an example, which is our prototype and evaluation target. As shown in Figure 2-b, the platform consists of (1) host adapters (i.e., FA400X [23, 24]) that extend the host server's PCIe subtree; (2) standalone chassis boxes (i.e., RB4082 [33]), where each encloses endpoint adapters with up to 8 GPUs per appliance, connected through a PCIe backplane; (3) an external fabric switch (i.e., RS4024 [25, 34]), which connects host servers and chassis via SFF-8644 [37] copper/optical cables. In the current generation, the SuperNODE can attach up to 32 GPUs to a single server host. FabreX and SuperNODE are built atop routable PCIe 3.0/4.0 [2], and are under upgrading to other interconnects [40, 54]. Thus, a single-node supercomputer is one commodity server equipped with tens of GPUs, all of which stay under the server's PCIe root complexes.

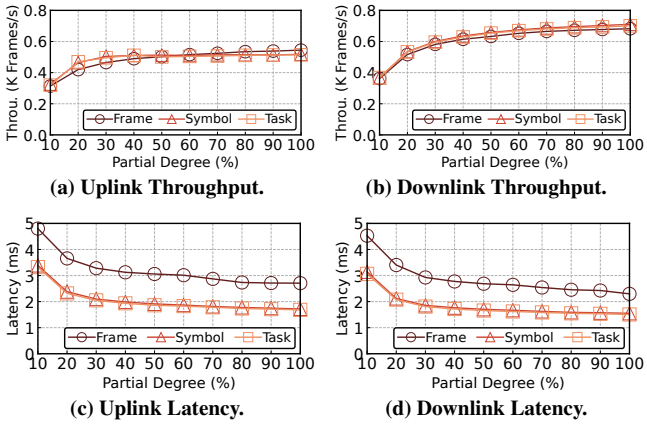
The platform has several features. First, each remote GPU appears as a local PCIe device, which is directly accessed from host applications through existing driver and system stacks. This differs from today's distributed GPU clusters in the HPC and data centers, where a GPU access should traverse the message passing layer and networking stack [48, 68, 72, 76, 81, 99, 119], entailing communication overheads. Second, all GPUs are located under a multi-rooted tree topology inherited from PCIe, where host-GPU and GPU-GPU communications are provisioned with adequate bandwidth (e.g., $\times$16 lanes). Third, the platform can be scaled incrementally, where one can add/remove GPUs on demand without considering the available PCIe slots and power of the host server, simplifying infrastructure planning and management. Besides, the system is physically compacted (4U in our lab setup) with air cooling in the remote chassis. A single-node supercomputer resembles an NVIDIA DGX platform [31, 32]. However, it is loosely coupled physically with less GPU-GPU bandwidth (compared with NVLink 3.0/4.0) but has a higher GPU consolidation ratio and better infrastructure flexibility.

We believe that SNC is a promising vRAN substrate, especially when handling the dynamic high computing demand of massive MIMO. This is because (a) it encloses high computing density (GPU #) without bandwidth oversubscription in a single server, alleviating the need to handle the cross-node communication complexity in distributed systems; (b) it is a physically compact setup and has better space efficiency when scaling than today's rack-scale vRAN infrastructures; (c) GPUs can be added/removed on-demand flexibly via the PCIe hotplug without changing the underlying computing setting, whose management cost is less than dealing with the addition and removal of standalone GPU servers.

3 Understanding the Execution Parallelism

To effectively use SNC for baseband processing, this section characterizes the impact of different execution parallelism.

3.1 Types of Software and Hardware Parallelism



SW Parallelism. As described in §2.1, the baseband processing pipeline encloses a sequence of stages that exhibit different execution granularities and incongruent parallel degrees. There are three ways to parallelize it (Figure 3).

- *Frame Level.* The first is a coarse-grained approach that concurrently processes a window of consecutive frames, which has been explored in LuMaMi [100]. Since the computing intensity is inconsistent across different stages, it is challenging to do resource provisioning;
- *Symbol Level.* The second one is to parallelize symbol processing within a frame, such as Hydra [71]. Except for the pilot symbol (§2.1), other symbol handling can happen concomitantly. It is finer-grained than the first case but requires tracking execution dependency at runtime;
- *Task Level.* The third strategy is to schedule computations at the finest granularity (like BigStation [121]) that harnesses the available parallelism at best. We define a task as a MIMO processing stage as in Figure 1. However, this approach complicates the pipeline design because one should not only track dependent tasks, but also introduce the synchronization barrier (through shuffle) when the parallel degree across different phases changes, e.g., FFT (antenna#) $\rightarrow$ EQ/DEM (subcarrier#) $\rightarrow$ DEC (user#).

HW Parallelism. We quantify the available parallelism as the number of GPU's streaming processors (SM), denoted as P. These SMs could come from one or several GPUs. We then represent the adequate parallelism (SM #) to run a job in our baseband processing as Q. Thus, we categorize the hardware parallelism scenarios as follows:

- *Full Parallelism*, where $P \geq Q$ and $P\ SMs \in 1\ GPU$. The job can be placed in one GPU with no performance loss;
- *Fragmented Parallelism*, where $P \geq Q$ and $P\ SMs \in x\ GPUs$ and $x > 1$. Even though there are enough parallel engines, the job needs to be partitioned across several GPUs, and data shuffle would be required for synchronization when crossing different stages, hurting performance;
- *Partial Parallelism*, where $0 < P < Q$ and $P\ SMs \in x\ GPUs$ and $x \geq 1$. There is inadequate parallelism to run the job and one would see performance interference due to GPU sharing. The problem becomes even worse when the available SMs are from different GPUs;
- *Delayed Parallelism*, where $P = 0$. This indicates all SMs are busy. A job has to be queued first and be awakened when one of the above three types of parallelism emerges.

The Dilemma. Ideally, we should devise an execution strategy that always makes the baseband processing job run in full parallelism mode. To satisfy the stringent performance

(a) Uplink Throughput. (b) Downlink Throughput.

(c) Uplink Latency. (d) Downlink Latency.

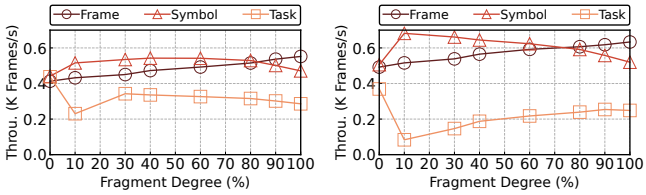


Figure 4: Baseband processing performance at three execution granularities varying the partial degree. We report the frame processing latency and throughput in all three cases.

requirements and high computing demand of massive MIMO, one should fully exploit the parallelism across three levels, i.e., parallelizing frame, symbol, and task processing as much as possible. As a result, the irregular software parallelism will gradually make fragmented, partial, and delayed hardware parallelism appear frequently, adversely impacting pipeline performance. We aim to characterize this dilemma and understand how different parallel executions perform under the above hardware parallel scenarios. Our experimental setup is described in §5.1 and the MIMO configuration is 128×32.

3.2 Partial Parallelism

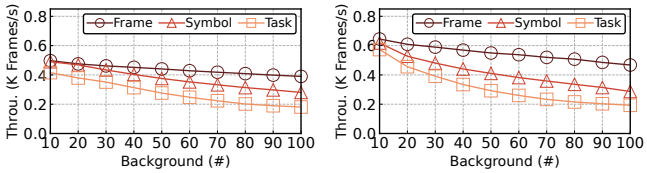
Setup. We configure the partial parallelism by co-locating the target baseband processing task with a persistently running background job (which spawns a number of busy polling threads to consume the SM resources). We vary the number of occupied SMs and explore how it impacts three execution granularities. We define the partial degree as $\frac{P}{Q}$.

Results. The three software parallelisms can tolerate a modest to high partial degree. As shown in Figure 4, when half of the SMs are occupied, we observe up to 7.3% performance drop in all three cases. This is because the parallelism of the baseband processing pipeline is determined by its most computing-intensive phase. Other tasks requiring fewer SMs can still run in full parallelism when the partial degree is high. Thus, the performance-affected parts due to inadequate SMs would only contribute to a small portion of the total execution according to Amdahl's Law. Symbol/Task-level parallelism outperforms the frame-level one by 56.9%/60.4% in terms of uplink/downlink frame processing latency on average across all cases. This is because finer-grained execution parallelizes different symbols and tasks within a frame over multiple SMs. In contrast, frame-level execution cannot fully utilize the GPU for a single frame, resulting in a higher per-frame latency but allowing more frames to be scheduled concomitantly. As a result, all three software parallelism methods achieve similar throughput. We further explore an extreme scenario that only configures 1 SM (1.0% partial degree). Regardless of running

(a) Uplink. (b) Downlink.

Figure 5: Baseband processing perf. at three granularities varying the fragment degree. We measure the per-(frame | symbol | task) throughput (K frames per second).

at which granularity, the performance is reduced by more than $10\times$, indicating that a heavily-loaded GPU can easily violate the performance requirements of baseband processing.



Takeaways. Partial parallelism with modest/high partial degree exhibits marginal performance degradation. However, as shown in Figure 4, the baseband processing performance drops significantly if a GPU has less than 20.0% free SMs. Therefore, one should carefully estimate the partial degree before allocating tasks to GPUs. Even though all three software parallelism options deliver similar throughput, frame-level parallelism presents the worst processing latency, making it ill-suited for an execution scenario with stringent deadlines.

3.3 Fragmented Parallelism

Setup. We provision required parallelism (Q SMs) from two composable GPUs and define the ratio of two GPUs' SMs as the *fragment degree*, i.e., $\frac{GPU1\ SM\#}{GPU2\ SM\#}$. The number of SMs is controlled via the same synthetic background job used in the partial parallelism section. We then examine how different execution granularities of the baseband processing behave when gradually varying the fragment degree.

Results. At the frame level, the pipeline proportionally schedules frames to two GPUs based on the number of SMs in a round-robin fashion. As shown in Figure 5, frame parallelism can tolerate high fragment degree. Compared to zero fragment degree, the throughput of the uplink/downlink increases by 34.1%/30.6% when fragment degree reaches 100.0%. The reason is that a single GPU exposes the FIFO queue structure [55, 105], limiting the number of concurrent scheduled frames. With one more GPU, the number of frames that can be scheduled simultaneously increases, causing overall throughput improvement. Although resources are split between two GPUs, each individual GPU exhibits partial parallelism. As shown in the partial parallelism, a slight reduction in the number of SMs can still be accommodated. This indicates that partitioning would not lead to a significant performance drop.

The execution strategy at the symbol level is similar; however, symbols (other than pilot) cannot run before the completion of the pilot symbol in each frame. If symbols do not stay within the same GPU as the pilot, extra data shuffling is required for another GPU to synchronize results. Also, symbols show up to 25.1%/65.1% increase under low fragment degrees (from 0.0% to 44.0%/16.0% fragment degree for uplink/downlink) thanks to the increasing hardware request

(a) Uplink. **(b) Downlink.**

Figure 6: Baseband processing perf. at three granularities varying background jobs #. We measure the per-(frame | symbol | task) throughput (K frames per second).

queue. It even outperforms the frame-level parallelism (up to 17.8%/33.3% higher) due to the fine-grained execution. This provides a GPU with a wider range of options for selecting smaller jobs to run when there are limited SMs, yielding higher utilization and performance improvement. Conversely, coarse-grained large kernels offer less flexibility, resulting in an inefficient use of fragmented resources. Nevertheless, symbol parallelism underperforms the frame case when the fragment degree exceeds 70.0%. At 100.0% fragment degree, we observe a 14.5%/17.4% uplink/downlink performance drop. The reason is that extra data shuffling required for symbol-level scheduling cannot be hidden by computation under a high fragment degree (discussed in Appendix A.1).

When parallelizing at the task granularity, we also partition tasks proportionally to two GPUs. A key challenge is to minimize data shuffling overheads. We follow the Hydra [71] approach that only synchronizes when the parallelism changes. This indicates that equalization and demodulation (precoding and modulation) tasks across the uplink (downlink) pipeline run in the same GPU. Task level experiment performs worst according to Figure 5, presenting a 48.2%/52.2% uplink/downlink throughput drop. In contrast to the symbol case that only synchronizes pilot computation once per frame, tasks synchronize data between every two stages for non-pilot symbol processing, resulting in 13 times of synchronization (excluding pilot) per frame in a typical 14-symbol frame.

Takeaways. Fragmented parallelism, albeit providing enough SMs, should carefully divide jobs based on the underlying GPU's computing capability to mitigate jeopardy. Finer-grained execution at the symbol level helps utilize the available SMs in each GPU. But one would see diminishing returns when synchronization overheads dominate. There is a trade-off between execution granularity and data shuffle frequency.

3.4 Delayed Parallelism

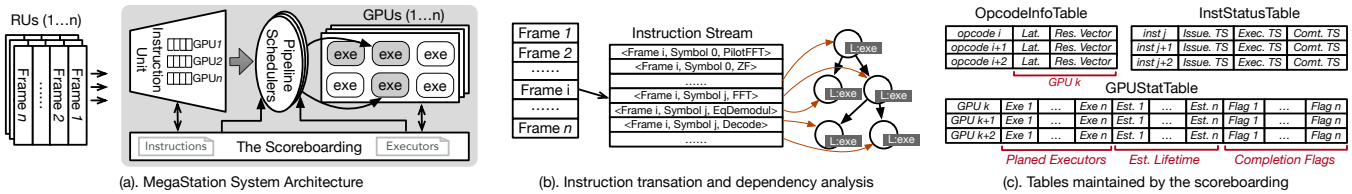
Setup. We design the delayed parallelism experiment by interleaving the target baseband processing job with special background kernels. They run large-scale GEMM (General Matrix Multiplication) tasks, where $M \times N \times K = 1280 \times 1024 \times 512$, consuming as many available SMs as possible. A bunch of such kernels is being pushed to the GPU consistently one after another. We investigate how the GPU internal scheduler affects different-sized baseband processing jobs.

