* $T_B \le T_B^{OPT} + \frac{M}{B} \cdot \frac{d}{P}$.

The cost $\frac{M}{B} \cdot \frac{d}{P}$ is negligible since P can easily be hundreds or even thousands while degree d is usually a small integer.

E.3 Heterogeneous BFB Schedule

The BFB LP (1) assumes a homogeneous network. It turns out that with little modification, (1) can become an LP for

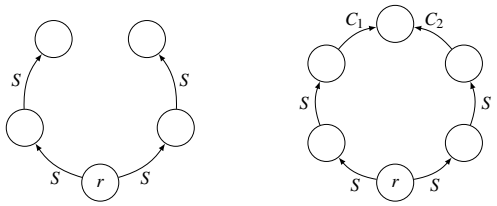

Figure 17: The broadcast paths of ring BFB allgather schedule. The left and right figures respectively show the broadcast patterns for odd- and even-sized bidirectional rings. Edges of the rings are omitted. C_1 and C_2 are two halves of shard S.

heterogeneous network too:

$$\begin{aligned} \min \quad & U_{u,t} \\ \text{s.t.} \quad & \alpha_{w,u} + \tfrac{M/N}{B_{w,u}} \sum_v x_{v,(w,u),t} \le U_{u,t}, \quad \forall w \in N^-(u) \\ & \sum_w x_{v,(w,u),t} = 1, \quad \forall v \in N_t^-(u) \\ & 0 \le x_{v,(w,u),t} \le 1, \quad \forall w, v. \end{aligned} \tag{14}$$

$\alpha_{w,u}$ and $B_{w,u}$ are the hop latency and bandwidth of link (w,u). In some cases, the α of some link (w,u) is so high that $\alpha_{w,u}$ alone dominates $U_{u,t}$ in (14) even though $\sum_v x_{v,(w,u),t} = 0$. This is problematic because one should not pay $\alpha_{w,u}$ if link (w,u) is not used. However, such a scenario can be easily detected after solving LP (14). One can avoid the issue by simply removing link (w,u) and solving the LP again.

F Generative Topologies

In this section, we introduce several topologies for which applying BFB schedule generation yields high-performance communication schedules.

F.1 Bidirectional Ring

Ring is the most common topology for allreduce. The traditional schedule on ring is to make each shard go a full circle to do reduce-scatter/allgather. In a bidirectional ring, one can simply make half the shard go clockwise and the other half go counterclockwise to utilize both directions of the links. Such a reduce-scatter/allgather schedule is BW-optimal but poor in total-hop latency with $T_L = (N-1)\alpha$. With BFB schedule generation, we discovered a new ring reduce-scatter/allgather schedule that achieves half the total-hop latency ($T_L = \lfloor N/2 \rfloor \alpha$) while maintaining BW optimality. From each node, the BFB allgather schedule broadcasts the *entire* shard clockwise and counterclockwise in parallel. Thus, each direction only needs to go half a circle instead of a full circle. If N is even, then the farthest node across the ring receives each half of the shard from each of its two neighbors in the end. Figure 17 shows examples in odd- and even-sized rings respectively.

F.2 Generalized Kautz Graph

Generalized Kautz graph [5, 25] is a low-T_L unidirectional topology that can be constructed for every N and d.

Definition 16 (Generalized Kautz Graph)**.** *The $\Pi_{d,m}$ digraph has the set of integers modulo m as vertex set. Its arc set A is defined as follows:*

$$A = \{(x,y) \mid y \equiv -dx - a, 1 \le a \le d\}.$$

If $m = d^{n+1} + d^n$, then $\Pi_{d,m} = K(d,n)$, where $K(d,n)$ is the Kautz graph $L^n(K_{d+1})$.

We apply BFB schedule generation to generalized Kautz graph. The resulting schedule is not always Moore optimal, but the following theorem shows that it is at most one α away from Moore optimality, i.e., $T_L \le T_L^*(N,d) + \alpha$:

Theorem 21. *Suppose $D(\Pi_{d,m}) = k$, then $m > M_{d,k-2}$.*

Remember Moore optimality is stricter than total-hop latency optimality, so it is possible that generalized Kautz graph is total-hop latency optimal. The special case, Kautz graph $K(d,n)$, is always Moore optimal and is, in fact, the largest known digraph in *degree/diamter problem* for any degree $d > 2$ [50].

As for BW performance, from Figure 18, one can see that generalized Kautz graph is also close to BW optimality, especially at higher degrees.

F.3 Distance-Regular Graph

In graph theory, distance-regular graphs are a family of highly symmetric undirected graphs. We can show that there exists a BW-optimal BFB schedule for any distance-regular graph, and thus LP (1) can always generate one. We borrow the following definition from [2]:

Definition 17 (Distance-Regular Graph)**.** *A connected graph G is distance-regular if for any vertices $x, y \in V_G$ and integers i, j, the number of vertices at distance i from x and distance j from y depends only on i, j and $d(x,y)$.*

In other words, there exists a constant $s_{i,j}^h$ for every h, i, j such that $s_{i,j}^h = |N_i(x) \cap N_j(y)|$ whenever $x, y \in V_G$ satisfy $d(x,y) = h$. Thus, we can apply Theorem 18 with $N_x = s_{x,x}^0$, $a_x = s_{x,x-1}^1$, and $b_x = s_{1,x-1}^x$.

The significance of distance-regular graph is not only about BW optimality. Many of distance-regular graphs have low diameters, so their schedules are not only BW-optimal but also close to, and in some cases exactly, Moore optimal. Table 8 gives examples of distance-regular graphs at $d = 4$. In addition, many of the base graphs mentioned in this paper are also distance-regular like complete bipartite graphs (Figure 1) and Hamming graphs. One can refer to [16] for a repository of distance-regular graphs.

F.4 Circulant Graph

Circulant graph is a well-studied topology in both graph theory and network design. Many popular network topologies like shifted ring, chordal ring, and loop network are either subcategories of or closely related to circulant graphs. The definition of circulant graph is as follows:

Definition 18. *The circulant graph $C(n, \{a_1, \ldots, a_k\})$ is a bidirectional graph with vertex set $\{0, 1, \ldots, n-1\}$ and each node i is adjacent to nodes $i \pm a_1, \ldots, i \pm a_k \pmod n$.*

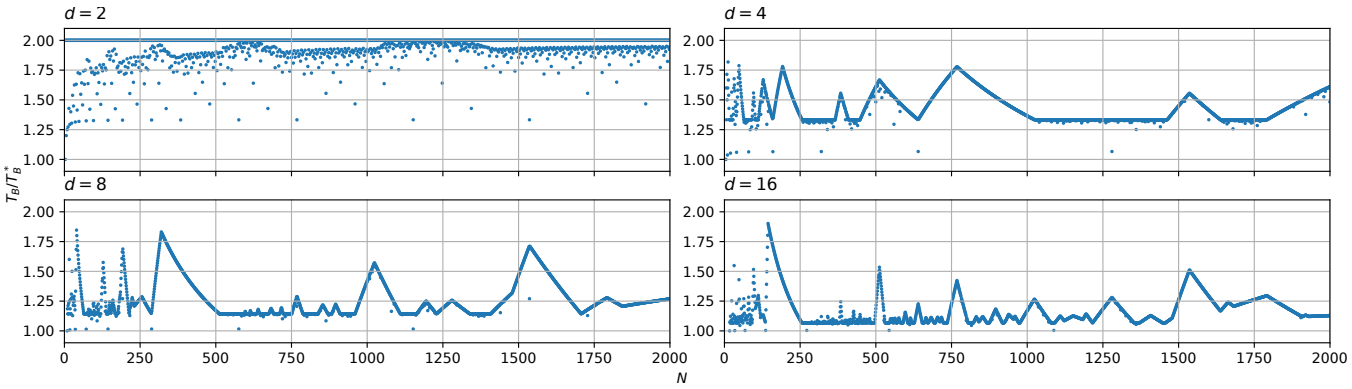

Figure 18: T_B/T_B^* **of generalized Kautz graph** $\Pi_{d,N}$ **up to** $N = 2000$**.** As shown, the BW runtime of $\Pi_{d,N}$ is less than or equal to $2T_B^*$ at all times for $d = 2,4,8,16$. In particular, the higher the degree is, the closer T_B is to optimal. As for total-hop latency, Theorem 21 shows that $T_L \le T_L^*(N,d) + \alpha$.

Graph Name	N	T_L	T_L^*	$T_L - T_L^*$	T_L^{**}	$T_L - T_L^{**}$
Octahedron J(4,2)	6	2	2	0	2	0

Incidence graph of GH(3,3)	728	6	5	1	6	0

Table 8: Examples of distance-regular graphs at $d = 4$ **[16].** T_L^{**} is the bidirectional Moore optimality.

Note that in this paper, we only consider connected circulant graphs, and $C(n,\{a_1,\ldots,a_k\})$ is connected if and only if $\gcd(n,a_1,\ldots,a_k) = 1$ [46, 51]. It is easy to see that $C(n,\{a_1,\ldots,a_k\})$ is an n-node $2k$-regular topology.

We have found that the BFB schedule generation seems to give BW-optimal schedules for all circulant graphs. In particular, we have the following conjecture:

Conjecture 1. *For any circulant graph* $C(n,\{a_1,\ldots,a_k\})$*, there exists a BW-optimal BFB schedule.*

While we leave a complete proof or disproof of this conjecture for future work, we have proved the conjecture holds when $k = 2$, which corresponds to the graph having degree 4.

Circulant graph revolutionized our Pareto frontier of topologies since it can be constructed for every N and even value d. It can provide a BW-optimal topology if our expansion techniques fail to produce one at some N and d. Since all circulant graphs seem to be BW-optimal, the question is what choices of $a_1,\ldots,a_k$ result in minimum total-hop latency, or equivalently, minimum diameter for a given n and k. While this remains largely an open question in graph theory [51], the case of $k = 2$ has been solved in [7]:

Theorem 22. *Given* $n > 6$ *and* $m = \lceil(-1+\sqrt{2n-1})/2\rceil$*, circulant graph* $C(n,\{m,m+1\})$ *has a diameter equal to* m*, which is the minimum diameter over all circulant graphs* $C(n,\{a_1,a_2\})$*.*

We can certainly use multiedge to apply this construction for any even degree that is ≥ 4. The resulting topology has $\Theta(\sqrt{N})$ diameter, which is a significant improvement in terms of total-hop latency when BW optimality is required. Previously, the only topology that is known to be BW-optimal for any N and d is ring, which has $\Theta(N)$ diameter.

G Proofs

Theorem 7. *Given a* d*-regular topology* G*, if* (G,A_G) *is an* N*-node allgather algorithm, then* $(L(G),A_{L(G)})$ *is a* dN*-node allgather algorithm satisfying:*

$$T_L(A_{L(G)}) = T_L(A_G) + \alpha, \tag{4}$$

$$T_B(A_{L(G)}) \le T_B(A_G) + \frac{M}{B}\cdot\frac{1}{N}. \tag{5}$$

Proof. Let $v'v,uw$ be arbitrary two distinct vertices in $L(G)$. We want to show there exists a sequence in $A_{L(G)}$ going from $v'v$ to uw like in Definition 4 for any $x \in S$. If $u = v$, then $((v'v,S),(v'v,uw),1)$ at the first comm step suffices. If $u \ne v$, because A_G is allgather, there exists a sequence in A_G:

$$((v,C_1),(v,w_1),t_1),((v,C_2),(w_1,w_2),t_2),\ldots \\ ((v,C_n),(w_{n-1},u),t_n),$$

where $t_1 < t_2 < \cdots < t_n$ and $x \in C_1 \cap C_2 \cap \cdots \cap C_n$. Thus, by Definition 1, there exists a sequence in $A_{L(G)}$:

$$((v'v,S),(v'v,vw_1),1),((v'v,C_1),(vw_1,w_1w_2),t_1+1),\ldots \\ ((v'v,C_n),(w_{n-1}u,uw),t_n+1),$$

as desired. The new algorithm $(L(G),A_{L(G)})$ has dM total data length, because the number of nodes has grown d-fold while the size of a shard remains the same.

As for $T_L(A_{L(G)})$ and $T_B(A_{L(G)})$, equality (4) trivially follows the Definition 1. Let $[A_{L(G)}]_t$ and $[A_G]_t$ be the subschedules of $A_{L(G)}$ and A_G at comm step t. Given $v \in V_G$, because G is d-regular, we have $|\{v'v \mid v'v \in V_{L(G)}\}| = |\{(v',v) \mid (v',v) \in E_G\}| = d$. Given any edge (uw,ww') and t, there are at most d number of $((v'v,C),(uw,ww'),t+1) \in A_{L(G)}$ for each

$((v,C),(u,w),t) \in A_G$ by Definition 1. Thus, given (uw, ww'),

$$\sum_{((v'v,C),(uw,ww'))\in[A_{L(G)}]_{t+1}} |C| \le \sum_{((v,C),(u,w))\in[A_G]_t} d\cdot|C|.$$

It follows that $T_B([A_{L(G)}]_{t+1}, dM, B) \le d\cdot T_B([A_G]_t, M, B)$ and hence $\sum_{t=2}^{t_{\max}+1} T_B([A_{L(G)}]_t, dM, B) \le d\cdot T_B(A_G, M, B)$. For the first comm step, we have

$$T_B([A_{L(G)}]_1, dM, B) = \frac{|S|}{B/d} = \frac{M/N}{B/d}.$$

Assuming $T_B(A_G, M, B) = \tau(M/B)$ for some constant τ, we have $d\cdot T_B(A_G, M, B) = T_B(A_G, dM, B)$. It follows that

$$T_B(A_{L(G)}, dM, B) = \sum_{t=1}^{t_{\max}+1} T_B([A_{L(G)}]_t, dM, B)$$
$$\le \frac{M/N}{B/d} + d\cdot T_B(A_G, M, B) = T_B(A_G, dM, B) + \frac{dM}{B}\cdot\frac{1}{N}.$$

Replacing dM by M gives (5) as desired. □

Corollary 7.1. *Given a d-regular topology G, if (G, A_G) is an N-node allgather algorithm with $T_B(A_G, M, B) = \tau(M/B)$ for some constant τ, then $(L^n(G), A_{L^n(G)})$ is a d^nN-node allgather algorithm satisfying:*

$$T_L(A_{L^n(G)}) = T_L(A_G) + n\alpha, \tag{6}$$

$$T_B(A_{L^n(G)}) \le T_B(A_G) + \frac{M}{B}\cdot\frac{d}{d-1}\left(\frac{1}{N} - \frac{1}{d^nN}\right). \tag{7}$$

Theorem 9. *If (G, A_G) is BW-optimal with N nodes, then $T_B(A_{L^n(G)})/T_B^*(d^nN) \le 1 + [(d-1)N]^{-1}$ for all n.*

Proof. If (G, A_G) is BW-optimal, then $T_B(A_G) = \frac{M}{B}\cdot\frac{N-1}{N}$ and

$$T_B(A_{L^n(G)}) \le \frac{M}{B}\left[1 + \frac{1}{d-1}\left(\frac{1}{N} - \frac{d}{d^nN}\right)\right]. \tag{15}$$

It is trivial to see that $(15)/T_B^*(d^nN) \nearrow 1 + [(d-1)N]^{-1}$ as $n \to \infty$. □

Theorem 1. *If A is a reduce-scatter/allgather schedule for G, then A^T is an allgather/reduce-scatter schedule for G^T.*

Proof. Suppose (G, A) is a reduce-scatter algorithm. For arbitrary $x \in S$ and distinct $u, v \in V_G$, there exists a sequence of tuples in A:

$$((v,C_1),(u,w_1),t_1),((v,C_2),(w_1,w_2),t_2),\ldots ((v,C_n),(w_{n-1},v),t_n),$$

where $t_1 < t_2 < \cdots < t_n$ and $x \in C_1 \cap C_2 \cap \cdots \cap C_n$. It follows that there exists a sequence of tuples in A^T:

$$((v,C_n),(v,w_{n-1}),t_n'),\ldots ((v,C_2),(w_2,w_1),t_2'),((v,C_1),(w_1,u),t_1').$$

where $t_i' = t_{\max} - t_i + 1$, so $t_n' < \cdots < t_2' < t_1'$. Since u, v, x are abitrary, A^T is an allgather schedule on G^T. One can similarly show that if (G, A) is an allgather algorithm, then (G^T, A^T) is a reduce-scatter algorithm. □

Corollary 1.1. *Suppose $G \mapsto f(G)$ is a function to construct reduce-scatter/allgather schedule given graph G, then $G \mapsto f(G^T)^T$ is a function to construct allgather/reduce-scatter schedule given graph G.*

Corollary 1.2. *Suppose $(G, A) \mapsto (f(G), f(A))$ is a mapping within reduce-scatter/allgather algorithms, then $(G, A) \mapsto (f(G^T)^T, f(A^T)^T)$ is a mapping within allgather/reduce-scatter algorithms.*

Theorem 2. *Suppose G is reverse-symmetric. Let G^T be the transpose graph, and let $f : V_{G^T} \to V_G$ be the isomorphism from G^T to G. If (G, A) is a reduce-scatter/allgather algorithm, then $(G, f(A^T))$ is an allgather/reduce-scatter algorithm with $T_L(f(A^T)) = T_L(A)$ and $T_B(f(A^T)) = T_B(A)$.*

Proof. By definition of $f(A^T)$,

$$((f(v),C),(f(w),f(u)),t_{\max}-t+1) \in f(A^T)$$
$$\Leftrightarrow ((v,C),(w,u),t_{\max}-t+1) \in A^T$$
$$\Leftrightarrow ((v,C),(u,w),t) \in A.$$

Note that $(u,w) \in E_G \Leftrightarrow (w,u) \in E_{G^T} \Leftrightarrow (f(w), f(u)) \in E_G$, so $f(A^T)$ is a valid schedule for G.

Suppose (G, A) is a reduce-scatter algorithm. For any $x \in S$ and distinct $u, v \in V_G$, there exists a sequence of tuples in A:

$$((v,C_1),(u,w_1),t_1),((v,C_2),(w_1,w_2),t_2),\ldots ((v,C_n),(w_{n-1},v),t_n),$$

where $t_1 < t_2 < \cdots < t_n$ and $x \in C_1 \cap C_2 \cap \cdots \cap C_n$. It follows that there exists a sequence of tuples in $f(A^T)$:

$$((f(v),C_n),(f(v),f(w_{n-1})),t_n'),$$
$$((f(v),C_{n-1}),(f(w_{n-1}),f(w_{n-2})),t_{n-1}'),$$
$$\vdots$$
$$((f(v),C_1),(f(w_1),f(u)),t_1'),$$

where $t_i' = t_{\max} - t_i + 1$, and $x \in C_n \cap C_{n-1} \cap \cdots \cap C_1$. Because f is a bijection, $(G, f(A^T))$ is an allgather algorithm. $T_L(A) = T_L(f(A^T))$ and $T_B(A) = T_B(f(A^T))$ are trivial, and one can similarly prove that if (G, A) is an allgather algorithm, then $(G, f(A^T))$ is a reduce-scatter algorithm. □

Theorem 3. *Every reduce-scatter/allgather algorithm (G, A) satisfies $T_L(A) \ge \alpha\cdot D(G)$, where $D(G)$ is the diameter of G.*

Proof. The proof is mentioned in text. □

Corollary 3.1. *An N-node degree-d reduce-scatter/allgather algorithm (G, A) is total-hop latency optimal if and only if $T_L(A) = \alpha\cdot D(G) = \alpha\cdot\min\{D(G') : |V_{G'}| = N, \deg(G') = d\}$.*

Theorem 4. *$\frac{M}{B}\cdot\frac{N-1}{N}$ is a lower bound of $T_B(A)$ for any N-node reduce-scatter/allgather algorithm (G, A).*

Proof. The proof is mentioned in text. □

Corollary 4.1. *An N-node reduce-scatter/allgather algorithm (G, A) is BW-optimal if and only if $T_B(A) = \frac{M}{B}\cdot\frac{N-1}{N}$.*

Theorem 5. *An allgather algorithm (G, A) is BW-optimal if and only if:*

1. $\frac{1}{B/d}\sum_{((v,C),(u,w))\in A_t}|C| = T_B(A_t)$ *for all* $(u,v)\in E_G$ *and* $t\in\{1,\ldots,t_{\max}\}$. A_t *is the subschedule of* A *at comm step* t.
2. *Pick any distinct* $u,v\in V_G$. *For each* $x\in S$, *there exists a unique* $((v,C),(w,u),t)\in A$ *such that* $x\in C$.

Proof. If $T_B(A) = T_B^*(N) = \frac{M}{B}\cdot\frac{N-1}{N}$, then the amount of data received by each vertex must be equal to $M\cdot\frac{N-1}{N}$, and the ingress bandwidth B must be fully utilized. If condition 1 does not hold, then some link (w,u) is not fully utilized. If condition 2 does not hold, then the amount of data received by some node is greater than $M\cdot\frac{N-1}{N}$.

If both 1 and 2 hold, then every vertex receives exactly $M\cdot\frac{N-1}{N}$ in total and bandwidth are fully utilized. Thus, $T_B(A) = T_B^*(N)$ and (G,A) is BW-optimal. □

Theorem 6. *Given a reduce-scatter algorithm* (G,A), *suppose* $T_B(A) = \frac{M}{B}\cdot y$, *then* $T_C(A)\le M\cdot\gamma\cdot y$.

Proof. At any comm step t, suppose the BW runtime is $T_B(A_t) = \frac{M}{B}\cdot y_t$. It follows at comm step t, the amount of data each node receives is at most $B\cdot T_B(A_t) = M\cdot y_t$, so $T_C(A_t)\le M\cdot\gamma\cdot y_t$. The theorem trivially follows $y = \sum_t y_t$. □

Corollary 6.1. *If allreduce algorithm* (G,A) *is BW-optimal, i.e.,* $T_B(A) = 2\frac{M}{B}\cdot\frac{N-1}{N}$, *then* $T_C(A) = M\cdot\gamma\cdot\frac{N-1}{N}$ *and* $T_B(A) + T_C(A) = 2M\cdot(\frac{1}{B}+\frac{\gamma}{2})\cdot\frac{N-1}{N}$.

Theorem 8. $(L^n(G), A_{L^n(G)})$ *is Moore optimal if and only if* (G,A_G) *is Moore optimal.*

Proof. Suppose $T_L(A_G) = \alpha k$. Thus, (G,A_G) is Moore optimal if and only if

$$N > M_{d,k-1} = \sum_{i=0}^{k-1} d^i = \frac{d^k}{d-1} - \frac{1}{d-1}. \tag{16}$$

$(L^n(G), A_{L^n(G)})$ is Moore optimal if and only if

$$d^nN > M_{d,k+n-1} \;\Leftrightarrow\; N > \frac{d^k}{d-1} - \frac{1}{d^n(d-1)}. \tag{17}$$

Because (17) − (16) < 1 and (16) is an integer, (16) and (17) are equivalent. □

Theorem 10. *Let* A_G *be a BFB allgather schedule for* d*-regular topology* G *with* $|N^+(u)|>1$ *for all* $u\in V_G$, *then the expanded schedule* $A_{L(G)}$ *is a BFB allgather schedule for* $L(G)$. *In particular, if* A_G *is the optimal BFB schedule for* G, *then* $A_{L(G)}$ *is the optimal BFB schedule for* $L(G)$ *satisfying:*

$$T_B(A_{L(G)}) = T_B(A_G) + \frac{M}{B}\cdot\frac{1}{N}. \tag{8}$$

Proof. It is trivial to see that $A_{L(G)}$ is a BFB allgather schedule on $L(G)$. For the sake of contradiction, suppose there exists a BFB schedule $A'_{L(G)}$ that $T_B(A'_{L(G)}) < T_B(A_G) + \frac{M}{B}\cdot\frac{1}{N}$. Let $x^*_{v'v,(wu,uu'),t}$s be the solution of BFB LP (1) corresponding to $A'_{L(G)}$. We build a schedule A'_G by constructing a solution of (1) such that

$$x_{v,(w,u),t} = \frac{1}{d}\sum_{v'\in N^-(v)} x^*_{v'v,(wu,uu'),t+1},$$

where $u'\in N^+(u)\setminus\{v\}$ is arbitrary. To verify the construction is a valid solution, given any $u\in V_G$ and $v\in N_t^-(w)$, the equality of (1) follows:

$$\sum_w x_{v,(w,u),t} = \frac{1}{d}\sum_{v'}\sum_w x^*_{v'v,(wu,uu'),t+1} = \frac{1}{d}\sum_{v'}\sum_{wu} x^*_{v'v,(wu,uu'),t+1} = \frac{1}{d}\sum_{v'} 1 = \frac{1}{d}\cdot d = 1.$$

The third equality follows the equality constraint in (1). Now, given $(w,u)\in E_G$, observe that

$$\sum_v x_{v,(w,u),t} = \frac{1}{d}\sum_v\sum_{v'} x^*_{v'v,(wu,uu'),t+1} = \frac{1}{d}\sum_{v'v} x^*_{v'v,(wu,uu'),t+1} \le \frac{1}{d}U^*_{uu',t+1}.$$

Thus, $U_{u,t} = \max_w\sum_v x_{v,(w,u),t} \le \frac{1}{d}U^*_{uu',t+1}$ and hence

$$\max_{u\in V_G} U_{u,t} \le \frac{1}{d}\max_{uu'\in V_{L(G)}} U^*_{uu',t+1}.$$

Note that $U^*_{uu',1} = 1$ for all $uu'\in V_{L(G)}$, as each node must send the full shard to every neighbor at the 1st comm step in any BFB allgather schedule. By (2), we have

$$T_B(A'_G) \le T_B(A'_{L(G)}) - \frac{M/(dN)}{B/d} = T_B(A'_{L(G)}) - \frac{M}{B}\cdot\frac{1}{N} < T_B(A_G),$$

contradicting A_G being the optimal BFB schedule. Thus, combined with inequality (5), we have proven $A_{L(G)}$ being optimal as well as the equality (8). □

Corollary 10.1. *Let* A_G *be a BFB allgather schedule for* d*-regular topology* G *with* $|N^+(u)|>1$ *for all* $u\in V_G$, *then the expanded schedule* $A_{L^n(G)}$ *is a BFB allgather schedule for* $L^n(G)$. *In particular, if* A_G *is the optimal BFB schedule for* G, *then* $A_{L^n(G)}$ *is the optimal BFB schedule for* $L^n(G)$ *satisfying:*

$$T_B(A_{L^n(G)}) = T_B(A_G) + \frac{M}{B}\cdot\frac{d}{d-1}\left(\frac{1}{N} - \frac{1}{d^nN}\right).$$

Theorem 11. *Given a* d*-regular topology* G *without self loops, if* (G,A_G) *is an* N*-node allgather algorithm with* $T_B(A_G,M,B) = \tau(M/B)$ *for some constant* τ, *then* $(G*n, A_{G*n})$ *is an* nN*-node allgather algorithm satisfying:*

$$T_L(A_{G*n}) = T_L(A_G) + \alpha, \tag{9}$$

$$T_B(A_{G*n}) = T_B(A_G) + \frac{M}{B}\cdot\frac{n-1}{nN}. \tag{10}$$

Proof. Let u_i, v_j be arbitrary two distinct vertices in $G*n$. Suppose $u\ne v$ in G, then for any $x\in S$, there exists a sequence in A_G:

$$((v,C_1),(v,w^{(1)}),t_1),((v,C_2),(w^{(1)},w^{(2)}),t_2),\ldots$$

$$((v,C_n),(w^{(n-1)},u),t_n),$$

where $t_1 < t_2 < \cdots < t_n$ and $x \in C_1 \cap C_2 \cap \cdots \cap C_n$. By Definition 2, there exists a sequence in A_{G*n}:

$$((v_j,C_1),(v_j,w_j^{(1)}),t_1),((v_j,C_2),(w_j^{(1)},w_j^{(2)}),t_2),\ldots$$
$$((v_j,C_n),(w_j^{(n-1)},u_i),t_n),$$

as desired. Now, suppose $u=v$ in G. By previous proof, the shard of v_j reaches every in-neighbor u'_α of u_i by the end of comm step $t_{\max}$ since $u' \neq v$. Then, the last comm step $t_{\max}+1$ added in step 2 of Definition 2 delivers the shard to u_i with each edge (u'_α,u_i) delivering $1/nd$ of a shard. Thus, A_{G*n} is a complete allgather.

In step 1 of Definition 2, we have $T_B([A_{G*n}]_t,nM,nB) = T_B([A_G]_t,M,B)$ and hence $\sum_{t=1}^{t_{\max}} T_B([A_{G*n}]_t,nM,nB) = T_B(A_G,M,B)$. The nM and nB are due to the fact that both the number of nodes and degree have grown n-fold. Thus,

$$\begin{aligned}T_B(A_{G*n},M,B) &= T_B(A_{G*n},nM,nB)\\ &= T_B(A_G,M,B)+T_B([A_{G*n}]_{t_{\max}+1},nM,nB)\\ &= T_B(A_G,M,B)+(n-1)\cdot\frac{(nM)/(nN)}{nd}\cdot\frac{1}{nB/(nd)}\\ &= T_B(A_G,M,B)+\frac{M}{B}\cdot\frac{n-1}{nN}.\end{aligned}$$

The first equality follows the assumption that $T_B(A_G,M,B) = \tau(M/B)$ for some constant τ. □

Corollary 11.1. *If (G,A_G) is BW-optimal and $T_B(A_G,M,B) = \tau(M/B)$ for some τ, then $(G*n,A_{G*n})$ is BW-optimal.*

Theorem 12. *Given a d-regular topology G, if (G,A_G) is an N-node allgather algorithm with $T_B(A_G,M,B) = \tau(M/B)$ for some constant τ, then $G^{\square n}$ is an nd-regular topology, and $(G^{\square n},A_{G^{\square n}})$ is an N^n-node allgather algorithm satisfying:*

$$T_L(A_{G^{\square n}}) = n\cdot T_L(A_G), \tag{11}$$

$$T_B(A_{G^{\square n}}) = T_B(A_G)\cdot\frac{N}{N-1}\cdot\frac{N^n-1}{N^n}. \tag{12}$$

Proof. We will show that $A^{(1)}$ is a valid allgather schedule. Since $A^{(i)}$s are simply starting at different dimensions, this also shows that $A^{(i)}$s and hence $A_{G^{\square n}}$ are all valid allgather schedules for $G^{\square n}$.

Let $\mathbf{u}$ be arbitrary vertex in $G^{\square n}$. For any $x \in S$, we will show that schedule $A^{(1)}$ broadcasts x from $\mathbf{u}$ to all vertices in $G^{\square n}$. At $j=1$, $A^{(1)}$ performs an allgather over vertices $\{(v_1,\mathbf{u}[2:n]) \mid v_1 \in V_G\}$ which induce a subgraph of $G^{\square n}$ isomorphic to G. Thus, x has been broadcast to all vertices in $\{(v_1,\mathbf{u}[2:n]) \mid v_1 \in V_G\}$. At $j=2$, $A^{(1)}$ performs an allgather over vertices $\{(v_1,v_2,\mathbf{u}[3:n]) \mid v_2 \in V_G\}$ for each v_1. By the end of $j=2$, x has been broadcast to all vertices in $\{(v_1,v_2,\mathbf{u}[3:n]) \mid v_1,v_2 \in V_G\}$. By the end of $j=n$, x has been broadcast to all vertices in $\{\mathbf{v} \mid \mathbf{v} \in V_G^n\} = V_{G^{\square n}}$. Since $\mathbf{u}$ and x are arbitrary, $A^{(1)}$ is a valid allgather schedule for $G^{\square n}$.

As for performance, (11) is trivial. To prove (12), observe that at each j in $A^{(1)}$, allgather A_G is performed with a data size $N^{j-1}M/n$ over the subgraph induced by $\{(\mathbf{y},v,\mathbf{z}) \mid v \in V_G\}$ for each $\mathbf{y} \in V_G^{j-1}, \mathbf{z} \in V_G^{n-j}$. The bandwidth of each node within the subgraph is $1/n$ of that in $G^{\square n}$. It follows that

$$\begin{aligned}T_B(A^{(1)},N^{n-1}M/n,nB) &= \sum_{j=1}^{n} T_B(A_G,N^{j-1}M/n,B)\\ &= \sum_{j=1}^{n}\frac{N^{j-1}}{n}T_B(A_G,M,B)\\ &= \frac{N^n-1}{n(N-1)}T_B(A_G,M,B).\end{aligned}$$

Therefore,

$$\begin{aligned}T_B(A_{G^{\square n}},M,B) &= \frac{n}{N^{n-1}}T_B(A_{G^{\square n}},N^{n-1}M,nB)\\ &= \frac{n}{N^{n-1}}T_B(A^{(1)},N^{n-1}M/n,nB)\\ &= \frac{n}{N^{n-1}}\cdot\frac{N^n-1}{n(N-1)}T_B(A_G,M,B)\\ &= T_B(A_G,M,B)\cdot\frac{N}{N-1}\cdot\frac{N^n-1}{N^n}.\end{aligned}$$

□

Corollary 12.1. *If (G,A_G) is BW-optimal and $T_B(A_G,M,B) = \tau(M/B)$ for some τ, then $(G^{\square n},A_{G^{\square n}})$ is BW-optimal.*

Theorem 13. *Let $G_1,G_2,\ldots,G_n$ be topologies that*

1. *$G_1,\ldots,G_n$ are nontrivial simple digraphs;*
2. *Every G_i has BW-optimal BFB allgather schedule.*

Then, the optimal BFB allgather schedule, i.e. the schedule generated by BFB LP (1), for $G_1\square\ldots\square G_n$ is also BW-optimal. The total-hop latency of the schedule equals $\alpha\cdot D(G_1\square\ldots\square G_n) = \alpha\cdot\sum_i D(G_i)$.

Proof. To prove the theorem, it is sufficient to show that if G_1 and G_2 have BW-optimal BFB schedules, then $G_1\square G_2$ has a BW-optimal BFB schedule. By Theorem 16, let $x^*_{v_1,(w_1,u_1),t_1}$s and $x^*_{v_2,(w_2,u_2),t_2}$s be the solutions of (1) on G_1 and G_2 respectively. Let $\mathbf{u}=(u_1,u_2),\mathbf{v}=(v_1,v_2)$. Define $r \in [0,1]$, which we will decide later. We construct a solution of (1) for $G_1\square G_2$ such that:

$$\begin{aligned}x_{\mathbf{v},((w_1,u_2),\mathbf{u}),t_1+t_2} &= \begin{cases} r\cdot x^*_{v_1,(w_1,u_1),t_1} & \text{if } u_2 \neq v_2,\\ x^*_{v_1,(w_1,u_1),t_1} & \text{if } u_2 = v_2,\end{cases}\\ x_{\mathbf{v},((u_1,w_2),\mathbf{u}),t_1+t_2} &= \begin{cases} (1-r)\cdot x^*_{v_2,(w_2,u_2),t_2} & \text{if } u_1 \neq v_1,\\ x^*_{v_2,(w_2,u_2),t_2} & \text{if } u_1 = v_1.\end{cases}\end{aligned} \tag{18}$$

First of all, because $d_{G_1\square G_2}(\mathbf{v},\mathbf{u}) = d_{G_1}(v_1,u_1)+d_{G_2}(v_2,u_2)$, it is easy to verify that (18) gives a BFB schedule. In addition, for any distinct $\mathbf{u},\mathbf{v} \in G_1\square G_2$ with $u_1 \neq v_1$ and $u_2 \neq v_2$,

$$\begin{aligned}\sum_{\mathbf{w}} x_{\mathbf{v},(\mathbf{w},\mathbf{u}),t_1+t_2} &= r\sum_{w_1} x^*_{v_1,(w_1,u_1),t_1}+(1-r)\sum_{w_2} x^*_{v_2,(w_2,u_2),t_2}\\ &= r+(1-r)\\ &= 1\end{aligned}$$

satisfying the equality in (1). The $u_1=v_1$ or $u_2=v_2$ case is trivial. Because G_1 and G_2 have BW-optimal BFB schedule,

by Theorem 17, for any $(w_1,u_1)\in E_{G_1}$,

$$\sum_{v_1\in N_t^{-G_1}(u_1)} x^*_{v_1,(w_1,u_1),t} = \frac{N_t^{-G_1}}{d_1}, \tag{19}$$

where $N_t^{-G_1}(u_1)$ is $N_t^-(u_1)$ in G_1. Define $N_{t_1,t_2}^{-G_1\Box G_2}(\mathbf{u}) = N_{t_1}^{-G_1}(u_1)\times N_{t_2}^{-G_2}(u_2)$, then it holds that

$$N_t^{-G_1\Box G_2}(\mathbf{u}) = \bigcup_{t_1=0}^{t} N_{t_1,t-t_1}^{-G_1\Box G_2}(\mathbf{u})$$

$$= N_t^{-G_1}(u_1)\times\{u_2\}\cup\{u_1\}\times N_t^{-G_2}(u_2)\cup\bigcup_{t_1=1}^{t-1} N_{t_1,t-t_1}^{-G_1\Box G_2}(\mathbf{u}).$$

Thus, (19) gives

$$\sum_{\mathbf{v}\in N_t^{-G_1\Box G_2}(\mathbf{u})} x_{\mathbf{v},((w_1,u_2),\mathbf{u}),t} = \frac{N_t^{-G_1}}{d_1} + r\sum_{t_1=1}^{t-1}\frac{N_{t_1}^{-G_1}N_{t-t_1}^{-G_2}}{d_1}. \tag{20}$$

for any $((w_1,u_2),\mathbf{u})\in E_{G_1\Box G_2}$. For G_2, one can similarly get

$$\sum_{\mathbf{v}\in N_t^{-G_1\Box G_2}(\mathbf{u})} x_{\mathbf{v},((u_1,w_2),\mathbf{u}),t} = \frac{N_t^{-G_2}}{d_2} + (1-r)\sum_{t_2=1}^{t-1}\frac{N_{t-t_2}^{-G_1}N_{t_2}^{-G_2}}{d_2}. \tag{21}$$

The value of r is the solution to (20)$=$(21):

$$\frac{N_t^{-G_1}}{d_1} + r\sum_{t_1=1}^{t-1}\frac{N_{t_1}^{-G_1}N_{t-t_1}^{-G_2}}{d_1} = \frac{N_t^{-G_2}}{d_2} + (1-r)\sum_{t_2=1}^{t-1}\frac{N_{t-t_2}^{-G_1}N_{t_2}^{-G_2}}{d_2}.$$

To see there is always a solution $r\in[0,1]$, we have $N_t^{-G_1}\le d_1\cdot N_{t-1}^{-G_1}$ and $N_t^{-G_2}\le d_2\cdot N_{t-1}^{-G_2}$, so

$$\frac{N_t^{-G_1}}{d_1} - \frac{N_t^{-G_2}}{d_2} \le \frac{N_t^{-G_1}}{d_1} \le N_{t-1}^{-G_1} \le \sum_{t_2=1}^{t-1}\frac{N_{t-t_2}^{-G_1}N_{t_2}^{-G_2}}{d_2},$$

$$\frac{N_t^{-G_2}}{d_2} - \frac{N_t^{-G_1}}{d_1} \le \frac{N_t^{-G_2}}{d_2} \le N_{t-1}^{-G_2} \le \sum_{t_1=1}^{t-1}\frac{N_{t_1}^{-G_1}N_{t-t_1}^{-G_2}}{d_1}.$$

The last inequality follows that because G_2 is nontrivial simple digraph, $N_1^{-G_2}=d_2$ and hence $N_{t-1}^{-G_1}=N_{t-1}^{-G_1}N_1^{-G_2}/d_2$. Note that $a+rb=c+(1-r)d$ always has a solution $r\in[0,1]$ if $a-c\le d$ and $c-a\le b$. With (20)$=$(21), by Theorem 17, we have constructed a BW-optimal solution of (1) for $G_1\Box G_2$. The theorem trivially follows by induction. □

Theorem 14. *A schedule A for G is a BFB allgather schedule if and only if the following are satisfied:*

1. *If $((v,C),(w,u),t)\in A$, then $d(v,u)=d(v,w)+1=t$;*
2. *For any distinct $u,v\in V_G$, the collection of chunks $\mathcal{C}_v=\{C\mid((v,C),(w,u),t)\in A\}$ satisfies $S=\bigcup_{C\in\mathcal{C}_v}C$.*

Proof. Let v_0,v_k be arbitrary two distinct vertices in V_G with $d(v_0,v_k)=k$. For any $x\in S$, we want to show that there exists a path taking x from v_0 to v_k. At comm step k, conditions 1 and 2 guarantee that there exists $v_{k-1}\in N^-(v_k)$ and $((v_0,C_k),(v_{k-1},v_k),k)\in A$ such that $d(v_0,v_{k-1})=k-1$ and $x\in C_k$. At comm step $k-1$, similarly, it is guaranteed that there exists $v_{k-2}\in N^-(v_{k-1})$ and $((v_0,C_{k-1}),(v_{k-2},v_{k-1}),k-1)\in A$ such that $d(v_0,v_{k-2})=k-2$ and $x\in C_{k-1}$. Thus, we have a sequence of tuples in A:

$$((v_0,C_1),(v_0,v_1),1),((v_0,C_2),(v_1,v_2),2),\ldots ((v_0,C_k),(v_{k-1},v_k),k),$$

where $x\in C_1\cap C_2\cap\cdots\cap C_k$ as desired. In the other direction, if condition 1 fails, then A is not a BFB schedule; if condition 2 fails, then A is not a valid allgather schedule. □

Theorem 15. *If A is a BFB schedule for G, then the total-hop latency $T_L(A)=\alpha\cdot D(G)$.*

Proof. The proof is trivial. □

Theorem 16. *Given any topology G, linear program (1) gives the optimal BFB schedule of G.*

Proof. The proof is mentioned in text. □

Theorem 17. *Suppose (G,A) is a BFB allgather schedule. (G,A) is BW-optimal if and only if:*

1. *There exists a sequence $N_1^-,N_2^-,\ldots,N_{D(G)}^-\in\mathbb{N}$ such that for any $x\in\mathbb{N}$ and $u\in V_G$, $|N_x^-(u)|=N_x^-$.*
2. *For any $(w,u)\in E_G$, $\sum_{((v,C),(w,u))\in A_t}|C|=\frac{M}{N}|N_t^-(u)|/d=\frac{M}{N}N_t^-/d$.*

Proof. At comm step t, each vertex needs to receive shards from vertices in $N_t^-(u)$. By condition 1 of Theorem 5, each in-edge of vertex u receives equal amount of data, so each in-edge receives $\frac{M}{N}|N_t^-(u)|/d$. In addition, condition 1 of Theorem 5 also forces every edge in G receiving equal amount of data at any given comm step, so BW optimality is achieved if and only if $\frac{M}{N}|N_t^-(u)|/d=\frac{M}{N}|N_t^-(v)|/d=\frac{M}{N}N_t^-/d$ for all $u,v\in V_G$. Note that condition 2 of Theorem 5 is automatically satisfied. Thus, the conditions of Theorem 17 lead to Theorem 5, and vice versa. □

Theorem 18. *There exists a BW-optimal BFB schedule for undirected graph G if for every distance x, two of the following constants exist:*

1. *$N_x=|N_x(u)|$ for any $u\in V_G$;*
2. *$a_x=|N_x(u)\cap N_{x-1}(w)|$ for any $u\in V_G$ and $w\in N(u)$;*
3. *$b_x=|N(u)\cap N_{x-1}(v)|$ for any $u\in V_G$ and $v\in N_x(u)$.*

Moreover, if two of N_x,a_x,b_x exist, then the third one must also exist with $N_x=da_x/b_x$.