Results. We find that the frame-based execution adapts to delayed parallelism the best, followed by symbol and then task granularity. For example, when there are 100 interleaved kernels, the uplink/downlink frame pipeline observes 23.5%/30.9% degradation while uplink/downlink symbol is dropped by 47.2%/60.8%, and uplink/downlink task is 60.0%/74.7% lower. The key reason is that GPUs employ a strict FCFS scheduling policy with a limited amount of hardware execution queues [55, 105, 106], providing little fairness guarantees. When execution contention happens, coarse-grained scheduling submits a sequence of jobs in batches and thus would receive more GPU computing cycles. Besides, frequent kernel launches and completions at a finer granularity cause more GPU interruptions and jeopardize performance.

Takeaways. The impact of delayed parallelism stems from how the computing resource of a GPU is shared among competing kernels. The inherent FCFS policy and kernel-agnostic partition make inefficient multi-tenancy support on the GPU. Thus, when determining the execution granularity under GPU contention, one should collaboratively consider the kernel size distribution of co-located baseband processing jobs.

3.5 Summary

There is no *one-size-fits-all* execution granularity that allows the baseband processing pipeline to accommodate different irregular hardware parallelism. Therefore, an ideal baseband processing solution over an SNC should be execution adaptive, aware of the underlying target status at runtime, and collectively consider co-located kernels. None of the prior solutions [28, 30, 58, 65, 71, 100, 114, 121] can achieve this.



4 MegaStation: Design and Implementation

This section describes MegaStation and shows how we address the above dilemma. Our system design goals are:

- **Delay deadline.** MegaStation should satisfy the processing latency requirements of each time frame. It should ensure the average/tail delay stays within the constraint;
- **High utilization.** MegaStation should fully harness the available hardware parallelism (no matter which type) and minimize stalled or idle GPU cycles. It should strive to consolidate baseband processing tasks on just enough GPUs without over- or under-subscriptions;
- **Adaptability.** MegaStation makes no assumption about the frame structure and can handle different uplink/downlink frames. It should automatically adapt its processing capability to the target spectrum, and client rate.

4.1 Key Idea and System Overview

Key Idea. MegaStation effectively leverages the massive parallelism of a single-node supercomputer to process data frames. *Our key insight is that one can adjust the execution granularity and reconstruct the baseband processing pipeline on the fly based on the hardware parallelism status.* We are inspired by the dynamic instruction scheduling [115, 116] from computer architecture field. Dynamic instruction scheduling reorders instructions to prevent stalls by scheduling indepen-

Figure 7: (a) provides an overview of MegaStation. (b)/(c) depict the details of the instruction unit and scoreboarding.

dent instructions when the execution engine is free. We view the baseband processing task on GPUs as instructions and apply dynamic scheduling. This flexible approach allows us to make real-time adjustments to the software parallelism based on the status of the GPUs. Hence, *we model the single-node supercomputer as a tightly coupled microprocessor and employ a scoreboarding-like algorithm* to schedule "baseband processing" instruction streams over the composable GPU pool. MegaStation continuously bookkeeps the occupancy of the GPU's computing resources (e.g., SMs, registers, and shared memory), and issues an instruction when it is ready. Within the frame deadline, MegaStation coalesces one or several instructions with data locality to maximize the probability of full parallelism, mitigates the fragmented/partial parallelism via instruction reordering, and tackles the delayed parallelism via managed over-commitment.

System Overview. MegaStation comprises four components (Figure 7-a): (a). *Processing Functional Units or Executors (§4.3)*, running baseband processing tasks over the GPU SMs; (b). *Instruction Unit (§4.4)*, which takes data frame sequences as inputs, translates them into instructions, and places them into an instruction queue; (c). *The Scoreboarding (§4.5)*, a centralized bookkeeper that continuously tracks the execution status of inflight instructions and performs resource accounting of the GPU pool, serving as the basis for other system components; (d). *Pipeline Scheduler (§4.6)*, which orchestrates instruction execution, determines what and how to run the next tasks based on committed status. MegaStation can support one or multiple radio units concomitantly [62, 71].

4.2 Baseband Processing Tasks as Instructions

MegaStation models a baseband processing task as an instruction, represented as $\langle$`Opcode`, `Operand1`$_{src}$, `Operand2`$_{src}$ (optional), `Operand`$_{dst}\rangle$. Our current design uses 4 bits to denote an opcode and supports 11 different opcodes (Table 1 in Appendix A.2), i.e., Data load & store, PilotFFT, UpFFT, iFFT, zero-forcing (ZF), equalization + demodulation (EqDemodul), modulation (Modul), precode, decode, and encode. Among them, equalization and precoding take three operands, the second source operand being a beamforming matrix, while the rest require two. An operand is mostly a pointer to the data input/output location. Thanks to the local view of GPUs on a single-node supercomputer, multiple GPUs share a unified memory address space when presenting a src/dst operand.

The lifecycle of an instruction comprises three basic execution stages: **ISSUE**, **EXEC**, and **COMMIT**. First, the instruction unit conducts dependency analyses of each enqueued instruction and marks it ready for issuing when data and executor are in place. Next, an instruction is scheduled and inserted into the request queue of a GPU executor. A functional unit processes requests following its prescribed order. Finally, upon completion, commit notification is broadcast to other architectural components (like the scoreboard), pushing the pipeline forward. At the beginning of each stage, We collect the timestamps TS_{issue}, TS_{exec}, TS_{commit}.

4.3 Baseband Processing Executors over GPUs

MegaStation instantiates GPU-based task executors on demand and uses them to model instruction running on GPUs. Since a GPU does not expose any internal resource usage primitives at run-time, an executor is not a physical computing entity but a logical representation that describes its required resources. We use a tuple $\langle$CTA #, Warp #, Regs #, SMem Bytes$\rangle$ to represent the executor. Table 1 presents the executor information in our design for a 128×32 MIMO configuration. Warp #, Regs #, SMem Bytes information can be obtained from the compiler or profiler; while CTA # is specified at the kernel launch based on the MIMO settings. MegaStation uses this resource to provision executors when planning to make the computation placement decision, while the actual allocation happens after instructions are loaded.

Executor Planning. MegaStation preallocates executors when the instruction unit has generated instructions for an incoming frame. We provision executors for all the enqueued instructions. This is a typical bin-packing problem [82, 122], whose goal is to find the minimal amount of GPUs to hold a list of executors without exceeding the capacity of any computing resources of a GPU. Since (a) the GPU pool keeps fluctuating with instructions issued and retired; (b) this process happens pre-execution; (c) resource allocation and partitioning inside GPU is a blackbox, finding an optimal allocation using an ILP (Integer Linear Programming) like solution is unnecessary. MegaStation resorts to an approximate approach following the first-fit strategy [67]. For each instruction, we first search the in-use GPUs and then the unoccupied ones to hold the executor such that the total amount of CTAs (or SMs), warps, registers, and shared memory of the candidate GPU stays within the device limit. This step updates the `GPUStatTable` of the scoreboarding (Figure 7-c).

Different GPU architectures exhibit diverse computing capacities [41]. Newer GPUs could hold more executors simultaneously with more CTAs and global memory. An executor's

21:    else
22:        return ESTIM_INST(T_inst)
```

resource tuple may vary depending on the GPU architecture it is compiled for. These all require us to keep track of the instructions' behavior in different GPUs (`OpcodeInfoTable`) and monitor the device limit and planned executors of a GPU (`GPUStatTable`), used by our scoreboarding scheme (§4.5). The scheduler (§4.6) then consults the scoreboarding to decide which instructions run next on which GPUs at runtime.

4.4 Instruction Unit

MegaStation receives IQ samples from the fronthaul link and delivers them to the instruction unit. It performs three tasks: instruction translation, dependency graph construction, and structural analysis. As shown in Figure 7-b, we first decode the frame structure, parse each pilot/uplink/downlink symbol, and then generate instructions for the pipelined tasks. MegaStation attaches a prefix to each instruction to facilitate later analysis: ⟨Frame i, Symbol j⟩+*Inst*.

Next, the instruction unit builds the directed acyclic graph (DAG) among pending instructions to capture the execution dependency. MegaStation explores this from both data and structural perspectives. Regarding data dependency, we construct the DAG graph by analyzing the RAW (read-after-write) relation, where the source operand of instruction $I2$ depends on the destination operand of instruction $I1$. For example, an *Inst*[equalization] can be executed when it receives the beamforming matrix from the preceding *Inst*[zero-forcing] and the output of *Inst*[FFT]. In our case, WAR (write-after-read) and WAW (write-after-write) rarely happen because the destination operands of subsequent tasks along the baseband processing pipeline differ from the source or destination operands of precedent tasks. Since time frames are independent, the DAG is per-frame, whose size is bounded.

For structural analysis, MegaStation analyzes each GPU status to determine its hardware parallelism. According to this analysis, MegaStation decides the GPU on which the executor of instruction should run. Unlike microprocessors, our functional units are the SMs of each GPU and are not fixed. This indicates that an instruction could have multiple executor candidates (§4.3) based on the runtime hardware occupancy. As runtime information fluctuates frequently with instructions being submitted and committed, merely obtaining the latest GPU status at runtime is insufficient. There exists a time gap between when an instruction is issued and when it actually runs on GPUs. In order to predict the GPU status at the time when the instruction is running, we maintain a `GPUStatTable` with the status of all the planned executors (§4.5), which is used to estimate the lifetime of an instruction.

ALG1 dispatches instruction executor to different GPUs based on hardware parallelism within instruction's running time range. To enhance estimation accuracy, MegaStation only schedules instructions that are set to begin within a two-frame time window. MegaStation employs a top-down approach, initially finding a fit for the entire frame before moving on to symbol and then instruction (ALG1: ESTIM_TIME). We prioritize GPUs with input locality, coalescing instructions with dependency. If the minimum number of available SMs during the instruction's running time range is less than threshold partial degree α times the total number of SMs of the GPU (indicating full or partial parallelism), we could safely schedule the instruction to that GPU (ALG1:L7-8). α is GPU architecture-dependent and profiled offline. When adding a new GPU architecture (discussed in §3.2), we vary the partial degree under three execution granularities, measure the uplink/downlink performance (Figure 4), and empirically determine α which yields marginal performance drops (10%).

When there are insufficient SMs in the GPU of precedent nodes or there are no precedent nodes (i.e., a new frame is received), we search for a GPU with the maximum number of free SMs within the instruction's time range. If the newly searched GPU exhibits an adequate number of SMs, it indicates fragmented parallelism. Based on the findings in §3.3, the algorithm must consider the wait time due to the SM scarcity and data transfer time between the GPUs (ALG1: L12-L13). For new incoming frames (no precedent GPUs), we always choose one GPU with the lowest occupancy.

When the newly searched GPU still lacks SM (ALG1: L10-L11), suggesting delayed parallelism, we enqueue the instruction to a delay priority queue where frames are sorted based on their deadlines. All incoming and unscheduled frames are redirected to the delayed queue until there are sufficient available SMs and the delayed queue is empty. Instructions in the delayed queue are assigned to the GPU with minimal occupancy at the frame level granularity and labeled as "delayed". When the frame's processing deadline is violated, it indicates that the incoming baseband processing load exceeds the MegaStation's capacity. All the obsolete frames are discarded

and MegaStation sends back a customized NACK signal that triggers load balancing (4.7). If a consistently heavy load is observed, we would add more GPUs from the current SNC (if there are free ones) or redirect traffic to another SNC.

4.5 The Scoreboarding

MegaStation bookkeeps execution statistics for instructions and GPU hardware using a scoreboarding mechanism. In terms of instruction tracking, as depicted in Figure 7-c, we introduce two tables. One is the `OpcodeInfoTable` that stores executor information regarding each instruction opcode. Each entry in this table contains the resource vector of its corresponding executor for each type of GPU and the average execution latency within a calibrating window. The resource vector of each opcode's executor is obtained from the compiler or profiler prior to MegaStation initialization and remains static unless a new type of GPU is added. In such cases, the resource vector is profiled for that type of GPU before executors can be scheduled to the GPU. Upon completion of an instruction, the execution time is calculated as $T_{inst} = TS_{commit} - \max(TS_{preced_commit}, TS_{exec})$, where TS_{preced_commit} denotes the commit timestamp of instruction's precedent instruction. The execution time (T_{inst}) is averaged within a calibrating window to mitigate fluctuations. Along with the execution time of each instruction, MegaStation also maintains the average execution time of each category of frame (T_{frame}) and symbol (T_{symbol}), and the average scheduling time in pipeline scheduler $T_{sched} = TS_{exec} - TS_{issue}$ in `OpcodeInfoTable`. The other is the `InstStatusTable` that keeps track of timestamps in the **ISSUE**, **EXEC**, and **COMMIT** stages for each instruction. When the instruction unit plans the executor, it records TS_{issue}. Upon submission of the executor by the pipeline scheduler, TS_{issue} is measured. Finally, when the GPU signals completion, TS_{commit} is stored.

Regarding monitoring the utilization of GPU hardware, as shown in Figure 7-c, we maintain a data structure called `GPUStatTable` for each GPU to track the status of each instruction executor deployed to that GPU. This table comprises (a) the number of SMs used by each executor; (b) the estimated start and end timestamp for each executor; and (c) a completion flag indicating the retirement of the executor. The SM usage of an executor is determined by CUDA's occupancy calculator [19], which considers warp, register, and shared memory information to calculate the number of CTAs that an SM can hold. This information helps obtain the number of SMs needed to execute a given instruction. The planned executor is inserted by the instruction unit with the estimated timestamp. The scoreboarding actively queries GPUs about the status of each executor and updates the completion flag.

4.6 Pipeline Scheduler

The pipeline scheduler instructs what to run next in each GPU with a finer granularity than ALGO1. It consults the scoreboarding (§4.5), fetches instructions (baseband processing tasks) from the instruction unit, and deploys them over its GPU, which adjusts the software execution granularity to the dynamic hardware parallelism adaptively at runtime. Each scheduler traverses its instruction queue (§4.4) (Figure 7-a) and fires out instructions using a new algorithm, called LROC (ALG2, Appendix A.2)–a careful synthesis of Least Slack Time First (LSTF) scheduling along with instruction Reordering, Over-commitment and Coalescing techniques.

LSTF Scheduling. As described before, the baseband processing of massive MIMO has stringent performance requirements, especially per-frame processing delay. Thus, we apply the LSTF scheduling discipline to prioritize task execution. MegaStation implements the instruction queue using a red-black tree with a list of keys. The first key is slack timestamp, which is computed with two factors: frame-induced hard deadline (TS_{ddl}), reserved executing time of the instruction and its succedents in the frame along the depth of the DAG (dubbed as $\sum^{Depth} T_{inst}$), where T_{inst} is acquired from the scoreboarding (§4.5) and calibrated online. $TS_{slack} = TS_{ddl} - \sum^{Depth} T_{inst}$.

Reordering. As discussed before (§3), the baseband processing performance is affected by the amount of execution parallelism, parallelism distribution, and data movement overheads. When planning (§4.4), MegaStation predetermines the executor of an instruction based on overall available resources across GPUs. When executing, it adjusts the instruction order with runtime status of the local GPU for performance maximization. The second key of the instruction queue is SM usage of each instruction. Our algorithm prioritizes scheduling instructions with the least SM usage to greedily occupy the remaining GPU resources after handling urgent instructions. In this way, it opportunistically reorders instructions with no dependency to improve GPU utilization.

Over-commitment. MegaStation strives to keep the GPU busy (i.e., work-conserving) and reduce the idle cycles when waiting for the host to launch CUDA kernels if the GPU's SMs become available. Our scheduler thus allows computation overloading, inevitably introduces delayed parallelism, and resolves it through the stream priority mechanism provided by CUDA. After the GPU is full, MegaStation schedules an instruction labeled as "delayed" and submits it to a low-priority CUDA stream. This allows the instruction to run whenever the GPU has available resources without interfering with higher-priority normal instructions.

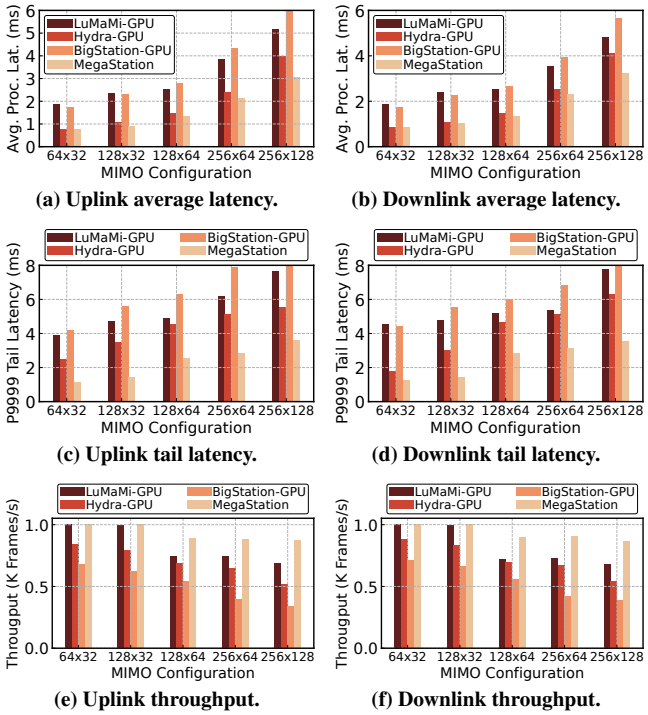
Coalescing. To avoid the synchronization gap between GPU completion and CPU being signaled, MegaStation provision instruction scheduling with the help of the sequential property within a single CUDA stream. If an instruction has precedent instructions on the local GPU that require a larger resource than the current instruction's executor, we preemptively submit the current instruction to the same CUDA stream with the precedent instructions without waiting for the completion signal. This preemptive submission has minimal impact on future scheduling, as the current instruction can inherit resources reserved by the precedent executor on the GPU.

4.7 Deployment and Failure Handling

Fault tolerance is crucial in practice. We apply Slingshot's approach [89] to handle failures, i.e., treating short-term loss of frames as bad signal quality effects in the wireless environment and recovering them through inherent cellular network impairments. All discarded frames in MegaStation are handled similarly to Slingshot [89]. Since frames are independent, some frame loss would not affect other frames' processing.

There are three failure domains in MegaStation: server host, interconnect fabric, and GPU pool. When the host fails, MegaStation enters fail-stop mode. All pending frames are discarded and incoming frames should be reissued to another backup vRAN server. For the interconnect failure, MegaStation loses connection with all the GPUs. One option is to use the same solution as host failure, or alternatively fall back to a CPU-only mode with a slower frame processing rate.

MegaStation depends on GPU drivers to detect GPU failure. If a GPU malfunctions, device exceptions are raised when trying to submit instructions or query instruction status, causing it to be excluded from the scoreboard. Any running and pending (uncommitted) instructions on the GPU are moved to the instruction queues for rescheduling. In the meantime, a daemon continuously monitors PCIe device lists for new GPUs. Once a new functional GPU is detected, it is installed by MegaStation to the scoreboard for instruction scheduling.



4.8 Implementation Details

We implement MegaStation atop Agora [65] and NVIDIA Aerial SDK [30] in C++ with 8372 LOC and CUDA with 2147 LOC. Regarding the baseband processing instruction, MegaStation uses CUTLASS [22] and cuSOLVER [21] when computing the CSI matrices, and cuFFT [26] for FFTs. For LDPC encoding and decoding, we use the NVIDIA Aerial SDK [30] and enhance it with inline data copy. We reimplement precoding, equalization, modulation, and demodulation functions in CUDA following Agora's algorithms. Our executors leverage the GPU hardware features. For example, we use tile-based iterators [120] to fuse data transformation into the data loading and storing stage. We develop a lightweight mechanism for instruction synchronization, where each instruction allocates a flag on GPUs. These flags are manipulated via CUDA stream operation [20] on GPU side and are synchronized via GDRCopy [27] to CPU side. MegaStation employs a master-slave architecture. A master thread realizes the instruction unit, where per-GPU slave threads run the pipeline scheduler. Each slave thread also manages a pool of memory blocks, which translates the operand label to the actual memory pointer. Appendix A.3 presents more details.

5 Evaluation

5.1 Experimental Methodology

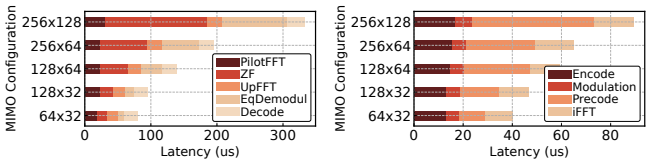