Proof. It is easy to see $N_x=da_x/b_x$. Constant N_xs satisfy condition 1 of Theorem 17. As for 2 of Theorem 17, at comm step t, consider a BFB schedule such that for any $u,v,w\in V_G$ with $d(v,u)=d(v,w)+1=t$, node w sends $1/b_t$ of v's shard to u. Thus, $\sum_{((v,C),(w,u))\in A_t}|C|=\frac{M}{N}a_t/b_t=\frac{M}{N}N_t/d$. □

Theorem 19. *The workloads can be balanced if and only if there exists no subset $J\subseteq\{j_1,j_2,\ldots,j_m\}$ such that*

$$\frac{|J|}{\left|\bigcup_{j\in J}f(j)\right|} > \frac{m}{d}.$$

Proof. Consider a flow network, where each j_a is connected to each $p_b \in f(j_a)$ with ∞ capacity. Source s is connected to each j_a with capacity 1, and each p_b is connected to sink t with capacity m/d. Thus, the workloads can be balanced if and only if the max flow is m. Given any subset J, consider the s-t cut $(A, \bar{A})$ that $A = s + J + f(J)$. The cut has capacity $m - |J| + \frac{m}{d}|f(J)|$, which is less than m if and only if the inequality is true. □

Theorem 20. *Rounding LP gives a solution with BW runtime* $T_B \le T_B^{OPT} + \frac{M}{B} \cdot \frac{d(d^{D(G)}-1)}{(d-1)PN}$. *In addition, if topology G is Moore optimal, then* $T_B \le T_B^{OPT} + \frac{M}{B} \cdot \frac{d}{P}$.

Proof. For any (w,u) at comm step t, since $|N_{t-1}^-(w)| \le d^{t-1}$,

$$\sum_v y_{v,(w,u),t} < \sum_v 1 + y^{\text{LP}}_{v,(w,u),t} \le d^{t-1} + \sum_v y^{\text{LP}}_{v,(w,u),t}.$$

Thus, we have $W_{u,t} \le W^{\text{LP}}_{u,t} + d^{t-1}$. By (2),

$$\begin{aligned} T_B - T_B^{\text{OPT}} &\le T_B - T_B^{\text{LP}} \\ &\le \frac{M/N}{B/d} \cdot \frac{1}{P} \sum_{t=1}^{D(G)} d^{t-1} = \frac{M}{B} \cdot \frac{d(d^{D(G)}-1)}{(d-1)PN}. \end{aligned}$$

Note that we need to divide (2) by P, because $y_{v,(w,u),t} \in [0,P]$ in (13) while $x_{v,(w,u),t} \in [0,1]$ in (1). If G is Moore optimal (i.e., $N > M_{d,D(G)-1}$), it follows that

$$T_B - T_B^{\text{OPT}} < \frac{M}{B} \cdot \frac{d(d^{D(G)}-1)}{(d-1)PM_{d,D(G)-1}} = \frac{M}{B} \cdot \frac{d}{P}.$$

□

Theorem 21. *Suppose* $D(\Pi_{d,m}) = k$, *then* $m > M_{d,k-2}$.

Proof. From [25], we know that $k \le \lceil \log_d m \rceil$. Then,

$$m \ge d^{k-1} > \frac{d^{k-1}-1}{d-1} = M_{d,k-2}.$$

□

Theorem 22. *Given* $n > 6$ *and* $m = \lceil (-1+\sqrt{2n-1})/2 \rceil$, *circulant graph* $C(n, \{m, m+1\})$ *has a diameter equal to m, which is the minimum diameter over all circulant graphs* $C(n, \{a_1, a_2\})$.

Proof. See [7]. □

Abstract

The increasing deployment of ML models on the critical path of production applications requires ML inference serving systems to serve these models under unpredictable and bursty request arrival rates. Serving many models under such conditions requires a careful balance between each application's latency and accuracy requirements and the overall efficiency of utilization of scarce resources. Faced with this tension, state-of-the-art systems either choose a single model representing a static point in the latency-accuracy tradeoff space to serve all requests or incur latency target violations by loading specific models on the critical path of request serving. Our work instead resolves this tension through a resource-efficient serving of the entire range of models spanning the latency-accuracy tradeoff space. Our novel mechanism, SubNetAct, achieves this by carefully inserting specialized control-flow operators in pre-trained, weight-shared super-networks. These operators enable SubNetAct to dynamically route a request through the network to actuate a specific model that meets the request's latency and accuracy target. Thus, SubNetAct can serve a vastly higher number of models than prior systems while requiring upto 2.6× lower memory. More crucially, SubNetAct's near-instantaneous actuation of a wide-range of models unlocks the design space of fine-grained, reactive scheduling policies. We design one such extremely effective policy, SlackFit, and instantiate both SubNetAct and SlackFit in a real system, SuperServe. On real-world traces derived from a Microsoft workload, SuperServe achieves 4.67% higher accuracy for the same latency targets and 2.85× higher latency target attainment for the same accuracy.

1 Introduction

Recent advancements in machine learning (ML) techniques have unlocked vast improvements in both accuracy and efficiency of a wide-variety of tasks [5, 11, 19, 31, 41, 50]. As a result, ML models have been quickly deployed across a wide-range of applications in both datacenters [26, 40, 44, 49, 62] and the edge [6, 20, 35, 42], where they are subjected to the stringent requirements of production applications.

Notably, ML models on the critical path of these applications must deal with *unpredictable request rates* that rapidly change at a sub-second granularity. For example, web applications in datacenters increasingly rely on ML models [49, 62], and have extremely bursty request rates, with a 50× higher peak demand than average [34]. Similarly, request rates in autonomous vehicles change rapidly as a function of the terrain (city vs. freeway driving), time of the day etc. [20].

In the presence of these unpredictable request rates, ML inference serving systems that cater to production applications must strike a careful balance between three key requirements:

R1: Latency. Production applications have extremely stringent latency requirements, quantified through a Service-Level Objective (SLO) [33]. For example, both web serving [25, 44, 49] in datacenters and autonomous vehicles [20, 35] on the edge must maximize the number of requests completed within a specified SLO ranging from $10-100$ ms [20, 60].

R2: Accuracy. Production applications demand the highest-accuracy results possible within the latency targets of their requests. For example, higher accuracy has been intricately tied to a better user experience for web applications [26, 56]. Similarly, the safety of an autonomous vehicle heavily relies on the accuracy of its different ML models [20, 21].

R3: Resource-Efficiency. Web applications at Facebook process 200 trillion ML model requests daily [53] – a significant fraction of datacenter usage [44]. The proliferation of ML models and their reliance on expensive resources such as GPUs, TPUs [1], AWS Inferentia [2] etc. has led to resource tensions in both datacenters and the edge [42]. Thus, inference serving systems must make judicial use of these resources.

The first-generation of inference serving systems [13, 14, 25, 32, 39, 40, 60] resolve this tension by choosing a static point in the tradeoff space between **R1**-**R3** and serving all requests of an application using the chosen model. As a result, applications either miss their SLO targets (**R1**) under bursty

[*]Work done as a student at Georgia Tech

request rates or suffer degraded accuracy (**R2**) under normal conditions. More recently, state-of-the-art inference serving systems [45, 61] enable applications to register multiple ML models spanning the entire pareto frontier of latency (**R1**) and accuracy (**R2**) targets, and *automatically* choose a model based on the incoming request rates. To achieve this, these systems must either keep the entire set of models in memory or rely on *model switching* to load the required models at runtime [61]. As GPU memory remains the key resource bottleneck in both datacenter and edge [34, 42], these systems choose between **R3** – effectively utilizing the resources (by incurring the prohibitive latency penalties of switching models), or **R1** – meeting SLO targets under bursty request rates.

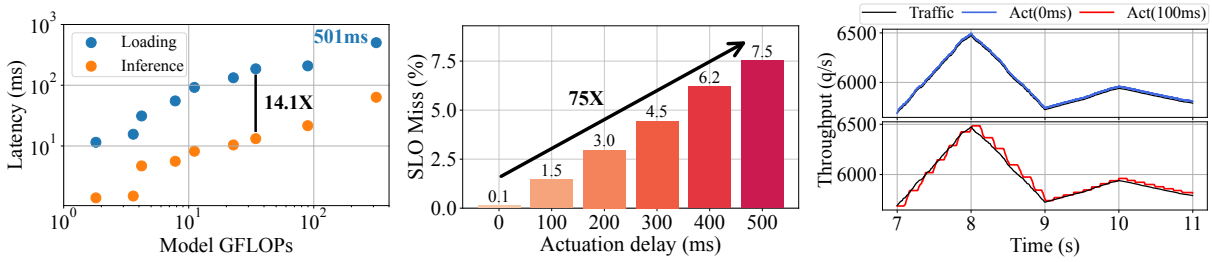
Conventional wisdom in inference serving literature touts the "*non-negligible provisioning time* [for ML models due to switching], *which can exceed the request processing times*" as a "*key characteristic of ML workloads*", and "*rules out reactive techniques*" for responding to bursty request rates [24]. This wisdom has been widely accepted [14, 25, 45] leading to the development of coarse-grained scheduling policies for inference serving that must account for the enormous latency penalty of switching models when reacting to bursty request rates. As a result, these coarse-grained policies typically avoid or minimize switching models by design [45], and are hence, unable to optimally navigate the tradeoff space between **R1**-**R3** under rapidly-changing, unpredictable request rates.

In this work, we challenge this conventional wisdom that forces a choice between **R1** and **R3**. We describe a mechanism, SubNetAct, to simultaneously serve the entire range of models spanning the latency-accuracy tradeoff space (**R1**-**R2**) in a resource-efficient manner (**R3**). At the core of our mechanism are novel control flow operators that SubNetAct carefully inserts into trained super-network [8, 47, 58] (SuperNet) neural architectures. SuperNets enable a fine-grained latency-accuracy tradeoff (**R1**-**R2**) by training a set of shared model weights for many neural networks, without duplication. Prior works [8, 47] propose efficient mechanisms for training SuperNets for both vision and NLP tasks, but require each model instance to be individually extracted for inference. This leads inference serving systems to a similar choice as before – either load all individual models or switch between them at runtime. However, SubNetAct's novel operators obviate the need to extract individual models and load them at runtime. Instead, SubNetAct dynamically routes requests within one SuperNet deployment with negligible overhead, enabling near-instantaneous *actuation* of different models. Thus, it unlocks orders of magnitude improvements in the navigation of the latency-accuracy tradeoff space (**R1**-**R2**), while substantially reducing the memory footprint (**R3**) (see §2).

In addition to being resource-efficient (**R3**), SubNetAct's agility in navigating the latency-accuracy tradeoff space (**R1**-**R2**) fundamentally changes the design space of scheduling policies. Instead of complex scheduling policies that must reason about future request rates in a bid to avoid paying the latency of switching ML models dynamically under bursts, SubNetAct enables the specification of simple policies that directly optimize for the key success metrics: **R1**-**R3**. While conventional wisdom deems such reactive policies infeasible, we explore one example point in this design space with a simple, yet effective policy that we call SlackFit. SlackFit is a reactive scheduling policy that exploits the near-instantaneous actuation property of SubNetAct to make fine-grained decisions about how many requests to serve in a batch, and which latency/accuracy choice to select for serving in real-time.

We summarize the contributions of this paper as follows:

- We introduce SubNetAct (§3), a novel mechanism that enables a resource-efficient, fine-grained navigation of the latency-accuracy tradeoff space. SubNetAct achieves this by carefully inserting novel control flow operators that dynamically route requests through a single SuperNet.
- We unlock the design of fine-grained, reactive scheduling policies and provide a mathematical formulation of their objective (§4.1). We then propose SlackFit (§4.2), a simple, yet effective greedy heuristic scheduling policy , and show how it accurately approximates the optimal objective.
- We instantiate SubNetAct and SlackFit in a real-world system, SuperServe, a real-time asynchronous model serving system with pluggable scheduling policies (§5).
- We evaluate SuperServe with both SlackFit and several state-of-the-art scheduling policies (§6). We find that SuperServe achieves 4.67% higher accuracy for the same SLO attainment and 2.85× higher SLO attainment for the same accuracy on the real-world Microsoft Azure Functions trace.



2 Motivation

In §2.1, we first motivate the need for a reactive, fine-grained scheduling policy for handling unpredictable, bursty request rates. To meet the SLO of the requests while maximizing the accuracy of the responses, we motivate the use of SuperNets (§2.2) that enable a fine-grained exploration of the latency-accuracy tradeoff space (**R1**-**R2**) for multiple latency targets.

2.1 Reactive, Fine-Grained Scheduling

Prior works in inference serving systems [34, 60] have exhaustively analyzed both production traces from Microsoft Azure Functions (MAF) [48] and synthetic application traces with a goal of highlighting their bursty request arrival patterns. For example, Zhang et al. [60] underscore the high coefficient of variance in request arrivals in production traces [48]. Further, the authors claim that the bursty "*sub-second request arrival patterns* [are] *nearly impossible to predict*", thus frustrating the goal of meeting the stringent SLO requirements (**R1**) of requests in an ML-based production applications.

A strawman solution to meeting SLOs under bursty request rates requires these systems to load the entire set of models

(a) Model switching is expensive **(b)** SLO misses wrt. actuation delay **(c)** Fine-grained scheduling

Fig. 1: Fine-grained scheduling policies are beneficial. (a) The latency of loading convolutional neural networks [27, 38, 59] and transformer-based neural networks [37] is greater than their inference latency across multiple batch sizes, making model switching expensive. This gap widens as model sizes increase, with a peak difference of up to 14.1×. (b) The higher actuation delay (due to model loading) leads to up to 75× higher SLO misses while serving the entire real-world, bursty MAF [48] trace. (c) A high actuation delay on a snapshot of the MAF trace shows 2% of the requests missing their SLO (**R1**) as request rates increase, and an inefficient utilization of resources (**R3**) as request rates decrease.

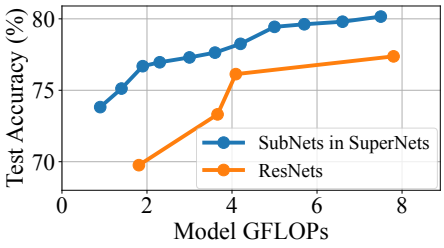


Fig. 2: Enhanced, fine-grained latency-accuracy tradeoff with SuperNets. The accuracy of SubNets extracted from OFAResNet SuperNet [8] is vastly superior to the hand-tuned ResNets from Fig. 1a for the same FLOP requirements (**R1**). Moreover, SuperNets can instantiate vastly higher number of points in the space.

spanning the latency-accuracy tradeoff space into GPU memory and switch between them as request rate fluctuates. While this reduces the latency of switching models, allowing serving systems to rapidly degrade accuracy (**R2**) under bursts to meet SLO targets (**R1**), it is resource-inefficient (**R3**).

As a result, state-of-the-art inference serving systems [45, 61] page models in and out when required, to efficiently utilize GPU memory (**R3**). However, Fig. 1a shows that the loading time of ML models into GPU memory is vastly more than the inference time, and the gap widens as the model sizes increase. Thus, reactive approaches that either provision resources or switch models upon arrival of bursty request rates must incur an *actuation delay* (i.e., the latency penalty of loading ML models) on the critical path of request serving, leading to an order-of-magnitude increase in missed SLOs (see Fig. 1b). In a bid to offset this latency penalty, inference serving systems rely on *predictive* scheduling policies that make coarse-grained estimations of future request arrival patterns [24]. Such policies are bound to be suboptimal owing to the difficulty of predicting the short bursts in request arrival rates coupled with their stringent SLO requirements [60].

We believe that the key to optimally serving bursty request rates instead lies in the ability to rapidly switch between ML models thus obviating the need for coarse-grained predictive scheduling policies. To validate our hypothesis, we simulate a coarse-grained policy with an actuation delay of 100ms and an ideal fine-grained policy with an actuation delay of 0ms. Fig. 1c plots the effects of these policies on a small bursty subtrace from the MAF trace. We observe that the coarse-grained policy leads to higher SLO misses (**R1**) under increasing request rates and wasted resources (**R3**) under decreasing request rates. Conversely, the fine-grained policy is able to instantaneously adjust to the request rates leading to no missed SLOs and effective utilization of the GPU.

2.2 Weight-Shared SuperNets

The problem of navigating the pareto-optimal frontier of the latency-accuracy tradeoff space (**R1**-**R2**) by finding highest accuracy ML models for a specific latency target is well studied in ML literature. Conventional Neural Architecture Search (NAS) [10, 36, 51, 63, 64] couple the search and training of ML models to produce a single architecture with the highest accuracy for a particular latency target. To satisfy multiple latency targets, these approaches must repeat the entire train and search procedure, thus becoming prohibitively expensive.

To solve this issue, recent NAS works [8, 28, 47, 58] decouple the search and training procedures by allowing multiple architectures to share their weights while training. These approaches first train one SuperNet and then extract subsets of its layers to form multiple *SubNets*, without requiring any further retraining. These SubNets are extracted to target vastly superior points in the latency-accuracy tradeoff space (**R1**-**R2**), as compared to hand-tuned ML models. For example, Fig. 2 highlights the accuracy benefits of SubNets extracted from a ResNet-based SuperNet when compared to the hand-tuned ResNets for an equivalent number of FLOPs.

SuperNets enable a fine-grained exploration of the latency-accuracy tradeoff space (**R1**-**R2**) by yielding specialized ML model architectures for a wide-variety of latency targets. This

is enabled by a search for multiple architectures, which relies on the following parameters: (*i*) *Depth* ($\mathbb{D}$), which describes the depth of a SubNet, and (*ii*) *Width Multiplier* ($\mathbb{W}$), which describes the width of a SubNet i.e., the number of heads in a multi-head attention layer or the number of channels in a convolution layer to be used. These parameters create a combinatorially large architecture space, Φ ($|\Phi| \approx 10^{19}$) [8], from which SubNets are extracted *statically* for inference. However, this static extraction in prior work [8, 28, 47, 58] again yields individual models that must either be simultaneously deployed (wasting resources; **R3**) or paged in as request rates fluctuate (missing SLOs; **R1**).

3 SubNetAct: Instantaneous Model Actuation

Motivated by §2, we seek to exploit SuperNets' fine-grained exploration of the latency-accuracy tradeoff to unlock the development of reactive scheduling mechanisms. To achieve our goal, we introduce SubNetAct, which addresses the challenges posed by static extraction of individual models in SuperNets, which force a choice between **R1** and **R3**.

Key Idea. To resolve this fundamental tension, we make the key observation that by virtue of performing architectural search *post* training, a SuperNet subsumes the entire architectural space of SubNets. Specifically, we follow the training procedure of prior NAS approaches [8, 28, 47, 58] to retrieve the architecture of the SuperNet, $\mathcal{M}$, along with its weights W[1]. The architecture of the SuperNet, $\mathcal{M}$, captures the set of all layers and weights that can be used in inference. Thus, instead of performing the search procedure and extracting individual SubNets, SubNetAct automatically modifies $\mathcal{M}$ to introduce its novel control flow operators. This allows SubNetAct to deploy the entire SuperNet $\mathcal{M}$, and *dynamically route* requests to the appropriate SubNet. §3.1 provides an overview of SubNetAct's novel control flow operators, and Appendix A.1 describes the procedure by which SubNetAct automatically inserts these operators into $\mathcal{M}$.

SubNetAct exploits the weight-sharing among the SubNets of a SuperNet to enable a memory-efficient model *actuation* mechanism (**R3**). Its fine-grained control flow operators near-instantaneously switch between SubNets in order to pick the optimal point in the latency-accuracy tradeoff space (**R1**-**R2**).

3.1 SubNetAct's Operators

SubNetAct's key insight lies in the introduction of the three novel operators (Fig. 3) that enable it to route requests to the required subnet dynamically and selectively use the trained supernet's weights. SubNetAct works on both convolution [8] and transformer-based [28] supernets. The three operators introduced in SubNetAct are as follows:

[1]We highlight that many NAS approaches make the trained $\mathcal{M}$ and W publicly available. Our evaluation uses these trained models, and does not require any further re-training.

LayerSelect operates at a block level in $\mathcal{M}$, where each block is a collection of multiple layers. The LayerSelect operator enforces control flow by either passing the input activation to the wrapped layers in the block or skipping the block and directly forwarding the input to the next block.

- *Convolution-Based SuperNet.* A convolution-based supernet [8] contains multiple stages, with each stage consisting of set of repeating blocks (bottleneck in OFAResNets [9]). The LayerSelect operator dynamically selects the first $\mathbb{D}_m$ blocks within m^{th} stage of the supernet. $\mathbb{D}_m$ is an external input provided to SubNetAct, as shown in Fig. 3 (2^{nd} row) for 2-stage supernet where $\mathbb{D}$ takes depth values per stage (m=2).
- *Transformer-Based SuperNet.* Unlike convolution-based supernets, transformer-based supernets [28] have a single stage. Hence, these supernets contain repeatedly stacked transformer blocks. The LayerSelect operator selects or deselects transformer blocks based on a single external input $\mathbb{D}$ that specifies the number of layers to use for inference. The block selection is based on the "every-other" strategy [17, 28]. In this strategy, n^{th} block is selected for inference if $n \mod \frac{L}{(L-\mathbb{D})} \equiv 0$, where L is the maximum number of stacked transformer blocks.

Overall, this operator enables layer-sharing among subnets that differ in depth ($\Phi_{\mathbb{D}} \subset \Phi$), which helps reduce GPU memory consumption (**R3**). For example, in a subnet with depth $\mathbb{D} = 1$, the blocks selected for execution by SubNetAct are shared with those in a subnet with depth $\mathbb{D} = 2$.

WeightSlice operates at each layer in a block of $\mathcal{M}$. For each layer, it dynamically selects the slice of the SuperNet's trained weights that participate in inference.

- *Convolution-Based SuperNet.* Each block in this supernet contains convolution layers. WeightSlice operator dynamically selects the number of channels of the convolution layer weights in a block (1^{st} row and 1^{st} column in Fig. 3). Precisely, the operator selects the first $\lceil \mathbb{W}_k * C_k \rceil$ channels in the k^{th} block (C_k represents the maximum channels). $\mathbb{W}_k$ is an input to the operator that is specified independently for each block. It denotes the fraction of channels to use in the weights of the convolution layers of the k^{th} block.
- *Transformer-Based SuperNet.* The blocks in this supernet consist of multi-head attention (MHA) and feed-forward layers [52]. WeightSlice operator dynamically selects the number of attention heads in the MHA layers (1^{st} row and 2^{nd} column in Fig. 3). Particularly, WeightSlice selects the first $\lceil \mathbb{W}_k * H_k \rceil$ heads, H_k represents the maximum heads in the k^{th} block. Here, $\mathbb{W}_k$ denotes the fraction of attention heads to use for inference in the k^{th} transformer block.

The operator enables partial layer-sharing among SubNets ($\Phi_{\mathbb{W}} \subset \Phi$,), thus increasing the number of available SubNet architectures. For example, for a SubNet with $\mathbb{W}_0 = 0.5$, WeightSlice selects the first 50% heads and shares its weights with the SubNet with $\mathbb{W}_0 = 0.75$. Together, LayerSelect and

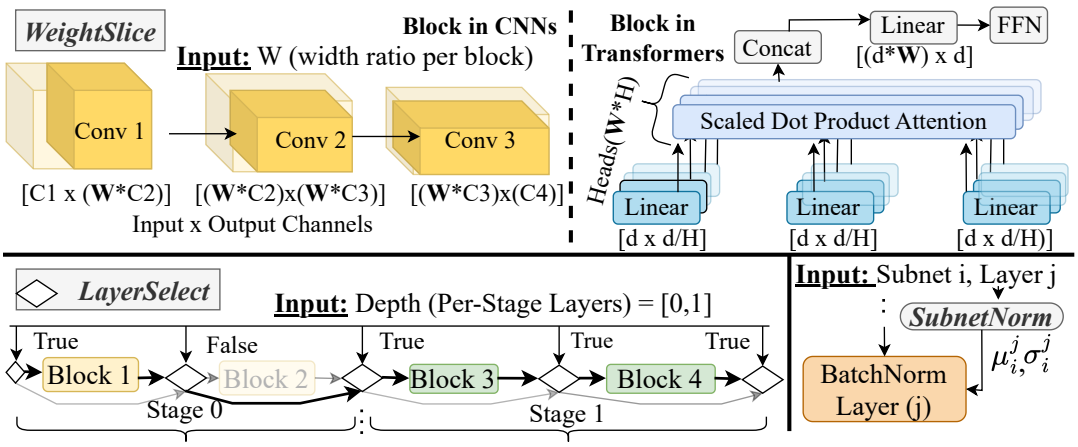

Fig. 3: SubNetAct's novel operators (LayerSelect, WeightSlice, SubnetNorm) dynamically actuate SubNets by routing requests through weight-shared layers and non weight-shared components.

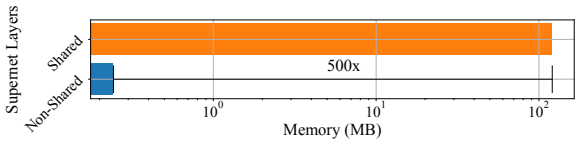

Fig. 4: SubNetAct's memory savings. The memory used by the normalization statistics is 500× smaller than the non-normalization layers. SubnetNorm decouples the normalization statistics for each SubNet and provides accurate bookeeping thus enabling high accuracy (**R1**), with minimal increase in memory consumption (**R3**).

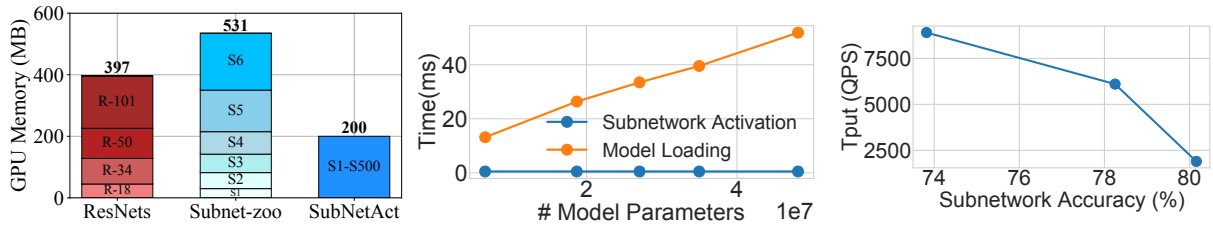
WeightSlice enable SubNetAct to dynamically actuate the entire set of latency-accuracy options (**R1**-**R2**).

SubnetNorm is specifically implemented only for *convolution-based SuperNets*. We observe that naively introducing the LayerSelect or WeightSlice operator leads to a significant drop in SubNet accuracy (as low as 10%) in the convolution-based SuperNet. This is due to the incorrect tracking of the mean (μ) and variance (σ) in normalization layers such as BatchNorm [29]. The transformer-based SuperNet uses LayerNorm [7] which doesn't require tracking of mean and variances, and hence doesn't face this issue. To account for the discrepancy in BatchNorm layers, SubNetAct introduces the SubnetNorm operator that precomputes and stores μ and σ for each possible SubNet by performing forward pass inference on the training data. SubnetNorm takes as input a unique SubNet ID (i) and a layer ID (j) and outputs the pre-computed normalization statistics $\mu_{i,j}$ and $\sigma_{i,j}$. The layer j then uses these statistics to perform normalization of activations, effectively specializing j for each SubNet i.

Although this bookkeeping increases the memory requirements of deploying the SuperNet, Fig. 4 shows that the overhead of these non-shared normalization statistics is 500× smaller than the memory requirement of the shared layers. SubNetAct can host thousands of SubNets in memory by only keeping the statistics unique to each subnet and sharing the non-normalization weights amongst all the SubNets.



Finally, we note that the input to these control flow operators (i.e., $\mathbb{D}$, $\mathbb{W}$) remains similar to the inputs for architectural search in NAS [8]. Moreover, these inputs are independent from the request served by the actuated SubNets, and are declaratively specified by a scheduling policy (§4). Given the arrival rate, the scheduling policy chooses a specific SubNet for a request (by specifying the control tuple $\mathbb{D}$ and $\mathbb{W}$), which is then actuated by SubNetAct near-instantaneously.

3.2 Discussion: Efficacy of SubNetAct

We now highlight SubNetAct's efficacy in achieving key application requirements (**R1**-**R3**) under bursty request rates.

Reduced Memory Requirements. SubNetAct's novel operators enable SubNets to share layers in place and dynamically route requests to the appropriate SubNet based on the control tuple $(\mathbb{D}, \mathbb{W})$. Thus, SubNetAct can simultaneously serve the entire range of models spanning the latency-accuracy tradeoff space while drastically reducing memory requirements. Fig. 5a demonstrates the requirements of serving the same accuracy range by comparing: (*i*) four different hand-tuned ResNets [27] (publicly available from prior literature), (*ii*) six uniformly sampled individual SubNets [8] from a ResNet-based SuperNet, and (*iii*) SubNetAct that enables dynamic actuation of 500 SubNets. We highlight that SubNetAct reduces memory usage by up to 2.6×, while serving vastly more fine-grained latency-accuracy tradeoff points.

Near-Instantaneous Model Actuation. While switching between individual models requires loading their weights to the GPU, SubNetAct's operators enable scheduling policies to actuate any SubNet *in place* without incurring additional loading overhead. Fig. 5b compares the time taken to perform on-demand loading of individual SubNets versus in-place actuation of a SubNet in SubNetAct. We highlight that SubNetAct's model actuation is orders-of-magnitude faster than

(a) Reduced Memory Requirements. **(b)** Instantaneous Model Actuation. **(c)** High dynamic throughput range.

Fig. 5: Efficacy of SubNetAct. (a) SubNetAct requires upto 2.6× lower memory to serve a higher-range of models when compared to the ResNets from Fig. 1a and six individual SubNets extracted from SuperNet [8] (b) SubNetAct actuates different SubNets near-instantaneously (< 1ms), which is orders of magnitude faster than the model switching time. (c) SubNetAct's instantaneous actuation of models enables it to sustain higher ingest rates thus inducing a wide dynamic throughput range ($\approx 2-8k$ queries per second) within a narrow accuracy range.

on-demand loading of ML models. This allows scheduling policies that use SubNetAct to rapidly actuate lower-accuracy models under bursty conditions (**R1**) and switch to higher-accuracy models under normal load (**R2**), without coarse-grained predictions about future request rates.

Increased Throughput & Accuracy. Through its instant model actuation, SubNetAct allows scheduling policies to rapidly scale the throughput of the system, thus inducing a broad throughput range within a narrow range of accuracy to help meet SLOs (**R1**-**R2**). Fig. 5c compares the maximum sustained ingest throughput for a point-based open-loop arrival curve for serving the largest, smallest, and a median SubNet on 8 GPUs. We observe that SubNetAct can serve a wide throughput range from 2000-8000 QPS, while being able to increase accuracy between 74% to 80%.

4 Fine-Grained Scheduling Policies

SubNetAct's resource-efficient (**R3**) near-instantaneous actuation of the entire latency-accuracy tradeoff space unlocks the development of fine-grained, reactive scheduling policies. These policies can quickly scale an inference serving system's throughput upon arrival of bursty request rates to ensure that the requests meet their SLO (**R1**) with the maximum possible accuracy (**R2**). Specifically, upon a *query*'s[2] arrival to an inference serving system, it invokes the scheduling policy, which must decide the following four decision variables:

- **SubNet** ϕ from the set of all possible SubNets Φ available for actuation by SubNetAct. As discussed in §3, a SubNet $\phi \in \Phi$ is uniquely identified by the control tuple $(\mathbb{D}, \mathbb{W})$.
- **Batch** B of size $|B|$ which groups the queries that are executed together on a GPU using the SubNet ϕ.
- **GPU** n upon which the batch B is executed.
- **Time** t at which the batch B must be executed on GPU n.

In this section, we first start with the mathematical formulation of an optimal scheduling policy that decides the above parameters (§4.1). We then describe our proposed policy SlackFit that approximates the optimal policy and aims to achieve both high accuracy and SLO attainment (§4.2).

[2]We use the term *query* and *request* interchangeably in this paper.

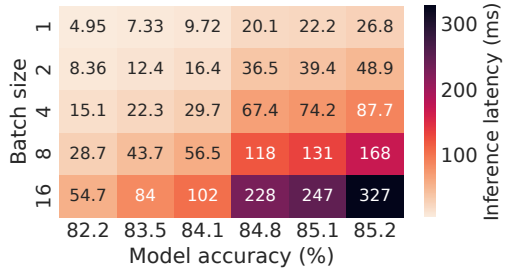
4.1 Optimal Scheduling Policy

We formulate an optimal scheduling policy with an oracular knowledge about all queries as a Zero-One Integer Linear Program (ZILP). The policy's decision is captured by the variable $I(\phi,B,n,t) \in \{0,1\}$, which represents the decision to execute all queries $q \in B$ (from the set of all possible batches $\mathcal{B}$) on GPU n at time t with the SubNet ϕ. The SubNet ϕ has an accuracy $Acc(\phi)$ and a latency profile $l_\phi(|B|)$, which is the latency of ϕ on the batch size $|B|$. We use $a(B)$ to refer to the earliest arrival time of all the queries $q \in B$, and $d(B)$ to refer to the earliest deadline. Intuitively, the policy's goal is to maximize the accuracy of the responses (to queries) within their SLO (**R1**-**R2**). This is represented in ZILP as follows:

$$\text{maximize} \sum_t \sum_n \sum_{\phi\in\Phi} \sum_{B\in\mathcal{B}} \text{Acc}(\phi)\cdot|B|\cdot I(\phi,B,n,t) \quad (1)$$

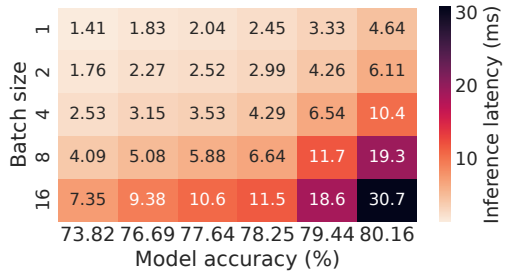
$$\text{s.t.} \sum_t \sum_n \sum_{\phi\in\Phi} \sum_{\{B|q\in\mathcal{B}\}} I(\phi,B,n,t) \le 1, \quad \forall q \quad (1a)$$

$$\sum_{B\in\mathcal{B}} \sum_{\{t'\le t\le t'+l_\phi(|B|)\}} I(\phi,B,n,t') \le 1, \quad \forall n,t,\phi \quad (1b)$$



$$a(B)\cdot I(\phi,B,n,t) \le t, \quad \forall n,t,B,\phi \quad (1c)$$

$$\sum_{\phi\in\Phi} I(\phi,B,n,t) \le 1, \quad \forall n,t,B \quad (1d)$$



$$\sum_{\phi\in\Phi} (l_\phi(|B|)+t)\cdot I(\phi,B,n,t) \le d(B), \quad \forall n,t,B \quad (1e)$$

$$I(\phi,B,n,t) \in \{0,1\}, \quad \forall n,t,B,\phi \quad (1f)$$

The ZILP maximizes the number of queries that satisfy their latency SLOs with the highest possible accuracy across all the selected query batches i.e., $\forall(\phi,B) : I(\phi,B,n,t) = 1, Acc(\phi)\cdot|B|$ is maximized. The constraints of the ZILP denote:

(a) Transformer-Based SuperNet

(b) Convolution-Based SuperNet

Fig. 6: SlackFit control parameter space. Latencies for six different (uniformly sampled w.r.t. FLOPs) pareto-optimal SubNets in SubNetAct as a function of accuracy (x-axis) and batch size (y-axis) shown for transformer and convolution-based SuperNet. The latency increases monotonically with batch size (**P1**) and accuracy (**P2**).

(1a) A query q can be assigned to at most one batch B.

(1b) A GPU n can only execute a single SubNet ϕ on a single batch B at a particular time t.

(1c) Batch B can only execute after its arrival time $a(B)$.

(1d) Each batch B can be served with a maximum of one SubNet ϕ on a GPU n at a time t.

(1e) The batch B should complete before its deadline $d(B)$.

(1f) The choice variable $I(\phi, B, n, t)$ is a boolean indicator.

Given that solving the above ZILP is NP-Hard [43, 60] and it is impractical to expect oracular query arrival knowledge, it cannot be used to serve models online. Instead, we approximate its behavior with a heuristic, *online* scheduling policy.

4.2 SlackFit: Online Scheduling Policy

We introduce SlackFit—a simple yet effective scheduling policy that aims to maximize the accuracy (**R1**) with which the requests meet their latency SLO (**R2**). SlackFit approximates the ILP-based policy in Eq. (1) and makes the decision making tractable by operating in two phases:

Offline Phase triggered upon the registration of a SuperNet $\mathcal{M}$ modified by SubNetAct (Appendix A.1) that the inference serving system must serve. This phase consists of two stages:

1. **Profile pareto-optimal SubNets Φ_{pareto}:** To make SubNet choices in reasonable time, SlackFit makes the design decision to operate on Φ_{pareto} instead of Φ. Φ_{pareto} is the set of pareto-optimal SubNets w.r.t. latency and accuracy obtained by using the search stage of prior NAS methods [8][3]. The size of $|\Phi_{\text{pareto}}| \approx 10^3$ is orders of magnitude smaller than $|\Phi| \approx 10^{19}$, contributing to rapid scheduling decisions.
2. **Bucketize SubNet ϕ and batch size $|B|$ choices:** As discussed in §4, SlackFit must decide the SubNet $\phi \in \Phi_{\text{pareto}}$ and the batch size $|B|$ for the incoming queries. To reduce the search space for this decision, SlackFit relies on three key properties of SubNets in Φ_{pareto} (visualized in Fig. 6): **P1**: the latency increases monotonically with batch size as observed by prior works [13, 14, 25], **P2**: the latency increases monotonically with accuracy due to the choice of SubNets retrieved by NAS in Φ_{pareto}, and **P3**: lower accuracy SubNets can serve higher batch sizes at similar latencies to lower batch sizes in higher accuracy SubNets, due to the SubNet's FLOPs distribution shown in Appendix A.2.

These properties enable SlackFit to reduce the search space of choices for ϕ and $|B|$ to a single dimension – *batch latency*. Thus, SlackFit constructs evenly-spaced buckets between the minimum and maximum latency of all SubNets in Φ_{pareto} (i.e., $l_{\phi_{min}}(|B|=1)$ and $l_{\phi_{max}}(|B|=16)$ respectively, where ϕ_{min} and ϕ_{max} are the lowest and highest accuracy SubNets; using properties **P1**-**P2**). Within each bucket, SlackFit chooses the $(\phi', |B'|)$ with the highest $|B'|$ such that $l_\phi(|B'|)$ is less than the bucket's latency. By **P3**, low latency buckets contain lower accuracy ϕ, higher $|B|$ (leading to higher throughput), and higher latency buckets contain higher accuracy ϕ and lower $|B|$ (leading to lower throughput).

Online Phase of SlackFit is triggered upon the arrival of queries or the availability of a GPU n to the serving system. The key insight of the online phase is that the remaining slack of the query with the earliest deadline provides a proxy to changes in the traffic. Specifically, bursts in traffic increase queuing delays which reduces the available slack, while slack remains high under normal conditions.