Hardware testbed. We use the GigaIO FabreX-based SuperNODE [8, 44] as the single-node supercomputer target.

(a) Uplink average latency. (b) Downlink average latency.

(c) Uplink tail latency. (d) Downlink tail latency.

(e) Uplink throughput. (f) Downlink throughput.

Figure 8: Average/tail uplink/downlink per-frame processing latency and throughput comparing five MIMO settings.



The host server is a 2U Dell R740 box, consisting of two 32-core Intel Xeon Gold 6248 processors (running at 2.5GHz), 192GB DRAM, and 1.92TB HDD. The load/store fabric uses routable PCIe [2], whose details are described in §2.4. We use NVIDIA V100 and A100 GPUs in the composable pool.

Comparison baselines. We compare MegaStation with three baselines: LuMaMi [100], Hydra [71], BigStation [121]. Since none of these prior systems target the GPU pooling, we develop the baseline over our target following their proposed design. The first one (*LuMaMi-GPU*) performs frame-level parallel execution and distributes frames to available GPUs in a work-conserving manner. The second one (*Hydra-GPU*) parallelizes the pipeline at the symbol level. Akin to Hydra [71], we place dependent stages in the same GPU to minimize the cross-GPU communication overheads. The third one (*BigStation-GPU*) implements task-level parallelism, where tasks are distributed to different executors.

Workload. We use the Agora [65] traffic generator to emulate an RU (radio unit). It applies the Rayleigh fading channel and transmits time-domain IQ samples. Our experiments use 2048 subcarriers and consider different MIMO configurations.

5.2 End-to-end Performance

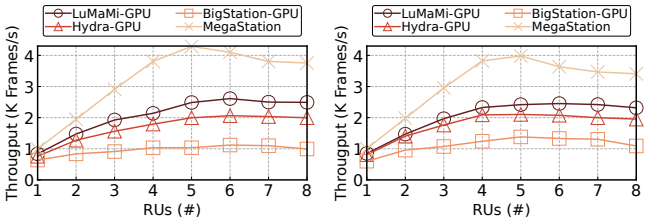
We set up 1 RU under 5 massive MIMO configurations (i.e., 64×32, 128×32, 128×64, 256×64, 256×128) and launched the experiment over just one chassis box with A100 GPUs. We measure the average and P9999 (tail) processing latency, and overall throughput for both 1ms uplink and downlink frames. As shown in Figure 8, MegaStation meets

(a) Breakdown on uplink path. **(b) Breakdown on downlink path.**

Figure 9: Latency breakdown for five MIMO settings.

the deadline requirements, with P9999 latency ranging from 1.2 to 3.6 ms for uplink frames, and 1.2 to 3.5 ms for downlink frames across different MIMO settings. We satisfy the stipulated 4m deadline for 1ms frames.

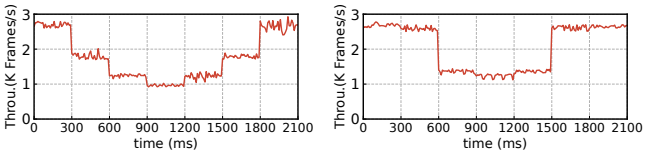
Across 5 MIMO cases, MegaStation achieves 50.6/58.9%, 12.2/46.9%, 53.7/66.2% lower average/tail latency on average for the uplink frames compared with *LuMaMi-GPU*, *Hydra-GPU*, and *BigStation-GPU* approaches, and 45.2/57.1%, 9.5/41.6%, and 47.9/61.9% for the downlink ones, respectively. For throughput, MegaStation performs 10.7/12.2%, 25.3/22.7%, and 44.9/41.8% better than three baselines on average for the uplink/downlink frames. MegaStation outperforms *BigStation-GPU* the most because the latter incurs too much cross-task synchronization. *LuMaMi-GPU* and *Hydra-GPU* perform suboptimally mainly because (a) their coarse-grained execution cannot fully leverage all available SMs promptly, especially when the GPU parallelism becomes irregular; (b) the scheduling mechanism is workload-agnostic, ignoring data locality and deadlines. Both are captured in our structural analysis, which places executors on suitable GPUs, and pipeline scheduler, which reorders instructions based on slack time and coalesces them with data locality.



5.3 Uplink/Downlink Pipeline Latency Breakdown

We break down the uplink and downlink processing latency of MegaStation (Figure 9). Overall, zero-forcing is the most expensive stage, consuming 36.3% of the whole pipeline on average across five MIMO cases. However, it only happens for the pilot symbols which could be amortized by uplink/downlink symbols. The next time-consuming stage is EqDemodul of the uplink path and Precoding of the downlink path, which spends 44.2% and 42.7%. We also compare the GPU executor with the CPU one (Agora [65]). Our experiment chooses the 64×16 MIMO, the largest one supported by Agora [65]. The CPU one uses 60 cores, while we use a single V100 GPU in MegaStation. The results (Figure 13 in Appendix A.4) demonstrate that the GPU can achieve an average speedup of $10\times$ compared to the CPU due to its massive parallelism.

5.4 Scalability



We increase the number of A00 GPUs on the SNC and analyze scalability in two dimensions: (a) how MegaStation performs as the number of RUs increases, and (b) how MegaStation scales with an increasing number of GPUs.

RU Scalability. We gradually increase the number of RUs from 1 to 8 under 128×64 MIMO for both uplink and downlink frames. Figure 10 presents the throughput per-

(a) Uplink throughput. **(b) Downlink throughput.**

Figure 10: We report the frame throughput as increasing the number of consolidated RUs for the 128×64 MIMO.

(a) 3 RUs 128×64. **(b) 3 RUs 128×32.**

Figure 11: We adjust the number of GPUs from 5 to 2 and back to 5 every 300 ms while measuring the throughput every 10 ms.

formance of four approaches. MegaStation scales the best and can harvest all the available SMs for frame processing. Over uplink/downlink frames, MegaStation achieves $1.5/1.4\times$, $1.8/1.6\times$, $3.2/2.6\times$ higher performance compared with *LuMaMi-GPU*, *Hydra-GPU*, and *BigStation-GPU*. They scale poorly due to the emergence of irregular hardware parallelism when more RUs send frames concurrently, yielding inefficient parallel execution and lower performance. MegaStation scales nearly linearly with the number of RUs regarding throughput. This is because MegaStation uses scoreboarding to track the real-time status of each GPU, allowing our scheduler to allocate tasks based on GPU availability and effectively manage congestion. Also, the over-commitment technique further helps exploit GPU computing power in the delayed parallelism and minimizes GPU idle cycles.

The number of RUs cannot be scaled infinitely. It is bottlenecked by the fabric interconnect between the host and chassis. The maximum number of RUs is theoretically bounded by $\frac{F \times S \times RU\#}{B} < T$, where F is frame rate (frames per second), S is frame size (bytes per frame), B is the bandwidth of interconnect (bytes per second), and T is frame duration (seconds). When the interconnect saturates, adding more GPUs would not help. One could load balance traffic among multiple SNCs via a fronthaul switch to solve this problem [89].

GPU Scalability. We add the number of GPUs from 1 to 5 under 3 RRUs under a 128×64 MIMO (Figure 14 in Appendix A.4). MegaStation achieves $1.9/1.8\times$ speedup for uplink/downlink frames. However, *LuMaMi-GPU*, *Hydra-GPU*, and *BigStation-GPU* only gain $1.3/1.2\times$, $0.9/1.0\times$, and $0.6/0.7\times$ improvement, respectively. The performance drop of *LuMaMi-GPU* is attributed to its coarse-grained execution granularity, which fails to fully utilize the increasing SM resources. *Hydra-GPU* and *BigStation-GPU* exhibit limited speedups due to higher communication overhead introduced by distributing symbols or tasks across more GPUs. MegaStation addresses these problems by (a) scheduling at

task-level granularity, which is the finest granularity in baseband processing; (b) in structural analysis, taking data transfer time into consideration when distributing instructions with dependency to different GPUs; (c) implementing coalescing technique to avoid GPU waiting for instructions.

5.5 MegaStation Drill-Down

We evaluate each system component in MegaStation via instruments and report their CDF. As shown in Figure 15 (Appendix A.4), we find that 90% of the instruction unit (IU) execution takes less than 12 μs, indicating that it is not the system bottleneck even if it is single-threaded. The per-GPU pipeline scheduler (PS) is 1.3$\times$ more costly than IU because it interacts with the CUDA driver on submitting instructions.

The pilot symbol processing is the most consuming part (Figure 15-b/c), where 90% of the execution takes 0.3ms to compute zero forcing and 0.12ms to transfer the zero-forcing (ZF) results to other GPUs. To accelerate ZF under large MIMO, we split the ZF instruction into multiple sub-instructions based on frequency bins and distribute them to multiple GPUs. Subsequent instructions would then have a dependency on the sub-instructions, captured in the DAG. To amortize large GPU-GPU communication, we balance irregular parallelism-induced waiting time and data shuffling overheads when copying tasks to idle GPUs.

5.6 Discussion

Reliability. There are three failure domains in MegaStation (§4.7). We manually toggle GPU availability in the GigaIO FabreX control panel to observe system response to the GPU fluctuation. We alternate between enabling and disabling GPUs, transitioning from 5 to 2 and back to 5 every 300 milliseconds. We configure 3 RRUs under the 128×64 and 128×32 MIMO and measure the throughput every 10 ms. The system throughput decreases with the number of GPUs, but returns to its original level when GPUs are restored to the initial setting (Figure 11). The scoreboarding scheme allows monitoring the status of each GPU in real time, preventing further scheduling instructions on unavailable GPUs.

Heterogeneous GPUs. We examine how performance is affected when utilizing heterogeneous GPUs. We compare A100+V100 GPUs vs. A100-Only. We show that *LuMaMi-GPU*, *Hydra-GPU*, and *BigStation-GPU* experience a 23.1%, 30.7%, and 32.8% average latency increase (Appendix A.4), respectively, while MegaStation only observes a 16.1% increase. Our method could handle heterogeneity better for two reasons. First, MegaStation takes different GPU architectures into account and dynamically adjusts its scheduling policy based on the available SMs. Second, MegaStation could capture the increased data movement overhead during profiling and rebalance the waiting and communication overhead.

In Appendix A.4, we show how MegaStation executes under small MIMOs, operates under other GPUs, and tackles the fragmented parallelism issue.

6 Related Work

Quantum Acceleration. Researchers have explored using quantum computing to tackle the high computing demand of massive MIMO. QuAMax [86] leverages quantum annealing to build the Sphere Decoder-based maximum likelihood (ML) MIMO decoders/detectors. HyPD [83] develops a hybrid classical-quantum decoder for polar error correction codes, where it employs CMOS processing for the decoder's binary tree traversal and quantum annealing processing for the polar decoder. Minsung Kim *et al.* [85] investigate a spin-level preprocessing approach for fine-grained decomposition that enables flexible parallel quantum signal processing.

Infrastructure Composability. Emerging high-bandwidth networks [1,16] and cluster interconnects [2,40,54,78] enable physical resource pooling. For example, [91,94,101,113,125] develop object/paging-based remote memory over CXL memory expanders. [57,74,80,87,88,92,96,102–104,126] build disaggregated storage. Researchers also develop composable accelerators [29,59,60] and explore efficient host-accelerator collaborated computation. The single-node supercomputer is another composable platform and we use it for accelerating the baseband processing of massive MIMO.

Network Function. Our work benefits from prior pioneering efforts of accelerating networking functions. RouteBricks [66] parallelizes router functionalities across multiple servers and multiple cores within a single server. PacketShader [75] examines using a commodity GPU to build a software router. NBA [84] introduces system techniques to optimize NF workloads on a CPU-GPU heterogeneous system. [61,69,73,77,90,93,95,97,98,107–112,124] offload networking functions onto reconfigurable switches and SmartNICs. MegaStation follows the past strategy and dynamically exploits the GPU's hardware parallelism at a fine granularity.

7 Conclusion

This paper makes a case for using an emerging single-node supercomputer for the massive MIMO baseband processing. We build MegaStation, an application-platform co-designed system that dynamically adjusts the execution granularity and reconstructs the baseband processing pipeline on the fly to accommodate the irregular underlying hardware parallelism. We model the single-node supercomputer as a tightly coupled microprocessor and employ a scoreboarding-like scheme to orchestrate baseband processing computations. Real system-based evaluations show that MegaStation outperforms comparable state-of-the-art approaches considerably and can fully leverage the capabilities of this new computing platform.

A Appendix

A.1 More Fragmented Parallelism Discussion

Under a low fragment degree (Figure 12-a), GPU0 (with the pilot symbol) has more symbols than GPU1 due to the round-robin strategy. GPU0's computation time exceeds the aggregated execution cost of data copying and GPU1's computation. As the fragment degree increases (Figure 12-b), symbol distribution becomes more balanced. GPU0 becomes idle during non-overlapping time intervals when its computing phase interleaves with the data copy and execution phase on GPU1.

A.2 MegaStation Details

Table 1 displays the logical representation of executors. The values for Wraps #, Regs #, and SMem are compiler-specific and remain constant regardless of kernel runtime. However, CTAs # is determined at runtime based on MIMO configuration. MegaStation calculates CTAs # and pass it to the kernel when kernel is launching.

The LROC algorithm described in ALG 1 illustrates the scheduling process in our pipeline scheduler. It starts by prioritizing the most urgent instructions. When there is available space left in the GPU, it continues by reordering instructions whose precedents have been completed. Once the GPU is fully utilized, the algorithm assigns instructions marked as "delayed" to a lower priority stream. Additionally, the algorithm takes advantage of opportunities to combine instructions with dependencies if precedent instructions have already allocated larger GPU resources.

Algorithm 2 LROC Algorithm.

```
1:  procedure LROC_SCHEDULER

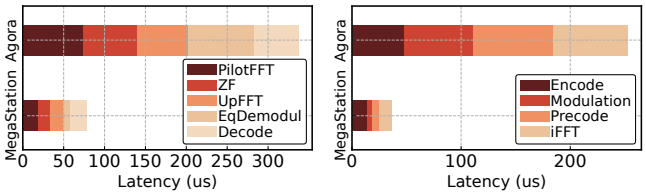
12:             SUBMIT(inst, low_prior_stream)
13:             break
14:     for inst ∈ instQ do                                  ▷ Coalesce
15:         if pred_insts.running & inst.SM ≤ pred_insts.SM then
16:             SUBMIT(inst, pred_insts.stream)
```

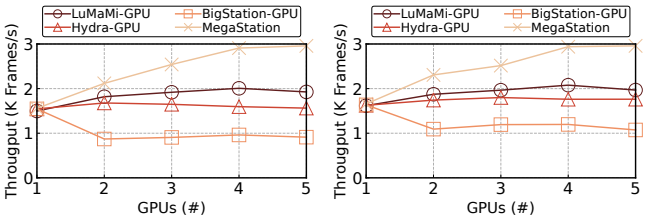
A.3 More MegaStation Implementation



To take advantage of GPU's shared memory and reduce the number of CUDA kernels within instructions, we use tile-based iterators [120] to fuse data transformation into the data loading and storing stage of a kernel computation. In this way, intermediate results are not written back to the global memory and thus data read/write round trips are reduced.

We develop a lightweight mechanism for instruction synchronization. We register and manage a 64KB buffer inside each GPU and map it to host memory. Upon an incoming frame, MegaStation allocates a free array ($sizeof(array) = instruction\#_in_frame \times 4B$) from the buffer, where the CPU actively fetches the array via GDRCopy [27] during the frame execution. Each element in the array is a completion flag of the instruction. When an instruction is finished, we use the CUDA stream operation [20] (`cuStreamWriteValue`) to signal the completion by writing the completion status word to the corresponding place. To enforce the execution order of two dependent instructions in two different CUDA streams, we insert `cuStreamWaitValue` before the second instruction to wait for the completion of the first one without blocking the GPU execution engine.

MegaStation employs a master-slave architecture. A master thread realizes the instruction unit, where per-GPU slave threads run pipeline scheduler and track the status of instructions. To minimize allocation overhead, MegaStation reserves memory for every type of operand in each GPU and manages them in a free list on the host side. Similar to the idea of register renaming, our memory manager translates the operand labels to the actual memory pointer before submitting the instruction to GPU. An exception will be triggered when the free list is empty, where we either allocate a new chunk or signal the scheduler to block.



A.4 More MegaStation Evaluation

GPU Scaling. Figure 14 explores how MegaStation scales with an increasing number of GPUs.

MegaStation Drill-down. Figure 15 reports the CDF of different system components in MegaStation.

Small MIMOs. We investigate the performance of MegaStation under small MIMO configurations (32×8, 64×16 MIMO). Using the same hardware setup described in §5.2, we depict the average and tail latency of five different methods in Figure 16. Our results show that in contrast to large MIMO scenarios, *Hydra-GPU* performs the best. Compared with MegaStation, it achieves a 20.1%/15.6% improvement on average in average/tail latency due to the lower scheduling overhead of static methods. *Hydra-GPU* outperforms *LuMaMi-GPU*/*BigStation-GPU* because of the finer-grained execution and fewer data synchronizations, respectively.

(a) Average Latency. (b) P9999 Tail Latency.

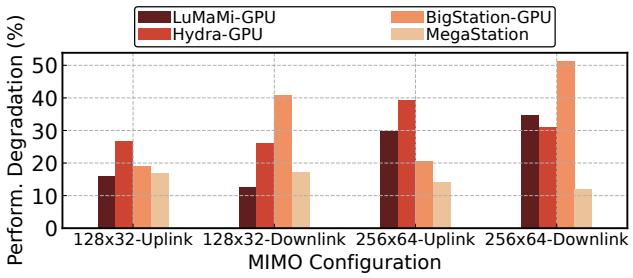

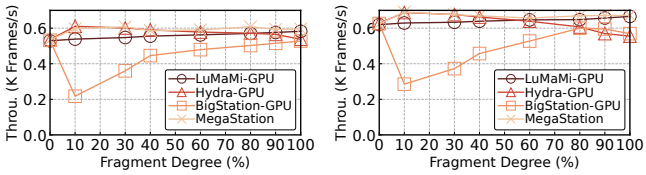

Figure 18: Performance drop on V100+A100 with respect to results on two A100s

(a) Uplink throughput. (b) Downlink throughput.

Figure 19: Throughput varying the fragment degree.

V100 GPUs. We examine the performance when running MegaStation on different types of GPUs. Specifically, we compare 2 V100 GPUs in a single chassis with two A100 GPUs and report overall average and tail latency. As shown in Figure 17, we observe that the A100 GPUs outperform the V100 GPUs by 27.2%. This is due to higher FLOPS and a greater number of SMs in the A100 GPUs (108 SMs compared to 80 SMs in the V100, which is 25.9% higher).

Tackling Fragmented Parallelism. While developing MegaStation, we find that fragmented parallelism happens frequently. Accurate computing resource accounting and careful scheduling are essential to ensure minimal frame processing deadline violation. We then revisit how MegaStation addresses the fragmented parallelism, where resources are partitioned among multiple GPUs and we should trade off communication overhead with executor distribution.

Similar to the characterization setup (§3.3), we evaluate the performance of these four approaches as the fragment degree increases under 128×64 MIMO with half uplink and half downlink symbols in one frame. As previously discussed, symbol-level execution granularity (*Hydra-GPU*) outperforms frame-level (*LuMaMi-GPU*) at low fragment degrees because data copying is hidden by computation. However, at high fragment degrees, frame-level execution performs better than symbol-level, as data copying cannot be overlapped with computation. Taking the data shuffling overhead into consideration in structural analysis, MegaStation leverages the benefits of both execution granularities, as illustrated in Figure 19. MegaStation employs a top-down approach that first selects a GPU for one frame and then assigns its symbols to that GPU. If the GPU reaches its capacity, MegaStation trade-offs between finding a new GPU (i.e., introducing communication overhead) or waiting for the current one to become capable. By dynamically adapting the execution granularity based on the fragment degree, MegaStation is able to achieve high performance across all fragment degrees.

Efficient Multi-WAN Transport for 5G with OTTER

Mary Hogan[‡], Gerry Wan[•], Yiming Qiu[†], Sharad Agarwal[*], Ryan Beckett[*], Rachee Singh[°], Paramvir Bahl[*]
[‡]Oberlin College, [•]Google, [†]University of Michigan, [*]Microsoft, [°]Cornell University

Abstract

In the ongoing *cloudification of 5G*, software network functions (NFs) are replacing fixed-function network hardware, allowing 5G network operators to leverage the benefits of cloud computing. The migration of NFs and their management to the cloud causes 5G traffic to traverse an operator's wide-area network (WAN) to the cloud WAN that hosts the datacenters (DCs) running 5G NFs and applications. However, achieving end-to-end performance for 5G traffic across two WANs is hard. Placing 5G flows across two WANs with different performance and reliability characteristics, edge and DC resource constraints, and interference from other flows is different and more challenging than single-WAN traffic engineering. We address this challenge and show that orchestrating paths across a multi-WAN overlay[1] allows us to achieve average 13% more throughput, 15% less RTT, 45% less jitter, or reduce average loss from 0.06% to under 0.001%. We implement our multi-WAN 5G flow placement in a scalable optimization prototype that allocates 26%–45% more bytes on the network than greedy baselines while also satisfying the service demands of more flows.

1 Introduction

The majority of 5G access networks today use legacy telecom equipment and architecture. The next generation of 5G is designed to deliver superior Quality-of-Service (QoS) through a combination of new frequency bands, new radio technology, and the *cloudification* of telecom network functions (NFs). These innovations are expected to revolutionize 5G and subsequent generations of access networks. In this work we focus on the implications of improved QoS and cloudification of access on wide-area networking (WAN).

As part of the cloudification of 5G, monolithic and proprietary hardware implementations of mobile wireless NFs are evolving into disaggregated software-based NFs that run on commodity off-the-shelf compute [79]. This disaggregation allows 5G operators to deploy their virtualized radio access networks (vRAN) on edge compute close to end users, and packet cores in datacenters (DCs) [56, 61].

Cloudification is driving performance-sensitive inter-domain traffic onto cloud WANs. For instance, traffic from user equipment (UEs) traverses a 5G operator's WAN to a cloud WAN to reach 5G Core NFs and applications hosted in the cloud [56, 61]. The burden of providing QoS to this traffic is now shared between two WANs: the 5G operator's WAN and the cloud WAN. However, existing traffic management mechanisms lack the ability to orchestrate paths shared between two WANs. In fact, 5G networks are already bottlenecked on WAN performance [91], and this will get worse as the upcoming 5G New Radio (5G NR) unlocks ultra-low latency and high-bandwidth radio modes.

Improving the performance of inter-domain 5G traffic is challenging for three main reasons. First, cloudified access traffic is destined to cloud DCs that host 5G NFs and applications. The location of these 5G services in the cloud is itself dynamic [33, 80] and conditional on the availability of compute resources, making it hard to achieve performance-optimal routing. Second, the primary mechanism to achieve network performance goals in WANs today is *intra-domain traffic engineering* (TE) [39, 41, 44] which does not capture inter-domain route performance goals or fine-grained service objectives of 5G traffic. Third, the dynamic nature of 5G traffic requires on-demand flow placement, which is not achievable by traditional TE mechanisms that operate on periodic (*e.g.,* 5 minute) allocation intervals.

We develop OTTER (Overlay Traffic Transport and Efficient Resource allocation), a system that provides efficient, on-demand transport across operator and cloud WANs for 5G traffic with differing QoS needs. It uses a multi-WAN overlay to co-optimize the placement of 5G NFs and applications, and the network paths of 5G traffic. OTTER dynamically computes optimal routes for multiple performance metrics and implements them using scalable forwarding mechanisms involving VMs and cloud routing gateways. OTTER is cloud-agnostic, allowing operators to deploy it on cloud providers of their choice.

Our contributions. OTTER makes two key contributions. First, it develops an efficient algorithm for allocating network and compute resources to 5G demands across operator and cloud WANs. This algorithm forms the core of OTTER's multi-WAN SDN (Software Defined Networking) controller. Second, OTTER implements the optimal routing and compute placement strategy of the controller using a novel multi-WAN forwarding mechanism. We develop the multi-WAN forwarding mechanism as part of the OTTER Orchestrator, which programmatically creates multi-WAN overlay networks with fine-grained routing policies for operators to deploy their 5G NFs.

[1] OTTER topology release: https://OTTER-5GWAN.github.io/

We design OTTER with the observation that the operator and cloud have newly aligned economic incentives for 5G, as their business relationship goes beyond peering to also include SaaS and compute. The OTTER Orchestrator scales to country-wide sizes of large operators by leveraging cloud-native support. The OTTER Optimizer dynamically places both compute and network workloads on multi-WAN overlays, for multiple traffic classes simultaneously.

Results. OTTER's path orchestration across two commercial WANs outperforms both public paths as well as topologies designed for enterprise-grade privacy and security. Our deployment topology scaled out to the continental US shows 13% higher throughput on average, with a best case of 136% higher, which can be 6-10 Gbps more. For flows that care about round trip time (RTT), we achieve 15% average reduction, up to 42 ms less. Jitter-sensitive flows can expect an average reduction of 45% and loss is 0.06% less on average. OTTER's on-demand allocation outperforms greedy baselines by up to 26-45% in allocated bytes (the amount of demand that is satisfied), and comes close to what an infeasible, infinitely-fast optimizer can achieve.

2 Cloudification of Access

Traditionally, vendors have implemented cellular technology on monolithic and proprietary hardware. However, 5G cellular networks are being re-architected using SDN and NF virtualization (NFV) [9]. This new architecture enables operators to scale up and out NFs on statistically multiplexed compute at operator edge sites (at or near cellular base stations and mobile switching centers), cloud edge sites (at hosting centers or peering points), and cloud DCs [55]. The use of the same compute management plane across all three allows NFs and interactive applications (*e.g.,* AR/VR) to be deployed flexibly, as user demand dictates. This allows operators to unlock the elasticity and efficiency of cloud computing. This convergence of access networks and hyperscalers is known as the *cloudification* of 5G [27, 64, 65].

2.1 Implications for WANs

Performance-sensitive demands over multiple WANs. The deployment of 5G applications and NFs on the cloud puts the cloud WAN on the critical path of 5G traffic that originates in the operator WAN, as shown in Figure 1. Extremely performance-sensitive NFs, such as RAN (Radio Access Network) NFs are hosted in operator far edges [37, 64], close to cell sites. Other NFs, such as the 5G Core, are hosted in the cloud, in its edges and/or DCs. For example, Nokia's 5G Core runs on the AWS cloud [61], Microsoft's 5G Core runs on both on-prem servers and Azure DCs [56], and its voicemail NF is hosted on Azure DCs [52]. Multiple operators have already moved parts of their 5G infrastructure

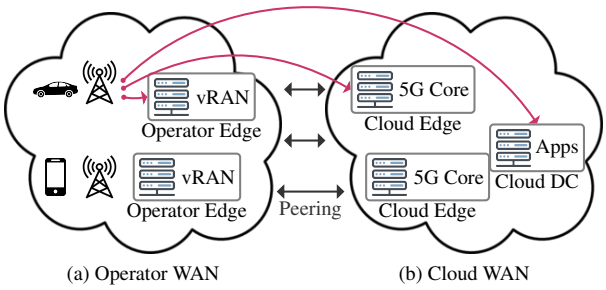

Figure 1: A simplified example of a 5G network

to the public cloud. AT&T is using Azure [8, 60]. Verizon is using AWS [12], leveraging multiple cloud technologies including Amazon EKS, AWS Wavelength, and HashiCorp Consul. The operator and cloud WANs peer [69] directly in multiple locations. An edge or DC can serve traffic flows from operator cell sites depending on where the destination NF or application is hosted [55]. Applications may include operator applications such as phone storage backup, private enterprise applications such as industrial AR/VR, and consumer applications such as game streaming.

Heterogenous network demands. 5G NFs have different performance requirements. For example, some NFs in the vRAN have stringent RTT, loss, and jitter requirements, while others such as UPF (User Plane Function) in the 5G Core need high throughput, and voicemail is performance-insensitive. Furthermore, upcoming releases such as 5G NR enable new applications, each with diverse performance requirements. For example, interactive AR/VR requires sub-20 ms network RTT for acceptable user experience [79, 91], beyond 4K video streaming needs 100+ Mbps throughput, and remote surgery demands high reliability. The 5G specification supports these diverse requirements through multiple radio-layer modes [65, 67, 79, 84], including: (1) *Ultra-reliable low latency communication (URLLC)* with ∼1 ms latency and 99.999% reliability, (2) *Enhanced mobile broadband (eMBB)* with multi-Gbps data rates, and (3) *Massive machine-type communication (mMTC)* for ultra-low energy communication at scales of up to 1 million nodes per KM^2.