Thus, SlackFit chooses a bucket $(\phi, |B|)$, where $l_\phi(|B|)$ is closest to but less than the slack of the query with the earliest deadline. It then packs $|B|$ queries with the earliest deadline into a batch B and executes it on an available GPU n at time t.

By making decisions based on the minimum remaining slack, SlackFit can automatically adjust accuracy (**R2**) and throughput of the system by choosing appropriate latency bucket on variable arrival traffic to maintain high SLO attainment (**R1**). Under normal conditions, a higher slack leads to the choice of buckets with higher $l_\phi(|B|)$, which is strongly correlated with the choice of higher accuracy models (**P2**). Conversely, bursty request arrivals lead to buckets with lower $l_\phi(|B|)$, as SlackFit operates under reduced latency slack. These buckets maximize $|B|$ (due to **P3**), thus opportunistically maximizing accuracy while satisfying SLO.

[3] It takes $\leq$ 2 minutes to perform this NAS profiling on SuperNets.

4.2.1 SlackFit's Approximation of Optimal Offline ZILP

We now provide insights on how SlackFit emulates behavior of the optimal offline ZILP. To understand the behavior of ZILP, we formulate a proxy utility function that captures the inner-term of the ZILP objective function in Eq 1, the utility function is defined for a SubNet ϕ, batch size $|B|$ and the earliest deadline d_B among all queries:

$$\mathbb{U}(\phi,|B|,d_B) = \begin{cases} \text{Acc}(\phi)\cdot|B|, & \text{if } l_\phi(|B|) < d_B \\ 0, & \text{otherwise} \end{cases} \quad (2)$$

This utility is non-zero iff SubNet ϕ performs inference on batch size $|B|$ within the deadline d_B, and is zero otherwise. This maximizes both the number of queries processed within their SLO (**R1**) and the accuracy of their responses (**R2**).

A. ZILP and SlackFit prefer pareto-optimal SubNets. SlackFit's key design choice is to operate on pareto-optimal SubNets w.r.t. latency, accuracy (Φ_{pareto}) (§4.2). We claim that the ZILP also tends towards pareto-optimal SubNets , as these SubNets yield higher utility.

Lemma 4.1. *The utility of pareto-optimal SubNets is higher than non pareto-optimal SubNets if they have similar inference latency for a batch of queries.*

$$\mathbb{U}(\phi_p,|B|,d_B) > \mathbb{U}(\phi_q,|B|,d_B), \qquad \forall B, d_B$$
$$s.t.\ \ \phi_p \in \Phi_{pareto},\ \phi_q \in \{\Phi \setminus \Phi_{pareto}\},\ l_{\phi_p}(|B|) \approx l_{\phi_q}(|B|)$$

This validates SlackFit's design choice to operate on pareto-optimal SubNets only.

Proof By Contradiction. Assume a non-pareto optimal subnet (ϕ_q) such that it has higher utility than pareto optimal subnet (ϕ_p) for a batch B and $l_{\phi_p}(B) \approx l_{\phi_q}(B)$ i.e., $\mathbb{U}(\phi_p,B,d_B) < \mathbb{U}(\phi_q,B,d_B)$. Now, due to the pareto optimal property $Acc(\phi_p) > Acc(\phi_q)$, this implies $Acc(\phi_p)\cdot|B| > Acc(\phi_q)\cdot|B|$ which implies $\mathbb{U}(\phi_p,B,d_B) \geq \mathbb{U}(\phi_q,B,d_B)$ for any delay d_B as $l_{\phi_p}(B) \approx l_{\phi_q}(B)$. This is contradiction. Hence Proved.

B. ZILP and SlackFit prioritize lower accuracy & higher batch sizes under bursts. We make a key observation that the utility of a lower accuracy, higher batch size $(\phi_{low}, |B_{high}|)$ configuration is higher than a higher accuracy, lower batch size $(\phi_{high}, |B_{low}|)$ configuration in Φ_{pareto}.

This is because the factor difference in accuracy of SubNets in Φ_{pareto} (< 1) is less than the factor differences of batch sizes as seen in Fig. 6 i.e., $\frac{\text{Acc}(\phi_{high})}{\text{Acc}(\phi_{low})} \leq \frac{|B_{high}|}{|B_{low}|} \Rightarrow \text{Acc}(\phi_{high})\cdot|B_{low}| \leq \text{Acc}(\phi_{low})\cdot|B_{high}|$. Therefore, $\mathbb{U}(\phi_{low},|B_{high}|,d_q) \geq \mathbb{U}(\phi_{high},|B_{low}|,d_q)$ may hold true under bursts, in cases where the query q with the earliest deadline in a batch of k queries ($q \in B_k$) can be served either by: a) low accuracy model (ϕ_{min}) with batch size $|B_k|$ or b) higher accuracy model (ϕ_{max}) on a subset of queries (say m, $q \in B_m$) with remaining queries ($B_k \setminus B_m$) missing the deadline due to high load. In such cases, the optimal offline ILP will tend to option (a), similar to SlackFit.

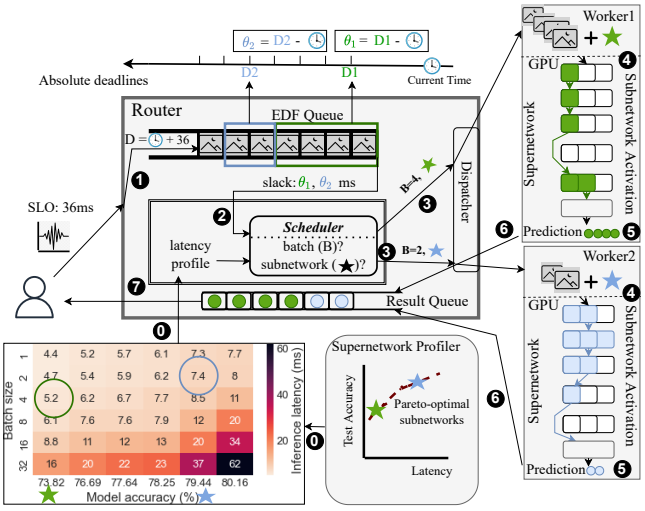


Fig. 7: SuperServe's Architecture comprises of a SuperNet profiler, a router, a fine-grained scheduler (SubNetAct), and GPU-enabled workers. Clients register SuperNets for SuperServe to serve, whose profiling and insertion of control-flow operators is done before queries arrive. Clients submit queries to the router with a specified SLO asynchronously. The query follows the critical path ❶ - ❼.

C. ZILP and SlackFit prefer higher accuracy under normal conditions. The utility of serving more requests with a high-accuracy subnet and fewer requests with a low-accuracy subnet is more than serving all the requests with a medium-accuracy subnet.

We make another observation from the latency profiles of SubNets from Φ_{pareto} in Fig. 6. For a batch size $|B|$, such that $|B| = |B_1| + |B_2|$ where $|B_1| > |B_2|$, the following holds true in many cases - $B_1\cdot\text{Acc}(\phi_{high}) + B_2\cdot\text{Acc}(\phi_{low}) > B\cdot\text{Acc}(\phi_{mid})$. Therefore, $\mathbb{U}(\phi_{high},B_1,d_q) + \mathbb{U}(\phi_{low},B_2,d(B_2)) \geq \mathbb{U}(\phi_{mid},B,d_q)$, may hold true under low load, where the query q in batch B can be served by either: a) mid accuracy model (ϕ_{mid}) with batch size B, or b) high accuracy model (ϕ_{high}) with larger partition B_1 ($q \in B_1$) with rest of the queries in batch B_2 served with the low accuracy model (ϕ_{low}) and meeting deadline $d(B_2)$. In such cases, ILP will tend to option (b) i.e., an option with higher average accuracy, simiar to SlackFit (as described in §4.2).

5 SuperServe: System Implementation

SuperServe is a system that instantiates both the SubNetAct mechanism and the SlackFit policy. SuperServe's architecture is illustrated in Fig. 7. Clients first register the SuperNet that they want SuperServe to serve, which invokes SubNetAct to automatically insert the control flow operators for dynamic actuation of SubNets (Appendix A.1). SuperServe then profiles the SuperNet to enable SubNetAct to operate on the pareto-optimal SubNets.

SuperNet Profiler. The profiler employs neural architecture search (NAS) [8] to find pareto-optimal SubNets from the Su-

perNet for each latency target. The latency of each SubNet is a function of the batch size and the environment of execution (i.e., the GPUs on the available workers). NAS and the model profiling is efficient, taking ≤ 2 minutes to complete, and providing significant benefits for the online phase of SlackFit.

Post SuperNet registration, the clients submit queries to the SuperServe router with a deadline via RPC asynchronously. These queries are enqueued to a global earliest-deadline-first (EDF) queue (❶). As soon as any worker becomes available, SuperServe's fine-grained scheduler is invoked (❷). It decides on the query-batch (B) and the subnet (ϕ) which are then dispatched to the worker (❸). Upon receiving this query-batch, the worker that instantiates the supernet instantaneously actuates the chosen subnet in-place on the GPU using SubNetAct (❹), performs inference (❺), and returns predictions for the query-batch (❻). The router redirects these predictions to the client (❼). We discuss the components of SuperServe below:

Router. The router runs the fine-grained scheduling policy and interacts with workers via RPCs. All queries are received, enqueued, and dequeued asynchronously in the router. It maintains pending queries in a global EDF queue, ordered by query deadlines (SLOs). The router invokes the scheduler whenever (a) a worker signals availability and (b) the EDF queue is not empty. It sends query-batches decided by the scheduler to workers and returns the predictions to the clients.

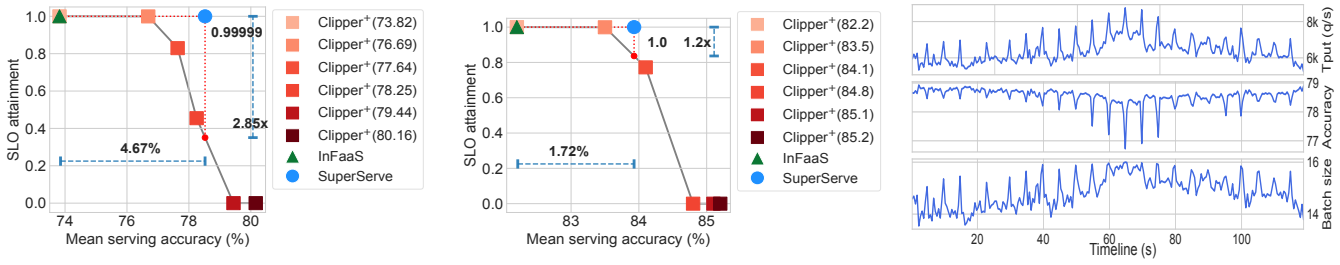
Fine-grained Scheduler. The scheduler's control decision is a batch-size and subnet ($\phi = (\mathbb{D}, \mathbb{W})$). The scheduler provide pluggable APIs for different policy implementations. SlackFit is one such policy implemented in the scheduler. All policies in scheduler leverage two key properties to make control decisions: (a) predictability of DNN inference latency, (b) fast actuation of SubNetAct on the query's critical path.

Worker. The DNN worker employs the SubNetAct mechanism to host a SuperNet (**R3**). SubNetAct's operators are implemented in TorchScript's intermediate representation (IR) [16]. After receiving a query-batch and subnet ($\mathbb{D}$, $\mathbb{W}$) from the router, the worker actuates the desired SubNet using SubNetAct. A forward pass on the actuated SubNet produces predictions that are returned to the router.

6 Evaluation

We assess SuperServe's end-to-end performance i.e., its ability to maximize SLO attainment (**R1**) and accuracy (**R2**) under a variety of traffic conditions, on a real-world Microsoft Azure Functions (MAF) trace (§6.2) and synthetic traces (§6.3). SuperServe is resource-efficient (**R3**) due to the use of SubNetAct mechanism, already established in §3.2. We conclude with microbenchmarks (§6.4).

6.1 Experimental Setup



Success metrics. *SLO attainment* is the fraction of queries that finish within the deadline (**R1**). *Mean serving accuracy* is calculated for queries meeting their SLO and is the average of models' profiled accuracy used to serve them (**R2**).

Traces. We evaluate SuperServe on three sets of traces: real-world, bursty and time-varying. MAF [48] provides a real-world trace. Bursty and time-varying traces are synthetic, similar to those used in InferLine [13]. *Bursty traces* have a base traffic with mean ingest rate λ_b ($CV^2 = 0$) and a variant traffic with mean ingest rate λ_v drawing inter-arrival times from a gamma distribution (Fig. 13a). We vary λ_b, λ_v and CV^2. *Time-varying* traces differ from bursty by varying the mean ingest rate over time. We change the mean from $\mu = 1/\lambda_1$ to $\mu = 1/\lambda_2$ at rate τ q/s^2 with a fixed CV_a^2. Higher ingest acceleration τ q/s^2 denotes faster change from $\lambda_1 \rightarrow \lambda_2$.

Baselines. We compare SuperServe with the single model serving systems that don't perform accuracy trade-offs (and the models are manually selected by users, non-automated serving systems in §7). These systems are represented as Clipper$^+$ baseline and include systems like Clipper [14], Clockwork [25], and TF-serving [40]. Clipper$^+$ is manually configured to serve six different accuracy points (SubNets) that uniformly span the SuperNet's accuracy range and result in its six different versions. We also compare SuperServe with INFaaS and note that INFaaS is designed to "pick the most cost-efficient model that meets the [specified] accuracy constraint" [18,45,46]. However, in the presence of unpredictable, bursty request rates, the choice of the model accuracy to serve in order to meet the SLO requirements is unknown. Since, unlike SuperServe, INFaaS does not automatically discover the accuracy of the model to serve under unpredictable request rates and instead requires queries to be hand-annotated with accuracy thresholds, we choose to run INFaaS with no accuracy thresholds provided (§6.3.1,§6.3.2). In such a scenario, it reduces to serving the most cost-efficient model (which is the model with the minimum accuracy). We confirmed this behavior with the INFaaS authors, who agree that "[our] representation of INFaaS as a baseline that always chooses the same model is correct in the absence of an accuracy threshold, or a fixed (never changing) accuracy threshold." [18].

Subnet-Profiling. We use a ResNet-based SuperNet trained on ImageNet [15] and Transformer-based SuperNet trained on MNLI [55]. We extract pareto-optimal SubNets (Φ_{pareto}) by running NAS (publicly released by [8]) on the trained SuperNet. The pareto-optimal SubNets in the ResNet-based and Transformer-based SuperNet span accuracy ranges of $73-80\%$ and $82-85\%$ respectively. The SubNets are profiled with varied batch sizes on Nvidia RTX2080Ti.

Test bed. SuperServe is implemented in 17.5k lines of C++. gRPC [23] is used for communication between the client, the router and workers. The experiments use 8 RTX2080Ti GPUs and 24 CPU cores, with each worker assigned one GPU.

(a) Serving CNNs on MAF Trace **(b)** Serving Transformers on MAF Trace **(c)** SuperServe System Dynamics

Fig. 8: SuperServe on Real World Trace. SuperServe on Microsoft Azure Functions (MAF) [48] trace. (a, b) SuperServe achieves the best tradeoffs w.r.t. SLO attainment and accuracy when serving both Convolution and Transformer neural networks. (c) System dynamics w.r.t. batch size and subnet activation control decisions over time in response to ingest rate in (a).

6.2 End-to-End: Real Workloads

We investigate if: (a) SlackFit is capable of achieving a better trade-off between SLO attainment and mean serving accuracy on real workloads (**R1-R2**), and (b) SubNetAct contributes to serve highly unpredictable workloads at high SLO attainment.

We use the MAF trace [48] to evaluate SuperServe (similar to Clockwork [25]). The trace is collected on Microsoft's serverless platform and serves as a reasonable workload to evaluate SuperServe as serverless ML inference is an active research area [30, 57]. It consists of number of invocations made for each function per minute and contains nearly 46,000 different function workloads that are bursty, periodic, and fluctuate over time. We use 32,700 function workloads from the MAF trace. The 24-hour-long trace is shrunk to 120 seconds using *shape-preserving* transformations to match our testbed. We use the mean ingest rate of 6400 qps and 1150 qps to serve convolution and transformer networks respectively on MAF.

Result. Fig. 8a compares SuperServe with Clipper$^+$ and InFaaS when convolution and transformer networks are served on the real-world MAF trace. While serving CNNs, SuperServe achieves an SLO attainment (**R1**) of 0.99999 (five '9's). Compared to Clipper$^+$ and InFaaS , SuperServe is 4.65% more accurate (**R2**) at the same level of SLO attainment. It also achieves a 2.85x factor improvement in SLO attainment at the same mean serving accuracy. While serving transformers, SuperServe achieves a 1.2x factor improvement in SLO attainment at the same mean serving accuracy or 1.72% higher accuracy at the same SLO attainment level.

System Dynamics. Fig. 8c shows the ingest throughput (qps), serving accuracy, and batch size control decisions made by SlackFit for serving CNNs on the MAF trace. As seen in the figure, the trace contains periodic short-interval spikes that reach upto 8750 qps, demonstrating the agility of the system. SlackFit selects both smaller accuracy model and higher batch size during the load spikes to meet the deadline (**R1**). SlackFit makes such control decisions because it uses query's slack as a signal to maximize batch size. As the query slack decreases, it selects maximum batch size control parameters in the lower latency buckets. Furthermore, these control decisions increase the system throughput instantly through SubNetAct. Lastly, SlackFit serves higher accuracy models when the ingest rate is low and hence, achieves better mean serving accuracy (**R2**).

6.3 End-to-End: Synthetic

We aim to answer the following questions, whether SuperServe (a) *automatically* serves queries using appropriate models (accuracy) for different traces (**R2**), (b) achieves a better trade-off w.r.t. the success metrics (**R1-R2**), (c) withstands sharp bursts while maintaining high SLO attainment (**R1**) and (d) *instantaneously* changes system throughput. To answer these questions, we evaluate SuperServe by serving CNNs on the bursty and time-varying traces (§6.1).

6.3.1 Baseline comparison with burstiness

Fig. 9 compares SuperServe with the baselines over a range of traces increasing mean ingest rate λ_v across and CV_a^2 down. All traces are configured with 36ms SLO. Achieving high SLO attainment (**R1**) and high mean serving accuracy (**R2**) is desirable, which implies the *best trade-off is in the top-right corner of the graph*. We demonstrate that no single choice of a model is *sufficient* for different mean arrival rates and CV_a^2. For instance, the SLO attainment of Clipper$^+$(76.69) decreases as the CV_a^2 increases for $\lambda_v = 5550$ (row 3). Similarly, the SLO attainment of Clipper$^+$(78.25) decreases with increase in λ_v for $CV_a^2 = 2$ (column 1). We draw the following takeaways: **(1)** SuperServe achieves a significantly better trade-off between SLO attainment and accuracy (**R1-R2**) than the baselines (Clipper$^+$ and InFaaS). It is 4.33% more accurate than the baselines at an SLO attainment level of 0.9999 and 2.06x higher SLO attainment at the same accuracy level. SuperServe is consistently at the top-right corner in Fig. 9 across all the traces. **(2)** SlackFit *automatically* selects appropriate models for sustaining different traffic conditions. As λ_v increases, SuperServe reduces serving accuracy while maintaining high SLO attainment (columns).

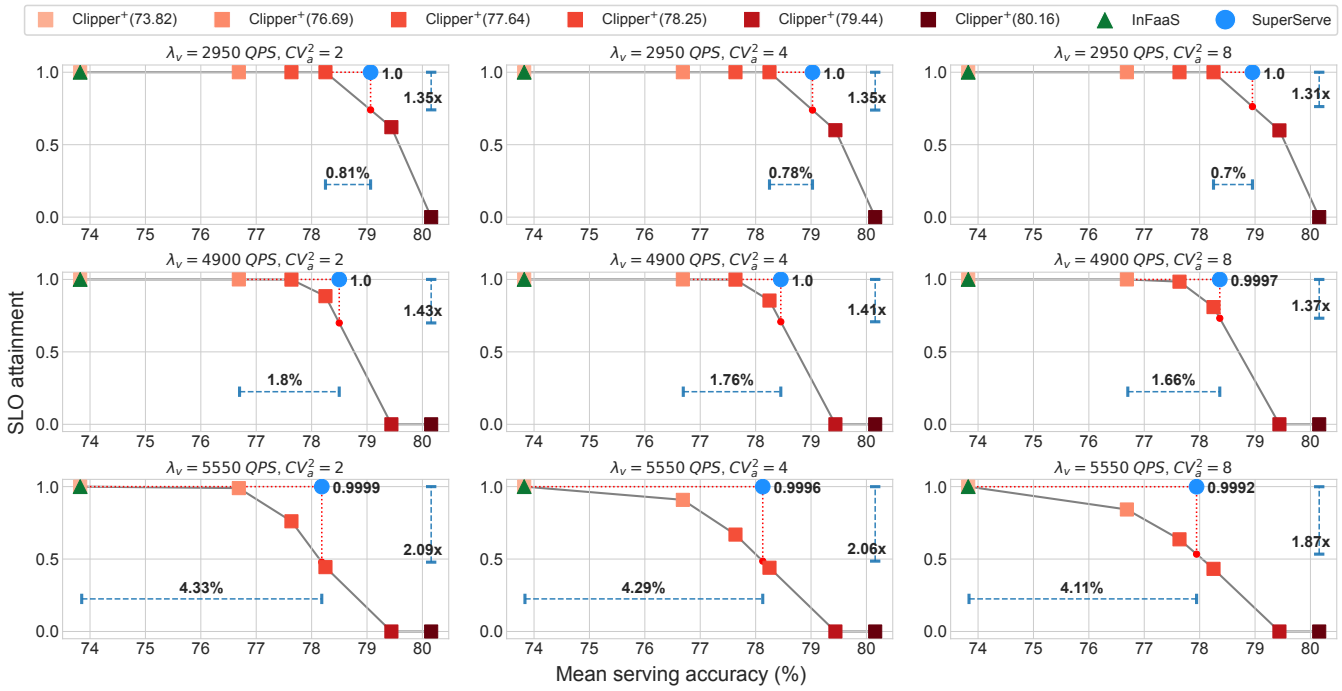


Fig. 9: SuperServe with variable burstiness. SuperServe outperforms Clipper$^+$ and INFaaS baselines by finding better tradeoffs and consistently achieving > 0.999 SLO attainment on bursty traces. Variable ingest rate $\lambda_v = \{$ 2950, 4900, 5550$\}$ q/s increases vertically (down). $CV_a^2 = \{2,4,8\}$ increases horizontally (across). SuperServe achieves a better trade-off in SLO attainment (y-axis) and mean serving accuracy (x-axis) in all cases. SuperServe consistently achieves high SLO attainment > 0.999.

Note that, across all the traces, InFaaS achieves an optimal SLO attainment but with a significantly smaller mean serving accuracy (by up to 4.33%) than SuperServe. InFaaS's policy serves the min-cost (and hence min accuracy) model for the trace without accuracy constraints. Whereas, SuperServe achieves a better trade-off between the success metrics because (a) SubNetAct allows in place activation of different subnetworks *without* affecting SLO attainment (**R1**); (b) SlackFit opportunistically selects higher accuracy models based on query's slack (**R2**). Also, the difference between SuperServe and Clipper$^+$ narrows w.r.t. accuracy as CV_a^2 increases, since SlackFit switches to lower accuracy models more frequently with burstier traffic. The system dynamics are detailed in Appendix A.3.

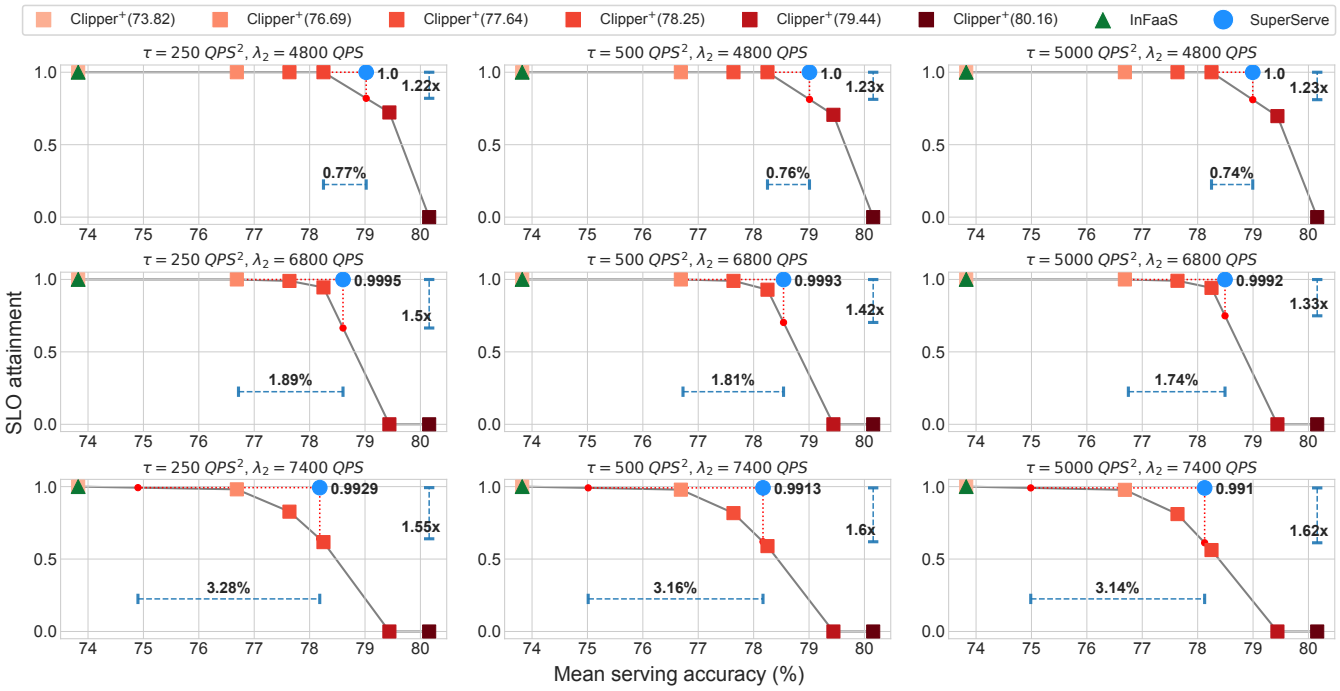
6.3.2 Baseline comparison with arrival acceleration

Fig. 10 evaluates SuperServe's performance at different levels of arrival rate change (i.e., arrival *acceleration*). Traces start at λ_1 and increase to λ_2 with acceleration τ. Traces fix $\lambda_1 = 2500 qps$ and $CV_a^2 = 8$ but change λ_2 and acceleration τ .

The τ and λ_2 are chosen to demonstrate that single, pre-configured model choices are inadequate to sustain different rates of arrival (mean λ) and acceleration (τ). Clipper$^+$(79.44) starts diverging as τ increases (λ_2 is 6800 qps (row 2)). Similarly, Clipper$^+$(79.44) starts diverging with increase in λ_2 ($\tau = 250\ q/s^2$ (column 1)). The key takeaways are:

- SuperServe *rapidly* scales system throughput and achieves a high SLO attainment (0.991-1.0) even with high values of τ (5000 q/s^2). The experiment demonstrates two key properties of SuperServe— (a) the *actuation delay* in SuperServe is indeed negligible, (b) the lower *actuation delay* helps achieve higher SLO attainments for time-varying traces (**R1**). SuperServe empirically demonstrates "agile elasticity" (§2), and withstands high acceleration in arrival rate (τ).
- SlackFit *dynamically* adjusts the serving accuracy over time (**R2**) and achieves a better trade-off between success metrics (**R1-R2**). When the mean ingest throughput is low (λ_1), SuperServe uses higher accuracy models. It quickly switches to lower accuracy models when mean arrival rate is high (λ_2), as evident in system dynamics Fig. 13b.

Fig. 10 experiments exhibit interesting trends. As the τ increases, the gap between SuperServe and Clipper$^+$ w.r.t. mean serving accuracy narrows. This is because SlackFit selects smaller accuracy sooner with the increase in τ. Lower τ values give enough time to SuperServe to serve intermediate mean arrival rates with higher accuracy models while gradually moving to lower accuracy models as mean ingest rate increases to λ_2 qps. Whereas, InFaaS continues to serves min accuracy model for all traces as its policy doesn't maximize accuracy by design.



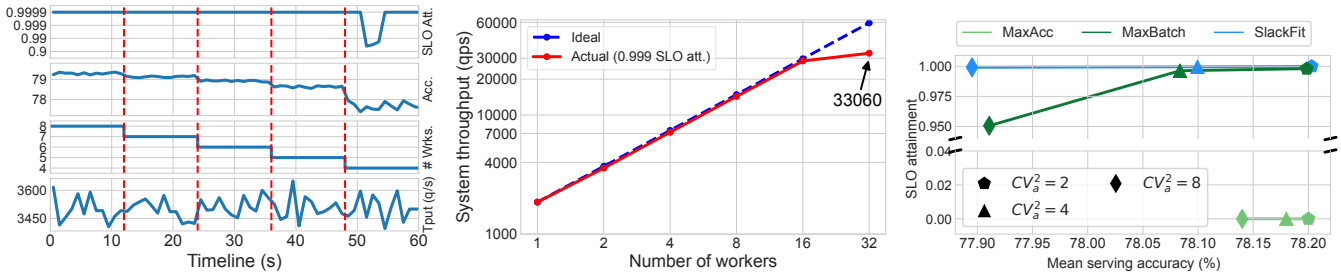


Fig. 10: SuperServe with arrival acceleration. SuperServe outperforms Clipper$^+$ and INFaaS baselines by finding better tradeoffs on time varying traces. Mean ingest rate accelerates from λ_1 to λ_2 q/s with τ q/s^2. $\tau = \{250, 500, 5000\}$ increases horizontally (across), while $\lambda_2 = \{4800, 6800, 7800\}$ increases vertically (down) with $\lambda_1 = 2500$ q/s and $CV_a^2 = 8$ staying constant. SuperServe finds a better trade-off in SLO attainment (y-axis) and mean serving accuracy (x-axis).

(a) Fault-Tolerance **(b)** Scalability **(c)** Policy-SE

Fig. 11: SuperServe's Micro-benchmarks. (a) SuperServe resiliency to faults. The system maintains high SLO attainment by dynamically adjusting served accuracy as workers drop out over time. The trace stays statistically the same ($\lambda = 3500$ qps, $CV_a^2 = 2$ (last row)). **(b)** SuperServe scales linearly with the number of workers, achieving up to 33000 qps while maintaining high .999 SLO attainment. **(c)** SlackFit finds the best tradeoff on the SLO attainment/ accuracy maximization continuum automatically (§6.4).

6.4 Microbenchmarks

Fault Tolerance. SubNetAct mechanism provides an additional advantage of transparent fault tolerance. We run SuperServe with 100% capacity (8 workers) with a bursty traffic trace ($\lambda = 3500$ qps, $CV_a^2 = 2$) for 60 seconds and gradually kill a worker every 12 seconds to simulate faults. SuperServe shows resilience to decreases in system throughput to as low as 50% by maintaining SLO attainment as high as 0.999 for the unchanging trace as it leverages subnetwork activation to serve lower accuracy models automatically. Similar methodology was used in [54]. Fig. 11a shows SLO attainment as a function of time (along with other system dynamics). As the faults occur (workers killed, dotted red lines), SuperServe *automatically* transitions to lower accuracy models to maintain high SLO attainment. We attribute SuperServe's fault tolerance to (a) a wide-dynamic throughput range afforded by SubNetAct (Fig. 5c) that allows SuperServe to serve the workload even with 50% capacity, and (b) SubNetAct's low actuation delay that provides *agility* to rapidly increase system-throughput (during faults) without SLO violations (**R1**).

Scalability. We assess if SuperServe reaches high SLO attain-

ment at scale. To show this, we scale the number of workers and observe the maximum throughput SuperServe sustains to reach SLO attainment of 0.999. We serve ResNet-18 [27] across all the workers with clients providing a batch of 8 images[4]. Scalability experiments are conducted with $CV_a^2 = 0$. Fig. 11b shows sustained ingest throughput with the increase in workers. SuperServe achieves an SLO attainment of 0.999 while reaching throughputs as high as $\approx$ 33000 qps.

Policy Space Exploration. We compare different policies implemented in SuperServe (Fig. 11c). We show that SlackFit achieves the best tradeoff w.r.t. our success metrics compared to both MaxAcc (greedily maximizes accuracy) and MaxBatch (greedily maximizes throughput) as CV_a^2 is varied. Details of the policies and the experiment are in §A.5.

7 Related Work

Training SuperNets was first proposed by OFA [8]. Recent works such as CompOFA [47] and BigNAS [58] propose improvements to the SuperNet training. CompOFA makes the training of SuperNets faster and more accurate by training a fewer number of SubNets simultaneously. On the other hand, BigNAS trains the SuperNet in one-shot with a wider range of SubNets. DynaBERT [28] trains a SuperNet based on the Transformer architecture for text datasets. Similarly, AutoFormer [12] trains SuperNets derived from vision transformers. NasViT [22] trains the SuperNet for semantic segmentation tasks and achieves a better trade-off between accuracy and latency. SuperServe provides system support for serving Supernets trained using any existing technique. We believe that SuperNets are an emerging phenomenon, and system support for serving them is the need of the hour.

Model serving systems can be divided into two categorizes — a) Non-Automated, and b) Automated. *Non-automated serving system* expect developers to provide the prediction models and make explicit choices in the accuracy-latency trade-off space. TensorFlow Serving [40] serves the models trained in TensorFlow framework while Clipper [14] and Triton [39] support models trained from multiple frameworks. Clockwork [25] guarantees predictable tail latency for DNN inference by making cross-stack design decisions explicitly for worst case predictability. Inferline [13] provides support for provisioning inference pipelines that consist of multiple models, but the models are still hard coded in the pipeline vertices. Prior works in this category are complementary to SuperServe. For instance, SuperServe's workers can be made more predictable by consolidating choices like Clockwork. Inferline's autoscaling policy can be used on top of SuperServe. Triton's model optimizations can be done to the SuperNet itself.

In contrast, *automated serving systems* [3, 4, 45, 61] automate the navigation of the accuracy-latency trade-off space with a policy, resulting in automatic DNN selection at runtime. However, both [45] and [61] use state-of-the-art DNNs (e.g., ResNets, MobileNets) and rely on model loading mechanisms instead of SuperNets, which offers better pareto-optimality and orders of magnitude faster model switching enabled via proposed SubNetAct. More importantly, these mechanisms implicitly bias their policies to avoid model switching, which limits their ability to respond to bursty request rates in an agile fashion. Specifically, InFaaS's DNN switching policy is biased towards selecting the least accurate DNNs that satisfy accuracy constraints, as the goal of the stated goal of the system is to satisfy constraints instead of treating accuracy as an optimization objective. Proteus [3] formulates the accuracy scaling problem as an MILP. However, the accuracy scaling action remains coarse-grained as MILP solver is invoked every 30 seconds in Proteus. Such coarse-grained decision-making has limitations like InFaaS: SLO violations with high actuation delays. Moreover, Proteus's batching technique is complementary to SlackFit. It introduces a delay in scheduling to account for heterogeneous resources. Such delays can be introduced in SlackFit to extend it to heterogeneous resources. Loki [4] tackles accuracy and hardware selection for ML inference pipelines. Extending fine-grained decision-making to ML inference pipelines is future work. SuperServe supports model serving via SubNet activation, thus addressing the model switching overhead and enabling fine-grained decision-making for bursty workloads.

8 Conclusion

We describe a novel mechanism SubNetAct that carefully inserts specialized control flow operators into SuperNets to enable a resource-efficient, fine-grained navigation of the latency-accuracy tradeoff space. SubNetAct unlocks the design space of reactive scheduling policies. We design a simple, yet effective greedy heuristic-based scheduling policy SlackFit. SuperServe, which uses SubNetAct and SlackFit, achieves 4.67% better accuracy at the same level of SLO attainment or 2.85x better SLO attainment at the same level of accuracy compared to state-of-the-art inference serving systems.

A Appendix

A.1 SubNetAct: Automatic Operator Insertion

We introduce SubNetAct's control flow operators automatically. Specifically, the LayerSelect operator is introduced at every stage of $\mathcal{M}$, and each block within the stage (such as Bottleneck in OFAResNets [8] or TransformerBlock in Dynabert [28]) is converted to a boolean module whose boolean handle is tracked by the LayerSelect operator. Each convolution or attention layer of $\mathcal{M}$ is modified by wrapping it with the WeightSlice operator. Finally, all the batchnorm layers in $\mathcal{M}$ are converted to the SubnetNorm operator with additional information provided to it about each subnet's tracked statistics. The algorithm to automatically enable control flow operations in M is provided in Alg. 1.

Input: Supernet Arch. $\mathcal{M}$, Supernet Weights W, Tracked Mean and Variances $TrackedStats$

```
newOperators = {}
for s ∈ STAGES(M) do
    // layerSelect operator selects layers within each stage
    ls = LAYERSELECT()
    newOperators[s] = {}
    for m ∈ GETMODULES(M, s) do
        if m.type == Bottleneck || m.type ==
          TransformerLayer then
            bool select_m // boolean switch for layer
            m_new = TOBOOLMODULE(m, select_m)
            // layerSelect controls boolean of stage's layers
            ls.REGISTERBOOL(select_m)
        end
        else if m.type == Attention || m.type == Conv then
            // WeightSlice applied to attn or conv layers
            m_new = WEIGHTSLICE(m.type, W[m.id])
            newOperators[s][m.id] = m_new
        end
        else if m.type == BatchNorm then
            // SubnetNorm only applied to BatchNorm
            m_new=SUBNETNORM(W[m.id], TrackedStats)
            newOperators[s][m.id] = m_new
        end
        MODIFYMODULE(M, m, m_new)
        newOperators[s]["layerSelect"] = ls
    end
end
REGISTERCONTROLFLOWOPS(M, newOperators)
```

Algorithm 1: Introducing SubNetAct Operators in Supernets. The algorithm introduces control-flow operates to enable SubNetAct for latency/accuracy navigation. The pre-requisites to enable SubNetAct are trained weights and architecture of the supernet that are obtained from existing NAS approaches [8, 28, 47, 58].

A.2 SubNet Profiled GFLOPs

As discussed in §4.2, SlackFit bucketizes SubNet $\phi \in \Phi_{\text{pareto}}$ and batch size $|B|$ using three properties. While Fig. 6 showed that inference latency increases monotonically with both batch size (**P1**) and accuracy (**P2**), the analytical basis for it is shown in Fig. 12. This heatmap of GFLOPs (Giga Floating Point Operations) quantifies the computational demand for each pair of neural network model architecture (SubNet ϕ) and batch size ($|B|$). Fig. 12a and Fig. 12b demonstrate that the computational demand for any SubNet ϕ increases as its batch size increases. Moreover, SubNets with higher accuracy require more FLOPs in both Transformer-based and Convolution-based SuperNets. Thus, given a specific hardware (in our case NVIDIA RTX2080Ti GPU), the inference latency increases as computational demand from (SubNet ϕ, $|B|$) increases, validating properties **P1** and **P2**.

Finally, the FLOPs distribution also shows multiple instances where the FLOP count for lower accuracy SubNet with higher batch size is similar to or less than the FLOP for a higher accuracy SubNet with lower batch size. For e.g., in Fig. 12b, (73.82, BS16) requires FLOPs slightly less than (80.16, BS2). This reduced GFLOP demand influences the inference latency, and allows lower accuracy SubNets to serve higher batch sizes at similar latencies as higher accuracy SubNets with lower batch sizes, validating **P3**.

A.3 System Dynamics: Synthetic Traces

We also derive key observations from the dynamics to understand how SuperServe achieves high SLO attainment and better trade-offs (**R1-R2**) for synthetic traces.

Fig. 13 shows the system dynamics of SuperServe for both bursty and time-varying traces. The mean ingest rate of the bursty traces is 7000 qps and they vary in $CV_a^2 = \{2, 8\}$. Similarly, in case of the time-varying traces, the ingest rate is increased from λ_1 qps to λ_2 qps at varying accelerations $\tau = \{250\ q/s^2, 5000\ q/s^2\}$. The control decisions made by SlackFit (subnetwork (accuracy) and batch size) are shown over time.

Fig. 13a shows system dynamics for the bursty traces. The trace with $CV^2 = 8$ (blue line) has higher spikes than the trace with $CV^2 = 2$ (orange line). First, note that SuperServe operates at an accuracy range of $76 - 78\%$ and never selects a higher accuracy subnetwork such as the subnetwork of 80.16% accuracy. This is because the subnetwork of 80.16% accuracy diverges at the mean ingest rate of 7000 qps (also seen in Fig. 9 last row). Hence, SuperServe *automatically* selects appropriate subnetworks for different mean ingest rates. Moreover, SuperServe uses lower accuracy models more frequently with increasing CV_a^2. This is because increased jitter reduces query slack, causing SlackFit to pick lower latency buckets more often. This corroborates the trend seen in Fig. 9 where the mean serving accuracy of SuperServe monotonically decreases as CV_a^2 increases. Lastly, during the load spikes, SlackFit usually selects control parameters with high batch size and smaller subnetwork (§4.2.1). This control decision allows SuperServe to drain the queue faster, resulting in a high SLO attainment on the traces (**R1**).