Compute selection and routing decisions jointly matter. Placement of applications and NFs on compute that is *near* vs. *far* from the user [73], and the choice of network routes between users and this compute both impact performance. While operator edges are closer to users (few ms away) and hence are an ideal target in which to place highly responsive workloads (*e.g.,* vRAN), they have very limited compute due to physical space and power constraints at cellular base stations and mobile switching centers [74]. On the other extreme, the DC is furthest away (tens to hundred ms away) but has far more available compute.

Traditional selection techniques, such as those in CDNs (Content Delivery Networks), fall significantly short here. Directing all traffic from an entire subnet or LDNS (local

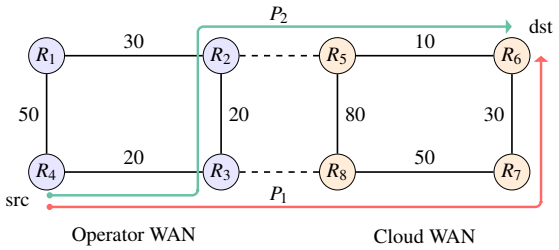

Figure 2: Sub-optimal routing for independent WANs.

DNS) coverage area to a single destination leads to undifferentiated performance for multiple flows with different requirements. Similar to DNS, the 5G NRF [33,80] (NF Repository Function) maintains profiles of available instances of NFs, and provides discovery and load balancing. However, it is not network-aware and only considers compute load. The problem is further exacerbated by the use of SFC (Service Function Chaining) [20] in 5G, where instances of different NFs are dynamically chained together to serve a request.

Picking a destination for a network demand based on compute capacity alone can lead to poor E2E performance. Picking a destination for a network demand based on network performance alone can lead to overloaded compute. Performance studies of existing 5G networks [91] have already found that "the untamed latency in the wireline paths, which is beyond mobile carriers' control, may neutralize 5G's latency advantage" and argue that "the wireline paths, upper-layer protocols, computing and radio hardware architecture need to co-evolve with 5G."

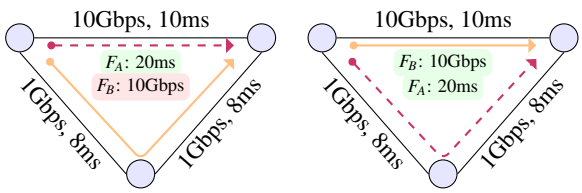
Need for multi-WAN coordination. Cloudification forces operators and clouds to share responsibility for tight performance guarantees of 5G workloads. Individual routing and compute placement decisions leads to sub-optimal performance. Figure 2 shows a latency sensitive flow traversing two WANs from source R_4 to destination R_6. Each link has an associated latency. The operator chooses the best egress point-of-presence (PoP) R_3 and path R_4R_3 to R_3 to minimize RTT on its network. The cloud routes traffic from R_8 to R_6 following the optimal RTT path, resulting in the E2E path P_1. However, a more efficient path P_2 exists. We show in §7 that decision making across both the cloud and operator unlocks such performance improvements.

Given the multitude of 5G networks across the world, multiple cloud providers, and dynamic nature of traffic and operational WANs, manual coordination to address performance problems as they appear does not scale.

New incentives for multi-WAN co-operation. Historically, it has been challenging to achieve collaborative routing beyond traditional peering agreements on the Internet. However, the cloudification of access has aligned the economic incentives of cloud and operator networks. The operator is not only selling access to end users to the cloud, it is now also a customer of the cloud for hosting 5G applications and NFs. There is a shared responsibility to manage compute and network between the two WANs for 5G demands.

3 OTTER

Prior empirical work [91] has shown that as 5G performance over-the-air has improved, WANs have become the bottleneck. We tackle this problem by placing heterogenous performance demands on the most appropriate compute and network paths across operator and cloud WANs. We refer to this as the multi-WAN flow placement problem, and it requires two core capabilities — the ability to direct a flow to a specific compute endpoint over a specific network path, and the ability to calculate that optimal path and endpoint.



3.1 Design Goals

We design OTTER with the following goals:

Co-exist with non-5G WAN traffic. 5G traffic will share operational WANs that serve existing customers. For example, operator WANs already provide wireline connectivity to consumers or *eyeballs*. Cloud WANs carry enterprise and consumer workloads. Moreover, both types of WANs operate existing TE systems to engineer the capacity of their network efficiently [11,25,26,39,41,89]. However, both operator and cloud TE systems aim to achieve network welfare goals such as high utilization or bandwidth fairness [39,41], rather than optimizing for individual service objectives. Instead of overhauling existing TE systems in cloud and operator WANs, we design OTTER to be an overlay that operates in a layer of abstraction above existing WAN TE.

Dynamic flow placement. This overlay design choice further allows OTTER to place 5G flows on network paths and compute endpoints on-demand. In contrast, existing TE and other optimizations operate on batched traffic demands by periodically (*e.g.,* every 5 minutes) computing flow allocations from a predicted traffic matrix [39,41], or running a single optimizer instance for a single input demand [40]. A broker [39] enforces those periodic allocations by squelching flows that exceed them. While existing TE will continue to run on each WAN separately, OTTER can dynamically place flows without being subject to periodic allocations nor requiring bandwidth brokers in 5G deployments.

Support multiple, fine-grained service objectives. Today's WAN TE systems provide service differentiation using only a small number of priority classes (*e.g.,* high priority vs. low priority) [10, 39]. Such few classes are insufficient to express the more complex and fine-grained objectives of 5G traffic. These coarse-grained priority classes can fail to capture the demands of lower priority flows, even when there exists an allocation that maps all flows to acceptable paths. Consider a simple example in Figure 3, where each link can carry at most one flow. Flow F_A has high priority with a latency requirement of 20 ms, and flow F_B has low priority

(a) Preferential (b) Non-preferential

Figure 3: Two flow allocation strategies

with a throughput requirement of 10 Gbps. On the left, we show the allocation where flows are assigned in strict priority order, preferring shorter paths—this is how modern TE systems like OneWAN [45] and SWAN [39] operate. F_A will be assigned first to the top path while F_B will be assigned to the remaining bottom path and fall short of its throughput requirement. On the right, we show an alternate allocation that can map both flows to paths that meet their service demands. However, it is not trivial to find such an allocation at the scale of hundreds of endpoints and thousands of flows, each with their own performance demands across a variety of metrics.

Take inter-domain routing protocols as a given. Inter-WAN routing leads to sub-optimal E2E routes due to limited information disclosure and different goals between WANs [47, 48]. While prior work has shown that ASes can exchange information to produce E2E optimal routes, such negotiation entails heavyweight communication overheads that may not be practical [47, 48]. In the context of 5G, this overhead is further exacerbated by numerous traffic flows, each with widely varying objectives. So, we design OTTER without requiring changes to inter-domain routing protocols, policies, and implementations.

Not require private WAN data. While sharing intra-WAN topologies could lead to better multi-WAN paths, ASes have economic incentives to limit such visibility [47, 48, 75, 81]. 5G cloudification presents a unique opportunity for efficient cross-domain routing without sharing such private data. The operator, as a customer of the cloud, owns the workloads deployed on VMs in cloud edges, DCs, and operator edges. The cloud provides the control plane for managing bare metal at these locations, such as provisioning VMs and establishing connectivity. Thus both the operator and the cloud have visibility into network performance at an overlay layer between all compute locations. OTTER uses this visibility to make informed flow and compute placement. We show that the operator can deploy and run OTTER across both WANs, without access to private data or capabilities, and still provide significant performance improvements.

Multi-cloud support with open interfaces. 5G operators want to avoid cloud-lock in and deploy their NFs to one or more cloud providers of their choice. To achieve this, we design OTTER as a multi-cloud network overlay across operator and cloud WANs. OTTER uses publicly available VMs as nodes in the overlay, and a variety of public cloud NFs for

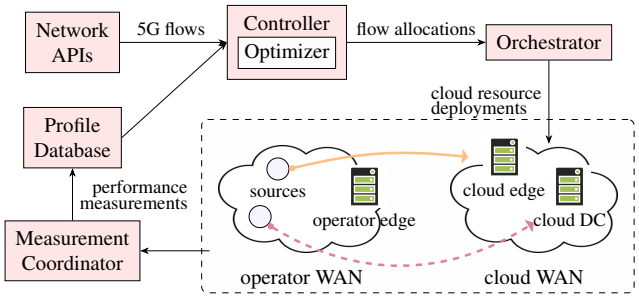


Figure 4: Overview of OTTER

routing between the nodes. This allows operators to use OTTER in multi-cloud deployments, without requiring private or special privileges from an underlying cloud.

3.2 OTTER Overview

OTTER places flows in a multi-WAN environment to satisfy their service demands. It does so by co-optimizing which 5G application / NF compute will serve the flow, and the route that flow will take to it. Figure 4 shows OTTER's architecture consisting of the Controller and Orchestrator. The Controller accepts flow demands to 5G NFs and applications using APIs [28, 34, 53, 57]. These "Quality on Demand" APIs [3] allow an application to create a session by issuing an HTTP POST to the */sessions* API, providing flow identifiers (IP addresses, port ranges, device phone number, etc.) and a QoS profile that best matches the application needs (see the "quality-on-demand v0.11.1" API on Swaggger [3]). Such standardized APIs have been implemented by 5G operators (see the implementations by Deutsche Telekom, Orange, and Spry Fox Networks posted on GitHub [3]) and by clouds that offer to host 5G services [15]. In addition to allowing application developers to specify their 5G flow needs, these APIs allow for termination of a session, extending a session, and getting notified when the requested QoS cannot be fulfilled. A UE that disconnects and reconnects, or incurs an inter-RAT (Radio Access Technology) handover, can create a new session with this API.

The Controller allocates compute to meet these performance requirements within the limits of compute availability on edges and DCs. The Controller calculates the most appropriate network paths to the allocated compute. Unlike TE systems, OTTER relies on available compute capacity at destination sites, as well as periodic measurements of network paths that it makes. This not only allows OTTER to route flows along alternate paths, but also to alternate destinations. The Orchestrator manages cloud resources and implements the forwarding mechanism to steer traffic along routes computed by the Controller. It provisions compute as per the Controller's optimal placement.

While similar challenges can be faced by other applications across WANs, OTTER is designed to serve 5G deployments. The business alignment between "eyeball" networks and cloud networks, where 5G deployments are hosted

across both, drives the necessary incentive to orchestrate both WANs. The diversity of 5G applications requires a design that supports multiple classes of traffic, not just bulk traffic [40]. End-user flows have to be placed in real time, not at traditional, periodic TE intervals. OTTER leverages APIs [28,34,53,57] already deployed by 5G providers to accept these application demands, where such APIs have not been deployed at scale for other applications nor networks. Finally, we design OTTER as an overlay without forcing one WAN to have administrative control nor require use of private capabilities – this design hence does not preclude a cloud from supporting multiple 5G operators, and a 5G operator from relying on multiple clouds.

4 OTTER Controller

The OTTER Controller maps traffic demands to network paths and compute resources. It does so while maximizing the allocated traffic and minimizing the degree to which 5G application-specific service requirements are violated. The resulting mapping of flows to destination compute sites and the network paths to reach them is an input to the OTTER Orchestrator. It informs the Orchestrator at which of the available edge sites or DCs to terminate 5G flows and which network paths to use. In this section, we formalize this problem, referred to as the *5G multi-WAN flow placement* problem, explain the constraints on the Optimizer, and describe techniques used to ensure its scalability.

The Optimizer takes as input the set of paths P that are available in the multi-WAN network. Each path $p \in P$ is represented by the tuple $(s,d,L,\sigma)_p$, where s_p is the source, d_p is the destination, L_p is the set of links used by the path, and σ_p is a vector of performance metrics for path p. σ_p^m refers to the value of metric m for path p. For example, the RTT, jitter, and packet loss of path p are represented by $\sigma_p^{rtt}, \sigma_p^{jit}, \sigma_p^{loss}$. L is the set of links in the network, and each link $l \in L$ has capacity c_l. Let P_l be the set of paths that share a link l, and P_d be the set of paths that share a destination d.

The Optimizer takes as input a set of 5G flows F that need to be allocated. Each flow $f \in F$ is represented by the tuple $(s,D,\mathcal{D},bw,r)_f$. s_f is the source of the demand. D_f is the set of destinations (specific edges & DCs) that can serve the flow. $\mathcal{D}_f$ represents the service demands of the flow with $\mathcal{D}_f^m$ giving the demand for metric m. bw_f is the requested bandwidth. r_f is a vector of destination resource requirements of the flow – compute, memory, and storage. We write r_f^π to refer to the requirements of flow f with respect to resource type π. Unlike TE, an OTTER flow is not limited to a single destination. Rather, we leverage the agility of the cloud to place compute resources for serving a 5G application or NF across multiple destinations. This allows OTTER to further optimize path performance by adjusting the destinations of flows. Compared to resource-constrained edge sites, a destination d that is a DC has $\approx \infty$ capacity c_d^π. For scalability, individual flows with the same source, destination set, service demands, and resource requirements are treated as part of a single "flow aggregate" for the Optimizer to allocate. The Optimizer solves the flow placement problem such that all flows within the same flow aggregate are routed in the same way and to the same destination.

Modeling service demands. We encode the service demand of a flow that is obtained from operator APIs (§ 3.2) as a vector of *demand functions* $\mathcal{D}_f$. A demand function $\mathcal{D}_f^m$ maps a flow's performance expectation, *i.e.,* what the flow expects to achieve for a given allocation, to a *tolerance coefficient* $\mathcal{D}_f^m(\sigma_p^m) \in (0,1]$. The tolerance coefficient is a measure of how good the path is for a flow. For example, an application may consider a path RTT under 100 ms acceptable, over 200 ms unacceptable, and linearly decrease its preference for a path between 100 and 200 ms. In this case, the Optimizer computes the tolerance coefficient to be 1 for all paths with an RTT under 100 ms, ε for all paths greater than 200 ms, and a value inversely proportional to the RTT for paths between 100 and 200 ms:

$$\mathcal{D}_f^{rtt}(\sigma_p^{rtt}) = \left\{ \begin{array}{ll} 1, & \text{if } \sigma_p^{rtt} \leq 100 \\ -\frac{1}{100}\sigma_p^{rtt} + 2, & \text{if } 100 < \sigma_p^{rtt} \leq 200 \\ \varepsilon, & \text{if } \sigma_p^{rtt} > 200 \end{array} \right\}$$

The Optimizer's goal is to allocate demands such that the degree of satisfaction (tolerance coefficients) is maximized. All tolerance coefficients are constant, allowing the objective function to be linear and the optimization problem to be a linear program (LP). The use of demand functions allows the Optimizer to scale over numerous path metrics and performance demands, as well as future-proof it for new applications that have arbitrary service demands.

Modeling resource requirements. Each flow specifies a resource requirement vector r_f. Each element represents compute in vCPUs, RAM, and disk storage needed to serve the 5G workload. While we focus on those three resources, the vector can be expanded and compared component-wise to the resource capacities of destination sites.

Decision variables. The Optimizer assigns network flows to paths in P and compute resources to destination sites in D. We have two decision variables: $x_{f,p}$, the amount of bandwidth of flow f assigned to path p, and $y_{f,d}^\pi$, the amount of resources of type π for flow f allocated at destination d. OTTER co-optimizes the flow allocation and the destination placement. See Table 1 for a summary of variables.

Objective function. The Optimizer aims to assign network flows to multi-WAN paths such that as much traffic is allocated as possible while still satisfying performance demands. The cost of a single flow assignment is the product of its allocated bytes and the overall tolerance coefficient summed over all performance metrics. To prevent bias towards large flows, we normalize this cost by the requested bandwidth of the flow bw_f. The objective function is as follows:

Inputs	
P	paths in network
s_p, d_p	source and destination of path p
L_p	links used by path p
σ_p^m	performance metric m for path p
L	links in network
c_l	capacity of link l
F	flows to allocate
s_f, D_f	source and destination set of flow f
$\mathcal{D}_f^m$	path performance demands for metric m of flow f
bw_f	requested bandwidth of flow f
r_f^π	resource requirements of flow f for resource π
c_d^π	resource capacities of destination d for resource π
Outputs	
$x_{f,p}$	amount of flow f assigned to path p
$y_{f,d}^\pi$	amount of resource π for flow f assigned to destination d

Table 1: Symbol table for the OTTER optimizer.

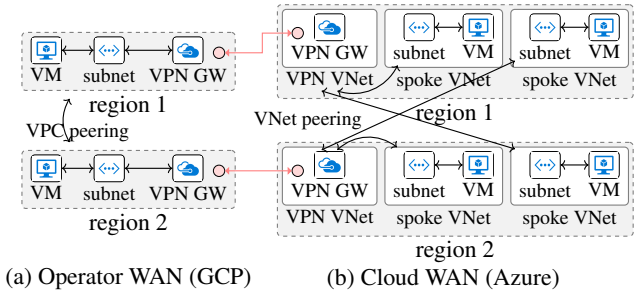
maximize	$\sum_{f\in F}\sum_{p\in P}\left(\frac{1}{bw_f}x_{f,p}\cdot\sum_m \mathcal{D}_f^m(\sigma_p^m)\right)$		
subject to			
	$x_{f,p} \geq 0$	$\forall f,p$	(c1)
$\sum_{p\in P}$	$x_{f,p} \leq bw_f$	$\forall f$	(c2)
$\sum_{f\in F}\sum_{p\in P_l}$	$x_{f,p} \leq c_l$	$\forall l$	(c3)
$\sum_{f\in F}$	$y_{f,d}^\pi \leq c_d^\pi$	$\forall d,\pi$	(c4)
$\sum_{d\in D_f}$	$y_{f,d}^\pi = r_f^\pi * \left(\sum_{p\in P_d} x_{f,p}\right)/bw_f$	$\forall f,\pi$	(c5)

Table 2: OTTER optimizer formulation.

$$\text{argmax}\sum_{f,p}\left(x_{f,p}\cdot\sum_{m\in\{rtt,jit,loss,bw\}}\mathcal{D}_f^m(\sigma_p^m)\right)/bw_f$$

We note that our objective function does not inherently prioritize one metric over another. Rather, applications can indicate priority through the demand functions.

Constraints. Table 2 summarizes the constraints in OTTER's optimization. Constraint $c1$ ensures that the total allocated flow is non-negative. $c2$ and $c3$ ensure that the allocated flows are bounded by their requested bandwidth as well as the bottleneck capacity of the paths. Destination sites have resource constraints that limit how many flows can map to them, and $c4$ prevents overload. Constraint $c5$ requires that the proportion of resources assigned to a flow at a destination is equal to the proportion of the amount of bandwidth allocated to the flow at the same destination.



On-demand 5G flow allocation. Unlike TE systems which allocate flows periodically (*e.g.,* every 5 minutes) for predicted traffic demands, the OTTER Controller must perform on-demand flow placement. This difference arises due to the dynamic and unpredictable nature of 5G traffic [24] compared to typical WAN workloads. Unfortunately, re-running the Optimizer too frequently incurs a large delay. While the Optimizer computes newly optimal flow allocations, stale routes remain in-use, potentially leading to service demand violations [93]. To handle this, the Controller implements a greedy heuristic that approximates the optimal (*i.e.,* invoking the Optimizer on every new flow) configuration. It greedily allocates flows to available paths and destinations to provide the best demand satisfaction, while adhering to resource constraints. The Controller then periodically runs the full Optimizer in the background to optimally place new flows and those that were greedily assigned since the previous call to the Optimizer. The Controller can then shift those flows to achieve a globally optimal allocation, or it can pin flows to specific paths or destinations to avoid packet re-ordering. While shifting flows *could* result in an individual flow experiencing lower service demand satisfaction compared to its initial greedy allocation, reallocation still improves overall satisfaction across more flows, as shown in §7.

Computational complexity of OTTER. OTTER's optimizer is a linear program. Off-the-shelf optimization solvers implement polynomial time algorithms to solve linear programs, making it possible to solve OTTER's optimization quickly. While linear programs are quick to solve in practice, increasing the size of the problem can increase the run time of the solver. OTTER has two ways of dealing with high run times. First, OTTER reduces the set of possible destinations for each flow to a set of size n prior to solving the optimization. We estimate the n "best" destination sites using a flow's service demands ($\mathcal{D}_f^m$) to rank candidate destinations by preference. This effectively reduces the number of variables in the linear program. Second, depending on the size of the linear program, OTTER can run the full optimization at longer periodic intervals (*e.g.,* ten minutes) since the greedy flow allocation can assign flows to paths without waiting for the next interval. We evaluate the performance of greedy flow allocation between consecutive runs of the Optimizer, as well as the Optimizer, in detail in §7.

5 OTTER Orchestrator

The Orchestrator includes the forwarding mechanism necessary to steer traffic along routes computed by the Controller (§4). It also manages compute as per the Controller's optimal placement. We design the Orchestrator as a multi-WAN overlay on a cloud WAN and an operator WAN. To evaluate OTTER without impacting an operational 5G network, we substitute the operator WAN with GCP (Google Cloud Platform). Figure 5 shows one small deployment of OTTER, and Figure 19 in Appendix A shows a larger one. The Orchestrator uses only existing, native cloud functionality, which satisfies our design goal of not requiring private WAN data (§3).

Connectivity in the OTTER Orchestrator overlay. We host multiple VMs in each Azure region to represent 5G NF and application servers. VMs in GCP serve as 5G cell sites with far edges, while virtual private network (VPN) gateways behave like 5G near edge sites. We create private subnets in each GCP region and virtual private cloud (VPC) peer-

(a) Operator WAN (GCP) (b) Cloud WAN (Azure)

Figure 5: OTTER Orchestrator's multi-WAN topology.

ing connections in full-mesh between GCP regions. We use virtual network (VNet) peering between clusters of VMs in different regions to connect them to each other and to VPN gateways. Given that much of the 5G infrastructure, including cell sites and NFs, use private IP address ranges to protect communication, VPN tunnels are necessary to establish private connectivity among them. We have configured the VPN gateways to allow transit with the 5G operator WAN where both clouds have regional DCs and underlying peering (see Appendix A).

Forwarding in the OTTER Orchestrator overlay. The OTTER Orchestrator leverages native functionality in each cloud to achieve high forwarding performance, ease of scale, and lower deployment complexity. To control the path that a 5G flow takes in the overlay, we use a combination of route tables with user-defined routes (UDRs) and choice of multiple VNets in the destination region, something that both GCP and Azure support without requiring the customer to deploy their own BGP speakers and packet forwarders. Other design choices, such as using SNAT and DNAT with VPN gateways and firewalls [51], or MP-TCP on source and destination VMs, incur different tradeoffs in flexibility and overheads. We configure advanced parameters on VNet peering and network firewalls to allow VMs in one region to use a VPN gateway in another and allow transit traffic between regions. Each cloud component supports scale-up and scale-out, allowing the entire topology to easily cover the continental US, for example, without any code changes to individual components. We use symmetric paths for a flow but can easily use different paths in each direction. The use of one system to identify, manage, and use routes across WANs allows us to satisfy the need for multi-WAN coordination (§ 2).

Secure multi-WAN routing. We use private VNets to host 5G cell sites, edge sites, and NFs. We use VNet peering to allow only authorized traffic to transit between VNets. We use VPN gateways to enforce encryption when transiting WANs. Our design choices were inspired by product demonstrations from industry 5G NF providers [61].

Extensible multi-WAN topology. This design allows both scale and flexibility. Given an arbitrary source in a GCP region and a destination in an Azure region, it can use any VPN connection and any intermediate Azure and/or GCP region to send and receive traffic. We achieve this through a combination of VPN connections, VNet peering, and selective route announcements. We trivially increase inter-WAN forwarding throughput by scaling out VPN gateways and tunnels.

6 System Implementation

We have implemented the entire OTTER system shown in Figure 4 to operate on top of Azure and GCP, with no special support from either underlying cloud. The Orchestrator is built with HashiCorp's Terraform [86]. Our evaluation topology (available in an anonymous repository [1]), listed in Table 3 and described in §7.1, is built in ∼4,100 LoC of HCL (HashiCorp Configuration Language), with ∼2,600 LoC for module deployments, ∼600 LoC for GCP resource declarations, and ∼900 LoC for Azure resource declarations.

We implemented the Measurement Coordinator in ∼1,200 LoC in C#. It uses the Azure and GCP SDKs to automate periodic execution of measurement tools for path bandwidth, RTT, jitter, and loss. We use iPerf3 [23] to measure throughput, configured to use TCP CUBIC with 60 parallel connections, 2 seconds of warm up, and 5 seconds of measurement. For packet loss, we use iPerf3 in UDP mode. For RTT and jitter, we use sockperf [49]. We use round-trip values, and jitter is calculated as the standard deviation of RTT.

The Measurement Coordinator analyzes the output of the Orchestrator's Terraform execution to determine the deployment topology and the names and IP addresses of its components, including source and destination VMs. It then creates a non-overlapping schedule of measurements. The output of the measurement tools is parsed and converted to JSON. That JSON is then inserted as a new document record into an Azure Cosmos DB NoSQL database [54].

The Optimizer issues simple SQL queries on that database to obtain sliding window values of median throughput, RTT, jitter, and loss for all paths. 5G flow requirements are modeled from a subset of application profiles in the 3GPP standard [79], which we describe in §7.2. However, we expect to integrate with network APIs [28, 34] such as Azure Programmable Connectivity [53, 57] that allow 5G applications to specify flow QoS requirements. We have implemented the Optimizer using the Gurobi [35] solver. The Optimizer is an LP of ∼500 LoC. We run our implementation on a VM with a 16 core 3GHz CPU and 48 GB of memory.

7 Evaluation

We evaluate OTTER in two ways. First, in §7.1, we demonstrate the value of orchestrating paths across two WANs, compared to the default path from traditional Internet routing. Second, in §7.2, we evaluate how OTTER's optimization algorithm performs under a wide variety of situations at scale, and in comparison to alternative algorithms.

Cloud	Element	Deployment strategy	Total
GCP	regions	cover US	8
	VPC	1 per region	8
	subnet	1 per region	8
	cloud router	1 per region	8
	VPC peering	full mesh	56
	32 core VM [31]	1 per VPC	8
	classic VPN GW	4 per VPC	32
	cloud VPN tunnel	2 per VPN GW	64
Azure	regions	cover US	8
	VpnGw5 GW [14]	1 per region	8
	VPN GW interface	8 per VPN GW	64
	32 core VM [13]	8 per region	64
	VNet	1 per VM and VPN GW	72
	VNet peering	each VPN GW VNet to VM VNet	64

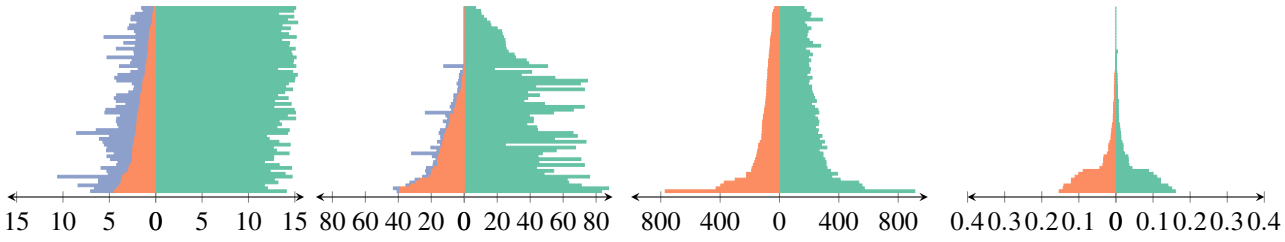
Table 3: Scale of OTTER topology across US regions.

7.1 OTTER Orchestrator Evaluation

§5 briefly describes how OTTER's Orchestrator works, with a secure, private, scalable design that allows flexible path selection to cater to multiple QoS requirements. We evaluate this orchestration at scale on two commercial cloud WANs.