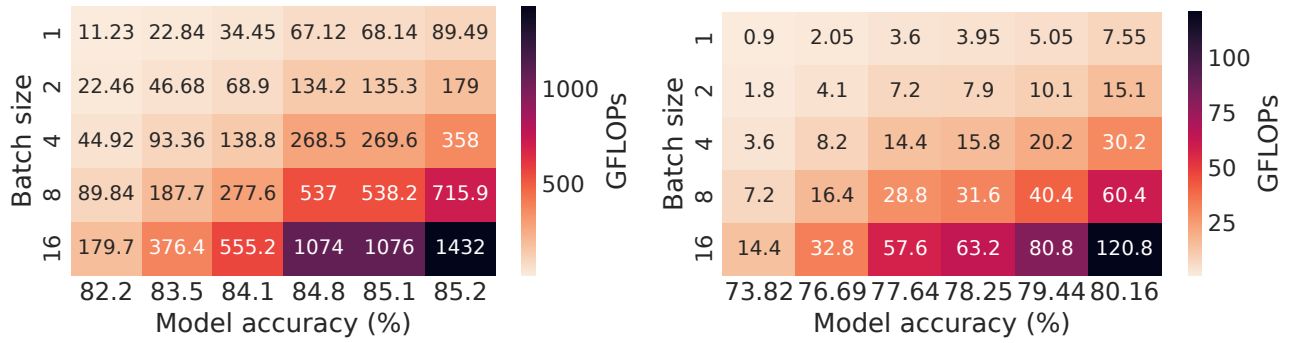

Fig. 13b shows the system dynamics for the time-varying traces. $\tau = 5000\ q/s^2$ (blue line) increases the ingest rate from 2500 qps to 7400 qps faster than $\tau = 250\ q/s^2$. For both the traces, SuperServe dynamically changes the accuracy from ≈ 79.2 to ≈ 77.5 as mean ingest rate increases. SuperServe's ability to dynamically adjust accuracy helps it achieve a higher mean serving accuracy (**R2**) compared to serving a single model statistically. Moreover, for $\tau = 5000\ q/s^2$, SuperServe jumps to lower accuracy and higher batch size control parameters quickly. While, for for $\tau = 250\ q/s^2$, SuperServe uses intermediate models to serve the intermediate ingest rate during $\approx 60 - 80$ seconds. A higher τ value forces query's slack to reduce drastically. Hence, SlackFit rapidly switches to selecting control parameters of smaller subnetwork and higher batch size from the low latency buckets (§4.2) to satisfy deadlines (**R1**). Therefore, increase in τ decreases mean serving accuracy (a trend observed in Fig. 10 across the rows).

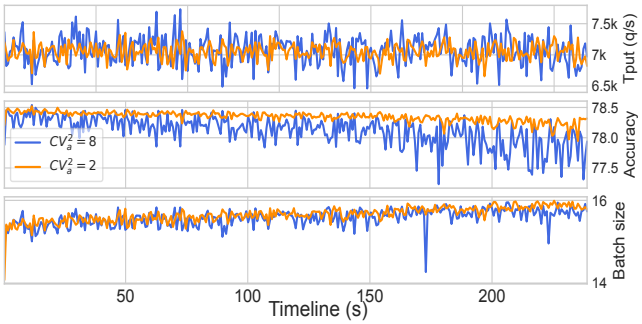
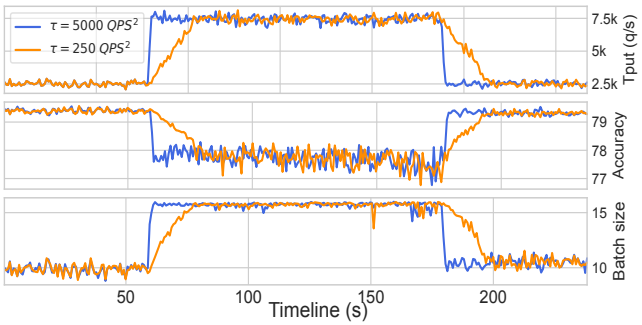
A.4 Scheduling policies

The core functionality of the SuperServe's scheduler is to maximize (a) SLO attainment and (b) prediction accuracy for any arrival trace dynamics. The scheduler offers a pluggable policy framework to support any application sensitivity to these metrics by allowing arbitrarily different trade-offs between them. SuperServe policy interface dictates that control decisions are made w.r.t. the batch size and subnetwork to activate. Both of these control parameters affect SLO attainment and serving accuracy. This is because the scheduler a) perpetually operates under a latency constraint and b) these control decisions have a cumulative effect over time (e.g., higher accuracy affects queue build-up later). Finding a globally optimal set of batch size and subnetwork control tuples over time is NP-hard. As our control decisions must be made on the critical path of queries' end-to-end latency, quick sub-millisecond control decision making is a key performance requirement. Thus, to meet the real time requirements, we primarily consider scheduling policies that are greedy w.r.t. time. The policies decide the batch size and subnetwork based on the remaining slack of the most urgent query. The slack is calculated using a fast (sub-ms) $O(1)$ EDF queue lookup operation.

A.5 Policy Design Space



MaxBatch Policy. This policy first maximizes the batch size and then the accuracy. It greedily finds a maximal batch size (b) for the smallest accuracy subnetwork that fits within latency slack θ.Within the chosen batch size MaxBatch finds



(a) Transformer-Based SuperNet

(b) Convolution-Based SuperNet

Fig. 12: SlackFit control parameter space. FLOPs for six different pareto-optimal SubNets in SubNetAct as a function of accuracy (x-axis) and batch size (y-axis) shown for both transformer and convolution-based supernet. The FLOPs are *monotonic* with batch size and accuracy. This trend in FLOPs forms the analytical basis of the trend in the inference latency of these models (as shown in Fig. 6).

(a) Dynamic accuracy and batch size control: bursty traces

(b) Dynamic accuracy and batch size control: time-varying

Fig. 13: System Dynamics on Synthetic Traces. Accuracy and batch size control decisions shown over time in response to ingest throughput (q/s). (a) bursty traces $\lambda = 7000 = (\lambda_b = 1500) + (\lambda_v = 5500)$ with burstiness of $CV_a^2 = 2$ (orange) and $CV_a^2 = 8$ (blue). (b) time varying traces accelerate from $\lambda_1 = 2500$ q/s to $\lambda_2 = 7400$ q/s with acceleration $\tau = 250q/s^2$ (orange) and $\tau = 5000q/s^2$ (blue). Batch size and subnetwork activation control choices over time show how SuperServe reacts to each of the four plotted traces in real time. This illustrates dynamic latency/accuracy space navigation.

the maximum accuracy subnetwork (s) such that the profiled latency $L(b,s) < \theta$. It returns the control choice (b,s). This policy leverages insights (**I1**) and (**I2**). It takes O($log(B)$) operations to find b and O($log(S)$) operations to find s (binary search on monotonically increasing latency w.r.t. batch size and accuracy). As a result, this lightweight policy scales well with the profile table, taking only O($log(B) + log(S)$) operations to make control decisions.

MaxAcc Policy. MaxAcc first maximizes the accuracy and then the batch size. Mirroring MaxBatch, MaxAcc performs a binary search for the largest accuracy (s') with $L(1,s') < \theta$ first. Then, it finds the maximal batch size (b') keeping the subnetwork choice fixed to the chosen s', such that $L(b',s') < \theta$ ms. Similarly to MaxBatch policy, it leverages insights (**I1**) and (**I2**) and takes O($log(B) + log(S)$) operations to return the control choice (b',s').

The proposed SlackFit Policy. This is our best performing policy. At a high level, SlackFit partitions the set of feasible profiled latencies into evenly sized latency buckets. Each bucket consists of control tuples (b,s) with $L(b,s)$ within the range of bucket width. Then the policy chooses a bucket with latency $\leq \theta$. Finally, from the choices within the selected bucket, it picks the control choice that maximizes batch size. Intuitively, selecting control parameters closest to slack θ configures the system to operate as close to capacity as possible.In other words, choices with latency less than that either reduce the throughput capacity or the serving accuracy, eventually lowering system's SLO attainment and accuracy. This draws on the monotonicity insights (**I1**) and (**I2**). SlackFit's novelty is in insight (**I3**). We observe that SlackFit *dynamically* detects and adapts to the runtime difficulty of the trace. A well-behaved trace (e.g., low ingest rate, variation, acceleration) results in higher θ. Higher θ leads to the choice of higher latency buckets. And higher latency buckets are correlated strongly with fewer control tuple choices (Fig. 6), maximizing the probability of choosing higher accuracy models. Conversely, mal-behaved traces (higher ingest rate, variation, acceleration) lead to lower latency bucket choices, as the scheduler is operating under much lower θ conditions. There

are more control choices in lower latency buckets, which leads to control tuples within those buckets to favor higher batch sizes. This leads to processing the queue faster.

Experiment Result. In Fig. 11c we show that SlackFit achieves the best tradeoff w.r.t. our success metrics compared to both MaxAcc – a policy that greedily maximizes accuracy and MaxBatch — a policy that greedily maximizes batches. The traces used mean $\lambda = 7000$ qps $((\lambda_b = 1500) + (\lambda_v = 5550))$ and $CV_a^2 \in \{2, 4, 8\}$. SlackFit reaches the highest SLO attainment(0.999) for all CV_a^2. MaxBatch starts under performing w.r.t. SLO attainment with CV_a^2 increase. The SlackFit and MaxBatch difference is most pronounced at the highest CV_a^2, eventually causing a significant 5% drop in the SLO attainment. Both policies maximize the batch size within latency slack θ when operating under small θ. When θ increases, however, MaxBatch continues to maximize the batch size unconditionally—a greedy choice that leads to packing larger batches. This greedy decision causes more time to be spent in a worker compared to SlackFit, which adaptively shifts to higher accuracy models under larger θ conditions with compound effect on queued queries, eventually missing their SLOs. maxAcc is unable to keep up with this trace. It never switches to policy decisions that process the queue faster. This policy comparison shows a continuum between faster queue processing and serving higher accuracy, with SlackFit automatically finding the best point in this continuum.

Pineapple: Unifying Multi-Paxos and Atomic Shared Registers*

Abstract

Linearizable storage systems reduce the complexity of developing correct large-scale customer-facing applications, in the presence of concurrent operations and failures. A common approach for providing linearizability is to use consensus to order operations invoked by applications. This paper explores designs that offload operations (from the consensus component) to improve overall performance.

This paper presents Pineapple, which uses logical timestamps to unify Multi-Paxos and atomic shared registers so that any node in the system can serve read and write operations. Compared to Multi-Paxos (or leader-based consensus), Pineapple reduces bottlenecks at the leader. Compared to Gryff, which unifies EPaxos and atomic shared registers, Pineapple has better performance because Pineapple has "*non-blocking* operation execution."

Our evaluation shows that Pineapple improves both throughput and tail latency, compared to state-of-the-art systems (e.g., Gryff, Multi-Paxos, EPaxos), in both wide-area networks and local-area networks. We also integrate Pineapple with etcd. In a balanced workload, Pineapple reduces median latency by more than 50%, compared to the original system that uses an optimized version of Raft.

1 Introduction

Large-scale customer-facing applications increasingly rely on linearizable storage systems. These systems ensure that a service is highly available and consistent in the presence of concurrent operations and node crashes. Modern applications prefer strong consistency over weaker consistency, because it simplifies application logic, which then significantly lowers the effort in development and maintenance [11, 15, 17, 19].

One common solution for developing linearizable storages is using consensus. Multi-Paxos [36, 39] and Raft [53], two popular leader-based consensus algorithms, have been adopted in many production storage systems, e.g., Google Spanner [17], Microsoft Azure Storage [11], Redis [2], RethinkDB [4], CockroachDB [3], and etcd [1]. To improve performance, this paper explores approaches that offload reads and writes from the leader to followers (or non-leaders).

Targeted Workloads. We focus on linearizable storages designed for large-scale web applications. For scalability and availability, these applications often rely on variations of key-value storages, NoSQLs, or NewSQLs, whose performance could be improved using our design.[1] Most modern storages support reads and writes on a single key-value pair, e.g., Cassandra [35], etcd [1], Redis [2], and Memcached [7, 52].

Example large-scale web applications that heavily use such single-key reads or writes include Facebook inbox search [35], WeChat's user account management [73], and Microsoft's OneDrive [15]. In these applications, the program logic and data models allow the developers to use single-key operations efficiently. For example, WeChat creates table(s) as per user account [73], and Microsoft uses a versioned object storage as the backend for OneDrive [15].

In fact, the need to optimize read and write performance can be found in many real-world systems. For example, WeChat designs PaxosStore [73] that uses a combination of quorum and leader lease to reduce latency for reads and writes. Google's Spanner [17] and Microsoft's Giza [15] use variations of techniques to achieve similar goals (e.g., Spanner's TrueTime and Giza's adoption of Fast Paxos [38]).

Performance studies from Facebook [7, 9] also support the goal of improving read and write performance: (i) Only 0.2% of operations involve a write in their distributed data store for social graph TAO; and (ii) 97% of operations are reads, writes, or deletes in Facebook's usage of RocksDB, a key-value store.

Pineapple. Motivated by these observations, we propose Pineapple, a high-performance *linearizable key-value storage*

*The work was partially done when the first three authors were with Clark University. First two authors have equal contribution. This material is based upon work supported by the National Science Foundation under Grant No. CNS-2045976 and CNS-2449640.

[1] In typical NoSQL databases, an entire row can be treated as a single key-value pair. Hence, our design could be compatible with data models in similar systems. For conciseness, the paper is focused on key-value storages.

that offloads reads and writes from the leader of Multi-Paxos to followers. As in [37,43,46,61], we assume that an operation touches a single key or a set of keys, where each key uniquely identifies an object (or a piece of data). With a slight abuse of terminology, we use "key" and "object" interchangeably. Pineapple supports three operations (definitions in §2.1):

(i) reading the value from a single key,
(ii) writing a value to a single key, and
(iii) performing a one-shot transaction [34], which either accesses or updates the values of a set of keys, or provides a stronger synchronization (e.g., read-modify-write, fetch-and-add, compare-and-swap), or both.

Pineapple: Blind Writes and One-shot Transactions. The single-key write in Pineapple is in fact a "blind write," which overwrites an existing key-value pair. While not as powerful as conditional writes, blind writes are still applicable to many web applications. For instance, many storage systems, such as Cassandra, Spanner, HBase, RocksDB, Redis, and etcd, support blind writes. Moreover, useful features for web applications can be implemented using blind writes. Examples include versioned objects for Microsoft Giza [15] and Amazon S3, and data structures with associative and commutative properties (e.g., data structures with statistical or probabilistic properties like Histogram and Hyperloglog) [12].

Pineapple supports one-shot transactions, which can be represented as *stored procedures* [34,48,49]. In these transactions, clients (or applications) send the transaction logic to servers, and the servers execute them *atomically*, without client interaction during the process. Additionally, the transactions' input and output key sets are known a priori. Therefore, servers can execute the transactions (once they are ordered) without further interaction with the clients.

While less powerful than general transactions, one-shot transactions are sufficient for many web applications [10,49]. For example, one-shot transactions can automatically update multiple users' accounts (e.g., money transfers) on payment platforms. They can also enable a scan or range query for files on cloud object-based storage. A key-value store, which provides only single-key reads/writes, and Gryff [10], which provides only single-key reads/writes/read-modify-writes, are not sufficient for supporting these operations. An application either has to sacrifice guarantees (e.g., relaxed consistency when doing a range query) or use general transactional storage (potentially with lower performance on single-key operations).

Pineapple: Key Techniques. Pineapple uses a quorum-based leaderless approach (ABD [8]) to serve reads and writes on a single key-value pair and relies on a leader-based consensus (Multi-Paxos) to agree on the order of one-shot transactions. Even though it is *not* as intuitive to combine a leaderless design with a leader-based one, such unification not only simplifies the overall design, but also improves performance.

Interestingly, we do not need a completely new design to unify the two components. In particular, we use a mature technique – logical timestamps – to unify Multi-Paxos and ABD. The main technical contribution is our insight to combine them together so that they can work seamlessly together, even in the period of leader change or leader failure.

Pineapple: Highlights. Pineapple provides the following features that would favor widespread adoption.

- Pineapple offloads single-key reads and writes to follower nodes. This helps reduce tail latency for reads and writes and increase overall throughput.
- In a 3-node system, Pineapple guarantees that single-key reads complete in 1 round-trip time (RTT). With more nodes, reads can complete in 1 RTT if there is no concurrent one-shot transaction or write on the same key.
- Pineapple supports one-shot transactions that can access or update the values of a set of keys and provide stronger synchronization power.
- All operations supported by Pineapple have "*non-blocking* execution," i.e., a node can execute any operation, after communicating with the leader or a quorum.

These features jointly allow Pineapple to improve performance over state-of-the-art systems, e.g., Gryff [10], Multi-Paxos, PQR [13], EPaxos [46], in both wide-area networks and local-area networks over a wide spectrum of workloads.

Non-blocking operation execution is a natural feature in consensus algorithms like Multi-Paxos and Raft. To improve performance, recent systems often choose to separate ordering and execution phases, causing the executions of some operations *blocking*. For example, EPaxos and Gryff need to resolve dependency before execution. PQR needs to wait for committed log entries before executing reads.

As we will see in §4, such blocking operation executions cause longer tail latency and reduced throughput. Moreover, the blocking nature is not ideal for practical deployment, because a slow node (e.g., due to intermittent connection issues, misconfigurations or garbage collection events [23,24,50]) could impact latency and throughput unexpectedly.

Pineapple also has one appealing feature for practitioners. Pineapple is built upon mature techniques that are well understood and tested, e.g., Mutli-Paxos, ABD (or quorum-based approach), and logical timestamps. Fundamentally, Pineapple adds one more round of communication into Multi-Paxos so that it could interact with ABD atomic registers. Therefore, we believe that our design of Pineapple could potentially be more straightforward to understand and integrate with production systems that use leader-based consensus.

Existing Solutions. There are roughly four categories of solutions on improving the performance of consensus-based linearizable storages: (i) a completely new consensus algorithm that relies on different assumptions and models, e.g., [6,23,24,37,44,46,54,55], (ii) a variant of existing consensus algorithm that better utilizes new hardware such as RDMA or SDN, e.g., [5,40,45], (iii) an engineering or software solution

	Latency			(Fast) Quorum Size	Non-blocking Exe.	Limitations
	Read	Write	Other			
Multi-Paxos [36]	1/2			$\lfloor n/2 \rfloor + 1$	all ops	leader bottleneck
PQR [13]	1/1	1/2	1/2	$\lfloor n/2 \rfloor + 1$	non-read ops	leader bottleneck & read tail latency
EPaxos [46]	1/2			$f + \lfloor (f+1)/2 \rfloor$	-	long tail latency
Gryff [10]	1/2	2/2	2/3	$f + \lfloor (f+1)/2 \rfloor$	reads and writes	lower throughput & no support of multi-key ops
Pineapple (this work)	1/2	2/2	2/3	$\lfloor n/2 \rfloor + 1$	all ops	3-RTT one-shot transactions

Table 1: **Pineapple vs. closely related systems.** • All of the systems tolerate up to f crashed nodes with $n = 2f+1$ nodes.
• The first number in Latency columns indicates the RTTs in the case of no conflict (for EPaxos, Gryff, and Pineapple's read) or the RTT in the case when the operation is served from a leader node (for Multi-Paxos, PQR and Pineapple's write and one-shot transactions, and the second is the RTT with conflict (for EPaxos, Gryff, and Pineapple's read) or the RTT in the case when the request is served from a follower node (for Multi-Paxos, PQR's writes and Pineapple's one-shot transactions. "Other" represents RMW for Gryff and one-shot transactions for other systems.
• The second column specifies the quorum size for Multi-Paxos, PQR, and Pineapple and the fast quorum size for EPaxos and Gryff.
• An operation has "*non-blocking* execution" if it can be executed immediately upon learning a decision of its ordering.

to scale an existing consensus algorithm, e.g., [14, 61, 64, 69], and (iv) a new algorithmic component that is integrated with an existing consensus algorithm, e.g., [10, 13, 31, 37, 38].

Table 1 compares key features between Pineapple and closely related systems. (More discussion on other related work in §5.) Pineapple belongs to category (iv). Two notable recent systems in this category are PQR [13] and Gryff [10]. PQR improves Multi-Paxos's performance by offloading reads to followers. Gryff allows any node to perform reads, writes and Read-Modify-Writes (RMWs) by unifying EPaxos [46] and atomic shared registers [8, 30]. Both demonstrate improved latency or throughput over prior solutions such as Multi-Paxos and EPaxos under workloads for web applications. Compared to Pineapple, there are a few limitations in PQR and Gryff:

- In PQR, only reads are offloaded to followers; hence, other operations can still saturate the leader.
- In PQR, reads have "*blocking* execution," i.e., reads may not be executed immediately and have to wait for a committed entry from the leader. The effect of blocking executions, which leads to longer latency, can be observed even during a light workload without leader change.
- Gryff's throughput is generally lower than *both* EPaxos and Multi-Paxos due to its more complicated execution logic and extra message overhead.
- Gryff's operations can *only* access or update a *single* key. In other words, it doesn't support one-shot transactions. Many operations used by modern web applications are not supported by Gryff. (More details in §2.3.)
- Gryff's RMWs have "blocking execution," i.e., the execution of RMW needs to wait until all the prior dependency have been resolved and executed. This is because Gryff uses a variant of EPaxos to handle RMWs. Our evaluation shows that such blocking execution affects both tail latency and throughput.

Pineapple: Performance. We evaluate Pineapple in both local-area networks (LAN) and wide-area networks (WAN). Our evaluation shows that Pineapple improves performance in both cases. In both WAN and LAN, Pineapple has roughly 10% to 20% of improvement over the closest competitor (i.e., EPaxos and PQR) in throughput when RMW ratio is less than 20%. As for tail-latency in WAN, Pineapple generally has better read tail latency than Multi-Paxos and PQR with low-conflict workloads, in 3-node and 5-node deployments.

We also integrate Pineapple with etcd [1], a backend system used by many large-scale production systems such as Kubernetes. We replace its consensus layer (powered by Raft [53]) by Pineapple. Pineapple improves median latency by more than 50% in LAN, under a YCSB balanced workload [16]. This demonstrates that our design effectively improves latency in an optimized production system.

Outline. We first discuss the preliminaries in §2. We then present our design of Pineapple and its analysis in §3. We evaluate Pineapple in §4. Related work is presented in §5.

2 Preliminaries and Background

2.1 System Model and Shared Objects

This paper is focused on systems consisting of n nodes (or servers) in a point-to-point communication network. Up to f nodes may fail by crashing, e.g., stopping execution at any point of time. We assume $n = 2f+1$.

The system is assumed to be *asynchronous*. That is, there is no upper bound on the time a message takes to be delivered, and there is no upper bound on the relative speed at which nodes proceed. Due to the asynchrony assumption, a failure is not detectable by others. Pineapple ensures safety with asynchrony. Reads and writes can be completed under asynchrony, due to the adoption of ABD registers [8]. One-shot transactions satisfy liveness under *partial synchrony* [22] – when there is a stable leader that can communicate with a quorum, then one-shot transactions are guaranteed to be completed.

Shared Objects. The system consists of m shared objects (i.e., key-value pairs) that can be accessed and updated concurrently.[2] Each object is uniquely identified by a key (or an

[2]The assumption of m is only for easiness of presentation. In practical

identifier). Pineapple provides the following three types of operations. Any client connects to a Pineapple node can use the interface to access or update any of the m shared objects:

- Read(k): it returns the value of key k;
- Write(k, v): it updates the value of key k to value v; and
- OT($f(\cdot), K_{input}, K_{output}$): it takes three parameters – a function $f(\cdot)$ and two sets of keys – and it atomically performs the following three steps:
  (i) read the values of input key set, i.e., $V_{input} \leftarrow$ values of key set K_{input}
  (ii) compute the value of output key set, i.e., $V_{output} \leftarrow f(V_{input})$
  (iii) update the values of key set K_{output} to V_{output}.

By definition, $|V_{input}| = |K_{input}|$ and $|V_{output}| = |K_{output}|$, where $|S|$ denotes the cardinality of a set S. K_{input} and K_{output} may have different sizes and may not have any overlap.

This definition of one-shot transactions captures a wide range of "transactions" used in modern large-scale applications. For example, $y \leftarrow x + 1$ can be represented as OT($f(\cdot), \{x\}, \{y\}$), where $f(v) = v + 1$.

Another common usage is "conditional write." For example, the following function can be used for a one-shot transaction that implements an atomic counter that starts with a default value 0 and increments by 1 when invoked:

$$f(v) = \begin{cases} v+1, & \text{if } v \text{ is non-empty} \\ 0, & \text{otherwise} \end{cases}$$

Here we assume that a returned value is empty (or null), if an object is not initialized yet.

The function $f(\cdot)$ can take multiple inputs, which is useful to support richer semantics like compare-and-swap. (An example can be found in §2.3.) An alternative view is that one-shot transactions can perform the If/Then/Else logic over any subset of the m objects "*atomically*."

Linearizability. Pineapple achieves linearizability [30], which requires that concurrent operations appear to execute in some total order O such that (i) O is consistent with the interface (i.e., it is legal with respect to the semantics), and (ii) O is consistent with the real-time ordering constraint. That is, for any operation o_1 completes before the invocation of operation o_2, o_1 must appear before o_2 in the total order O.

2.2 Ordering Read/Writes w/o Consensus

Herlihy's wait-free hierarchy [29] defines different synchronization power of shared objects in asynchronous systems. For example, atomic shared registers that provide read and write operations on a single key have the weakest synchronization power, whereas consensus objects provide the strongest power. This hierarchy explains why there exists a non-blocking linearizable solution for ordering reads and writes for atomic registers, but not for consensus objects.

systems, objects can be dynamically created or deleted.

The difference between atomic register and other objects in the wait-free hierarchy is that each write completely defines the state of the single object *without* any reliance on a previous state. As a result, the total ordering does not have to be "stable." In other words, the ordering does *not* need to be observed by all nodes. Only the operations that are required by real-time ordering constraints need to be observed by all nodes.

An implication of such an observation is that a node i can safely apply a write, say o_{24}, which comes with the largest logical timestamp that i has seen so far. Node i can apply o_{24}, even if it does not know any prior writes. Suppose at some later time, i receives an earlier write, say o_8, it can safely ignore that write because it already has a more recent state (as defined by o_{24}). This is why the usage of logical timestamp is sufficient for atomic shared registers. Note that because of asynchrony, operations may be received in an arbitrary order.

Multi-Writer ABD. We briefly discuss the multi-writer variant [42] of ABD [8], which allows multiple concurrent writer clients to read or write a single key. It associates a tag $t = (ts, id)$ with each key where ts is a logical timestamp and id is the identifier of the writer proxy, i.e., the ID of the proxy node that handles the write for the client. Writes and reads can be ordered lexicographically using the associated tags, to obtain the desired total ordering for linearizability.

For each key, a node stores a value v and the tag t where t is the largest tag a node has observed so far. Both reads and writes have two phases – get and put phase. In the get phase, reads learn the value to be returned, whereas writes learn the largest tag from a quorum. In the put phase, both operations need to ensure that a quorum has obtained the information – this phase ensures real-time ordering.

A read begins with reading the tag and value from a quorum. Upon receiving responses, the reader proxy then retrieves the value v^{max} with the largest tag t^{max} from them. Then the proxy transmits (v^{max}, t^{max}) to a quorum and waits for acknowledgments. Once a quorum of acknowledgements is collected, the proxy returns v^{max} to the reader client.

A writer proxy p follows the same two-phase structure. The difference is that in the put phase, the proxy transmits the value to be written with a new tag $t = (t^{max}.ts + 1, p)$. Upon receiving a quorum of acknowledgement of the second phase, the proxy lets the writer client knows that the write has been completed. Since there is no guarantee that all the writes will be observed in the same order at each node, the ordering observed be each node at any point of time is "*non-stable*." That is, the order might change in the future.

Consensus and SMR. On the contrary, consensus or state-machine replication (SMR) [59] requires a "stable" ordering. More concretely, the nodes have to agree on the same sequence of operations, so the state machine at each node can apply these operations one by one starting from the beginning of the sequence. Since the operations are deterministic, nodes are guaranteed to obtain the same state upon the execution

of the j-th operation in the sequence. Here, the sequence of operations is exactly the total ordering O required by the linearizability correctness property [30].

The reason that SMR's ordering is "*stable*" is that the position of an operation in the sequence will not change; otherwise, the linearizability guarantee could be violated. In comparison, the ordering of shared registers may change due to asynchrony. In the example above, node i may initially think that o_{24} is the first write. It is only until that i receives o_8, it learns that o_{24} should occur later in the ordering. However, because of the semantic of shared registers, such a non-stable ordering still suffices for linearizability.

The difference between stable and non-stable ordering also makes it difficult to use atomic shared registers to implement an SMR system.

2.3 Challenges

RMW and Gryff's solution. Gryff is focused on one-shot transactions that access only a single key, namely RMWs. RMWs require a stable ordering because its outcome depends on a previous state. Using the terminology introduced in §2.1, a previous state is the values of the keys specified in the second parameter K_{input}. Without a stable ordering of operations, the outcome of applying RMWs may lead to inconsistency.

More formally, suppose $K_{input} = K_{output} = \{k\}$ and $f(\cdot)$ defines a compare-and-swap (CAS):

$$f(old, new) = \begin{cases} new, & \text{if value of } k = \text{old} \\ \text{value of } k, & \text{otherwise} \end{cases}$$

Consider the case of a write o_8 that updates the value of key k to 8, and a RMW o_{24} with $f(\text{empty value}, 24)$. Now the order of how nodes apply these two operations matters. If the ordering is not stable, it is possible that node i applies o_8 before o_{24} and node j applies o_{24} before o_8. As a result, two nodes will have divergent states, even if they eventually receive and apply both operations.

Gryff [10] uses a novel design, called Consensus-After-Register timestamps (or carstamps), to enforce the stable ordering of RMWs, while allowing writes and reads to order in a non-stable manner. Gryff uses ABD [8] to order reads and writes (the "register" part), and uses EPaxos to order RMWs (the "consensus" part). The RMWs are ordered after some writes (the "after" part).

With carstamp, Gryff then uses EPaxos to keep track of dependency and execution order. In the prior example, assume o_{24} has observed o_8. By design, every node that applies o_{24} must wait until it has applied o_8. This ensures linearizability, but results into *blocking* execution in Gryff's RMWs.

Multi-Key Operations. Next, we discuss why it is non-trivial to extend ABD and Gryff to handle operations that may access or update multiple keys, namely multi-key operations. Figure 1 presents an example that shows why reading and writing each key separately using ABD is insufficient to support scan operations, i.e., an operation that returns the value of multiple keys. In the discussion below, let $\text{scan}(x, y)$ represent a scan operation that returns the values for keys x and y atomically.

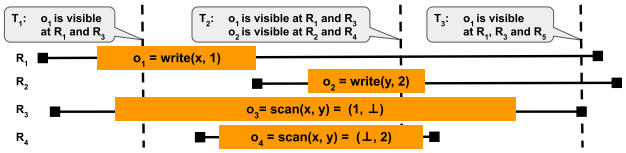

Figure 1: **An example of four operations in a five-node system.** The left dot and right dot represent the invocation time and completion time, respectively.

In this strawman example, a $\text{scan}(x, y)$ performs two ABD reads in parallel – one reading key x and the other reading key y. Suppose there are five replicas (R_5 is not shown for brevity) and four operations o_1 to o_4 such that:

- At time T_1: the write o_1 is visible only at R_1 and R_3;
- At time T_2: the write o_1 is visible only at R_1 and R_3, and the write o_2 is visible only at R_2 and R_4;
- At time T_3: the write o_1 is visible at R_1, R_3 and R_5; This is because the put phase of the ABD reads of o_3 helps propagate the value to a quorum, even though the operation o_1 has not completed at this point.

Now, consider the two scans:

- Scan o_3 returns $(x, y) = (1, \perp)$. This is possible if o_3 completes the get phase of two parallel ABD reads at T_1 with quorum R_1, R_3, R_5.
- Scan o_4 returns $(x, y) = (\perp, 2)$. This is possible if o_4 completes the get phase of the two parallel ABD reads at T_2 with quorum R_2, R_4, R_5. These nodes only know o_2 but not o_1, as at T_2, only R_1 and R_3 know o_1.

Consequently, we have "*incomparable*" operations. That is, in the total ordering that one needs to construct for linearizability, o_3 cannot be placed before nor after o_4. This is because such an incomparable scenario is impossible on a single machine.

This example can be extended for any algorithm, including Gryff, that does not perform coordination between different keys. Pineapple addresses this issue by relying on the leader to decide the order of multi-key operations. For example, if R_3 is the (Multi-Paxos) leader which orders o_3 before o_4, then o_4 will return $(1, 2)$, making the two operations comparable.

3 Pineapple: Design and Analysis

This section presents the design and analysis of Pineapple. We focus on the operations on a single key k and the common case when there is no leader change. That is, the one-shot transactions defined in §2.1 have $K_{input} = K_{output} = \{k\}$. Note that in this case, Pineapple provides the same semantic as Gryff. Hence, we will use "RMWs" and "one-shot transactions" interchangeably in the following presentation. Appendix A presents the generalization to multiple keys and how Pineapple handles the case when leader changes.

Algorithm 1 Pineapple: ABD Component at Node N_i

Write($key, value$) invoked by Writer Proxy N_i:
1: *// Get phase: obtain tag*
2: **send** $\langle$GET-TAG$, key\rangle$ **to all**
3: **wait until** receiving $\langle$ACK-TAG$, key, ps_j\rangle$ **from quorum** Q
4: $ps^{max} = (tag^{max}, slot^{max})$ is largest pstamp received from all $j \in Q$
5: $ps^{new} \leftarrow ((tag^{max}.ts + 1, i), slot^{max})$
6: *// Put phase: propagate write request*
7: **send** $\langle$PUT$, key, ps^{new}, value\rangle$ **to all**
8: **wait until** receiving $\langle$ACK-PUT$, key\rangle$ **from quorum**

Read() invoked by Reader proxy N_i:
9: *// Get phase: obtain value and tag*
10: **send** $\langle$GET-VALUE$, key\rangle$ **to all**
11: **wait until** receiving $\langle$ACK-VALUE$, key, value_j, ps_j\rangle$ **from quorum** Q
12: $ps^{max} = (tag^{max}, slot^{max}) \leftarrow$ largest pstamp received from all $j \in Q$
13: $v^{max} \leftarrow$ value associated with ps^{max}
14: *// Put phase: propagate learned value*
15: **send** $\langle$PUT$, key, v^{max}, ps^{max}\rangle$ **to all**
16: **wait until** receiving $\langle$ACK-PUT$, key\rangle$ **from quorum**
17: return v^{max}

Background Handlers at node N_i:
18: **Upon receiving** $(\text{GET-TAG}, key)$ **from** N_j:
19: **send** $\langle$ACK-TAG$, key, Storage_i[key].ps\rangle$ **to** N_j
20: **Upon receiving** $(\text{PUT}, key, ps_j, value_j)$ **from** N_j:
21: **if** $Storage_i[key].ps < ps_j$ **then**
22: $\quad Storage_i[key].ps \leftarrow ps_j$
23: $\quad Storage_i[key].value \leftarrow value_j$
24: **send** $\langle$ACK-PUT$, key\rangle$ **to** N_j
25: **Upon receiving** $(\text{GET-VALUE}, key)$ **from** N_j:
26: **send** $\langle$ACK-VALUE$, key, Storage_i[key].value, Storage_i[key].ps\rangle$ **to** N_j

Algorithm 2 Pineapple: Multi-Paxos Component at Leader N_l

RMW($f(\cdot), \{key\}, \{key\}$) invoked by Pineapple Leader N_l:
1: *// Get phase: obtain most recent values*
2: **send** $\langle$GET-VALUE$, key\rangle$ **to all**
3: **wait until** receiving $\langle$ACK-VALUE$, key, value_j, ps_j\rangle$ **from quorum** Q
4: $v^{max} \leftarrow$ value w/ largest ps^{max} received from all $j \in Q$ ▷$l \in Q$
5: $v^{new} \leftarrow f(v^{max})$ ▷`Apply RMW`
6: $ps^{new} \leftarrow (ps^{max}.tag, slot_i + 1)$ ▷`Increment slot index`
7: *// Put phase: propagate output*
8: **send** $\langle$PUT$, key, v^{new}, ps^{new}\rangle$ **to all**
9: **wait until** receiving $\langle$ACK-PUT$, key\rangle$ **from quorum**

3.1 Pineapple: Design

Pstamps: Timestamp for Pineapple. Similar to how Gryff uses carstamps, Pineapple uses a variation of timestamp – pstamps (which stands for Pineapple timeSTAMPs). Pstamps is a composition of tag used by ABD and the slot index uses by Multi-Paxos. Formally, pstamp p is a tuple $(tag, slot)$, where

- tag is an ABD tag – a tuple (ts, id) such that ts is the logical timestamp and id is the ID of the writer proxy;
- $slot$ is a positive integer that represents the slot index of the Multi-Paxos component.[3]

As in [8, 10, 42, 63], each write or RMW is associated with a unique pstamp, and Pineapple uses pstamps to determine the order of operations. These pstamps can be ordered lexicographically. That is, for two pstamps $p = (tag_p, slot_p)$ and $p' = (tag_{p'}, slot_{p'})$, we say that $p > p'$ if and only if:

- $tag_p.ts > tag_{p'}.ts$;
- $tag_p.ts = tag_{p'}.ts$ and $tag_p.id > tag_{p'}.id$; or
- $tag_p.ts = tag_{p'}.ts$ and $tag_p.id = tag_{p'}.id$ and $slot_p > slot'_p$

Interaction between ABD and Multi-Paxos. In Pineapple, ABD handles reads and writes, whereas Multi-Paxos takes care of RMWs. These two components use pstamps to interact with each other – both use pstamps to determine which operation is more recent.

ABD runs as usual by using the tag part in pstamps. Writes only updates the tag part, whereas reads need to use the ordering of pstamps to decide which value to return. The value returned could be a value generated by a write or a RMW.

Multi-Paxos in Pineapple needs to do one more round of communication, compared to the original Multi-Paxos. This is because the leader might not be in the quorum for an ABD write. More concretely, the leader performs the following steps to complete a RMW with $f(\cdot)$:

- Contact a quorum Q, which includes the leader itself, to retrieve the value v^{max} that has the largest pstamp ps^{max};
- Apply RMW by computing $f(v^{max})$. Let the output be v^{new}; and
- Compute new pstamp ps^{new} as $(ps^{max}.tag, slot_i + 1)$.
- Transmit (v^{new}, ps^{new}) to all and wait for an acknowledgement from a quorum.

The comparison of pstamps is defined in §3.1. Moreover, the quorum Q must include the leader itself, as in the common case with a stable leader, the leader has the most recent information about prior RMWs. This is also the reason that in the third step, the leader can update the pstamp by incrementing the local slot index $slot_i$ directly.

In the case when leader fails or changes, the leader N_l will use the meta-data of Multi-Paxos, e.g., ballots (not presented for conciseness), to detect such a scenario. Then Pineapple will need to participate in Phase 1 (the prepare phase) of Multi-Paxos to figure out the next leader. In this period, some operations might not be able to make progress. Same as other consensus algorithms, e.g., Multi-Paxos and Raft, Pineapple requires partial synchrony to elect a new stable leader and ensure liveness. Appendix A presents more details.

Furthermore, ABD reads in Algorithm 1 needs to be modified slightly so that they do not return inconsistent results when a leader change. Appendix A.2 discusses the extension.

Pineapple: Pseudo-code and Correctness. Algorithm 1 presents the ABD component of Pineapple. The logic is iden-

[3] In the full version of Pineapple, the slot index also needs to include necessary meta-data for Multi-Paxos, e.g., the ballot and leader ID. Such information is needed for handling leader changes. To keep our discussion concise, the second field is a single integer.

tical to the one described in §2.2, except that Pineapple uses pstamps except for tags. For each key *key*, $Storage_i[key]$ keeps two fields:

- $Storage_i[key].value$: the current value for key *key*, and
- $Storage_i[key].ps$: the associated pstamp.

Pineapple also adopts various optimizations mentioned in [10, 25, 42]. As a result, Pineapple is able to always complete reads in 1 RTT when $n = 3$.

Algorithm 2 presents the Multi-Paxos component, assuming that there is a stable leader N_l. Compared to the original Multi-Paxos, Pineapple needs to do the Get phase to learn the most recent value for the $K_{input} = \{key\}$. The Put phase is basically the same as Phase 2 (the propose phase) in Multi-Paxos, which updates a quorum (of acceptors) with the value generated by the RMW.

Analysis. Since both ABD and Multi-Paxos use a majority quorum, the quorum size is $\lfloor n/2 \rfloor + 1$. As in prior optimizations, ABD can complete on the fast path when the quorum returns the same response. RMW takes 3-RTT if the client is not co-located with the leader. All the operations have non-blocking execution, because they can be executed upon learning a decision either from a quorum or a leader.

Correctness. On a high-level, the correctness follows from three observations: (i) the correctness of ABD to order reads and writes; (ii) the correctness of Multi-Paxos to order RMWs; and (iii) the usage of pstamps to ensure that if a RMW o is visible to any read, then any future operation must also observe o or any operation that has pstamps larger than o's. Appendix B presents the full proof.

We use examples from §2 to provide an intuition on the correctness. First, RMWs go through the leader; hence the ordering is stable. In particular, if the leader sees o_8 when applying RMW o_{24} in the Get phase (Line 1 in Algorithm 2), then other nodes will order o_8 before o_{24}. The reasons that this ordering is stable are: (i) the leader decides the order, which holds true by the design of Multi-Paxos, even when there is a leader change; and (ii) the pstamps correctly capture the fact that o_{24} happens after o_8 – which is due to the design that the leader increments slot index (Line 6 in Algorithm 2).

Second, multi-key operations, such as scans and MSETs, are also ordered by the leader. Therefore, inconsistency (or incomparability) in Figure 1 is impossible. This is intuitively because that all nodes will observe the sequence (of the slots) following the stable order determined by the leader.

In Figure 1, both scans o_3 and o_4 are served by the leader N_l. Suppose N_l observes o_1, but not o_2 in the Get phase, so it returns $(1, \perp)$ for o_3. When serving o_4, N_l can only return $(1, \perp)$ or $(1, 2)$. This is because the quorum Q at Line 3 in Algorithm 2 must contain N_l itself. In other words, $(\perp, 2)$, an incomparable result in the example from §2, can never be returned by N_l, as it has already observed o_3.

Finally, the reason that writes can be ordered in a non-stable manner is because of the tag part of the pstamps and its semantic. If a node i receives a write with a pstamp larger than its local value, then i can safely overwrite its local value; otherwise, the write can safely be discarded. Furthermore, even though the ordering of concurrent writes is non-stable in general, whenever the leader observes them, the relative ordering between writes and RMWs becomes stable.

More concretely, consider a write w concurrent with a RMW r. We have two cases:

Case I: If the leader observes w during the Get phase, then r must have a larger pstamp, which allows all nodes to ignore w, after applying r. In other words, w *cannot* overwrite r.

Case II: If the leader does not observe w, then there are two subcases: (i) w's pstamp is larger than o's, or (ii) there is another write w' whose pstamp is larger than w and has the same tag part as in r's pstamp.

- In (i), the result of r will be overwritten by w. (The total ordering is r, w.)
- In (ii), w will be discarded by nodes that have applied r. (The total ordering is w, w', r)

In both subcases, linearizability and the semantics are satisfied, because the leader's observation in the Get phase makes the relative ordering among w, w' and r stable.

4 Evaluation

We aim to compare Pineapple with other systems that have similar goals and target general environments that are appropriate for Multi-Paxos. In other words, we target systems that do not make specific assumptions on the hardware or networks. Recall that §1 mentions four categories of solutions that can be used to improve consensus-based linearizable storages. The purpose of our evaluation is focused on category (iv) – understanding the performance of new algorithmic components that are integrated with existing consensus algorithms, since systems in other categories typically adopt different architectures and/or assumptions (more discussion in §5).

We compare Pineapple with five other systems – Multi-Paxos, Multi-Paxos with leader lease, PQR [13], EPaxos [46], and Gryff [10]. We evaluate throughput and latency in both local-area network (LAN) and wide-area network (WAN), with the focus on geo-replicated, large-scale web applications. For these evaluations, we focus on tail latency, because user-perceived latency in these applications is highly correlated with the tail latency of the underlying storage systems [7, 19, 52, 58]. Finally, we compare Pineapple with the optimized Raft in a production system etcd.

4.1 Implementation and Experiment Setup

Implementation. We implement Pineapple, PQR [13], and Multi-Paxos with leader lease in Go using the framework of EPaxos, Gryff and Multi-Paxos from [10, 46] to ensure a fair comparison. In the discussion below, we will use "Paxos

	CA	VA	IR	OR	JP
CA	0.2				
VA	72	0.2			
IR	151	88	0.2		
OR	59	93	145	0.2	
JP	113	162	220	121	0.2

Table 2: **RTT (in ms) between VMs in emulated geographic regions** [10]. For $n = 3$, we use region CA, VA, and IR.

systems" to refer to Multi-Paxos, Multi-Paxos with lease and PQR, as they have similar performance pattern in most cases.

Leases [27, 36, 65, 67, 73] are practical optimizations to reduce communication overhead, by requiring *additional assumptions* on timing (or synchrony). We implement the version of leader lease from [66, 67], which assumes a known bound on clock drift so that only one node holds a lease at a time. In the implementation, the leader can serve reads *without* communicating with another node, while holding the lease. Since we focus on the common case, we assume that the leader has the lease at all time during our evaluation.

We do *not* enable thrifty optimization *nor* batching, because these optimizations generally increase tail latency due to a higher chance of conflicts [10,46,61]. Thrifty operations send some messages to a necessary quorum only; however, it makes EPaxos easier to build a long chain of dependency, and makes nodes wait longer before an operation can be execugted. Since we are targeting large-scale customer-facing applications, we focus on configurations that favor low tail latency.

We also implement Pineapple in etcd by replacing the Raft algorithm. This allows us to study how Pineapple interacts with the other layers of a production key-value system. In addition, etcd persists the states to disk; hence, etcd experiments also allow us to investigate the impacts of persistence.

Testbed. We run our experiments on CloudLab [21] using c6525-25g (AMD 7302P at 3.00GHz, 16 cores, 128 GM RAM) for both node and client VMs. For LAN, the ping latency is around 0.15ms and the configured link bandwidth is 10 Gbps. For WAN, we adopt the same latency profile used in [10,63] – (i) $n = 3$: nodes in California (CA), Virginia (VA), and Ireland (IR); and (ii) $n = 5$: two more nodes in Oregon (OR) and Japan (JP). The WAN latencies are emulated using Linux's Traffic Control (tc) by adding delays to packets on all VMs with filters on different IPs. Table 2 shows the configured RTT between nodes and clients in different regions. These numbers were chosen to represent typical RTT between the corresponding Amazon EC2 availability regions [10, 63].

Experiment Setup. The systems are configured to commit and execute the operations before responding to client requests (close-loop clients). Since as observed in [10, 61, 63], most web applications depend on the confirmation returned by an operation. For example, both Redis [2] and ZooKeeper [32] return results for both reads and writes.

Each experiment is run for 180 seconds, and we collect statistics in the middle of 150 seconds. The statistics collected in this period are quite stable, after the removal of fluctuating numbers during warm-up and cool-down. Following prior setups [10, 46, 61, 63], each object is of 16B. This is because 16B gives the best performance for EPaxos and Gryff. Furthermore, this also reflects real-world observation. For example, the report from Facebook [7] suggests that 40% of the data in their Memcached workload is less than 11B. In Facebook's production TAO system [9, 52], 50% of its requests have the value field smaller than 16B. When evaluating Pineapple in etcd, we test it with a larger object size at 100B.

Following [10, 13, 46, 61, 63], all systems we test store data in memory, except for the etcd experiments. This strategy is reliable as long as the number of *concurrent* node failures is bounded, which is a common case with $n = 2f + 1$ [15, 17, 24]. Moreover, recent hardware solutions are being developed and adopted to prevent data loss from crashed machines, e.g., persistent memory or disaggregated memory [18, 62, 70, 72].

Two operations are said to be "*conflicting*" with each other if they are targeting the same object (or same key) [10, 15, 46, 61, 63]. A conflict rate p means that (i) with a probability p, a client chooses the same key that is defined in advance, and (ii) with probability $1 - p$, a client chooses a unique key.

Our evaluation does not use Zipfian distribution [16, 61], except when using YCSB for etcd experiments, because we want to pick favorable configurations for EPaxos and Gryff. Due to their execution logic, they suffer performance degrade under Zipfian workloads [10, 61].

4.2 Summary of Our Findings

We aim at answering the following questions:

- Does Pineapple improve maximum attainable throughput in both LAN and WAN? (§4.3)
- How do the read/write/RMW latency of Pineapple compare against state-of-the-art systems? (§4.4)
- How does Pineapple perform as the consensus layer in a production system etcd? (§4.5)

To summarize our findings,

- In LAN, Pineapple improves throughput by 10% – 20%, over the closest competitor (EPaxos) when the RMW ratio is less than 20%. In WAN, Pineapple has around 3.5x throughput, over the closest competitor (PQR and Multi-Paxos with lease) in a balanced workload.
- In WAN, Pineapple generally has better read tail latency than Paxos systems in 3- and 5-node deployments under web application workloads [10, 16]. Pineapple has better RMW tail latency than Gryff and EPaxos in a 3-node deployment under workloads with 25% conflict rate.
- We compare the performance of Pineapple and an optimized Raft in etcd [1]. Our evaluation using YCSB [16] shows that Pineapple reduces median latency by 20% to 50% in a balanced workload in LAN.

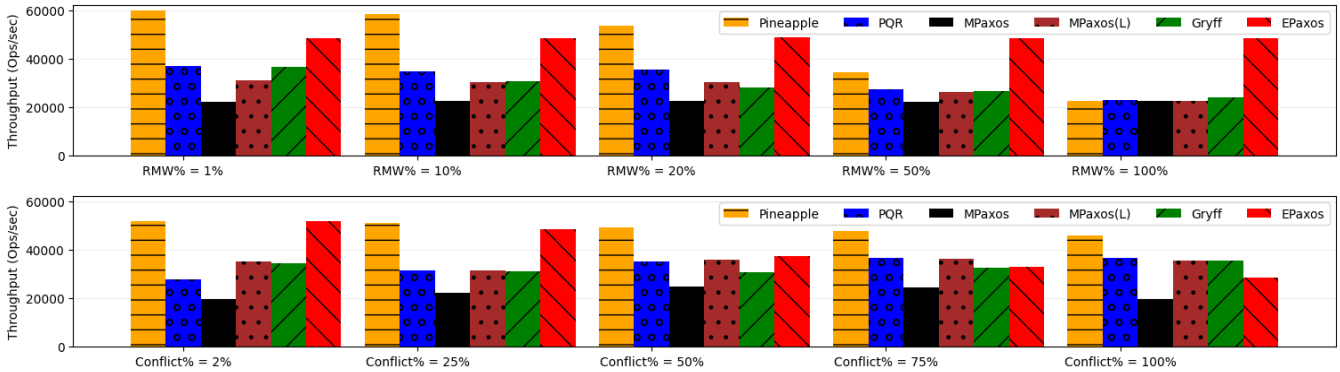

Figure 2: **Maximum attainable throughput in 5-node LAN** ($n = 5$, 49.5% reads, 49.5% writes). Top row varies RMW ratios with conflict rate 25%. Bottom row varies conflict rates with RMW ratio = 20%. MPaxos is the label for Multi-Paxos, whereas MPaxos(L) is the label for Multi-Paxos with leader lease.

4.3 Maximum Attainable Throughput

To achieve maximum throughput, we load each system up to saturation and we collect the median throughput during the period around saturation.

Throughput in LAN. Figure 2 shows the maximum throughput with 1% to 100% RMWs ratio. The remaining operations consist of an equal number of reads and writes. This reflects the balanced workload of YCSB-A [16]. In addition, the numbers help estimate the impact of RMWs and the bottleneck of the leader in Paxos systems and Pineapple.

In this experiment, $n = 5$. Each system requires different number of close-loop clients to saturate (ranging from 150 to 300 clients). In Pineapple, PQR, EPaxos, and Gryff, the clients are evenly distributed so that each node handles the same number of clients. In other two systems, the clients only communicate with the leader node. In PQR and Pineapple, some clients need to communicate with both the leader and one follower node. Top row has conflict rate = 25% so that we capture the effect of conflicting operations.

With RMW ratio $\leq 20\%$, Pineapple has 10% – 20% improvement over EPaxos, the closest competitor. When RMW ratio is 100%, Pineapple is slightly slower than Paxos systems, because RMWs go through the leader and Pineapple's leader needs to process more messages for RMWs.

EPaxos, on the other hand, remains stable throughout different ratios. It has best performance with higher RMW ratios, at around 2.2x over other systems. Compared to Pineapple and Paxos systems, EPaxos's leaderless design improves throughput. Compared to Gryff, it has simpler execution logic.

Bottom row demonstrates that all systems under test, except for EPaxos, have stable throughput under different conflict rates. This is because with higher conflict rates, EPaxos's throughput is affected by its growing dependency graph. Gryff is less affected because only RMWs need to resolve dependency. Multi-Paxos has the worst throughput, across all conflict rates, because of the saturated leader.

Throughput in WAN. In WAN, Pineapple has 4x to 10x throughput, compared to EPaxos, in read-heavy workloads (a variant of YCSB-B), and around 3.5x throughput in balanced workloads (a variant of YCSB-A). This is because as shown in [10, 61], EPaxos's dependency graph is easier to grow in size in WAN, which significantly affects its throughput. Due to page limits, we present details in Appendix C.

In read-heavy workloads, "Multi-Paxos with lease" has best performance, with 1.25x to 1.3x throughput, compared to Pineapple's. This is because with lease, the leader does not need to process as many messages as Pineapple does. In balanced workloads, Pineapple has best performance, which has 3x to 4x throughput improvement over the next closest competitor (PQR and "Multi-Paxos with lease"). This is because the leader in Paxos systems is saturated by writes and RMWs, whereas writes are evenly distributed in Pineapple.

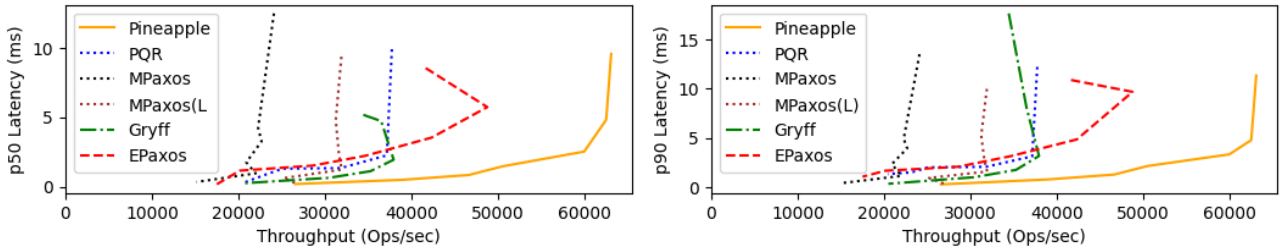
4.4 Latency

4.4.1 Latency-Throughput in LAN

Figure 3 plots the throughput against median (p50) and 90-percentile (p90) latency for all operations by increasing the number of concurrent closed-loop clients (3 to 360) in LAN with $n = 5$. We use a variation of YCSB-A balanced workload with 1% RMWs from [10] and 25% conflicts to measure the impact of RMWs and concurrent operations. Pineapple has around 20% improvement in throughput at saturation. Pineapple in general has smallest p50 and p90 latency across all loads. Gryff has low latency but has limited throughput. This demonstrates that compared to Gryff, the usage of Multi-Paxos in Pineapple effectively improves performance

4.4.2 Latency in WAN

Read-heavy Workload with $n = 3$**.** Same as in [10], we use a variant of YCSB-B [16] workload that contains 94.5% reads,



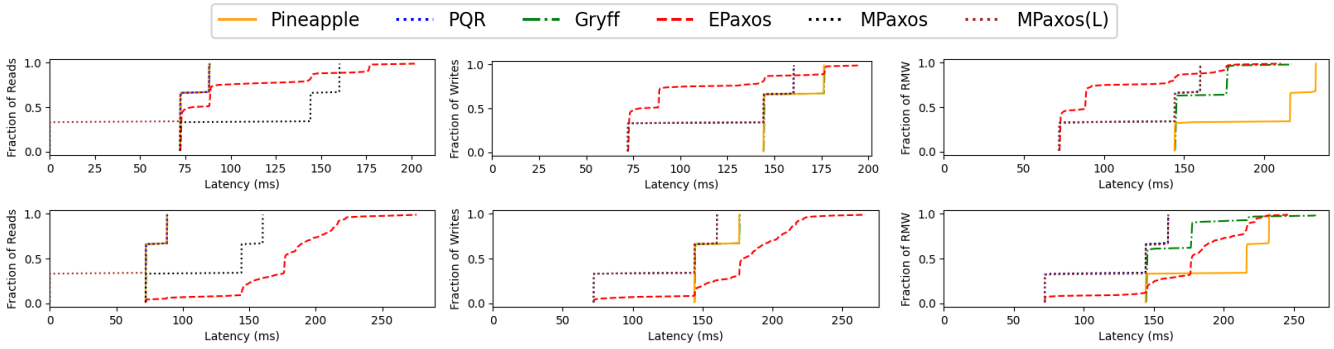


Figure 3: **Latency vs. Throughput in LAN** ($n = 5$, 49.5% reads, 49.5% writes, 1% RMWs, 25% conflict rate). Left figure presents median (p50) latency, whereas right figure presents 90-percentile (p90) latency.

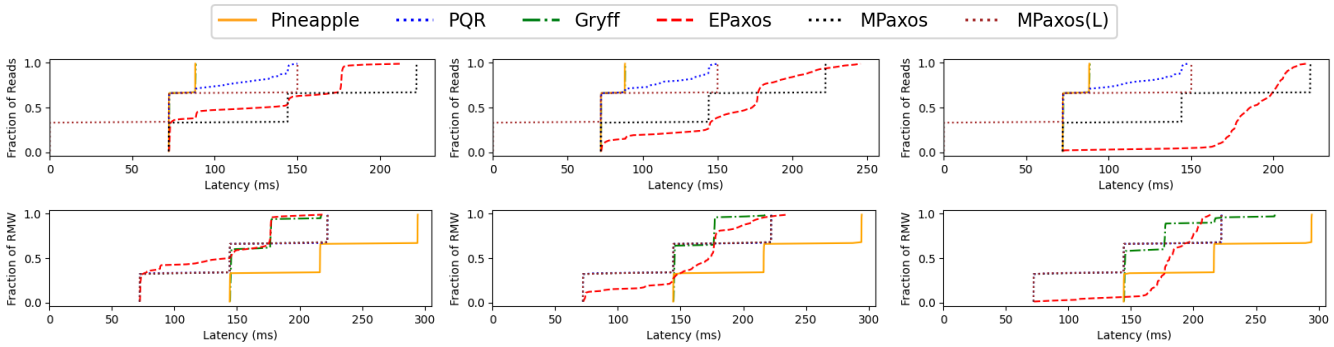
(a) **Reads** (b) **Writes** (c) **RMWs**

Figure 4: **Latency CDF** ($n = 3$, 94.5% reads, 4.5% writes, 1% RMWs). Top row has 2% conflict rate, whereas bottom row has 25%. Both Gryff and Pineapple complete reads in 1 RTT when $n = 3$. Leader of Paxos systems and Pineapple is in VA region.

4.5% writes, and 1.0% RMWs. The focus is on a read-heavy workload to reflect the pattern of web applications [9, 10, 16, 17]. In this set of experiments, the leader node is located in the VA region (c.f. Table 2). This setup is favorable to Paxos systems, as the leader is in the *nearest* quorum for both CA and IR. Following [10], each region has 16 concurrent clients. Figure 4 shows the latency CDF (cumulative distribution function) of all three operations with $n = 3$.

1-RTT Reads in Gryff and Pineapple. For $n = 3$, both Gryff and Pineapple always complete reads in 1 RTT. Figure 4a shows that an operation is completed after nodes spend 1 RTT to the nearest quorum, regardless of the conflict rate.

As in [10, 46, 61], clients and nodes are co-located; hence, RTTs between them is negligible. Clients in VA are closest to the nodes in VA and CA and vice versa for clients in CA. This results in around 66% of the reads completing in the RTT between VA and CA (72 ms). Clients in IR take 88 ms – these are the tail latency for reads.



Stable Performance in Paxos Systems. The leader is in the VA region; hence, the blocking execution of PQR's reads is negligible. This is because the leader is always in the closest quorum. For both writes and RMWs, PQR takes 1 to 2 RTTs to complete. The tail latency is at 160 ms, which occurs when the clients in IR contact the leader in VA (88 ms), which then contacts the nearest quorum (72 ms). $1/3$ of the reads in "Multi-Paxos with lease" have latency close to 0, because the leader can serve them immediately.

Tail latency of RMWs. Pineapple's RMWs take 3 RTT at follower nodes. Thus, the tail latency in Figure 4c is $72 * 2 + 88 = 232$, where the first part is the time from VA to the nearest quorum (CA) and the second part is the time the IR clients take for contacting the leader in VA.

With 2% conflicts and low percentage of non-read operations, Gryff has relatively stable RMW performance. With 25% conflicts, Pineapple has roughly 30 ms improvement at p99 latency relative to Gryff, because the execution of RMWs in Gryff is blocking. EPaxos in general has worse tail latency, due to its dependency tracking.

Blocking Operation Execution. Figure 5 presents the latency CDF for reads and writes under the same workload. To better demonstrate the blocking effect, the leaders are located in CA. PQR's reads cannot complete in 1 RTT, because the leader is not in IR's closest quorum. As a result, the tail latency of PQR is around 70 ms longer than Gryff's and Pineapple's.

Gryff's RMWs has longer tail latency under higher conflicts, because of longer dependency. In this case, due to Pineapple's 3-RTT RMWs, its tail latency is still the largest under low workload. Figure 6 uses exactly the same configuration as in the bottom row of Figure 5c, except with a higher number of clients at 250 clients per region. More concurrent

(a) 2% **conflict rate** (b) 10% **conflict rate** (c) 25% **conflict rate**

Figure 5: **Latency CDF** ($n = 3$, 94.5% reads, 4.5% writes, 1% RMWs). Top row plots the latency CDF for reads, whereas bottom row plots the latency CDF for RMWs. Leader of Paxos systems and Pineapple is in CA region.

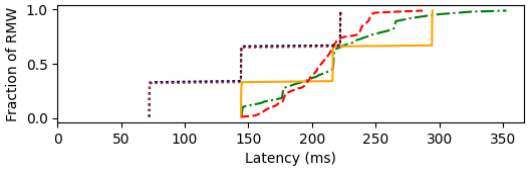


Figure 6: **Latency CDF** ($n = 3$, 94.5% reads, 4.5% writes, 1% RMWs, 250 clients)

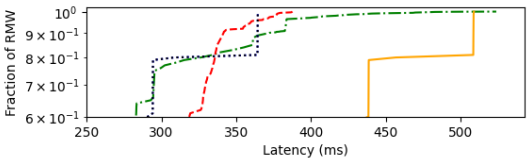

Figure 7: **Log-scale Latency CDF** ($n = 5$, 49.5% reads, 49.5% writes, 1% RMWs, 25% conflict rate, 120 clients).

operations lead to longer RMW tail latency in Gryff.

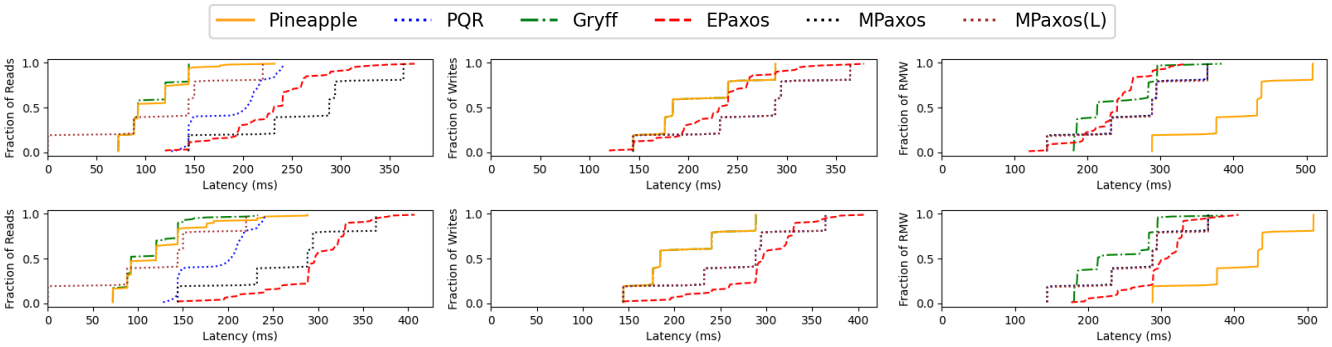
Balanced Workload with $n = 5$**.** We next use the same variant of YCSB-A from [10], which consists of 49.5% reads, 49.5% writes, and 1.0% RMWs with 2% and 25% conflicts. The balance between reads and writes and a higher conflict rate allow us to quantify the impacts of interleaving operations on latency. Figure 8 shows latency CDF for each operation type for $n = 5$. The leader is in the IR region.

1-RTT Reads. For $n = 5$, Gryff often completes reads in 1 RTT with 2% conflict rate (Figure 8a). Pineapple has slightly longer read tail latency, because Pineapple's slower RMWs increase the chance of concurrent operations. When conflict is low, Pineapple completes reads faster than Paxos systems.

2-RTT Writes. As indicated in Table 1, in the worst case, all systems have 2-RTT writes; however, the latency pattern is different as it depends on where the clients are located (Figure 8b). For Gryff and Pineapple, the furthest site is IR; hence, 2 RTTs to the nearest quorum take $2 * 145 = 290$ ms. In comparison, in Paxos systems, the tail latency for JP clients is $145 + 220 = 365$ ms.

Trade-offs. Pineapple has slower RMWs but faster writes and reads than Paxos Systems and EPaxos. It has longer read tail latency than "Multi-Paxos with lease" and PQR with 25% conflicts. Gryff has best latency in most cases under low workload. As a trade-off, Pineapple has better throughput. In these balanced workloads, Pineapple has 3x and 4x throughput, compared to closest competitors (c.f. Appendix C).

Figure 7 uses an identical configuration as in Figure 8, except with 120 clients per region. Under 25% conflicts, Gryff in fact has longer RMW tail latency than Pineapple.



4.5 Performance in Real-World System

We evaluate how Pineapple compares to optimized implementation of Raft in a production key-value storage designed for web applications. We replace the consensus layer in etcd by Pineapple. These experiments use a 5-node etcd deployment with YCSB client (Zipfian workloads with default key-value size 100KB). Each configuration runs roughly 1 to 2 minutes.[4] YCSB's threadcount ranges from 2 to 90. In our experience, this number allows etcd to have the most stable performance.

Figure 9a plots the throughput against p50 and p90 latency for all operations under YCSB-C (100% reads). Raft in etcd adopts the heartbeat-based batching optimization for improving read latency; hence, we use YCSB-C to see how Pineapple compares to a practical optimization. Figure 9b uses a variant of YCSB-A workload with 50% reads, 25% writes/RMWs, which allows us to see the impact of Pineapple's 3-RTT RMWs. Figure 9c uses a variant of YCSB-B workload with 95% reads and 2.5% writes/RMWs.

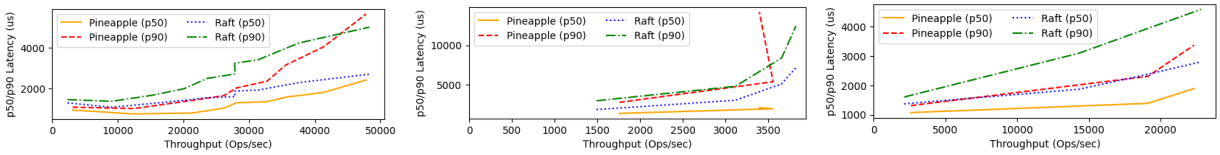


Figure 9a shows that before saturation, Pineapple has around 20% improvement in both p50 and p90 latency in all-read workload. Figure 9b demonstrates that before saturation, Pineapple has 50% improvement in p50 latency. Pineapple

[4]YCSB only allows the configuration on number of operations; hence, the experiment time varies.

(a) **Read** (b) **Write** (c) **RMW**

Figure 8: **Latency CDF** ($n = 5$, 49.5% reads, 49.5% writes, 1%RMW). Top row has 2% conflict rate, whereas bottom row has 25% conflict rate. Leader of Paxos systems and Pineapple is in IR region.

(a) YCSB-C (100% reads) (b) 50% reads, 25% writes/RMWs (c) 95% reads, 2.5% writes/RMWs

Figure 9: **Latency vs. Throughput in etcd**. ($n = 5$, Zipfian workloads)

has higher p90 latency and lower throughput mainly because of the high RMW ratio. However, Pineapple's p90 latency is within 10% and throughput within 15% of Raft. This indicates that Pineapple's RMWs has mild performance impact, when interacting with other components in a real-world system. Figure 9c shows that under read-heavy workload, Pineapple has a similar performance pattern, with 40% to 50% reduction in both p50 and p90 latency. In conclusion, offloading operations effectively reduces latency, even compared to an optimized implementation of Raft.

In these experiments, Pineapple's throughput is not higher, even when we observe the effect of saturated leader. This is mainly because Raft's read optimization enables an efficient disk batching (which is not implemented in Pineapple).

5 Related Work

Consensus is useful for making a service fault-tolerant [59]. Classical consensus uses a single leader, e.g., [33, 36, 39, 53]. Recent systems adopt a multi-leader design that distributes the ordering responsibility evenly to increase performance (e.g., Mencius [44], EPaxos [46], M^{2}Paxos [55], Caesar [6], ATLAS [24]). The multi-leader design uses a graph for keeping track of dependency, which often leads to long tail latency [57].

Recent systems make improvements by utilizing modern assumptions or hardware. For example, Copilot is focused on tolerating slow leader [51], Rabia on stable network [54], Mu [5] on RDMA, Speculative Paxos [56] and NOPaxos [40] on SDN, and Tempo [23] considers a small number of concurrent failures. Other systems focus on scenarios different from Pineapple, e.g., Giza [15], Pando [64] and CRaft [68] are focused on erasure coded storages. Nil-externality [26] utilizes operations that modify state within a storage but has no externalized effects. Clock-RSM [20], Caesar [6], EPaxos-TOQ [61] rely on loosely synchronized clock

Another category of systems target communication. For example, read leases allow reads to complete without any inter-replica communication [28, 47]. This design generally leads to slower writes. Compartmentalized Paxos [69] adopts the idea of proxy nodes to bypass various communication and computation bottlenecks. PigPaxos [14] uses piggybacking to reduce communication. These systems potentially require more resources or a better network infrastructure.

All these systems could potentially achieve better performance than Pineapple, under a right set of assumptions. Our focus is on general deployments targeted by Multi-Paxos and Raft, including both LAN and WAN, *without* specific assumptions on the environment or modern hardware.

Transactional systems, such as Janus [49], Calvin [60], and TAPIR [71]), provide richer semantics compared to Pineapple. In fact, Pineapple and Gryff are specifically designed and optimized for key-value storages with more restrictive operation semantics. Consequently, general transactional systems are facing more bottlenecks when serving single-key reads/writes and could have longer latency in general. For example, Janus requires the leader to resolve conflicting transactions, and Janus's use of dependency tracking (for reordering conflicting transactions) could also result in longer tail latency.

A Generalization of Pineapple

A.1 Handling Multi-key General Operations in One-shot Transactions

To handle multi-key operations, we need to modify Algorithm 2 in the following way:

- In the Get phase, send messages to read the value for each key in K_{input}.
- For each key in K_{input}, identify the value with largest pstamp from responses received from a quorum.
- Apply $f(\cdot)$ on the values identified in the previous step and generate output value for each key in K_{output}.
- All these output values will have the same pstamp, as the one generated in Line 6 in Algorithm 2.
- In the Put phase, contact a quorum to update the values.

The reason that this simple generalization works is because of the simplicity of Multi-Paxos. The existence of a leader simplifies the design. This is because the leader determines the order of the multi-key operation. Then later in the proof of linearizability, all the operations seen by the leader can be ordered beforehand.

On the other hand, in the case of Gryff, nodes make joint decision by using a dependency graph. It is not clear how they can jointly come to conclusion on the set of values that are the most recent ones for K_{input} and can be used by the one-shot transaction.

A.2 Handling Leader Change

To handle leader change or failures, we rely on the full version of Multi-Paxos to identify the leader. Moreover, we need to modify reads so that they do not return inconsistent values. Concretely, we need to make the following modifications:

- Include the ballot number and leader ID in the pstamp.
- Upon learning a larger ballot, the (potentially old) leader N_l knows that there exists another proposer that aims to be the leader. Hence, N_l needs to run the phase 1 of Paxos [36, 39] to elect a new leader.
- The comparison of pstamp needs to include the ballot number. In other words, any message from the old leader should be discarded (or reply with an NACK).
- Reads need to take extra caution, as if we adopt the same ABD reads, then read could return inconsistent results. This is because during leader change, a one-shot transaction from the old leader might get overwritten by the new leader.

To avoid this scenario, the reads need to back off and retry upon learning the existence of a new leader or a new proposer that is competing for becoming a leader. Reads can observe this from the ballot field in the received messages.

With this modification, a read is completed only if there exists a quorum that shares the same leader with the read and the same value-pstamp pair with the read.

Note that during the leader change, the one-shot transaction (from the old leader) might not be completed yet, as the Put phase has not get a confirmation from a quorum. However, it does not affect correctness, this is because as new leader completes phase 1 of Paxos, it will either learn and adopt the uncompleted one-shot transaction as its command for this slot, or it proposes a new one-shot transaction command. In the latter case, it means that there is no completed read observe the previously uncompleted one-shot transaction.

B Correctness Proof

Here, we prove that the algorithms presented in Algorithms 1 and 2 are correct. To prove linearizability, we need to show that under any execution of the algorithm, we can find a total ordering S which satisfies both the real-time constraint order and the semantic of the operations (i.e., the ordering is legal). Moreover, it satisfies liveness with partial synchrony.

B.1 Intuition

We use the pstamps to order operations. We start with the non-stable ordering of writes. After we place them in the order, we need to find the position for each RMW. Lastly, we find the place for each read.

To prove that the sequence we find following pstamps is correct, we need to show that pstamps correctly reflect real-time ordering and the semantics. This roughly follows the design of quorum intersection (of the Get phase), and the choice of using a single leader (in the Multi-Paxos component).

B.2 Proof

Given an execution of operations H, where operations may interleave with each other (as there are concurrent operations), we need to identify an ordering (or a sequence) S in which operations do not overlap with each other, i.e., the ordering that could occur on a single machine. Following the prior literature [8, 41, 42], we only need to consider completed operations. In the following proof, we assume that all operations are on a single key, as it is straightforward to extend the proof to multi-key operations.

Now we describe the following steps to find the position for each operation in S:

- Start with an empty sequence S.
- Order the writes using pstamps.
- For each RMW r that has a pstamp $(tag_r, slot_r)$, place them one by one, following the order of the slot index. There are only three possible cases:
  - tag_r is $(0,0)$ and $slot_r = 1$, meaning that this RMW is the first non-read operation: RMW r is placed first in S (before all writes);
  - There is another RMW m such that $tag_m = tag_r$ and $slot_m = slot_r - 1$: RMW r is placed right after m in S; and
  - Otherwise: in this case, there must exists a write w such that $tag_w = tag_r$: RMW r is placed right after w in S.

  Note that because of the guarantee of Multi-Paxos, there cannot exists two RMWs that have the same slot index but different pstamp.
- For each read o, since we consider only the completed operation, it must return a null value (the default value), a value either from a write, or a value from a RMW.
  - For a null value, o is placed first in S (before any writes or RMWs);
  - For a value from write w, o is placed right after w in S;
  - For a value from RMW r, o is placed right after r in S.

These steps place all the (completed) operations in S. Next we need to show that S is the total ordering that we are looking for.

Lemma 1. *S satisfies real-time ordering.*

Proof. This follows from the construction of pstamps. If an operation o_1 occurs before operation o_2, then o_2 must have the same pstamp (this only happens when o_2 is a read) or a larger pstamp. The reason is that any completed operation is observed by a quorum (due to the Put phase); hence, when o_2 starts, the Get phase for all three operations allows o_2 to observe o_1. Then the pstamp needs to be increased if o_2 is a write or a RMW. □

Lemma 2. *S satisfies the semantics of the interface defined in Section 2.1. That is, S is legal.*

Proof. First, we need to show that any read d returns the most recent value by a write w or a RMW r in S. This follows from how we find the position for d. In other words, because of how we place d right after the value it returns, there is no non-read operations between w and d or between w and r.

Note that between w and d and between r and d, there could be other reads, but these reads do not matter, since they do not change values.

Second, we need to show that RMWs are consistent. That is, the value after applying RMW is correctly observed by future reads. The proof is by contradiction. Assume that there are four operations: two writes w_1, w_2, one RMW r, and one read d such that

- w_1 is before w_2 in S;
- r is right after w_2 in S;[5]
- d is right after r in S;
- rd sees the effect of r does a RMW on w_1 – whereas a legal execution should have r does a RMW on w_2. This is because w_2 is the most recent write for RMW r, with respect to S.

The reason that we place r right after w_2 is that they have the same tag in associated pstamps. From the Get phase of Pineapple, this means that after this phase, the largest pstamp observed by the leader is from w_2. As a result, the v^{new} is the computation after applying $f(\cdot)$ on the value of w_2, not w_1. This implies that the read d cannot observe the effect of r does a RMW on w_1, a contradiction. This proves the lemma. □

The two lemmas above prove that Pineapple satisfies linearizability.

Finally, we prove liveness.

Lemma 3. *Each operation completes in Pineapple when there is a stable leader.*

Proof. When $n = 2f + 1$ and there is a stable leader, all the phases are non-blocking, as each node and the leader is always able to obtain a response from a quorum. Therefore, all the operation completes under this case. □

Since under partial synchrony, there is always a stable leader in Multi-Paxos. This together with the lemma above implies that Pineapple satisfies liveness.

C Throughput in WAN

Figure 10 shows the maximum throughput achieved by all the systems, except Gryff, with 80 to 130 close-loop clients that batch operations. The clients batch 5000 operations, send to a node, and wait for the completion of all the operations, before proceeding to the next batch. We choose this design to properly load the systems without the machines being throttled by the communication bottleneck. This is also how [46, 61] test the throughput of EPaxos in WAN. We did not evaluate Gryff, because the implementation of Gryff from [10] does not support client batching. As reported in [10], Gryff's throughput is similar to EPaxos.

We use the same workloads that we used in Section 4.4.2 but with different numbers of clients. The exact workloads are specified in the caption of Figure 10. We make the following observations:

- In read-heavy workloads, "Multi-Paxos with lease" has best performance. This is because with lease, the leader does not need to process as many messages.
- In a read-heavy workload with 25% conflicts, PQR performs slightly better than Pineapple. This is because with a higher number of concurrent conflicting operations, Pineapple's reads can no longer complete on the fast path. In contrast, PQR's reads complete after 1 RTT, reducing the among of message processing.
- In balanced workloads, Pineapple has 3x to 4x throughput improvement over the next closest competitor (PQR and "Multi-Paxos with lease"). This is because the leader in Paxos systems is saturated by writes and RMWs, whereas writes are evenly distributed in Pineapple.
- In balanced workloads, the throughput of PQR and "Multi-Paxos with lease" are only slightly larger than Multi-Paxos, because the leaders are already saturated and cannot no longer process reads as efficiently as in the read-heavy workloads.
- EPaxos in general has slightly better performance than Multi-Paxos, but has lower throughput than other systems. This is expected because the dependency grows much faster in WAN, as also reported in [10, 61].

[5] Again, there might be some other reads between w_2 and r, but we do not care about reads here.

Abstract

Recent literature proposes the use of Directed Acyclic Graphs (DAG) to enhance blockchain performance. However, current block-DAG designs face three important limitations when fully utilizing parallel block processing: high computational overhead due to costly block sorting, complex transaction confirmation process, and vulnerability to balance attacks when determining the pivot chain. To this end, we propose Ladder, a structured twin-chain DAG blockchain with a convergence mechanism that efficiently optimizes parallel block processing strategy and enhances overall performance and security. In each round, a designated convergence node generates a lower-chain block, sorting the forked blocks from the upper-chain, reducing computational overhead and simplifying transaction confirmation. To counter potential adversarial disruptions, a dynamic committee is selected to generate special blocks when faulty blocks are detected. We implemented and evaluated Ladder in a distributed network environment against several state-of-the-art methods. Our results show that Ladder achieves a 59.6% increase in throughput and a 20.9% reduction in latency.

1 Introduction

Background: Within blockchain networks, nodes process incoming transactions and collectively engage in a consensus protocol, assembling the transactions into a block that is securely linked to the distributed ledger using hash pointers. In traditional chain-based structures, if multiple blocks are generated by different nodes simultaneously, only one is accepted while the others are discarded, resulting in the wastage of the computational resources expended in producing those blocks [21]. In contrast, Directed Acyclic Graph (DAG)-based structures allow those blocks to become part of the blockchain such that all blocks are included when generating the ledger [3, 6, 17–19, 22, 24, 34]. Broadly, DAG-based structures can be classified into two types: **tx-DAG**, where nodes represent transactions, and **block-DAG**, where nodes represent blocks composed of multiple transactions [32]. This paper focuses on block-DAGs as they offer better compatibility with existing protocols and provide stronger scalability than tx-DAGs. Broader structures in block-DAG blockchains, while intuitively improving performance through parallel block generation, may also increase transaction ordering overhead, complicate confirmation processes, and exacerbate specific security risks. *Therefore, this paper explores how to fully leverage the advantages of the DAG by optimizing the parallel block processing strategy.*

Limitations of Prior Art: While several promising block-DAG based blockchain designs have been proposed [18, 19, 24–26], they have the following three important limitations when processing parallel blocks.

1) High Sorting Cost. Nodes need to independently sort blocks to maintain consistency when multiple valid blocks are generated in parallel. In approaches such as Conflux [19] and Inclusive [18], every node is required to recursively sort the newly generated blocks along with their predecessors, which leads to considerable redundant computations. As each node independently determines the order without a coordinated strategy, inconsistencies in block views arise, causing additional computational overhead as nodes attempt to reconcile these discrepancies. This lack of synchronization in the sorting process results in high sorting costs, leading to delays in block confirmation, especially under high concurrency.

2) Complex Confirmation Process. In DAG-based blockchains, the validity of individual transactions depends on the confirmation of their respective blocks, often requiring intricate inter-block validation processes. As multiple forks emerge, nodes need to independently verify and reference forked blocks, resulting in a buildup of cross-references that complicates the confirmation process. For example, in Spectre [24], the block-voting mechanism relies on each node incrementally accumulating support for previous blocks, which can be cumbersome as nodes attempt to reconcile conflicting views on the validity of numerous competing forks. Similarly, Conflux [19] utilizes forward references for faster pivot chain confirmation, but the absence of a coordinated approach to

managing these forks causes transactions in non-standard blocks to gain confirmation weight at a slower rate, further prolonging the finalization process. This lack of an efficient mechanism to centrally handle forks leads to a fragmented confirmation process, where the full potential of DAG's parallelism remains underutilized.

3) Susceptibility to Balance Attacks. DAG blockchains define rules to identify the pivot chain [18, 19, 26], allowing multiple valid blocks generated simultaneously to be added to the ledger without conflict. However, when multiple candidate pivot chains emerge, the lack of coordination leads to independent node decisions, hindering prompt convergence on a single pivot chain. This lack of synchronization allows adversaries to exploit decentralized decision-making to delay ledger updates and maintain parity between competing chains. For instance, while Conflux [19] employs a probabilistic method to address these issues, its independent chain weight evaluation at each node may introduce inconsistencies, which adversaries can exploit for balance attacks, delaying convergence to a single pivot chain. As a result, the absence of a mechanism to manage competing chains may lead to delays, threatening blockchain stability and reliability.

These limitations suggest that incorporating an effective convergence mechanism could better coordinate and optimize parallel block processing.

Proposed Approach: In this paper, we propose Ladder, a block-DAG-based blockchain that utilizes a convergence mechanism to achieve high transaction throughput and low confirmation latency, addressing the three key limitations of existing approaches. Ladder is composed of two chains: an upper-chain and a lower-chain, as shown in Figure 1. The upper-chain consists of blocks containing transactions, while the lower-chain coordinates the convergence of forked blocks in the upper-chain. In each round, nodes generate blocks for the upper-chain using Proof of Work (PoW). When multiple blocks are generated in a round, they form a block set. One block is selected as the standard block, while the rest are designated as forked blocks. The upper-chain continues from the standard block, as shown in Figure 1, but all forked blocks are retained to preserve the computational effort involved in their creation. A convergence node, responsible for each round, records the order of forked blocks in the lower-chain. This allows nodes to reconstruct the ledger efficiently by traversing both chains, ensuring a consistent view of the blockchain.

Technical Challenges: We identified two key challenges in the design of Ladder that required resolution. The first challenge is *how to use the lower-chain to effectively converge PoW-generated upper-chain blocks.* A node may lack sufficient computational power to complete the PoW in a timely manner to generate a lower-chain block. Such delays could impede Ladder's progress. To resolve this, we eliminate the PoW requirement for lower-chain blocks, enabling any node to generate a lower-chain block swiftly. To prevent malicious lower-chain blocks, the node that generated the previous round's standard upper-chain block is selected as the convergence node for the current round. This process ensures that no single node can dominate unless it controls a significant proportion of the computational power, which is highly unlikely.

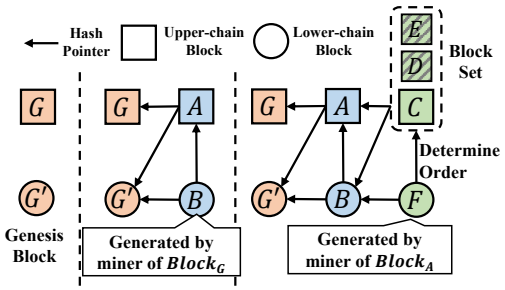

Figure 1: An introduction to the structure of Ladder.

The second challenge is *how to ensure system security by preventing adversaries from becoming convergence nodes.* An adversary could disrupt the blockchain by failing to produce or delaying the lower-chain block, hindering transaction confirmations and reducing throughput. Additionally, the adversary could ignore valid forked blocks or reference nonexistent blocks to disrupt the blockchain structure. To address this, Ladder introduces a super block in the lower-chain to override any faulty lower-chain block. If a fault is detected or a lower-chain block is not generated within a predefined duration, a committee forms and uses a Byzantine Fault Tolerance (BFT)-like consensus mechanism (*i.e.,* HotStuff) to generate a super block. BFT is a class of methods that ensures deterministic consensus within a fixed number of participants [16].

Key Advantages: In this paper, we propose a structured twin-chain DAG with a convergence mechanism for parallel block processing. The advantages of Ladder over the prior art are three-fold: i) compared to the block sorting by all nodes in [19, 24, 25], we introduce a mechanism that designates specific convergence nodes to handle upper-chain block sorting and record this information in lower-chain blocks, reducing sorting overhead and optimizing resource utilization; ii) compared to the complex transaction confirmation mechanism in [18, 19, 25, 26], our approach uses a convergence process to confirm transactions in unresolved upper-chain blocks, eliminating the need for intricate cross-referencing and weight accumulation, and thereby streamlining the transaction confirmation process; iii) compared to [18, 19, 25, 26], Ladder's structure inherently avoids additional computations for determining the pivot chain in the DAG topology, enhancing resistance to balance attacks and providing robust security guarantees against adversarial actions.

Summary of Experimental Results: We implemented Ladder and four state-of-the-art approaches: GHOST [26], Inclusive [18], Phantom [27], and Conflux [19]. Our experiments were conducted on a test bed of 80 servers deployed across a distributed network. Results show that Ladder outperformed prior approaches, achieving a 59.6% increase in throughput

Table 1: Comparison of block-DAG blockchains.

	Sorting by all nodes	Complex Confirmation logic	Balance attack resistance	Performance	
				Trans. txs / sec[1]	Confirmation time
GHOST	Yes	No	No	200	< 60min
Inclusive	Yes	Yes	No	350	< 1min
Spectre	Yes	Yes	-	-	< 1min
Phantom	Yes	Yes	No	40	< 1min
Conflux	Yes	Yes	No	2823	< 1min
OHIE	Yes	Yes	Yes	2513[2]	< 10min
Ladder	No	No	Yes	4506	< 1min

and a 20.9% reduction in transaction confirmation latency compared to the best-performing Conflux.

Limitation of Ladder: A limitation of PoW+BFT architecture is that while BFT consensus ensures security with fewer than $1/3$ malicious nodes, PoW's probabilistic nature does not guarantee this strict security threshold. For adversaries controlling less than 30% computational power, the committee can ensure with high probability that malicious nodes remain below $1/3$, satisfying BFT security requirements. However, the probability of more than $1/3$ of the committee being malicious in at least one of the R rounds is given by $1-(1-P)^R$, where P is the probability of selecting more than $1/3$ malicious nodes in a single BFT round. This probability increases with R, raising the risk of adversaries compromising the system by controlling over $1/3$ of the BFT committee, breaking consensus and disrupting system integrity. We analyze this limitation further in Sec. 4, where we study the effectiveness of increasing the BFT committee size on reducing the probability of malicious nodes exceeding $1/3$ of the committee.

2 Related Work

DAG for BFT Consensus: BFT consensus ensures agreement among distributed nodes with a bounded number of malicious participants and is more suited for permissioned networks [5, 16]. Several works have explored integrating DAG into BFT consensus, mainly in permissioned settings, such as Shoal [28], Bullshark [29], and Narwhal [8]. The fundamental difference between these solutions and Ladder is that Ladder is designed for permissionless blockchains. Ladder relies on PoW to ensure decentralization in trustless settings, while BFT is incorporated only as a lightweight fallback to handle adversarial scenarios.

DAG-based Structures: Prior work on utilizing DAGs in PoW-based blockchains can be broadly divided into two categories based on node representation: tx-based DAGs, where each node represents a single transaction [6, 17, 22], and block-based DAGs, where each node represents an entire block [18, 19, 24–26]. Tx-based DAGs enable decentralized validation but introduce challenges in transaction ordering and validation complexity. The independent nature of transactions increases communication overhead and complicates maintaining a consistent global transaction order. This is challenging in large-scale systems like Byteball [6], Tangle [22], and Nano [17], which face scalability and efficiency trade-offs. For block-based DAGs, a prominent block-based DAG design is GHOST [26], which extends Bitcoin's linear chain into a tree to enhance security. However, GHOST prioritizes security while offering limited improvements in throughput. Inclusive [18] extends GHOST by increasing block inclusion without full ledger ordering, limiting smart contract support. Similarly, Spectre [24] improves performance but sacrifices ledger ordering, restricting functionality. Phantom [25, 27] resolves the ordering issue but introduces a computationally expensive recursive sorting algorithm, hindering performance. Conflux [19] extends GHOST by leveraging a block-DAG structure to achieve high throughput. However, its reliance on probabilistic methods for balance attack defense leaves certain vulnerabilities unresolved.

Hierarchical and Parallel Structure: Meshcash [4] employs a hierarchical DAG, using block references as votes for confirmation. While enhancing security, this design disadvantages nodes with low computational power or poor network connectivity, leading to delayed confirmations and degraded performance. OHIE [37] improves throughput with a parallel chain architecture. However, each parallel chain in OHIE retains a linear blockchain structure, meaning block forks can still result in orphaned blocks. In contrast, Ladder utilizes a block-DAG structure to avoid valid orphaned blocks. Prism [2] adopts a decoupled design, using vote blocks to select a block for ledger ordering. However, vote blocks rely on PoW solely for voting, increasing resource consumption. Moreover, Prism's performance depends on near-ideal network conditions, such as a block propagation delay of less than one second. In contrast, Ladder packages transactions within vote blocks and does not require strict network assumptions, making it more adaptable to practical P2P networks.

Table 1 summarizes several related work, highlighting the limitations addressed by Ladder.

3 Detailed Design of Ladder System

In this section, we provide a detailed description of Ladder. We already provided an overview of Ladder in Sec. 1 under Proposed Approach. Here, we start with a system-level view of Ladder nodes and the system model. Based on this, we present various notations and terms that we use in this paper. Subsequently, we describe how nodes generate Ladder blocks and determine the pivot chain in the event of forking. We then explore various corner cases that may arise and how Ladder handles them. Finally, we end this section with a discussion about various performance-related aspects of Ladder.

3.1 System Model and Node Operations

We illustrate the system-level process of node participation in Ladder, as shown in Figure 2. Ladder operates under

[1] As measured in our experimental environment.

[2] We set the number of parallel chains to 40 in our experiments.

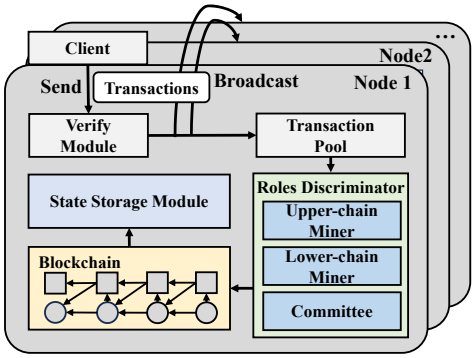

Figure 2: A system view of Ladder nodes.

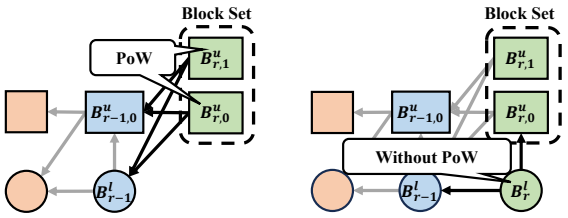

a δ-synchronous network assumption (following [21, 37]), where messages between honest nodes are delivered within a bounded time δ under normal conditions. The system tolerates temporary disruptions, such as message delays or node crashes, as long as the network eventually stabilizes. We assume that adversaries control at most p percent of the total computational power, where $p < 30\%$, ensuring the security of both upper-chain PoW and lower-chain BFT consensus with high probability. In Ladder, nodes participate as upper-chain miners, lower-chain miners, and/or BFT committee members, and are incentivized for their contributions to block generation. Upper-chain miners use PoW to generate blocks. Lower-chain miners handle transaction ordering and produce lower-chain blocks. In the event of waiting duration timeouts or faults, the BFT committee generates super blocks to ensure consensus continuity and maintain system integrity.

3.2 Model, Definitions, and Notations

We model Ladder using a DAG $\mathcal{G} = (\mathcal{B}, \mathcal{V}, \mathcal{E})$. Next, we describe in detail what $\mathcal{B}$, $\mathcal{V}$, and $\mathcal{E}$ represent.

Blocks $\mathcal{B}$: We represent the set of all valid blocks with $\mathcal{B}$. The set $\mathcal{B}$ consists of three types of blocks: B^u represents all valid blocks in the upper-chain. B^l represents all valid blocks in the lower-chain, and B^s represents all super blocks. Before we define these three types of blocks, we first introduce the concept of a *round*.

Round: A round in Ladder defines the position of a block within the upper- and lower-chains. Each round begins with the generation of the lower-chain block from the previous round and ends with the generation of the lower-chain block in the current round. During each round, one new block is added to the lower-chain and at least one block is added to the upper-chain. The upper-chain and lower-chain blocks generated in round r are denoted as B^u_r and B^l_r, respectively. Ladder does not require all honest nodes to have the same round number, as network delays may cause lower-chain blocks to be received at different times. The round number is simply used to track block order and maintain the local ledger. Even if nodes are temporarily in different rounds, the system ensures eventual consistency through block propagation and validation, within the bounds of the δ-synchronous network model.

(a) Upper-chain (b) Lower-chain

Figure 3: Normal operation of Ladder.

Upper-chain Blocks B^u: The upper-chain blocks in Ladder are generated by nodes using the PoW consensus mechanism. Despite being energy-intensive, PoW remains a cornerstone of blockchain security, and improving its performance and scalability is crucial for maintaining its relevance in decentralized and trustless environments. Upper-chain blocks are further categorized into standard and forked upper-chain blocks. Standard upper-chain blocks are those that become part of the upper-chain. We represent a standard upper-chain block in round r with $B^u_{r,0}$. $B^u_{r,0}$ contains two hash pointers. One pointer links to the standard upper-chain block $B^u_{r-1,0}$ of the preceding round, and the other links to the lower-chain block B^l_{r-1} of the preceding round. This process is shown in Figure 3(a). Forked upper-chain blocks are legitimate blocks generated by some nodes in the same round in which the standard upper-chain block is generated. We represent a forked upper-chain block in round r with $B^u_{r,i}$, where $i = 1, 2, 3, \ldots$ depending on how many forked upper-chain blocks were created during round r. A forked upper-chain block $B^u_{r,i}$ also contains two hash pointers. One pointer links to the standard upper-chain block $B^u_{r-1,0}$ of the preceding round, and the other to the lower-chain block B^l_{r-1} of the preceding round. The primary difference is that the upper-chain blocks in the next round will point to the standard upper-chain block of the current round, but not to forked blocks. In other words, the chain continues only from a standard upper-chain block, not from any forked upper-chain blocks. This process is shown in Figure 3(b).

Lower-chain Blocks B^l: Lower-chain block B^l_r in round r contains information about the standard upper-chain block, any forked blocks, and their respective sequence numbers. Lower-chain block B^l_r is generated in round r by the node that generated the standard upper-chain block $B^u_{r-1,0}$ in the previous round. The generation of lower-chain blocks is computationally inexpensive and does not require any PoW mechanisms. Lower-chain block B^l_r contains two hash pointers. One pointer links to the standard upper-chain block $B^u_{r,0}$ of the current round, and the other to the lower-chain block B^l_{r-1} of the preceding round. It also contains reference links to all forked upper-chain blocks in round r, facilitating the convergence of forks in the upper-chain.

Super Blocks B^s: A super block is added to the lower-chain when the referenced upper-chain blocks contain invalid trans-

actions from the current or previous rounds, or when a lower-chain block is not received within a predefined time duration despite the presence of valid upper-chain blocks. In Ladder, super blocks are generated through the HotStuff consensus mechanism [36]. Sec. 3.3 will provide further details on fault conditions and the generation process of the three types of blocks (upper-chain, lower-chain, and super).

Nodes $\mathcal{V}$: We represent the set of all nodes with $\mathcal{V}$ and any arbitrary node in $\mathcal{V}$ with V. The ratio of a single node V's computing power relative to the total computing power of all nodes is represented by $P(V)$, such that $\sum_{\forall V \in \mathcal{V}} P(V) = 1$.

Edges $\mathcal{E}$: We represent the set of link relationships among all blocks with $\mathcal{E}$. For example, if block $B^u_{r,0}$ points to block B^l_{r-1}, then $(B^u_{r,0}, B^l_{r-1}) \in \mathcal{E}$ represents a directed link from $B^u_{r,0}$ to B^l_{r-1}. More generally, expressing a link as (a,b), if $(a,b) \in \mathcal{E}$, a property of Ladder is that $a \neq b$ and $(b,a) \notin \mathcal{E}$.

Serial Numbers and Ledger Generation: To enable a node to generate the ledger from the blocks in the upper- and lower-chains of Ladder, we assign a serial number to each block. In any given round $r \geq 0$, the lower-chain block has the serial number $2r+1$ and the standard upper-chain block has the serial number $2r$. If round r has any forked upper-chain blocks, then the serial numbers of forked blocks are denoted by adding a subscript i to the value $2r$, where $i = 1, 2, 3, \ldots$. We represent the serial number of any block B with $O(B)$. For example, if B^u is a standard upper-chain block in round 3, then $O(B^u) = 6$. If B^u is the second forked upper-chain block in round 3, then $O(B^u) = 6_2$. Similarly, if B^l is a lower-chain block in round 3, then $O(B^l) = 7$. Suppose rounds 0, 1, 4, and 5 do not have any forked blocks but only standard upper-chain blocks. Suppose round 2 has one forked block, and round 3 has three forked blocks. To generate the ledger, the upper-chain blocks will be arranged in the following sequence: $0, 2, 4, 4_1, 6, 6_1, 6_2, 6_3, 8, 10, \ldots$. Transactions are inherently sequential, so while parallel block processing enables higher throughput, ordering the blocks ensures all transactions follow the correct sequence. This guarantees a totally ordered ledger, allowing Ladder to support not only simple transfer transactions but also complex smart contract executions.

3.3 Block Generation

Next, we describe the generation process for the different block types mentioned in Sec. 3.2.

Upper-chain Blocks: In each round r, each node attempts to find a nonce that meets the difficulty target required for block generation. Once a node finds a valid nonce, it broadcasts the resulting block to all nodes in the network. Round r concludes when the lower-chain block B^l_r is generated. Before the round concludes, it is common for multiple upper-chain blocks to be generated by different nodes. In such cases, one of these blocks is designated as the standard upper-chain block, while the others are classified as forked upper-chain blocks. If applicable, information about the standard and forked blocks in round r is stored in the corresponding lower-chain block B^l_r.

Lower-chain Blocks: Suppose we are currently in round r. This means that the standard upper-chain block and any forked upper-chain blocks from round $r-1$ have already been determined, with this information stored in the lower-chain block B^l_{r-1} of the previous round. In the current round r, the node whose block was designated as the standard upper-chain block in round $r-1$ is responsible for generating the lower-chain block. By generating the lower-chain block, Ladder achieves fast convergence of upper-chain blocks. Additionally, only the miner of the standard upper-chain block from round $r-1$ is required to generate the lower-chain block. The node collects upper-chain blocks for a predefined duration, checks for faults, discards faulty blocks, and selects the standard upper-chain block $B^u_{r,0}$ for round r according to the *Hardest Chain Principle*. This block must have hash pointers to the standard upper-chain block $B^u_{r-1,0}$ and lower-chain block B^l_{r-1}. It marks the remaining upper-chain blocks as forked and assigns them serial numbers $(2r)_1$, $(2r)_2$, and so on. It inserts this information into the lower-chain block B^l_r for round r, along with the hash pointers for $B^u_{r,0}$ and B^l_{r-1}. By producing lower-chain blocks, the convergence node exclusively records forked blocks and ensures a globally consistent transaction order. Unlike other solutions, Ladder optimizes block ordering while preserving decentralization, thereby enhancing both efficiency and finality. An upper-chain block in round r may reference $B^u_{r-1,0}$ and B^l_{r-1} but fail to reach the lower-chain block generator in time. Instead, it may arrive at the generator for round $r+e$ ($e \geq 1$) before its lower-chain block is generated. Consequently, this block will be sorted in round $r+e$, and it will be classified as a forked upper-chain block rather than a standard one.

Super Block: Suppose node V is in round r. It detects a fault if either of the following two situations occurs.

1. Node V receives a lower-chain block for round r, but the referenced upper-chain blocks contain transactions that conflict with those in the current or previous rounds.

2. Node V does not receive a lower-chain block for round r within a predefined time duration, despite receiving several valid upper-chain blocks.

To resolve such faults, Ladder employs the BFT consensus mechanism. Since lower-chain blocks must be unique, BFT consensus guarantees agreement on a single canonical lower-chain block among all nodes. As a deterministic consensus mechanism, BFT consensus has been widely used in various fields [1, 5, 7, 15, 30, 31, 35, 36]. The HotStuff consensus [36] is a BFT-based consensus executed by a committee comprising the nodes that generated the most recent n standard upper-chain blocks. HotStuff is selected for its simplicity, efficiency, and linear message complexity. Compared to other BFT mechanisms in some PoS proposals, HotStuff offers

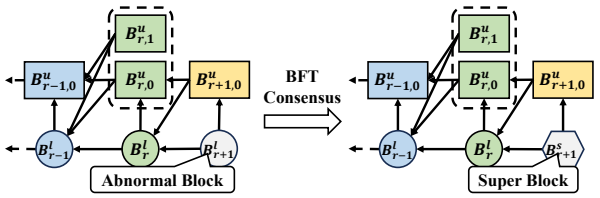

Figure 4: Example of the use of super block in Ladder.

superior scalability, making it suitable for super block generation. Upon committee formation, the leader is selected via VRF [12]. During Ladder's operation, if a node detects an issue, it notifies the committee members. The committee verifies the fault, discards conflicting upper-chain blocks, and reselects a standard upper-chain block based on the *Hardest Chain Principle*. The committee leader then generates a super block, replacing the lower-chain block, as shown by the hexagonal block B^s_{r+1} in Figure 4. This super block contains hash pointers to the previous round's lower-chain block and the current round's upper-chain block, along with references to any forked upper-chain blocks. Subsequent upper- and lower-chain blocks are generated through the standard process described earlier. Notably, a dynamically sized committee may cause inconsistencies in node perceptions, so we adopt a fixed size to ensure information consistency.

At the end of each round, nodes are rewarded based on their roles in that round, incentivizing sustained participation.

3.4 Hardest Chain Principle

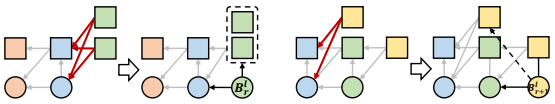
Unlike Bitcoin, to enable faster transaction insertion on the ledger, a blockchain may produce blocks at a high rate. However, this can cause honest nodes to link blocks to different sub-chains based on their local views, fragmenting their computing power. An adversary can take advantage of this. It can concentrate all its computing power on a target sub-chain to attack it. To address this issue, GHOST [26] proposes the *heaviest chain principle*, where the pivot chain is determined by the number of sub-blocks linked to a block. However, GHOST is vulnerable to liveness attacks, where an adversary delays transaction confirmations by creating multiple forks. To mitigate this, Conflux [19] proposed GHAST, which introduces dynamic block weight (*e.g.,* special blocks with high weights) to mitigate liveness attacks. While GHAST improves resilience, it may not fully address balance attacks.

Ladder proposes the *Hardest Chain Principle*, which extends the *heaviest chain principle* with dynamic weight adjustment to support efficient parallel block processing. Unlike the *heaviest chain principle*, which relies on the number of sub-blocks, the *Hardest Chain Principle* selects the pivot chain based on the cumulative difficulty of blocks in a sub-tree. The difficulty of block B_i, denoted as $\mathcal{D}(B_i)$, is calculated by the number of leading zeros in its hash and the hashes of all blocks in its sub-tree, as defined by the following equation:

$$\mathcal{D}(B_i) := \sqrt{\mathcal{Z}(B_i)} + \sum_{B_j \in S_i} \mathcal{D}(B_j) \quad (1)$$

Here, $\mathcal{Z}(B_i)$ represents the number of leading zeros in the hash of block B_i, and S_i denotes the set of all legal blocks with hash pointers pointing to block B_i. Putting $\mathcal{Z}(B_i)$ under square root achieves two properties. First, in the case of a fork, the side with more legal blocks following the forked block has higher difficulty and is selected. This makes it easier to select a side. Second, if the number of legal successor blocks on both sides is equal, as long as the number of leading zeros is different in all the sub-blocks, the difficulty of the two sides will be unequal, enabling the selection of one of the sides. This significantly reduces the likelihood of a balance attack. If both sub-chains have m legal blocks after the fork position, it can be proven that the probability of the blocks having equal difficulty is bound by $P \leq \frac{1}{12}(1-\frac{1}{4^k})$, where k is the maximum number of leading zeros in the hash value.

We now prove that the side with more legal blocks following the forked block has higher difficulty. Consider a scenario where a fork leads to the formation of two sub-chains. Let sub-chain 1 have m blocks with a leading zeros each, and sub-chain 2 have $m-t$ blocks with b leading zeros, where $a < b$. In other words, each block in sub-chain 2 has more leading zeros than those in sub-chain 1. The generation probability of a block with x leading zeros is given by $P = \frac{1}{2^{x+1}}$. Thus, the generation probability of all m blocks in sub-chain 1 is $\prod_{i=1}^{m} P_i = \prod_{i=1}^{m} \frac{1}{2^{a+1}} = \frac{1}{2^{m(a+1)}}$. Similarly, the generation probability of sub-chain 2 is $\frac{1}{2^{(m-t)(b+1)}}$. If the generation probabilities of the two sub-chains are equal (*i.e.*, the computing power is equally divided between the two chains), then $b = \frac{ma+t}{m-t}$. To show that sub-chain 1 has greater weight than sub-chain 2, we must prove $\sum_{i=1}^{m} \sqrt{a} > \sum_{i=1}^{m-t} \sqrt{b}$. Alternatively, we need to demonstrate $m\sqrt{a} > (m-t)\sqrt{\frac{ma+t}{m-t}}$, which can be simplified to $m^2 a > (m-t)(ma+t)$, implying $ma > m-t$. The conclusion holds given that $m > 0$, $a > 1$, and $t > 1$. This proves that the side with a greater number of valid blocks following a given block must have a higher difficulty.



The *Hardest Chain Principle* can mitigate liveness attacks and balance attacks by selecting the chain with the highest cumulative difficulty, where a block's difficulty is determined by the number of leading zeros in its hash and the hashes of all blocks in its subtree. This approach ensures that an attacker must generate blocks with higher difficulty to influence the pivot chain, requiring substantial computational power and making such an attack economically infeasible. Furthermore, the *Hardest Chain Principle* can serve as an alternative to GHOST [26] and GHAST [20] in their respective systems.

3.5 Exception Handling in Block Generation

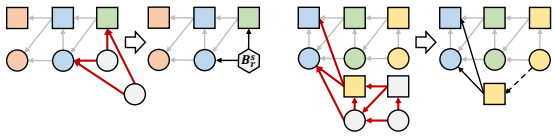
Exceptions in Upper-Chain Blocks: We categorize exceptions in the upper-chain into the following cases:

Invalid block: An invalid block is a block that contains duplicate or conflicting transactions either with itself or with previous upper-chain blocks. Its creator receives no reward.

Forks: Two types of forks may occur in the upper-chain:

(a) Tip fork in upper-chain (b) Chain fork in upper-chain

Figure 5: Exception cases in upper-chain.



tip forks and chain forks. A tip fork occurs when multiple valid upper-chain blocks are generated in round r. In this case, the convergence node selects one block as the standard block and designates the others as forked blocks for round r. The convergence node then generates block B_r^l to include this information, as shown in Figure 5(a). A chain fork occurs when a valid upper-chain block is generated in round r but does not arrive in time at the node responsible for generating the lower-chain block for round r, instead reaching the node responsible for round $r+1$. In this case, the lower-chain block B_{r+1}^l contains a pointer to this upper-chain block as a forked block, as shown in Figure 5(b). Such an upper-chain block is never used as a standard upper-chain block.

Exceptions in Lower-Chain Blocks: We also categorize exceptions in the lower-chain into the following cases:

Block timeout: Block timeout occurs when a node belonging to the BFT committee does not receive a lower-chain block within a specified time. In such cases, the committee initiates HotStuff consensus and generates a super block.

Invalid block: Similar to invalid upper-chain blocks, a lower-chain block is considered invalid if it contains faulty information or is generated by an unauthorized node. Invalid blocks are ignored. However, if an invalid block is generated by the convergence node of the current round, the BFT consensus is triggered to generate a super block.

Fork: If a lower-chain block is not generated by the convergence node in any given round, it is simply ignored by the nodes. Lower-chain forks can also be classified into tip forks and chain forks. A tip fork occurs in the lower-chain when the node responsible for generating the lower-chain block malfunctions and generates more than one lower-chain block in a given round, as shown in Figure 6(a). This triggers the HotStuff consensus to generate a super block B_r^s, where the node that malfunctioned is not allowed to participate. A chain fork occurs in the lower-chain when different nodes accept different upper-chain blocks as standard blocks in a given round, and consequently accept lower-chain blocks from different nodes in the next round. This results in the propagation of two separate Ladders in the network, as shown in Figure 6(b). When eventually any given node detects the existence of multiple Ladders, it employs the *Hardest Chain Principle*, as discussed in Sec. 3.4, to select one Ladder and discard the rest. Any Ladder may contain super blocks in place of lower-chain blocks. In such cases, when applying the *Hardest Chain Principle*, the difficulty of the super block is quantified by the number of nodes participating in HotStuff.

(a) Tip fork in lower-chain (b) Chain fork in lower-chain

Figure 6: Exception cases in lower-chain.

Exceptions in Super Blocks: A super block is considered invalid if it contains conflicting information or fails committee validation due to adversarial behavior. Since the committee uses BFT to generate super blocks, such issues can be mitigated through BFT's internal mechanisms as long as the proportion of adversarial nodes remains below $1/3$. When an invalid super block is detected, the committee initiates a view change [36] and elects a new leader to restart consensus, ensuring super block reliability.

3.6 System Analysis

This section discusses Ladder's performance in throughput, latency, and scalability, as well as the bootstrapping process.

Throughput: Effective utilization of a node's computing power is key to improving system throughput. Nodes use PoW to generate blocks. Following the *Hardest Chain Principle*, they can become miners of standard upper-chain blocks. This grants them the role of convergence nodes, giving them the right to generate lower-chain blocks. Ladder improves upon GHOST and GHAST for pivot chain selection while maintaining comparable computational overhead, as the required information can be derived from block metadata. Convergence nodes determine block order, reducing network-wide coordination overhead while preserving throughput. The lower-chain allows nodes to package more transactions without PoW, increase rewards, and eliminate computational bottlenecks, improving efficiency.

Latency: In Ladder, the analysis of Bitcoin's longest chain principle and confirmation rule is still applicable for the *Hardest Chain Principle*. Consider a scenario where the adversary fully controls the computing power of malicious nodes. Let p and q represent the proportion of total computing power of honest and malicious nodes, respectively, where $p+q=1$. After a transaction is included in a block, a waiting period of z upper-chain blocks is necessary to prevent selfish mining and anomalies in block processing caused by the adversary. Recall that the explanation of lower-chain forking cases was presented in Sec. 3.5. The adversary's selfish mining behavior follows a Poisson distribution, where λ represents the expected number of upper-chain blocks secretly generated by the adversary during the waiting period of z upper-chain blocks. Since the number of generated upper-chain blocks is proportional to computing power, we have $\frac{\lambda}{z} = \frac{q}{p}$, or equivalently, $\lambda = \frac{zq}{p}$. Thus, the probability of the adversary producing k upper-chain blocks during the waiting period of z

upper-chain blocks can be calculated using the formula $\frac{\lambda^k e^{-\lambda}}{k!}$. In the case where the adversary generates k (where $k \leq z$) upper-chain blocks, the probability of catching up to the z revealed upper-chain blocks is $(\frac{q}{p})^{(z-k)}$. If $k > z$, the probability of catching up is 1. Consequently, the probability of being caught up by the adversary after waiting for z upper-chain blocks is given by $1 - \sum_{k=0}^{z} \frac{\lambda^k e^{-\lambda}}{k!}(1 - (\frac{q}{p})^{(z-k)})$.

Scalability: Ladder demonstrates excellent scalability, allowing nodes to join or leave the system freely without affecting the PoW of other nodes. Furthermore, as the number of nodes increases, the system's total computing power grows, thereby optimizing parallel block processing, improving throughput and reducing confirmation delays. In contrast, solutions like OHIE [37] extend the ledger to multiple parallel chains, which improves throughput. However, due to their chain-like structure, OHIE's parallel chains still face the issue of orphan blocks. A promising future direction is to combine these methods, utilizing DAG-based parallel chains with local consensus and lightweight global synchronization, which could enhance throughput while ensuring consistency.

Bootstrapping: Ladder requires an initial BFT committee to operate. However, relying on a global random selection process could render the system susceptible to Sybil attacks [9]. To address this, the system employs Nakamoto consensus during the bootstrap phase, then transitions to the Ladder protocol after k blocks have been generated [14].

4 Parameter Settings

BFT Committee Size: In Ladder, the presence of a BFT committee may introduce two security risks: selfish mining and adversaries exceeding $1/3$ of the committee. Therefore, the BFT committee size is critical to system security, as it determines which nodes are responsible for generating the super block.

To mitigate selfish mining, a larger committee size is advantageous, as it increases the difficulty of generating super blocks, making it harder for adversaries to withhold and release blocks to manipulate the chain order [10]. We show in Appendix A that the probability of a selfish mining attack occurring is bounded by $P = \frac{1}{2^{2\sqrt{k}}}$.

For adversaries exceeding $1/3$ of the committee, as noted in the Limitation of Ladder section (Sec. 1), Ladder requires malicious nodes within the committee remain below $1/3$. However, due to the probabilistic nature of PoW, this guarantee cannot be strictly ensured. Appendix B shows that this probability decreases exponentially as the committee size increases. Furthermore, over multiple rounds, the probability of at least one successful attack accumulates. In Table 2, we present the per-round probability of adversarial dominance and the number of rounds required for the cumulative probability of at least one successful attack to reach 99%. As the committee size grows, the probability of more than $1/3$ adversaries decreases, and the required number of rounds increases.

Table 2: Impact of Committee Size on Adversarial Risk

Committee Size	120	180	240	300
Probability	4.9×10^{-3}	1.8×10^{-4}	6×10^{-6}	1.96×10^{-7}
Rounds for 99%	9.2×10^{2}	2.6×10^{4}	7.7×10^{5}	2.4×10^{7}

For example, when the committee size is 300, the probability of selfish mining is approximately 4.67×10^{-11}, while the probability of more than $1/3$ adversaries in a single round is about 1.96×10^{-7}. This event requires roughly 2.4×10^{7} rounds to reach a cumulative probability of 99%.

Node Incentive Mechanism: As previously introduced, Ladder employs an incentive model to reward nodes for their participation. The block generation rewards in the upper- and lower-chain are similar and correlated with the number of valid transactions stored in the block. The super block generation reward is evenly distributed among all participating committee members in the BFT consensus algorithm. If a block is not selected as the standard upper-chain block but is selected as a forked upper-chain block, its reward is influenced by the difference in the number of rounds between its creation and its inclusion in the upper-chain. Specifically, this reference is added to a lower-chain block. To calculate the reward accurately, the reward should be multiplied by a block generation reward factor, which is less than 1. Let the upper-chain block B^u be linked to block B. The block generation reward factor is defined as $S = \frac{e^{l-d}}{1+e^{l-d}}$, where $d = R(B^u) - R(B)$ represents the difference in the number of rounds, and l is a manually set parameter that determines the rate of decrease of the block generation reward as the difference in rounds approaches l. For the lower-chain block generation node, the reward received for adding a reference to an upper-chain block should also be multiplied by the block generation reward factor. This incentivizes the lower-chain block generation node to promptly reference upper-chain blocks within lower-chain blocks. Both the block generation reward and the reward for adding a reference to an upper-chain block are stored in the lower-chain block for the respective round.

The incentive for the node to mine a single upper-chain block is calculated as $r_u = Block\ Reward + \sum_{Tx \in B} Txfee * (1 - \alpha)$. Similarly, for the convergence node, the incentive to generate a lower-chain block is determined by $r_l = Block\ Reward + \sum_{B \in round} \sum_{Tx \in B} Txfee * \alpha_i$. Next, we explain what α_i represents. The blocks in each round are generated by different nodes, and each node selects the transactions to include in its block from the transaction pool. Thus, it is possible that one or more transactions get included in multiple blocks generated by different nodes in any given round, resulting in duplicate transactions. α_i represents the proportion of transaction i among all duplicate transactions in a given round. Formally, let x_i represent the number of occurrences of transaction i that appears at least twice among all the blocks generated in a given round. Then $\alpha_i = \frac{x_i - 1}{\sum_{\forall i}(x_i - 1)}$.

To execute a double spending attack with V, the attack

involves generating n blocks during its phase, and the cost for each individual block generation is denoted as c. According to Hoeffding's inequality, take $\varepsilon = 1/2 - q$, $Pr[|A| \geq n/2] \leq \exp(-\frac{(1-2q)^2 n}{2}) = \exp(-\frac{(p-q)^2 n}{2})$. Then, to make the attack gain in the desired sense not to exceed the cost, $Pr[|A| \geq n/2] * V \leq \frac{n}{2}(c - r_d)$ is needed to obtain $V \leq \frac{n(c-r_d)}{2exp(\frac{(p-q)^2 n}{2})}$.

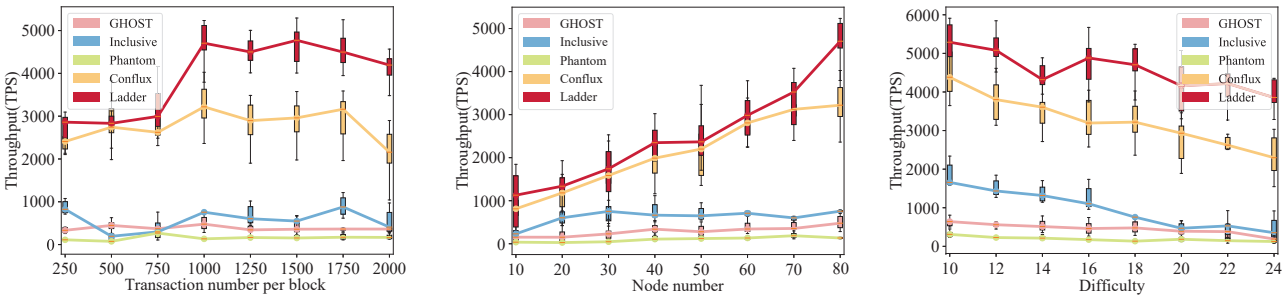
Waiting Time Duration: Following the generation of an upper-chain block in a specific round, the remaining nodes continue mining upper-chain blocks until they receive the lower-chain block from the designated convergence node. If the lower-chain block is not produced within the predefined waiting duration, the committee triggers the BFT consensus. Next we discuss how to set the waiting time duration.

Let W_i^j represent the waiting time for node j to receive a block with sequence number i, and T_i^j represent the timestamp when node j receives a block from node $V(i)$. We use $V(B)$ to represent the node that generated block B. $PT(V(i), j)$ indicates the time it takes for a block to propagate from node $V(i)$ to node j, and $MT(i)$ represents the mining time required by node $V(i)$ to generate a single block. Recall that the upper-chain block in round r is identified by the serial number $2r$, while the lower-chain block is denoted by the serial number $2r+1$. Assuming equal computing power, the mining time is the same for all nodes, while the propagation time varies. The waiting time W_i^j solely accounts for the propagation, excluding mining time, since any nonce can be used in the generation of lower-chain blocks. Thus, $W_i^j = PT(V(i), j)$. A node can estimate the mining and propagation times by analyzing the timestamps of the latest upper- and lower-chain blocks. Formally, this can be expressed as Eq.(2). Here, $MT(B^u_{r-1})$ is the mining time for the upper-chain block in round $r-1$, $PT(V(B^u_{r-1}), j)$ is the propagation time from the upper-chain block's generator to node j, and $PT(V(B^l_{r-1}), j)$ is the propagation time from the lower-chain block's generator to node j.

$$W^j_{2r+1} \approx \underbrace{(T^j_{2(r-1)} - T^j_{2(r-2)+1})}_{MT(B^u_{r-1})+PT(V(B^u_{r-1}),j)} - [\underbrace{(T^j_{2(r-2)} - T^j_{2(r-3)+1})}_{MT(B^u_{r-2})+PT(V(B^u_{r-2}),j)} - \underbrace{(T^j_{2(r-1)+1} - T^j_{2(r-1)})}_{PT(V(B^l_{r-1}),j)}] \quad (2)$$

The node responsible for generating the legal lower-chain block in round $r-1$ is the same as the node that generated the upper-chain block in round $r-2$ (denoted as $V(B^u_{r-2}) = V(B^l_{r-1})$), and the time for each node to generate a single block is equal ($MT(B^u_{r-1}) = MT(B^u_{r-2})$). Consequently, Eq.(2) can be simplified as $W^j_{2r+1} \approx PT(V(B^u_{r-1}), j)$. This means that the waiting time for node j to receive a block in the current round is equivalent to the propagation time it takes for a single block to propagate from the previous round's upper-chain block generator to node j.

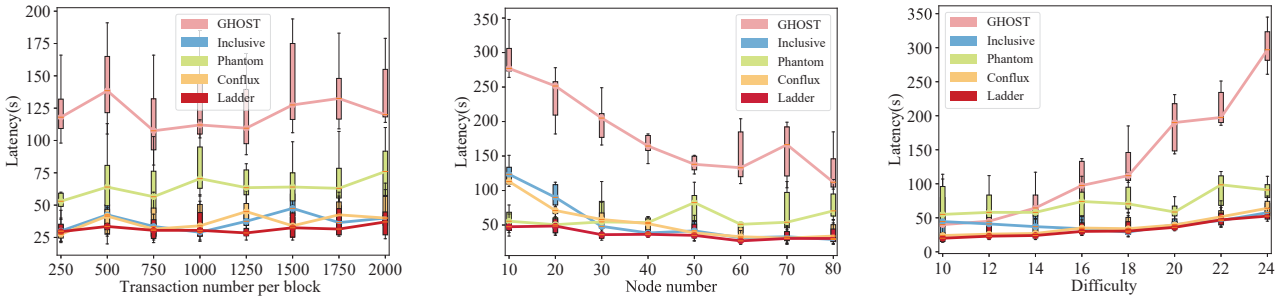
The analysis presented above demonstrates that in Ladder, any given node can determine the waiting time for lower-chain blocks by utilizing the historical information it has collected regarding the arrival times of the standard block in round $r-1$ and lower-chain blocks in the next round r.



5 Evaluations

In this section, we present results from a comprehensive evaluation of Ladder and compare them with prior approaches.

Setup and Experiments: We implemented a prototype of Ladder and compared it with four recent approaches: GHOST [26], Inclusive [18], Phantom [27], and Conflux [19]. Experiments are conducted on an 80-node LAN testbed, with each machine equipped with an Intel(R) Core(TM) i5-4590 CPU @3.30 GHz and 8 GB of RAM. The inter-node communication latency is set to approximately 80-120 ms to align with real-world network conditions [33]. We use a P2P communication protocol where each node is connected to approximately 10 other nodes. Experiments are run in a controlled, adversary-free environment to observe Ladder's optimal performance without adversarial interference. To align with Conflux, which confirms a block after 6 subsequent blocks, Ladder also confirms a block after 6 subsequent upper-chain blocks. Unlike using a fixed block interval [19, 37], we employ PoW for block generation. In our experiments, the throughput results of previous approaches match their reported values under the following conditions: block difficulty requires 18 leading zeros, and each block contains 1000 randomly generated payment transactions (each approximately 300 bytes), as derived from our interpretation of the protocol specifications.



Metrics: We primarily evaluate the end-to-end performance of Ladder and prior approaches. Throughput is measured as the number of confirmed transactions per second (TPS), while confirmation latency is defined as the time from a transaction's submission to its block confirmation. All experiments are repeated 10 times. We conduct experiments over a 10-minute stable operation starting from the genesis block, following Conflux's methodology [19] to ensure a consistent evaluation period. Metrics are recorded every minute, yielding 10 data points per experiment and 100 in total across all runs. This ensures statistically meaningful measurements while accounting for PoW's inherent randomness in block generation intervals. Box plots are used to assess variance, preventing short-term fluctuations from distorting metric trends. To capture metric variations caused by PoW's stochastic nature, we use whiskers, which extend to the most extreme data points within $1.5 \times IQR$ from the first ($Q1$) and third ($Q3$) quartiles, minimizing the impact of outliers. Additionally, we use line plots with points representing the medians of the metrics.

Aggregate Observations: The results show that Ladder outperformed all prior approaches. Among prior approaches, Conflux performed the best, with a median throughput of 2823 TPS and a confirmation latency of 43 seconds. Compared to Conflux, Ladder showed a 59.6% improvement in

(a) Throughput with different block sizes (b) Throughput with different number of nodes (c) Throughput with different block difficulties

Figure 7: Throughput of Ladder and its comparison with prior approaches.

Figure 8: Confirmation latency of Ladder and its comparison with prior approaches.

throughput and a 20.9% reduction in latency under the same settings. Ladder achieved a median throughput of 4506 TPS and a confirmation latency of 34 seconds. Next, we analyze the impact of block size, network size, and difficulty on the performance of Ladder and prior approaches.

Impact of Block Size: Figures 7(a) and 8(a) show the throughput and confirmation latency of various approaches across different block sizes under a difficulty level of 18. Results indicate that Ladder outperformed all prior approaches across the evaluated block sizes. For block size below 1000, Ladder exhibits lower throughput. As the block size increases from 1000 to 1750, throughput remains stable between 4000 and 5300 TPS. In this stage, the increased transaction capacity of larger blocks compensates for the growing propagation delay, maintaining stable throughput. However, at a block size of 2000, both Ladder and Conflux show a noticeable drop in throughput, likely due to higher network overhead and resource strain from larger block propagation. Throughput in Ladder fluctuates by around 1000 TPS, while latency varies by approximately 20 seconds. These fluctuations are primarily caused by PoW's randomness in block generation, with additional contributions from LAN congestion and scheduling delays affecting transaction propagation. Despite these fluctuations, Ladder maintains the highest efficiency among all tested approaches.

Impact of Network Sizes: Figures 7(b) and 8(b) show the throughput and confirmation latency of various approaches across different network sizes, with a fixed block size of 1000 and a difficulty level of 18. As the network size grows, throughput increases significantly, primarily due to the higher total computational power from more nodes participating in the PoW, resulting in more frequent block generation. Ladder's median throughput rises from 1043 TPS with 10 nodes to 4506 TPS with 80 nodes. Larger network sizes may introduce longer block propagation delays. However, confirmation latency decreases from a median of 47 seconds with 10 nodes to 34 seconds with 80 nodes, a reduction of 27.7%. The primary reason for this improvement is that increased computational power accelerates block generation, reducing the time required for transactions to be included in a block. This helps mitigate the impact of longer propagation delays by enabling faster confirmation through parallel processing.

Impact of Difficulty: Figures 7(c) and 8(c) show the throughput and confirmation latency at different block difficulty levels with a block size of 1000. Block difficulty significantly affects both throughput and confirmation latency. As the difficulty increases, throughput decreases, and confirmation latency increases across all prior approaches. Specifically, when the difficulty level is 10, the median throughput of Ladder reaches 5314 TPS, which is 27.2% higher than at level 24. This behavior occurs because higher difficulty reduces the block generation frequency, resulting in longer confirmation times. Despite the decline in performance with increasing difficulty, Ladder consistently outperforms all prior approaches.

Result Analysis: Ladder achieves higher throughput and lower latency across varying conditions due to several key

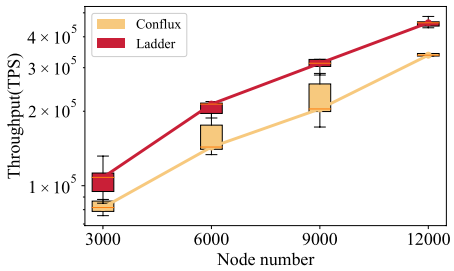

Figure 9: Throughput under large-scale node conditions.

factors. The convergence nodes streamline ledger consolidation by handling transaction ordering. This reduces the computational burden on other nodes, allowing them to focus on parallel block generation. Additionally, Ladder's convergence mechanism simplifies lower-chain block generation and transaction confirmation, thereby reducing overall system complexity. Even during anomalies that require committee intervention, upper-chain block production continues until a new lower-chain block is generated.

Large Scale Simulation: The simulation is conducted on a server with 128GB of memory, with time delays introduced to simulate the block generation and broadcasting processes. Block generation time is positively correlated with block difficulty, while broadcasting time is affected by both block size and the number of participating nodes. The experiments simulated networks of 3000, 6000, 9000, and 12000 nodes. As shown in Figure 9, the results indicate that Ladder's throughput improves by 34.2% compared to Conflux as the number of nodes increases to 12000.

Heterogeneous Nodes: We conduct experiments on Alibaba Cloud using a heterogeneous node setup of 80 virtual machines (VMs): 30 VMs with 4 cores and 8 GB RAM, 30 VMs with 4 cores and 16 GB RAM, and 20 VMs with 8 cores and 16 GB RAM. Due to the intensive hash computations required by PoW, CPU utilization on each VM remains high, ranging from 90% to nearly 100%. Memory usage averages 22.5% on 8 GB VMs and 13.25% on 16 GB VMs, primarily allocated for the transaction pool, blockchain state, and PoW computation caching. We evaluate system performance under varying bandwidth constraints of 10, 20, and 30 Mbps, with 1000 transactions per block and a difficulty level of 18. At 10 Mbps, throughput is 2011 TPS, indicating that bandwidth is the primary bottleneck. Increasing bandwidth to 20 Mbps raises throughput to 3986 TPS, approaching the theoretical maximum. At 30 Mbps, throughput reaches 4652 TPS, showing only marginal improvement over the 20 Mbps results, suggesting that PoW computation efficiency becomes the new bottleneck. These experiments show Ladder's ability to adapt to heterogeneous environments and optimize performance based on available resources and network conditions.

Impact of BFT Committee: We also perform latency testing on the committee in Ladder. Based on our analysis in BFT Committee Size section (Sec. 4), we choose a committee size of 300 nodes. Since committee consensus operates as an independent module, we conduct separate experiments simulating a scenario where nodes simultaneously receive two conflicting lower-chain blocks. We use 80 VMs to emulate a 300-node committee, including 99 Byzantine nodes. Under this setup, the average time cost for committee consensus is 3.25 seconds, which exceeds the lower-chain broadcast time. Although the committee introduces some performance overhead, it plays a crucial role in maintaining system security by mitigating the impact of malicious nodes and ensuring consensus integrity.

6 Security Analysis

6.1 Transaction Trustworthiness

Ladder consists of a growing structure, similar to chain growth in conventional blockchains, where upper and lower-chain blocks serve as the key elements binding the structure. Although the node whose block was selected as the standard upper-chain block in the previous round chooses the next standard block, it cannot always select its own block due to the competitive nature of upper-chain block generation. The probability of a node repeatedly generating blocks without faults is negligible, as it must also handle verification, sorting, and parallel processing of received upper-chain blocks. This makes it further improbable for a node to consistently generate lower-chain blocks in subsequent rounds and keep adding blocks to the upper-chain with invalid transactions. This establishes the trustworthiness of confirmed transactions.

6.2 Resistance Against Common Attacks

This subsection demonstrates how Ladder is resilient against some common attacks.

Sybil Attack [9]: In a Sybil attack, the attacker creates a large number of nodes to manipulate the consensus protocol. As Ladder relies on PoW rather than node count to determine if a given block can be added to the upper-chain, it is resilient against Sybil attacks. Furthermore, only nodes that have previously contributed a standard upper-chain block can generate lower-chain blocks or participate in HotStuff consensus for super block generation. This makes launching a successful Sybil attack on Ladder prohibitively costly.

Denial of Service (DoS) Attack: In PoW-based blockchains, block verification is fast, while block generation is slow and resource-intensive, providing inherent protection against DoS attacks. However, predictable leader election can expose specific nodes to targeted DoS attacks. To mitigate this, Ladder uses VRF for leader selection, reducing the likelihood of successful targeting by adversaries. Even if an attack occurs, other nodes can continue verification and mining without interruption, ensuring the system remains functional.

Double-Spend Attack: To perform a double-spend attack, the adversary cannot immediately engage in malicious activities but must first generate a block that is selected by the pivot chain node as an upper-chain block. The adversary must also

keep the pivot chain operating normally while mining in the next round to generate the lower-chain block. The limited computing power and the hardest chain principle make it nearly impossible for an attacker to execute a double-spend attack within any practically meaningful time frame (*e.g.*, one day). Attacks become highly improbable when adversary resources fall below a certain threshold in Ladder [23].

Eclipse attack [13]: Ladder relies on computing power to establish credibility. While the Eclipse attack impacts the HotStuff consensus component, other nodes that are not part of the BFT committee still generate blocks using PoW. This practically eliminates the impact of Eclipse attacks on the overall system performance.

6.3 Security and Availability

A blockchain network must ensure two key characteristics: security, which ensures that only valid transactions are included in the ledger, and availability, which guarantees that transactions are confirmed within a finite time. Prior work [11] has shown that the three properties of common-prefix, finality, and liveness are sufficient to achieve these characteristics. We define these three properties along with an additional one, and prove that Ladder satisfies both security and availability through lemmas and theorems. Theorems are proven in this section, while proofs of lemmas are provided in the Appendix.

Common-prefix: At any given time, if all nodes in the blockchain network have, with very high probability, the same knowledge of the verified portion of the ledger, the blockchain satisfies the common-prefix property.

Finality: If the verified portion of the ledger of any honest node does not change over time (such as in response to an attempted attack or due to intermittent inconsistencies among nodes), the blockchain ledger satisfies the finality property.

Liveness: If a valid transaction becomes part of the verified portion of the ledger within a predefined amount of time, the blockchain satisfies the liveness property.

l-balance: A sequence of $m \geq l$ nodes is said to be l-balanced when in any subsequence of l or more consecutive nodes, the honest nodes are in majority.

Lemma 1. *The probability that an adversary gets to cast more than $1/3$ of the votes in Ladder's BFT committee (which generates the super block) decreases exponentially with the committee size.*

Lemma 2. *Let k represent the number of blocks in the lower-chain. If the sequence of nodes that generated the given sequence of standard upper- and lower-chain blocks is $2k+2$-balanced, the blockchain ledger generated from the corresponding rounds satisfies the common-prefix property.*

Lemma 3. *If the sequence of nodes that generated the given sequence of standard upper-chain and lower-chain blocks is $2k$-balanced, the blockchain ledger generated from the corresponding rounds satisfies the finality property.*

Lemma 4. *If the sequence of nodes that generated the given sequence of standard upper-chain and lower-chain blocks is $2k$-balanced, the blockchain ledger generated from the corresponding rounds satisfies the liveness property.*

Lemma 5. *The sequence of nodes that generate the given sequence of standard upper-chain and lower-chain blocks is, with very high probability, $2k$-balanced.*

Theorem 1. *Any block in the lower-chain of Ladder is a valid block with very high probability.*

Proof of Theorem 1. For an adversary to generate a lower-chain block in a given round, the adversary must first gain the authority to generate the lower-chain block in that round, which can happen with the probability of just $\frac{q^3+q(1-q)}{q^3+1-q}$ (Appendix B). If an adversary is able to contribute a lower-chain block where it enters any malicious/incorrect information, that will be detected and a super block generation process will start.To succeed in the BFT consensus, the adversary must control more than $1/3$ of the committee. According to Lemma 1, the probability of this happening is extremely low. □

Theorem 2. *Ladder satisfies common prefix, finality, and liveness properties.*

Proof of Theorem 2. By Lemma 5, we know that the sequence of nodes that generated the given sequence of k lower-chain blocks in Ladder satisfies the $2k$-*balance*. Consequently, by Lemmas 2, 3, and 4, we conclude that the resulting blockchain ledger in Ladder satisfies the common prefix, finality, and liveness properties. □

These two theorems, together, prove that Ladder has both security and availability characteristics.

7 Conclusion

We propose Ladder, a structured twin-chain DAG blockchain that optimizes parallel block processing to achieve high throughput, low latency, and resilience against balance attacks. Ladder improves sorting efficiency by designating a convergence node per round, eliminates PoW for lower-chain blocks, and incentivizes node participation for enhanced performance and security. To counter adversarial disruptions, a committee is deployed to generate special blocks when faulty blocks are detected. Experiments on an 80-node network show that Ladder improves throughput by 59.6% and reduces latency by 20.9% compared to state-of-the-art methods.

A Selfish Mining Analysis

We analyze the probability of adversary-generated upper-chain blocks exceeding the difficulty of super blocks in the context of selfish mining. If the adversary generates at least m blocks with x leading zeros, it may exceed the difficulty of the k-member super block committee. The probability of generating these blocks, which would exceed the super blocks, can be calculated as $P = \frac{1}{2^{m(x+1)}}$. The difficulty of these upper-chain blocks is $\sum_{i=1}^{m} \sqrt{x} = m\sqrt{x}$, while the super blocks have a difficulty of $\sqrt{k}$. Therefore, the condition for the adversary to surpass the super block's difficulty is $\sqrt{k} \leq m\sqrt{x}$, which implies $x \geq k/m^2$. Substituting this into the probability expression for P, we can obtain that $P = \frac{1}{2^{m(x+1)}} \leq \frac{1}{2^{m(k/m^2+1)}} = \frac{1}{2^{k/m+m}} \leq \frac{1}{2^{2\sqrt{k}}}$.

B Proof of Lemmas

Proof of Lemma 1

Proof. Let $Pr(H|H)$ represent the probability that the honest lower-chain block generation node selects an honest node as the next round lower-chain block generation node. Let $Pr(A|H)$ represent the probability that the honest lower-chain block generation node selects an adversary node as the next round lower-chain block generation node. Let $Pr(H|A)$ represent the probability that the adversary lower-chain block generation node selects an honest node as the next round lower-chain block generation node. Finally, let $Pr(A|A)$ represent the probability that the adversary lower-chain block generation node selects an adversary node as the next round lower-chain block generation node.

If the block generation node in the current round is an honest node, the probability that the block generation node in the next round is an honest node or the adversary corresponds to the respective computing power share. Let q represent the fraction of the computational power contributed by the adversary to the blockchain network. Since there must be a next block generation node, we have $Pr(H|H)+Pr(A|H) = 1$, and $Pr(A|H) = q$, $Pr(H|H) = 1-q$.

If the block generation node in the current round is an adversary node, then if the adversary can compute a legal block within the waiting duration (see Waiting Time Duration in Sec. 4), then the block generation node in the next round will still be an adversary node with probability $Pr(A|A) = \frac{q}{q^2+1-q}$ If the adversary fails to compute a legal block and an honest node computes a legal block, then the block generation node in the next round will be an honest node with probability $Pr(H|A) = \frac{(1-q)^2}{q^2+1-q}$.

The selection of the lower-chain block generation node depends only on the current round's lower-chain block, independent of previous rounds. According to the Markov property, the steady-state probability distribution can be calculated with the calculated state transfer probability, and it can be solved that the probability of the next block generation node being an adversary in each round is less than $1/3$ when the q is less than 0.3.

As we know, the probabilities $Pr(H)$ and $Pr(A)$ can be expressed using the following equations:

$$Pr(H) = Pr(H|H)Pr(H) + Pr(H|A)Pr(A)$$

$$Pr(A) = Pr(A|H)Pr(H) + Pr(A|A)Pr(A)$$

By substituting the expressions for various terms, we can get

$$Pr(H) = \frac{(1-q)^2}{q^3+1-q}$$

and

$$Pr(A) = \frac{q^3+q(1-q)}{q^3+1-q}$$

Let the committee size $k = 3m$, then

$$\begin{aligned} Pr(|A| > 1/3) &= \sum_{i=m}^{3m} Pr(H)^{3m-i} Pr(A)^i \\ &< \sqrt{\frac{8m}{3\pi}} (\frac{16\sqrt{2}}{27})^m \end{aligned}$$

As m increases, the upper bound on the probability decreases exponentially, where $m \geq 3$. □

Proof of Lemma 2

Proof. Suppose the block sequence does not satisfy common-prefix property when the sequence of block generation nodes satisfies $2k$+2-balance. Let the first round be numbered 0. Let the two rounds when the ledger appears to have conflicting transactions/blocks be d and d', such that $d' - d \geq k$. Clearly, there exist at least $2k$+2 block generation nodes. The number of honest nodes $\leq d'$ in the ledger when honest nodes produce at most one block at each height. In the ledger, the number of adversary nodes $\geq (d-0) + (d'-d) = d'$, and the number of adversary nodes $\geq$ honest nodes in the ledger for the block sequence initial block to block d' block generation node sequence, which contradicts the $2k$+2-*balance* property. □

Proof of Lemma 3

Proof. Suppose the block sequence does not satisfy the **Finality** property when the given sequence of block generation nodes is $2k$-balanced. In other words, there exists a block b in round d that is part of ledger when ledger is generated in round $i > d+k$ but not a part of the ledger when ledger is generated in round $j > i$. At this point, for the last $\geq k+1$ blocks of the ledger, there is an inconsistent view, and that would require the block generation nodes to not be $2k$-balanced, contradicting the lemma statement. □

Proof of Lemma 4

Proof. After $2kt$ rounds, the height of the ledger increases by $\geq (k+1)t$, where $\leq (k-1)t$ is generated by the adversary.

Then $\geq (k+1)t-(k-1)t = 2t$ blocks are honest, and among them, $\geq 2t-k$ have been confirmed. This means that at least $2t-k$ honest blocks are added to the block sequence in every $2kt$ rounds.

Therefore, a transaction that is recognized by all honest nodes will definitely be added to the block sequence (ledger) and finally confirmed. □

Proof of Lemma 5

Proof. For a given sequence of length l, where the probability that the adversary accounts for more than 50% does not exceed $exp(-cl)$

By Chernoff's inequality $Pr[X \geq (1+\delta)\mu] < exp(-\frac{\mu\delta^2}{2})$, where $\mu = ql, \delta = \frac{1-2q}{2q}$, we obtain

$$\begin{aligned} Pr[X \geq (1+\delta)\mu] &= Pr[X \geq \frac{l}{2}] \\ &\leq exp(-\frac{l(1-2q)^2}{8q}) \\ &= exp(-cl), c > 0 \end{aligned}$$

For a sequence of block generation nodes of length L, any subsequence of length at least l has a probability of at most $\frac{(L-l+1)(L-l+2)}{2} exp(-cl) < L^2 exp(-cl)$ that the adversary controls more than 50%.

Then $Pr[Ladder's\ node\ sequence\ satisfies\ 2k\text{-}balance] > 1-\delta(l)$ and $\delta(l)$ decreases exponentially with l. □

Vegeta: Enabling Parallel Smart Contract Execution in Leaderless Blockchains

Abstract

Consensus and smart contract execution play complementary roles in blockchain systems. Leaderless consensus, as a promising direction in the blockchain context, can better utilize the resources of each node and/or avoid incurring the extra burden of timing assumptions. As modern Byzantine-Fault Tolerant (BFT) consensus protocols can order several hundred thousand transactions per second, contract execution is becoming the performance bottleneck. Adding concurrency to contract execution is a natural way to boost its performance, but none of the existing frameworks is a perfect fit for leaderless consensus.

We propose *speculate-order-replay*, a generic framework tailored to leaderless consensus protocols. Our framework allows each proposer to (pre-)process transactions prior to consensus, better utilizing its computing resources. We instantiate the framework with a concrete concurrency control protocol Vegeta. Vegeta speculatively executes a series of transactions and analyzes their dependencies before consensus, and later deterministically replays the schedule. We ran experiments under the real-world Ethereum workload on 16-vCPU virtual machines. Our evaluation results show that Vegeta achieved up to 7.8× speedup compared to serial execution. When deployed on top of a leaderless consensus protocol with 10 nodes, Vegeta still achieved 6.9× speedup.

1 Introduction

Blockchain or state machine replication (SMR) is a promising solution for providing trustworthy services among a group of untrusted entities or *nodes*. To mask failures, blockchain systems rely on a consensus protocol [32, 50, 51, 58] to reach an agreement on the sequence of blocks (and transactions). Each node is abstracted as a state machine [65], which sequentially executes the ordered transactions based on the same initial *world state*. Towards wide-scale adoption, boosting performance of blockchain systems is becoming a hot topic in both academia and industry [36, 59, 68, 77].

As Nakamoto-style consensus (such as Bitcoin [58] and Ethereum 1.0) has limited performance, modern permissionless and permissioned blockchains [17, 24, 37] are adopting Byzantine-Fault Tolerant (BFT) consensus protocols [22, 25, 29, 49, 57, 78] as their consensus layer. Most classical BFT protocols are leader-based [22, 25, 39, 78], meaning that a single leader is in charge of disseminating proposals and coordinating consensus. To select a single and stable leader, however, they rely on additional timing assumptions which may not be realistic in large-scale Wide Area Networks (WANs). Besides, such a single node may easily become the performance bottleneck [47, 68, 76].

Recently, many leaderless protocols are proposed targeting deployment in blockchain systems. Leaderless variants either have no timing assumption to elect any special role [17, 29, 41, 55, 57, 60], or assign the leader role to every node [28, 68]. Each node is required to act as a proposer and make a block proposal, and the final decision is a (sub)set of all proposals. Leaderless protocols are becoming an appealing solution to blockchain systems. For instance, Sui [7, 38], HashGraph [17] and Conflux [52] use a DAG-based protocol as their consensus layer, while AntChain leverages an asynchronous consensus for adaptive advancement [55].

BFT consensus protocols nowadays can process hundreds of thousands of transactions per second (TPS) [29], or even beyond one million [19] when deployed within a LAN. In contrast, the serial transaction execution engine of Ethereum platform only achieves around 100 TPS throughput [44], throttling the whole system. A natural way to improve efficiency of smart contract execution is to leverage modern multi-core architecture and add concurrency to transaction processing [26, 30, 36, 53].

When designing a concurrency control protocol in blockchain contexts, we argue that the consensus layer should also be taken into consideration as they play complementary roles. Currently, there are two trends in designing such pro-

*Equally contributed authors.
#Corresponding author: shengyun.liu@sjtu.edu.cn

tocols [66]: the *order-execute* framework [15, 36, 48], where transactions are (concurrently) executed after consensus in a deterministic way and produce the same results; and the *execute-order-validate* framework [14, 42, 46], where transactions are first speculatively executed by proposer(s) before consensus, and (re-)executed and/or validated by other nodes after consensus. In the order-execute framework, transaction execution is totally decoupled from consensus and thus can be readily plugged into any consensus protocol (leader-based or leaderless). The execute-order-validate framework allows proposer(s) to orchestrate transaction execution before consensus, such that other nodes can follow the order produced by proposer(s) and execute them in an efficient manner.

Despite being a more promising direction towards blockchain deployments, leaderless consensus introduces new challenges for efficient transaction processing, and neither of the aforementioned frameworks is a perfect fit. On the one hand, the order-execute framework cannot fully inherit the scalability feature from leaderless consensus, as each node must execute every block after consensus. Besides, they must schedule transactions in a deterministic way in order to produce the same execution results, limiting speedups when inconsistency resolution is frequently involved. On the other hand, the execute-order-validate framework either targets leader-based consensus [15, 42, 44, 46], or aborts transactions if new conflicts are introduced after consensus [14]. In the second case, aborted transactions must go through the whole procedure (i.e., execute, order and validate) again. Besides, neither takes leaderless consensus into special consideration.

We observe that the transaction execution layer of any blockchain system or SMR protocol can be divided into two parts: the pre-consensus part that allows every node to individually process distinct transactions, and the post-consensus part that requires every node to perform the same set of tasks (e.g., transaction execution and validation). To better adapt to leaderless consensus and improve scalability, in general we should place more work in the former if this can effectively reduce the burden of the latter.

Notably, the idea of allowing nodes to (pre-)process transactions prior to replication has been extensively explored in deterministic databases [40, 45, 69, 73, 79]. For instance, for transactions which cannot determine read/write sets a priori (also named dependent transactions), reconnaissance queries [72] is typically performed before replication. This pattern is a natural fit for transferring the scalability feature of leaderless consensus to the smart contract layer and thus deserves further study.

We accordingly propose a *speculate-order-replay* framework for efficient smart contract execution in leaderless blockchains. Before disseminating block proposals, each node first speculatively executes a series of transactions and/or performs any task that may help accelerate post-consensus tasks. Once blocks are totally ordered, each node enters the *replay* phase, during which it tries to (efficiently) execute transactions with the help of the information provided by speculation. Because in leaderless consensus there exist other concurrent proposals, such information may not be accurate with regard to the actual execution context. In case some transactions/operations introduce new conflicts in the replay phase, they must be processed in a deterministic way.

We instantiate this framework by a concrete concurrency control protocol (Vegeta). Vegeta realizes transaction-level parallelism, meaning that each transaction is treated as an indivisible unit. In the speculation phase, Vegeta executes transactions in a fully parallel manner, and obtains their read/write sets in order to construct a DAG that encapsulates the dependency information. In the replay phase, each node tries to "replay" the schedule provided by speculation. If a transaction tx produces the same read/write sets, its execution is finalized. Otherwise, if tx introduces new dependencies by accessing new keys, tx is re-executed after other transactions complete. The rationale of Vegeta is simple: although proposers are less likely to obtain correct execution results based on an inaccurate world state, the dependency information provided is most likely accurate.

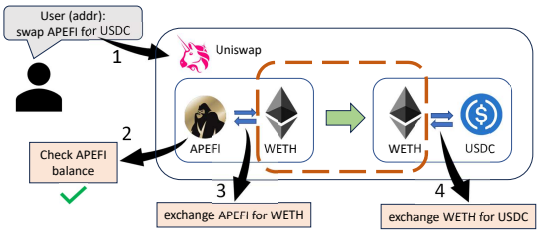
We have implemented Vegeta in Golang and evaluated it with the Ethereum workload, meaning all the transactions and blocks are real and taken from the most representative smart contract platform. We ran experiments on Amazon EC2 platform, both on a single virtual machine and among a group of at most 10 machines in order to evaluate Vegeta with a leaderless consensus protocol. The evaluation results demonstrate that Vegeta on a single machine achieved an average speedup of 7.8× compared to serial execution. We also evaluated the performance of AriaFB [56], a deterministic optimistic Concurrency control protocol. Vegeta outperformed AriaFB by up to 2.1×. We postpone the proof of Vegeta to Appendix A due to space limit.

2 Background and Related Work

2.1 System Model

We focus on the blockchain or state machine replication (SMR) problem [65], a solution to which is a highly reliable and available distributed system. Each node is abstracted as a state machine and sequentially executes a series of requests or *transactions* issued by clients. We target authenticated Byzantine failure model [51], meaning that the faulty nodes may exhibit any malicious behavior except for breaking cryptographic schemes. We assume at most f nodes can be faulty and there are a total of $n = 3f + 1$ nodes, the lower bound for BFT SMR protocols under asynchrony assumption [32].

Transaction semantics. Each transaction contains several operations and may read and/or write a set of keys or objects, which are collectively maintained as a world state in blockchains [5]. The world state can be simply considered a key-value store. Blockchain systems provide serializabil-



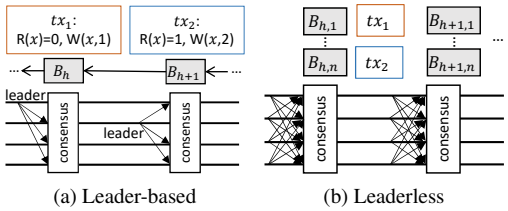


Figure 1: Example for Ethereum smart contract invocation.

(a) Leader-based (b) Leaderless

Figure 2: Comparison between leader-based and leaderless consensus protocols.

ity [21] semantics, in the sense that any execution result is equivalent to the outcome of sequentially executing all transactions in some (pre-defined) order. To enable parallel processing, we further distinguish between conflicting and non-conflicting transactions. We say two transactions tx_1 and tx_2 are *conflicting* if they access the same key x and at least one of them writes x. Otherwise, tx_1 and tx_2 are *non-conflicting*.

2.2 Smart Contracts

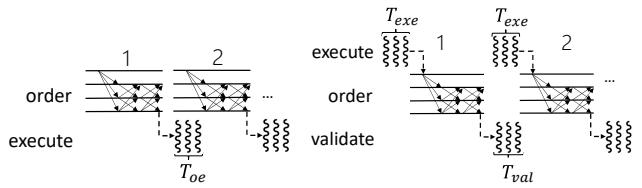
Smart contracts [71] implement application logic and can be simply considered a piece of code deployed on top of blockchains. Each transaction invokes the code of a contract, which may recursively invoke another contract.

In Figure 1 we give an example for Ethereum smart contract invocation. This example [2] is stripped off from the Ethereum mainnet. A user wanted to trade some Ape Finance tokens (APEFI) [1] for USDC [9], a stablecoin pegged to US dollar. Uniswap [8] is a Decentralized Exchange (DEX) contract for facilitating token swap. The user first invoked the Uniswap contract (step 1), which then checked the balance of the user by invoking the APEFI contract (step 2). At that particular moment, there was not a liquidity pool available for exchanging APEFI and USDC. Hence, the Uniswap contract leveraged Wrapped ETH (WETH) [10] as an intermediary token for achieving the desired trade (step 3). Finally, the Uniswap contract exchanged WETH for USDC (step 4). By this example we can observe, when a user initiates a transaction, the user is not aware of the (full) list of addresses (or keys) that the transaction will access. To accurately obtain such information, an Ethereum node must execute this transaction based on the most recent world state.

2.3 Leader-Based vs. Leaderless Consensus

Existing SMR protocols can be roughly classified into two categories according to the ways they order proposals: leader-based and leaderless. Leader-based protocols rely on a special role (named leader) to coordinate consensus, i.e., disseminating proposals to and/or collecting votes from other nodes.

We take PBFT [25] and HotStuff [78], two representative leader-based BFT protocols for example. PBFT assigns the leader role to a single node until this node is faulty or partitioned, upon which a view change sub-protocol is triggered to elect a new leader. HotStuff proactively rotates the leader role, ensuring that every node has the opportunity to propose. Upon making a new block proposal B_{h+1} (see Figure 2a), the leader is aware of the most recent proposal B_h that precedes B_{h+1}. Transitively, the leader knows all the previous proposals. Thus, the leader can pre-execute tx_2 based on the execution result of tx_1, which is included in B_h. In summary, leader-based protocols have the following feature:



Definition 1. *(Perfect Context) we say a consensus protocol has perfect contexts, if when any node makes a proposal $\mathcal{B}$, the node is aware of an ordered list of all proposals that are (or will be) committed before $\mathcal{B}$.*

Both PBFT and HotStuff and several permissionless blockchains such as Bitcoin [58] and Ethereum [5] have perfect contexts. With this feature, the proposer (e.g., the single leader) can (pre-)execute all transactions before consensus, give a total or partial order among them and insert (the digest of) execution results as well as transaction dependencies into the proposal. Other nodes, upon receiving the proposal, can (re-)execute the transactions in the same pre-defined order and obtain the same results.

Leaderless protocols, in contrast, have no fixed leader role but allow every node to act as a proposer. One type of leaderless protocols [16,28,68] pre-partitions sequence space and assigns them to every node, while another type [29,31,38,41,57] is designed under asynchrony assumption. The final output of leaderless protocols is a combination of all committed proposals. By allowing each node to act as a proposer, leaderless protocols can distribute workloads and better utilize resources (e.g., CPU and network capacity). Since leaderless protocols allow concurrent proposals made by multiple proposers, they have no perfect context. For instance, in Figure 2b, concurrent proposals $B_{h,1},\ldots,B_{h,n}$ are proposed by distinct nodes, and hence are totally ordered only after consensus. Their proposers have no perfect knowledge of other concurrent proposals and thus cannot get correct results.

2.4 Parallel Execution

To integrate parallel execution into blockchains or SMR protocols, existing approaches can also be categorized into two types: the order-execute and execute-order-validate frameworks, as shown in Figure 3.

(a) order-execute (b) execute-order-validate

Figure 3: Existing frameworks for parallel execution.

Order-execute. The order-execute framework [15, 36, 48] (Figure 3a) orchestrates a (parallel) execution phase that emerges after consensus. Each node individually tries to parallelize transaction execution in a deterministic way. Typically, the results of parallel execution must be equivalent to the ones obtained by sequentially executing those transactions in the order given by consensus. The order-execute framework "blindly" imposes constraints on the order of transactions and may incur additional costs for, e.g., sequentially executing non-conflicting transactions and/or re-executing conflicting ones. The execution component in order-execute is decoupled from consensus, and thus can be integrated into any consensus protocol (leader-based or leaderless). Saber [54] improves transaction execution by allowing different groups to execute different transactions. The idea of Saber is akin to inter-node parallelism and largely orthogonal to our contribution.

Execute-order-validate. The execute-order-validate framework [14, 18, 42, 46, 67] (Figure 3b), in contrast, enables proposer(s) to (pre-)execute transactions before consensus. There are two trends in instantiating this framework: they either target a leader-based consensus protocol [18, 42, 67] or resolve conflicts in a trivial way [14, 46]. In the former case, the single leader orchestrates transaction execution and re-orders them if necessary, while other nodes follow the schedule and accordingly execute transactions in the same pre-defined order. In the latter case, existing protocols tend to *trust* the execution results obtained prior to consensus, but resort to a heavy fallback mechanism to resolve newly-introduced conflicts. For example, Eve [46] assumes the read/write sets of each transaction can be obtained a priori, otherwise it must rely on a leader-based protocol (i.e., PBFT) to resolve conflicts. Hyperledger Fabric [14] requires every peer to speculatively execute transactions and later reach consensus also on execution results, so as to deal with non-deterministic operations. If new conflicts are introduced after consensus, conflicting transactions must go through the whole procedure again.

Deterministic database systems. Concurrency control has long been a hot topic in database systems [13, 21, 64]. There are numerous works targeting deterministic scheduling and execution [12, 33, 34, 43, 72–74]. To enable parallel execution while still producing identical results, deterministic databases usually require the reach/write sets of each transaction can be obtained a priori. Otherwise, reconnaissance queries [33, 61, 62, 72, 73] or speculative execution should be performed before transaction scheduling. Such a technique [72] decomposes a *dependent transaction* with unknown read/write sets into a combination of some read-only transactions and a conditional-write transaction. The read-only transactions discover the read/write sets (say, before replication),while the conditional-write transaction commits (after replication) if the read values match. Calvin [73] adopts a lock-level concurrency control protocol and orchestrates lock acquisition based on a pre-defined total order. Calvin does not readily support dependent transactions, but can leverage the mechanism discussed above (also named Optimistic Lock Location Prediction, OLLP) to obtain read/write sets. Caracal [62] and Epic [61] utilize multi-version concurrency control (MVCC) to reduce conflicts and can also run a similar identification phase to determine read/write sets. Reconnaissance query is analogous to the speculation in Vegeta, but Vegeta and our framework specifically target leaderless blockchains (under Byzantine faults) and are more focused on co-design between pre- and post-consensus tasks. Besides, Vegeta does not consider the speculation output as potential results, but only relies on it for dependency analysis.

Aria [56] does not require read/write sets to be known before execution but first executes transactions batch by batch in a fully parallel manner. If any transaction *tx* introduces conflicts with an earlier transaction in the same batch, *tx* is aborted and re-tried with the next batch. When a workload results in a very high abort rate, Aria further resorts to a fallback mechanism (e.g., Calvin [73]) to deterministically resolve the conflicts, instead of repeatedly trying aborted transactions. In a sense, Vegeta uses a similar batching mechanism in the replay phase, but further leverages the speculation phase to wisely group transactions into batches. Morty [23] is a recently-proposed concurrency control method that leverages transaction re-execution to improve throughput. Our method instead introduces re-execution to ensure consistency among different nodes. Basil [70] is a newly-proposed BFT transactional storage system, which demonstrates that the leaderless feature can effectively improve performance.

3 The Speculate-Order-Replay Framework

We observe that the successful story of leaderless consensus protocols stems from the equality of all nodes in disseminating proposals and processing transactions [75], thus effectively balancing workloads. We intend to further achieve such a feature in the contract execution layer. To this end, we study a generic framework called speculate-order-replay (SOR, as shown in Figure 4). Similar to utilizing resources of all nodes in a leaderless consensus protocol, the speculate-order-replay framework allows each node to process and speculatively execute distinct transactions before consensus. We call this step *speculation*. Although proposers do not have a perfect execution context, they may still obtain crucial information about transaction conflicts, read/write sets and program traces,

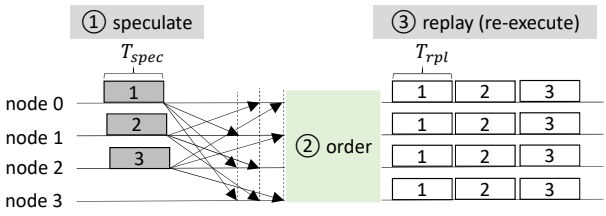


Figure 4: The speculate-order-replay framework.

which can greatly help maximize parallelism.

Once the speculation phase completes, each proposer takes the transactions and other information as input and enters the *ordering* phase. The ordering phase is run solely by a consensus protocol, and thus we omit its detail in this paper. Once the sequence of committed proposals is agreed upon by consensus, each node enters the *replay* phase. In general, conflicting operations must be executed in the same (serial) order, while non-conflicting operations can be processed in parallel. If the information provided by speculation is almost accurate, nodes in the replay phase may execute transactions with a maximum degree of parallelism, while at the same time paying no/few extra costs for handling (unnecessary) aborts. However, if some transactions impose new conflicts, they must be carefully treated. We postpone the detail to §4 as it is related to specific parallelism schemes.

Analysis of speedups. We give a simple analysis for demonstrating why the SOR framework may scale better with regard to the speedup achieved. The results are also shown in Table 1. We assume on average, sequentially executing a block of transactions takes T_{seq} seconds, which is the baseline for further comparison. Executing m blocks takes mt_{seq} seconds. Similarly, the order-execute framework (Figure 3a) takes mT_{oe} seconds to execute m blocks if each block on average costs T_{oe} seconds. Compared to serial execution, the speedup achieved by the order-execute framework is $\frac{T_{seq}}{T_{oe}}$.

As for the execute-order-validate framework (Figure 3b), each block first goes through an execution phase, which takes T_{exe} seconds. After consensus, each node validates the execution results by (re-)executing them, which takes T_{val} seconds. Thus, each block incurs $T_{exe}+T_{val}$ seconds for execution. Due to pipelining techniques, the execution phase of B_{h+1} can be overlapped with the validation phase of B_h. By doing so, the speedup approaches $\frac{T_{seq}}{T_{exe}}$ if m is large and $T_{exe} \geq T_{val}$. The latter assumption holds because the leader usually takes more time to orchestrate transaction execution [15].

Finally, we assume in SOR, the speculation phase takes T_{spec} seconds, while the replay phase takes T_{rpl} seconds (Figure 4). We further assume transactions are equally distributed to each node, which is an ideal assumption for SOR and in practice can be implemented by, e.g., applying load-balancing [68]. For each block, the speculation phase is only executed by one node, and different blocks can be speculatively executed in parallel. Thus, each block still takes $T_{spec}+T_{rpl}$ seconds, but the speedup, which takes m blocks into consideration, is $\frac{mT_{seq}}{mT_{spec}/n+mT_{rpl}} = \frac{T_{seq}}{T_{spec}/n+T_{rpl}}$.

Table 1: Analysis of speedups of different frameworks. $T_{oe} \approx \frac{T_{seq}}{\#cores} \approx T_{exe} \approx T_{val}$ if very few conflicts between transactions exist (which is not the case for Ethereum workloads). In contrast, $T_{rpl} \approx \frac{T_{seq}}{\#cores}$ if the information provided by the speculation phase is almost accurate and the degree of parallelism is approximately equal to the number of cores (though with many conflicts).

	latency	speedup
sequential	T_{seq}	-
order-execute	T_{oe} (Figure 3a)	$\frac{T_{seq}}{T_{oe}}$
execute-order-validate	T_{exe}+T_{val} (Figure 3b)	$\frac{T_{seq}}{T_{exe}}$
speculate-order-replay	T_{spec}+T_{rpl} (Figure 4)	$\frac{T_{seq}}{T_{spec}/n+T_{rpl}}$

We can observe that the bottleneck of speculate-order-replay mainly locates at the replay phase, which must be performed by every node. Intuitively, we may (moderately) put additional efforts into speculation if T_{rpl} can decrease. In contrast to order-execute, nodes in our framework can freely choose in what order transactions are executed, thus maximizing parallelism and alleviating re-execution burden. Compared to execute-order-validate, our solution is tailored to leaderless protocols and may better scale as nodes can speculate in parallel.

The SOR framework can be instantiated on different layers, e.g., transaction-level parallelism (Vegeta), lock-level parallelism or instruction-level parallelism. One may even integrate other techniques (e.g., zero-knowledge rollups [11] or I/O prefetching [27]) into SOR, so long as they help alleviate the burden of replay and the extra costs of speculation are acceptable.

4 Vegeta

We then elaborate on Vegeta, which follows the speculate-order-replay framework and implements transaction-level parallelism. Vegeta does not need to maintain a multi-version key-value store, nor does it need to roll back any transaction.

4.1 Speculation

The main purpose for the speculation phase is to give a specific (partial) order among transactions within a block, such that by following this order each node (in the replay phase) can efficiently execute them. A primary advantage of processing transactions prior to consensus lies in the absence of (unnecessary) ordering constraints between transactions. In

Algorithm 1: Speculation phase

```
Variables: BLOCK: a block containing a list of transactions
           DAG: a two-dimensional array storing dependencies
           access: a map from key to tx_chain
1  procedure Speculate():
2      txs ← BLOCK.transactions
3      ParallelExecute(txs)
4      tx_chains ← SortDependencyChains(txs)
5      txs ← ∅
6      for chain ∈ tx_chains do
7          for tx ∈ chain do
               /* Adjust the order of txs                    */
8              if tx ∉ txs then
9                  append(txs, tx)
10     BLOCK.transactions ← txs
11     DAG ← BuildDAG(txs)
12     call Consensus(⟨BLOCK, DAG⟩)
13 function ParallelExecute(txs):
14     for tx ∈ txs do
           /* Run in parallel mode                           */
15         (tx.RS, tx.WS) ← execute(tx)
16 function SortDependencyChains(txs):
17     for tx ∈ txs do
18         for ∀ key ∈ tx.RS ∪ tx.WS do
19             append(access[key], tx)
20     for chain ∈ access do
21         append(tx_chains, chain)
22     Sort tx_chains from the longest to the shortest
23     return tx_chains
24 function BuildDAG(txs):
25     for tx ∈ txs do
26         for ∀ tx′ : tx′.idx < tx.idx do
27             if tx′.WS ∩ tx.WS ≠ ∅ then
28                 DAG [tx][tx′] ← WAW
29                 continue
30             if tx′.RS ∩ tx.WS ≠ ∅ then
31                 DAG [tx][tx′] ← WAR
32             if tx′.WS ∩ tx.RS ≠ ∅ then
33                 if DAG [tx][tx′] == WAR then
34                     DAG [tx][tx′] ← WAW
35                 else
36                     DAG [tx][tx′] ← RAW
37     return DAG
```

other words, each proposer can orchestrate an order at will, maximizing parallelism as much as possible.

On the contrary, any pair of conflicting transactions need to be processed sequentially (if they access the same key and one of them writes the key). Those conflicting transactions form a so-called dependency chain, which is the main enemy of high degree of parallel processing. The long dependency

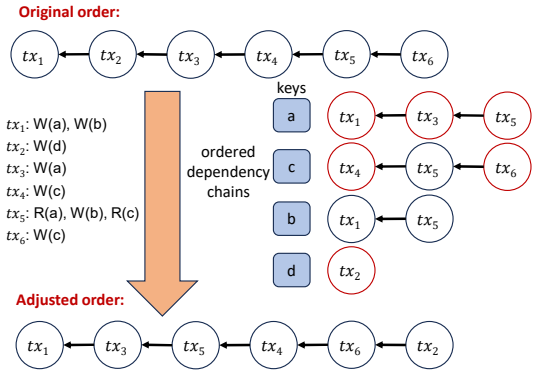

Figure 5: Example for the speculation phase. After obtaining the read/write sets, transactions are (re-)ordered according to the lengths of dependency chains. The corresponding DAG is depicted in Figure 6.

chain problem also appears in the Ethereum workload and was discussed in [35]. The heuristic here is we should give transactions within a longer dependency chain a higher priority, and thus in the replay phase the longer chain starts execution prior to other shorter chains. We thus have the following rule:

Rule 1. *Transactions should be sequenced in descending order based on the lengths of their dependency chains.*

The pseudocode is given in Algorithm 1. First, each node gets a series of transactions and executes them in parallel (Line 2-3). To obtain transaction dependencies, the proposer only needs the read/write sets of each transaction. Thus, at this stage transactions are executed in parallel and will not modify the world state. Based on the read/write sets, we are able to analyze transaction dependencies and create a schedule for the replay phase.

To this end, we first count the number of transactions that have accessed a given key and group them into a dependency chain (Line 17-21). A transaction may appear in several chains. Note that this simple method only obtains an approximation of accurate dependency chains, as each chain only takes one key for consideration. Nonetheless, this simple solution already leads to prominent performance (as shown in §6). Then, we sort different chains according to their lengths (Line 22). We finally arrange the transactions within a longer chain in front of those within a shorter chain and obtain an ordered list *txs* (Line 6-9).

Based on the order given in *txs*, we can analyze their dependencies and accordingly build a Directed Acyclic Graph (DAG) (Line 24-36). The dependency relationship forms a DAG (with no circle) because any transaction may only depend on ones with lower indices, but not vice versa. There are three types of dependencies: write after read (WAR), write after write (WAW) and read after write (RAW). If a transaction writes the same key that its previous transaction reads, the corresponding place of these two transactions in DAG is tagged with WAR. Other two types of dependencies are

tagged similarly. Note that if two transactions have multiple dependencies, we prioritize WAW (Line 27-29) due to a specific optimization [56] that we will elaborate on §4.2. Also note that if two transactions have both WAR and RAW dependencies (for different keys), we treat them as having a WAW dependency (Line 34). Finally, the transactions, their read/write sets, as well as the DAG are inserted into a block proposal (Line 12). With such information, every node in the replay phase can process these transactions deterministically.

4.2 Replay

After consensus, blocks are totally ordered and each node enters the replay phase. The main purpose for replay is to deterministically and efficiently execute all transactions within each block. We only exploit intra-block parallelism, though enabling inter-block parallelism may further speed up execution, which we leave for future work. The replay phase is further divided into two stages: (1) the first stage that follows the DAG and execute transactions accordingly; and, (2) the second stage that re-executes transactions that may introduce new dependencies. For the first stage, our concurrency control method is inspired by Aria [56]. For the second stage, we first describe a scheme that simply re-executes all possibly affected transactions. In §4.3 we describe an optimization that further reduces re-execution rate.

The pseudocode is given in Algorithm 2. Each node gets a block, the read/write set of each transaction, as well as the DAG from the consensus component (Line 2). To enable parallel processing, transactions within a block are further divided into several *batches*, where in each batch all the transactions can be executed in parallel (if they do not access some new keys compared to the ones obtained in the speculation phase). Transactions within a block are executed in a batch-by-batch manner, and in each batch the execution results will not update the world state until all the transactions complete.

Each node repeatedly obtains a batch of transactions that have no *forward dependency* from the transaction list *txs* (Line 4), then executes them in parallel. We have the following specific rule for defining whether a transaction has no forward dependency:

Rule 2. *A transaction tx has no forward dependency if: (1) tx has no WAW dependency on any previous transaction that has not completed, and (2) tx does not have both WAR and RAW dependencies on any previous transactions that have not completed.*

The intuitions of Rule 2 are: (1) even if transaction tx WAR depends on tx', tx can start execution immediately because its update will not be visible to tx', as they are in the same batch; and (2) even if tx RAW depends on tx', tx can be re-ordered before tx' because the update of tx. The idea of Rule 2 is elaborated in [56].

Once tx finishes execution, we need to check its newly-generated read/write sets. If the read/write sets have changed

Algorithm 2: Replay phase

```
   Variables: TxsRe: a set of transactions to be re-executed
1  procedure Replay():
2      (BLOCK, DAG) ← Consensus()
3      txs ← BLOCK.transactions
4      ready ← PopTxsBatch(txs)
5      while ready ≠ ∅ do
6          for tx ∈ ready do
               /* Run in parallel mode                    */
7              (rs, ws) ← execute(tx)
8              if rs ≠ tx.RS ∨ ws ≠ tx.WS then
9                  append(TxsRe, tx)
10                 ready ← ready \ {tx}
11         for tx ∈ ready do
12             commit(tx)
13         ready ← PopTxsBatch(txs)
14 procedure ReExecute():
15     for tx ∈ TxsRe do
16         execute(tx)
17         commit(tx)
18 function PopTxsBatch(txs):
19     ready_txs ← ∅
20     for tx ∈ txs do
21         if tx has no WAW-dependencies then
22             if no WAR ∨ no RAW then
23                 append(ready_txs, tx)
24                 txs ← txs \ {tx}
25     return ready_txs
26 function commit(tx):
27     Apply updates in tx.WS to the world state
```

compared to the results obtained in the speculation phase, tx may introduce new dependencies with other transactions in the same block, and thus will be *re-executed* at the end of the replay phase (Line 8-10). Nonetheless, we can still commit other transactions in *ready* by updating the world state according to their write sets (Line 11).

Finally, we present a simple re-execution stage that happens at the end of the replay phase (Line 14-17). Transactions in $TxsRe$ are sequenced based on their indices and executed in serial order. In §A we prove that $TxsRe$ is the same among all correct nodes. In Figure 6 we depict an example for demonstrating the replay phase.

4.3 Reducing Re-Execution Rate

Because transaction re-execution may badly affect performance, we further improve our strategy for determining whether a transaction needs to be re-executed. The new strategy is described in Algorithm 3, which replaces Line 5-12 in Algorithm 2.

Remember that in Algorithm 2, a transaction should be re-

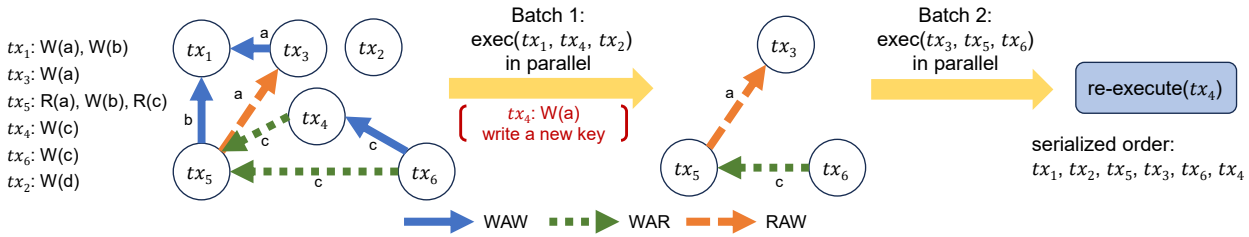

Figure 6: Example for the replay phase. On the left we show the read/write sets of each transaction obtained in the speculation phase. Batch 1 contains tx_1, tx_4 and tx_2 as they have no forward dependency (Rule 2). tx_4 newly writes key a, and thus will be re-executed at the end. Batch 2 contains tx_3, tx_5 and tx_6, even though tx_6 WAR depends on tx_5. The execution results are equivalent to executing tx_1, tx_2, tx_5, tx_3, tx_6 and tx_4 in serial order.

Algorithm 3: Improved replay strategy

```
1  all_keys ← all keys accessed by tx in txs in speculation
2  while ready ≠ ∅ do
3      for tx ∈ ready do
           /* Run in parallel mode                    */
4          (rs, ws) ← execute(tx)
5          if tx reads/writes a new key key' ∈ all_keys then
6              append(TxsRe, tx)
7              ready ← ready \ {tx}
8              continue
9          if tx reads a new key key' ∉ all_keys then
10             append(read, tx)
11         if tx writes a new key key' ∉ all_keys then
12             new_keys ← new_keys ∪ {key'}
13     read ← read \ {tx : tx has not read any key ∈ new_keys}
14     commit (tx ∈ ready \ read) based on DAG
15     for tx ∈ read do
16         execute(tx)
17         commit(tx)
```

executed once its read/write sets have changed. In fact, some changes do not necessarily lead to re-execution, as they do not introduce new dependencies. For instance, if tx accesses fewer keys in the replay phase. We intend to further reduce re-execution rate, but at the same time keeping the method simple and straightforward to be implemented. To this end, we first group all the keys that have been accessed in the speculation phase (Line 1 in Algorithm 3). Then we further distinguish the following three cases:

1. If a transaction tx reads/writes a new key that other transactions also accessed during speculation (Line 5-8), it is highly possible that tx will introduce new dependencies. In this case, tx will be re-executed.

2. If tx reads a new key key' that other transactions did not access during speculation (Line 9-10, 15-16), key' may not necessarily introduce new dependencies, but tx (in *read*) has to wait until other transactions in the batch complete execution. If some transaction has newly written key' (in *new_keys*), tx will be executed again and get committed. Otherwise, tx is removed from *read* and committed with other transactions by following the serial order extracted from DAG.

3. If tx writes a new key key' while other transactions did not access key' during speculation (Line 11-14), we record key' in *new_keys*. tx will also be committed with other transactions once all the transactions complete execution.

In other cases, tx will not be re-executed.

4.4 Further Discussion

This paper solely focuses on improving the performance of contract execution. In decentralized finance applications, however, transaction ordering is also crucial for participants' profits. Regarding the speculation phase in Vegeta, miners or proposers may be motivated to initiate frontrunning and sandwich attacks [3, 63] to increase their profits, rather than maximizing parallelism. To defend against adversarial players, existing literature either introduces additional restrictions on transactions ordering (e.g., by providing a fairness property [80]), or resorts to some economic mechanism (e.g., the proposer/block-builder separation [6]). For the former case, proposers cannot freely choose at what order transactions are replayed, thus limiting its performance gains. For the latter case, we may quantify the degree of parallelism and also leverage an incentive mechanism to motivate rational proposers.

5 Implementation

We have implemented Vegeta in Golang and adopted Go-Ethereum, a.k.a., Geth as our Ethereum execution environment. We integrated Ethereum Virtual Machine (EVM) [4] with Vegeta to enable transaction execution. We still used the data structure *StateDB* in EVM for caching and storing the world state in memory. *StateDB* can be simply considered an in-memory key-value store. As EVM only provides single-threaded execution, we modified *StateDB* in order to support shared access. To do so, we used a sync.Map structure

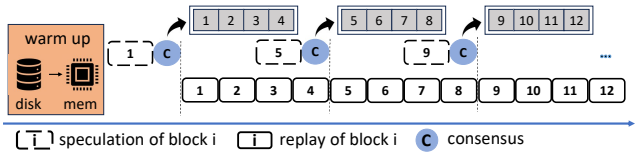

Figure 7: Example from node 1's perspective for consensus-integrated implementation ($n = 4$).

for thread-safe state management. We started a new EVM instance for each transaction, and all instances can concurrently access *StateDB*.

To focus on transaction execution performance, we skipped updating the Merkle Patricia Trie (MPT) in *StateDB* (after each execution). MPT is a combination of Patricia trie and Merkle tree. MPT is used to cryptographically authenticate and verify the content of the world state. One exception is we used MPT for correctness validation (§6.1), which updated MPT after the execution of each block. We also disabled data persistence to eliminate its impact on performance evaluation, allowing us to focus solely on transaction execution.

Consensus integration. In Vegeta the speculation phase of a given block B_h may overlap with the replay phase of some earlier block $B_{h'}$ ($h' < h$), so the two phases may compete for computing resources on each node. To study this impact, we also integrated a consensus component, which is a seminal leaderless consensus protocol proposed by Ben-Or, Kelmer, and Rabin (BKR) [20]. BKR is the core component of several recent works [31, 57, 77]. We chose BKR also because it allows us to easily distribute Ethereum blocks to each node, in such a way that the total order given by the consensus protocol is the same as given by Ethereum. In general, BKR requires each node to make a proposal in each consensus instance (i.e., for each sequence number). The final output of each instance is a subset of all proposals (ranging from $n - f$ to n proposals). To strictly follow the order of Ethereum workloads, we further restrict the number of proposals output by BKR to n, ensuring that no proposal is abandoned.

We assigned block B_h to a node i for speculation if $i = h\%n$, where n is the number of nodes[1]. We also configured a parameter K, where on each node i, if only K blocks are left for replay, node i takes the next block and starts its speculation phase. In principle, the smaller the K, the better the accuracy for speculation, as node i is with a more recent world state. However, to effectively pipeline the two phases of different blocks, K should not be too small. In our experiments, we set K to 2, as on average the time it takes to speculatively execute a block is less than twice the time it takes to replay a block (see §6.2). Before each test there is a warm-up phase, which loads the world state and all blocks after that state into memory. Figure 7 demonstrate how we integrate Vegeta into the consensus protocol. Our code is available at https://github.com/Decentralized-Computing-Lab/Vegeta.

[1]Note that in real-world cases, nodes continuously receive new transactions and batch them into blocks. No pre-defined order exists.

Table 2: Ethereum datasets used in our evaluation.

Tag	Date	Block range (height)	Tx count	Longest chain	Ratio
S_1	3/7/2023	16774645-16779644	739863	88136	8.39
S_2	3/7/2023	16774645-16777644	436115	52862	8.25
S_3	3/7/2023	16774645-16774745	15129	1779	8.50
S_4	11/17/2023-11/18/2023	18581726-18586725	747651	89961	8.31

6 Evaluation

We evaluated Vegeta under the real-world Ethereum workloads. We compared Vegeta with serial execution and a deterministic optimistic concurrency control protocol, AriaFB, which was derived from Aria [56]. AriaFB is a typical way of instantiating the order-execute framework. We adopted the same execution and commit phases used in Aria, and also integrated a fallback strategy (i.e., our replay phase) to get AriaFB, as vanilla Aria cannot handle high abort rates (see §6.2).

Testbed. We conducted experiments on Amazon EC2 platform. Our testbed consists of up to 10 m6i.4xlarge instances, with 3.5 GHz Intel Xeon Ice Lake 8375C processor of 16 vCPUs, 64 GB RAM, running Ubuntu 20.04 LTS. Every node has downloaded Ethereum workloads.

Datasets. Our evaluation was conducted mainly with the Ethereum datasets shown in Table 2. S_1 contains 5,000 blocks and is used to evaluate the performance in single-node mode and validate the correctness of Vegeta. S_2 contains 3,000 blocks and is used for multi-node test. S_3 contains 101 blocks and is used for time-consumption analysis of each phase (Figure 8 in §6.2). S_4 contains 5,000 more recent blocks and is used to evaluate the performance in both single-node and multi-node modes. In Table 2, tx count refers to the total number of transactions of all blocks. For each block, we first calculate the length of its longest dependency chain, i.e., the maximum number of transactions that have accessed a given key. Then, we sum the lengths of the longest chains of all blocks and get the longest chain in Table 2. Finally, the ratio equals to the tx count divided by the longest chain. The ratio approximately represents the maximum speedup Vegeta can achieve for a specific workload, if we assume every transaction has equal execution time. For simplicity, we did not change the block structure of Ethereum, but in practice we may only treat the workload as a transaction stream.

6.1 Correctness Validation

The correctness of Vegeta has been extensively validated as a by-product of our evaluation. This is because Ethereum

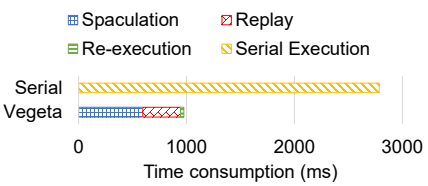

Figure 8: Time consumption of each phase.

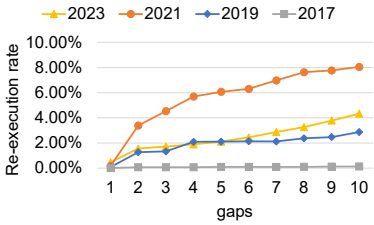

Figure 9: Re-execution rates.

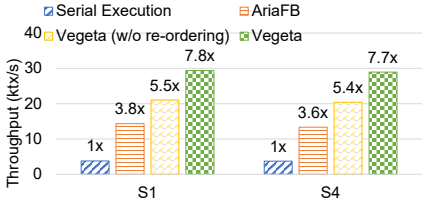

Figure 10: Throughput and speedups in single-node test.

maintains the world state as an MPT. Two states are identical if and only if the values of their MPT roots are equal. Every block carries a value of the state's MPT root after all the transactions in the block are executed. Although the execution result of Vegeta differs from the original state of Ethereum due to the re-ordering rule we adopted in the speculation phase, we can still perform the execution repeatedly (i.e., the speculation and replay phases) with the same series of blocks and validate whether their MPT root values are equal. We have managed to process a total of 5,000 blocks (S_1) carrying 739,863 transactions for 100 times, always resulting in a matching value of the MPT root in every block.

6.2 Single-Node Performance

We demonstrate the performance of Vegeta and other protocols when they were deployed on a single node.

Time consumption of each part. We first tested 101 blocks carrying 15,129 transactions (S_3 in Table 2) to measure the time consumption of each phase in Vegeta. Figure 8 depicts the results. In this measurement, the speculation phase was based on the latest Ethereum world state, i.e., block B_h is speculatively executed based on the world state of block B_{h-1}. The speculation yields 1.47% re-execution rate. The cost of re-execution is insignificant compared to other parts. The speculation phase consumed more time than the replay phase because of the overhead of ordering transactions and building the DAG for capturing dependencies. It can also be observed that Vegeta spent much less time in executing all phases compared to serial execution. Note that in real systems the speculation phase is executed only by a single node and can be further overlapped with the replay phase of some previous blocks.

Re-execution rate. We conducted evaluation in the re-execution rate by performing the speculation phase based on different world states. We then counted how many transactions are re-executed in the relay phase and accordingly calculated the rate. The results are shown in Figure 9. We performed the similar experiment based on the Ethereum data ranging from 2017 to 2023. X-axis indicates the gap of block heights between the speculation and the world state it is based on. For instance, 0 means the speculation results of block B_h is based on the world state of block B_{h-1}, while 9 means the speculation results of block B_h is based on the world state of B_{h-10}. With more recent world states the speculation can obtain more accurate dependencies among transactions, thus reducing the re-execution rate. Even with the most recent state, the re-execution rate is still a non-zero value. This is because in the speculation phase Vegeta executes transactions in a fully parallel manner. A concrete example is actually depicted in Figure 1, where the check-balance operation (step 2) for APEFI token failed during speculation but succeeded in the relay phase, because another transaction (within the same block) transferred a sufficient number of tokens to the user's address. The re-execution rate is relatively small except 2021, presumably due to the explosion of DeFi and NFT applications.

Speedup. We compared Vegeta with AriaFB and serial execution to demonstrate the effectiveness of our approach. In the speculate-order-replay framework, the burden of speculation can be evenly distributed to every node and amortized by pipelining, while the replay (and re-execution) phase must be performed by every node. Therefore, in the single-node test, we only measured the time it takes to perform the replay phase and compared it with that of other approaches. The speedup can be considered the upper bound Vegeta can achieve for the given Ethereum workloads.

The evaluation was conducted on the datasets S_1 and S_4 (in Table 2), each of which contains 5,000 blocks. The results are depicted in Figure 10. The performance bottleneck of Vegeta for Ethereum datasets mainly stems from the longest dependency chain, which was also discussed in [35]. Transactions in the same dependency chain must be executed in serial order. We also observe that the longest dependency chain is generated by Wrapped Ethereum (WETH) decentralized application [10], which swaps ethers (cryptocurrency in Ethereum) between layer-1 (native coin) and layer-2 (token) for facilitating trade with ERC-20 tokens. The ratio shown in Table 2 also reflects an upper limit to some extent (8.39× versus 7.8× and 7.7×).

AriaFB treated each block as a batch and first executed all transactions in parallel. If any transaction had a forward dependency (according to Rule 2), the transaction was aborted. We found that without fallback, aborted transactions in vanilla Aria kept accumulating and eventually led to out-of-memory error. We thus integrated our replay phase into vanilla Aria

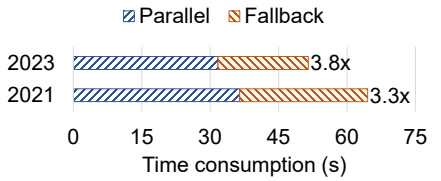

Figure 11: Time consumption and speedups of AriaFB.

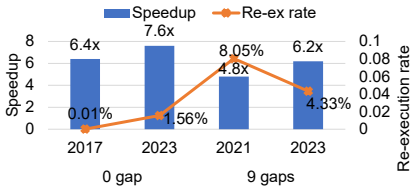

Figure 12: Speedups with different re-execution rates.

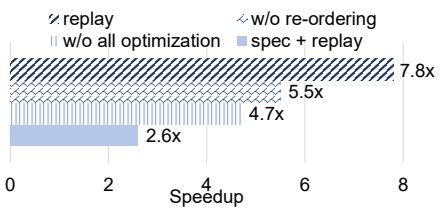

Figure 13: Ablation study of Vegeta.

and obtained AriaFB[2]. For datasets S_1 and S_4, respectively, 40.2% and 42.3% transactions were aborted and further re-sorted to the fallback for re-execution. Compared to AriaFB, the speedup gain of Vegeta largely comes from the speculation that wisely orders transactions and groups them into batches, effectively reducing abort (re-execution) rate. We further measured the execution time of each part under the datasets of 2021 and 2023 (as shown in Figure 11). The abort rate of 2023 dataset is 40.2%, and the corresponding speedup is 3.8×, while the abort rate of 2021 dataset is 52.1%, so the speedup decreased to 3.3×.

To assess the impact of re-execution rates, we also measured the speedups with the datasets from different years (thus leading to different re-execution rates), as shown in Figure 12. The datasets from 2017 and 2023 exhibit lower re-execution rates, resulting in higher speedups. However, the longest dependency chain problem in the 2017 dataset has a greater impact on the degree of parallelism, leading to a lower speedup compared to the 2023 dataset. To evaluate the performance with even higher re-execution rates, we then purposely performed the speculation phase with a gap of 9 blocks. The speedups were negatively affected.

Ablation study of Vegeta. We evaluated the influence of each optimization in Vegeta. The results are shown in Figure 13. To assess the impact of re-ordering in the speculation phase, we purposely disabled this approach (i.e., sorting and selecting dependency chains, Line 4-9 in Algorithm 1) and preserved the original order in each Ethereum block. The speedup (without re-ordering) decreased to 5.5×, as transactions in some longer dependency chains may start execution later during the relay phase, highlighting that transaction order significantly impacts performance improvement. We emphasize that in real-world deployment, there is no concept of re-ordering, as proposers can freely choose in what order transactions are executed. We then stepped further and removed the optimization for re-execution, which is described in Algorithm 3. The speedup decreased to 4.7×. Finally, we evaluated the performance of Vegeta when both phases (i.e., speculation and replay) are performed after consensus by every node. It can be regarded as a deterministic concurrency control protocol based on the order-execute framework. The speedup decreased to 2.6×. This result demonstrates the benefit of distributing speculation across all nodes.

[2]As also discussed in [56], any deterministic concurrency control can potentially be used.

Table 3: Re-execution rates in multi-node test.

	S_2	S_4
4 nodes	1.66%	1.58%
10 nodes	1.89%	1.82%

Multi-core scalability. To evaluate the multi-core scalability, we conducted experiment with different configurations of 2, 4, 8, 16 and 32 cores. The results are shown in Figure 14. The speedup of Vegeta grows linearly from 2 to 8 cores. As the number of cores continues to increase, this trend diminishes.

6.3 Multi-Node Performance

When it came to multi-node deployment, we integrated transaction execution with a consensus module. We set the number of nodes n to 4 and 10 in this experiment, which respectively tolerates 1 and 3 Byzantine nodes. We did not conduct even larger-scale experiments because the Ethereum workloads were generated sequentially. With larger n, there will be a larger gap between speculation and replay, which are not realistic in practice. Nonetheless, as Vegeta aims to provide scalability in the speculation phase, we expect Vegeta will perform even better when n becomes larger. The evaluation was conducted on the datasets S_2 and S_4 in Table 2.

As with a leaderless consensus protocol, we evenly assigned blocks to every node, i.e., node i is responsible for speculatively executing block B_j (in Vegeta) and proposing B_j in consensus if $j\%n = i$. When the consensus layer outputs, n blocks are delivered to the upper layer for execution. These n blocks are totally ordered based on proposers' IDs.

Re-execution rate. As already shown in Figure 9, a more recent world state can provide a higher precision for dependency analysis. Due to this reason, a node would not perform speculation of a new block until its remaining blocks ready for replay is equal to or less than K. We set K to 2 in this experiment because as shown in Figure 8, the time taken by speculation is less than twice the replay time. Table 3 shows the re-execution rate.

Leaderless vs. leader-based protocols. We first compared the performance of Vegeta integrated with BKR (a leaderless protocol) with that integrated with a leader-based protocol.

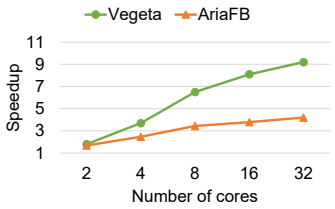

Figure 14: multi-core scalability.

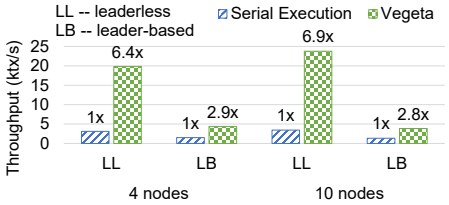

Figure 15: Throughput of leaderless and leader-based protocols.

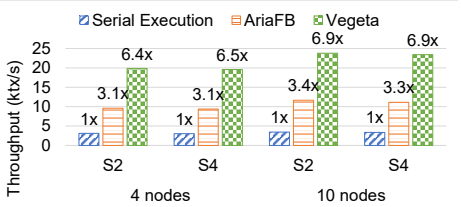

Figure 16: Throughput and speedups in multi-node test.

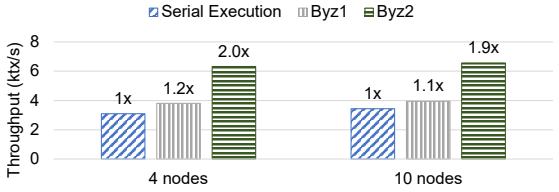

Figure 17: Throughput under Byzantine faults.

For the latter case, our evaluation chose PBFT [25] as the ordering module. The single leader performs the speculation phase, while every node replays the block after consensus. The evaluation was conducted on the datasets S_2 in Table 2, and the results are shown in Figure 15. Because the single leader took the heaviest burden of computation, the leader node throttled Vegeta's performance.

Speedup. The results are shown in Figure 16. Being affected by consensus, the throughput of all protocols decreased compared to Figure 10. Because of the competition between speculation and replay for computing resources, the performance of Vegeta is further affected. Although for 10-node case the re-execution rate is slightly higher than that for 4-node case (Table 3), the $n = 10$ throughput raised because with larger n, leaderless consensus can commit more proposals in each instance. The performance of serial execution and AriaFB exhibited a similar trend due to the same reason.

6.4 Performance under Byzantine Faults

As blockchain systems target Byzantine faults, in this experiment we evaluate their impact on performance by configuring f nodes to exhibit two typical Byzantine behaviors. Specifically in our design, a Byzantine node can purposely generate incorrect dependencies and/or read/write sets in the speculation phase. Such an anomaly cannot affect the safety property of Vegeta but may badly affect its performance.

The results are shown in Figure 17. In the first scenario (Byz1), f Byzantine nodes provided a serial order and empty read/write sets for each block proposal, which forced other correct nodes to sequentially execute each transaction twice (one for replay, and the other for re-execution). Note that the proposals of other correct nodes were still correctly speculated. The performance gains coming from correct nodes are almost eliminated by Byzantine nodes. Although in 10-node case Vegeta had higher speedup compared to 4-node case (Figure 16), it also suffered more badly than 4-node case due to the higher proportion of Byzantine nodes (1/4 versus 3/10). We argue that the impact of this typical malicious behavior may be simply mitigated by, e.g., sequentially executing each transaction only once, as the speculation already provided serial order.

The second scenario (Byz2) is a bit more subtle, where Byzantine nodes provided correct dependencies but empty read/write sets, which still led to 100% re-execution rate for their proposals. The throughput of Vegeta still significantly decreased. For the block proposals made by Byzantine nodes, all the transactions were first executed (efficiently) in the replay phase and then re-executed in serial order. Note that Byzantine behaviors may also badly affect the performance of AriaFB, e.g., by deliberately orchestrating a sequence of transactions that causes frequent aborts.

7 Conclusion

Towards efficient transaction processing in blockchains, we presented the speculate-order-replay framework. Our framework is tailored to leaderless consensus, which brings both challenges for deterministic parallelism and opportunities for boosting performance. Our framework allows each node to independently pre-execute transactions and analyze their dependencies in the speculation phase, in order to provide information that enables efficient parallel execution in the replay phase. We instantiated our framework through Vegeta, a transaction-level concurrency control protocol. Experimental evaluation under Ethereum workload showed promising performance compared to other parallel processing schemes.

A Correctness proof of Vegeta

We prove that the execution results on each node are equivalent to the same serial order. Since all information (e.g., transactions and their dependencies) leveraged by the replay phase is agreed upon using consensus and each node executes transactions in a batch-by-batch manner, we only need to prove that each batch produces the same execution results. Note that within a batch, transactions are ordered by their indices. We give the following three lemmas.

Lemma 1. *If nodes i and j execute batch b according to the same world state and tx is re-executed on node i, then tx is re-executed on node j.*

Proof. Within b, every transaction is executed based on the same world state and no one updates any key until they all complete execution. If tx is re-executed on node i, then tx must change its read/write sets (Line 8 in Algorithm 2) or read/write a new key $key' \in all_keys$ (Line 5 in Algorithm 3). Then obviously node j should also re-execute tx because the read/write sets of each transaction are obtained during speculation and agreed upon by consensus. □

With Lemma 1, in the following we only consider the transactions that are not re-executed. We discuss the cases without and with an improved replay strategy, respectively.

Lemma 2. *(With a simple re-execution strategy in Algorithm 2) The execution results of each batch are equivalent to the same serial order on every node.*

Proof. For any two transactions tx and tx' in the same batch, they should not have WAW dependency, nor should they have both WAR and RAW dependencies (Line 34 in Algorithm 1). Without loss of generality, we assume the serial order of transactions in the batch is: $\cdots \rightarrow tx' \rightarrow \cdots \rightarrow tx \rightarrow \cdots$. We then discuss three cases:
Case 1: If they are non-conflicting, they are serializable. And we determine their order based on the order of their indices.
Case 2: If tx WAR-depends on tx', then since the result of execution will only be committed after all transactions in the batch finish execution, tx' cannot read the value written by tx, they are serialized as tx' happens before tx, the assumed serial order is satisfied.
Case 3: If tx RAW-depends on tx', their execution is equivalent to tx happens before tx' (i.e., re-ordering), so the serialized order can be changed to $\cdots \rightarrow tx \rightarrow \cdots \rightarrow tx' \rightarrow \cdots$. Also note that tx in this case must have no WAR dependency with any other transaction, so no dependency circle will be generated in the same batch.

In all cases, the execution results of all the transactions within each batch are equivalent to a certain serial order. It is also trivial to see that every node proceeds based on the same world state and consensus-provided information. So their execution results should be equivalent, □

Lemma 3. *(With an improved strategy in Algorithm 3) The execution results of each batch are equivalent to the same serial order on every node.*

Proof. With the proof of Lemma 2, we only need to discuss the following three cases.
Case 1: Neither tx nor tx' reads a new key that is (newly) written by some transaction. In this case, both tx and tx' are committed by following the serial order extracted from DAG (Line 14 in Algorithm 3). Even if tx and tx' newly write the same key key', there is no RAW-dependency between them, so their execution results are still equivalent to the serial order.
Case 2: tx reads a new key key' that is also (newly) written by some transaction, while tx' does not. In this case, tx' gets committed before tx (Line 14), while tx is executed again and committed (Line 16). Even if tx' also writes key', tx can read the update of key' if necessary. Anyway, tx' is executed before tx in the serial order.
Case 3: both tx and tx' read some new keys, say key' and key'', that are also written by some transactions. In this case, both tx and tx' are executed (sequentially) again and committed. Without loss of generality, tx is executed before tx' in the serial order. □

With Lemma 1, every node re-executes the same set of transactions sequentially. With Lemma 2, Lemma 3 and every node executes batches one after another, the execution results of all transactions are equivalent to the same serial order.

Shoal++: High Throughput DAG BFT Can Be Fast and Robust!

Abstract

Today's practical partially synchronous Byzantine Fault Tolerant consensus protocols trade off low latency and high throughput. On the one end, traditional BFT protocols such as PBFT and its derivatives optimize for latency. They require, in fault-free executions, only 3 message delays to commit, the optimum for BFT consensus. However, this class of protocols typically relies on a single leader, hampering throughput scalability. On the other end, a new class of so-called DAG-BFT protocols demonstrates how to achieve highly scalable throughput by separating data dissemination from consensus, and using every replica as proposer. Unfortunately, existing DAG-BFT protocols pay a steep latency premium, requiring on average 10.5 message delays to commit transactions.

This work aims to soften this tension, and proposes Shoal++, a novel DAG-based BFT consensus system that offers the throughput of DAGs while reducing end-to-end consensus commit latency to an average of 4.5 message delays. Our empirical findings are encouraging, showing that Shoal++ achieves throughput comparable to state-of-the-art DAG BFT solutions while reducing latency by up to 60%, even under less favorable network and failure conditions.

1 Introduction

This paper presents Shoal++, a novel partially synchronous DAG-based Byzantine Fault Tolerant (BFT) consensus protocol that matches the throughput of contemporary DAG-BFT protocols while significantly reducing latency, narrowing the gap with the theoretical optimum.

BFT consensus offers the attractive abstraction of a single, always available server, that remains correct even as a subset of replicas may fail arbitrarily. Fueled by recent advances to simplicity and practicality [15, 19, 35, 47], interest and adoption of BFT protocols is skyrocketing: it is at the core of aspiring multi-national projects such as the digital Euro [2], confidential data sharing frameworks [6] and the growing Web3 industry [1, 5]. Already today, numerous blockchain companies [40–42, 44] are actively deploying BFT protocols [16, 22, 31, 34, 35], supporting millions of daily worldwide users.

Following the seminal PBFT [15] protocol, most traditional BFT consensus protocols [24, 28, 47] operate in a primary-backup like regime in which a single, dedicated leader replica proposes an ordering of commands, and follower replicas vote to ensure consistency and durability.

*The work was done while the authors were interns at Aptos Labs.

As demonstrated by PBFT, this approach can enjoy excellent latency in fault-free executions, requiring only three message delays (md) to order a leader's proposal, the optimum achievable for BFT protocols. A dedicated leader, however, poses not only a single point of failure, but constrains the achievable throughput to the processing and networking bandwidth available to a single server. To improve scalability, and meet the high throughput demands of modern applications, recent proposals emphasize maximizing resource utilization and balancing load across *all* replicas.