We have scaled out the topology shown in Figure 5 to cover the US and support a large number of flows. Table 3 lists how many of the main components we use, though there are many other sub-components that we do not list, such as VM drives, NICs, custom routes, firewalls, and security rules. We use the biggest VPN GWs and multiple connections. We create VPN connections between the two clouds in nearby regions, listed in Appendix A. This topology is sized similarly to that of large 5G operators [21]. We use the largest VMs that have sufficient CPU and network bandwidth such that the VMs themselves are not bottlenecks in any of our measurements. We validate this through intra-cloud testing, where for example we achieve >25Gbps throughput between any two VMs in GCP in our topology, more than what is possible between two VMs across the two clouds.

We have run experiments on different weekdays and observed qualitatively similar results. For brevity, we show results from a 24 hour period starting on 09 Feb 2023 13:00PM (PT), where we repeatedly measure $8^3 = 512$ paths over 20 times. When comparing any two paths between the same source on GCP and the same destination on Azure, we only consider measurements immediately adjacent in time to each other. This ensures an "apples to apples" comparison, since comparing a path at 2am with one at 2pm is not useful for real-time demands.



Figures 6a, 6b, 6c, and 6d show the network performance improvements that the OTTER Orchestrator is able to achieve. Each horizontal bar corresponds to one of 64 unique source-destination (Src-Dst) pairs, with the source in GCP and destination in Azure. The bar on the right represents the median performance observed for a Src-Dst pair when the OTTER Orchestrator is not invoked, *i.e.,* the default path [32] that a flow experiences when we do not specify which VPN connection to use and do not force traffic through an intermediate region (see Figure 5). The first bar on the left shows the median improvement that the OTTER Orchestrator achieves for the same Src-Dst pair when considering the best performing path across all possible combinations of VPN connections and intermediate regions. This median is computed as follows: for each round of measurements, we calculate the performance improvement of OTTER orchestration over the default path, and then use the median value across the ~20 rounds that happen over 24 hours. The second bar on the left shows the maximum improvement observed. The Src-Dst pairs in each figure are sorted by median improvement.

For example, the bottom bar in Figure 6a shows that this Src-Dst pair can achieve 14.1 Gbps, in the median across the 24 hour period, but the OTTER Orchestrator can improve that by 4.4 Gbps to achieve 18.5 Gbps in the median, and in the best case improves throughput to 21.1 Gbps. The bottom bar in Figure 6b shows a Src-Dst pair with 83.2 ms median RTT, but the OTTER Orchestrator can reduce that by 39.4 ms to achieve 43.8 ms in the median, and in the best to 42.4 ms.

Consider one Src-Dst pair example in Figure 7. From a source in GCP's US West 3 region to a destination in Azure's South Central US region, 13.6 Gbps throughput and 40.6 ms RTT is the median performance, on the typical [32] hot potato path, where traffic is handed off to Azure at the nearest location in Azure's West Central US region. OTTER has two other paths between the same source and destination that the Orchestrator can use with different RTT and throughput tradeoffs. When sending traffic via GCP's US South 1 region, the median RTT is significantly better at 35.0 ms, but at a slight degradation in throughput (13.5 Gbps). Instead, via GCP's US West 4 and Azure's West US 3 region, there is significantly higher throughput of 19.4 Gbps, but at slightly worse RTT of 42.8 ms. There is not one path with the best throughput, RTT, jitter and loss—different paths have different performance. OTTER is able to exploit the spectrum of paths to send traffic along the appropriate path for a flow, using scalable mechanisms involving VPN tunnels, VNet peering, and user-defined routes (§5).

Appendix B has additional presentations of these experimental results. We summarize our findings as:

- For flows prioritizing throughput, the OTTER Orchestrator offers higher throughput than the underlying networks. On average, it is 13% higher and in the best case 136% higher. In some cases, the throughput increases by 6-10 Gbps. The peak throughput OTTER achieves between two VMs across the clouds is >20 Gbps.
- For RTT, the average reduction is 15%, with a maximum of 56%. In some cases this is a RTT reduction of 42 ms, within the continental US.
- The average jitter reduction is 45%, with a maximum of 99%, which in some cases is a reduction of over 10 ms.
- Excluding some outliers, packet loss is reduced from 0.06% on average to less than 0.001%. In some cases

(a) Throughput (Gbps) (b) RTT (ms) (c) Jitter (μs) (d) Loss (%)

Figure 6: Improvements that the OTTER Orchestrator achieves per Src-Dst pair for each of 4 performance metrics. Bars on right show performance of default path, bars on left show median improvement and max improvement. Max improvements for jitter and loss are excluded for clarity.

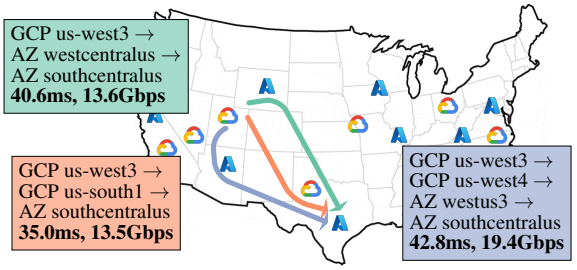


Figure 7: Examples of improvements in performance OTTER can achieve between the same Src-Dst pair.

the maximum reduction is more than 0.4%.

- Our scalable, secure, and private multi-WAN architecture achieves higher throughput than a simple architecture of VMs with public IPs. While some cloud components such as VPN tunnels can slightly worsen RTT and jitter, the OTTER Orchestrator compensates by finding better paths, providing the highest throughput, lowest RTT, jitter, or loss for any Src-Dst pair.

Prior work [40, 48, 91] has observed inefficiencies in the default intra- and inter-WAN paths provided by existing networks. Here, we comprehensively identify what OTTER can achieve across multiple objectives in the context of a deployment topology that is secure, private, and scalable, and achieves higher throughput than previously shown [40]. As seen in many TE algorithms [39, 41], the primary objective function is satisfying as much traffic demand as possible, with a possible secondary objective of minimizing RTT. This makes sense in a commercial WAN, where the cost of building and operating it has to be amortized over as much customer demand as possible. In contrast, OTTER's goal is to provide best performance to individual flows, and as such utilizes multiple paths that offer different QoS, without having to scale to the TE demands of the underlying networks. Further, OTTER utilizes virtual routing techniques (see §5), to react to real-time performance changes without requiring the underlying network infrastructure to issue route updates and converge, forcing all traffic to use those routes.

7.2 OTTER Controller Evaluation

Setup. We evaluate the Controller on the same continental US-wide, multi-WAN topology on which the Orchestrator is evaluated (§5). In Appendix F, we also evaluate synthetic smaller and larger topologies, including those that match the scale of contemporary TE systems, and show qualitatively similar results. To avoid limiting findings to specific network performance values, we evaluate the Controller on a distribution of values listed in Table 4. Path attributes are sampled at random from the distribution of measured path metrics in our multi-WAN topology, while destination and flow attributes are chosen uniformly at random from the specified range to mimic 5G traffic [79].

Flows arrive according to a Poisson process with a mean arrival rate. We evaluate multiple flow arrival rates as listed in Table 4. We use 10 seconds as the mean flow duration, and we show qualitatively similar results for varying durations in Appendix C. We randomly assign an application profile to each flow and generate a demand function for each performance metric using one of three function types: step, linear, or rational, with inflection points in each function derived from the guideline service demands in Table 5. Those demands are based on 5G application profiles from the relevant 3GPP standard [79], described in more detail in Appendix D. To account for flow diversity, we select inflection points at random from within $\pm$25% of the guideline metric. We also evaluate the effect of assigning application profiles from varying distributions based on RTT requirements, instead of random assignments, and show qualitatively similar results in Appendix E.

Heuristics. We implement several heuristics in the Controller, with different levels of optimality, compute needs, and impact on ongoing flows:

- GREEDY: Flows are allocated greedily in arrival order to the best paths based on the tolerance coefficient.
- PER: Same as GREEDY, but the Optimizer also periodically runs to shift all active flows to optimal paths. While the Optimizer is computing allocations, incoming flows are allocated greedily.

Topology			value/range		units
Num sources				8	#
Num destinations (DC)				2	#
Num destinations (edge)				6	#
Num paths per src/dst pair				8	#
Path Attributes	min	max	avg	std	units
Throughput	4.0	20.8	13.7	1.6	Gbps
RTT (DC)	69.2	150.8	92.2	18.2	ms
RTT (edge)	3.2	34.6	24.8	7.2	ms
Jitter	0.008	38.0	0.62	1.38	ms
Loss	0.0	4.3	0.06	0.16	%
Destination Attributes			value/range		units
CPU capacity (edge)			128-4096		cores
Memory capacity (edge)			128-4096		GB
Storage capacity (edge)			1024-32768		GB
Flow Attributes			value/range		units
Flow arrival rate			20K-40K		flows/s
Flow duration mean			10		s
Flow duration std			10		s
Application profile			1-8		index
Demand function			{step, linear, rational}		type
CPU requirement			1-128		#
Memory requirement			1-128		GB
Storage requirement			8-1024		GB

Table 4: Evaluation Parameters. Values are sampled at random from the specified ranges. Path attribute values are actual measurements from our multi-WAN topology.

Application name	**Throughput** (Mbps)	**Latency** (ms)	**Jitter** (ms)	**Loss** (rate)
Conversational Voice	0.3	100	-	10^{-2}
Live Streaming Video	1.5	150	-	10^{-3}
Buffered Streaming Video	15	300	-	10^{-6}
MC-PTT Voice	1	75	-	10^{-2}
Augmented Reality	20	10	-	10^{-6}
Real-time Gaming	10	50	10	10^{-3}
Remote Driving	1	5	-	10^{-4}
Intelligent Transport	1	30	-	10^{-5}

Table 5: Application profiles for flows (see Appendix D for details).

- PER+PATHPIN: Same as PER, except RTT and jitter-sensitive flows are pinned to their destinations and paths and not shifted even if the Optimizer finds a better path.
- PER+DSTPIN: Same as PER, except RTT and jitter-sensitive flows can be assigned to a new path without changing the destination.
- OPT+PATHPIN: An unattainable version of PER+PATHPIN that uses an infinitely fast optimizer. This removes the need to greedily allocate during optimizer compute time.
- OPT+DSTPIN: An unattainable version of PER+DSTPIN that uses an infinitely fast optimizer.
- OPT: An unattainable version of PER that uses an infinitely fast optimizer, which invokes a re-optimization of the network on every flow arrival and can re-allocate flows to optimal paths with no restrictions.

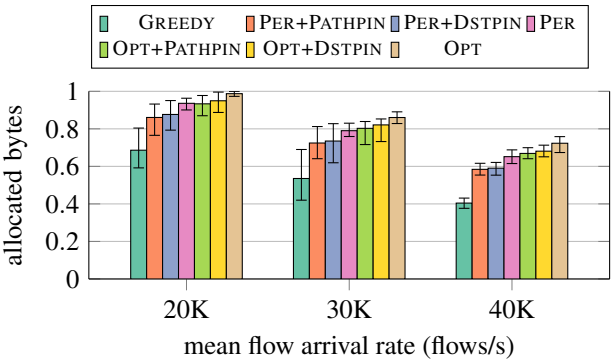

Figure 8: Average fraction of allocated bytes across all flows. Error bars show min-max over multiple runs.

Traffic allocation. Figure 8 shows the average fraction of bytes allocated across all flows for each allocation method for varying flow arrival rates. We define allocated bytes for a flow as the amount of requested bandwidth bw_f successfully allocated multiplied by its duration. We see that OTTER with periodic re-optimizing (PER) always allocates more traffic compared to the baseline GREEDY method, while still reacting quickly to on-demand flows. As expected, as the flow arrival rate increases, the number of allocated bytes decreases across all allocation methods. This is explained by the increase in resource contention when more active flows are present on networks of the same size with similar link and destination capacities. We also see that PER+PATHPIN and PER+DSTPIN on average allocate 26–45% more bytes than GREEDY, and just 10% fewer bytes than their unattainable optimal counterparts. In Appendix F, we scale to mean flow arrival rates of up to 512K flows/s without observing a large drop-off in gap-to-optimal performance.

For intuition into how the OTTER Controller allocates flows, Figure 9 has a time series of the average fraction of requested bandwidth that is successfully allocated by each method. It shows results for a mean flow arrival rate of 40K flows per second. Note that for instantaneous bandwidth allocation, we do not weight the allocation by the size of the flow, and only show the unweighted average across all flows at each point in time. OTTER's periodic re-optimizing methods exhibit a sawtooth behavior, with a jump in allocated bandwidth after each optimizer run and a steady decrease during the solve time due to falling back to GREEDY allocation for new flows. PER+PATHPIN and PER+DSTPIN provide a less optimal solution after each Optimizer run due to pinning, as shown by smaller sawtooths, but can run more frequently since the additional constraints reduce solve time.

These results also show how OTTER's Optimizer better maps flows to suitable paths without starving flows that may be considered "lower priority" in other schemes. While GREEDY also uses our notion of tolerance when ranking paths, it will greedily assign a flow to the best available path

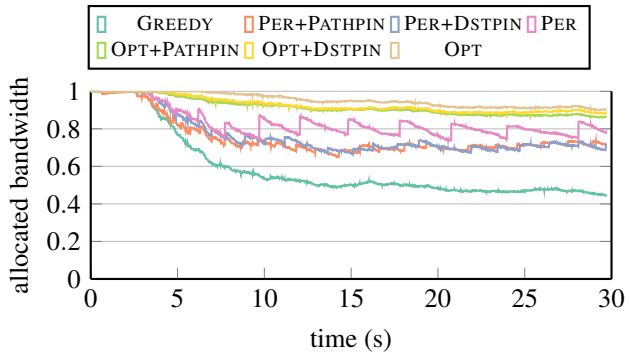

Figure 9: Average fraction of allocated bandwidth across all flows over time.

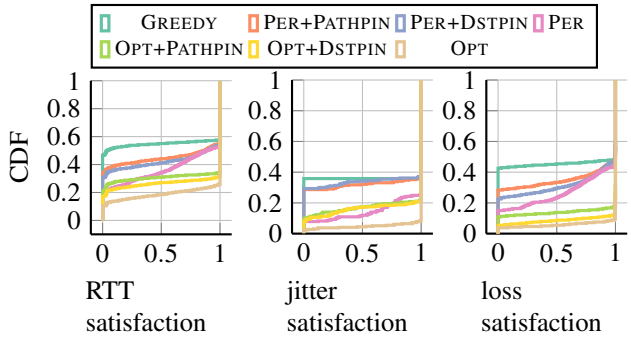

Figure 10: Service demand satisfaction for RTT, jitter, and packet loss. Value of 1 means perfect satisfaction.

even if there are alternate paths with worse performance but still just as satisfactory. The other allocation methods spread flows across available paths instead of assigning them to a single, attractive path, and those details are in Appendix G.

Service demand satisfaction. We now show that OTTER meets the design goal of placing fine-grained flow service demands. We choose a mean flow arrival rate of 40K flows/sec, which is the most difficult workload we evaluate, to show a lower bound on service demand satisfaction. All other parameters remain as in Table 4. For each flow, we compute its average "satisfaction" for each performance metric over its assigned paths, defined as the tolerance coefficient normalized to the fraction of bytes successfully allocated.

Figure 10 shows flow satisfaction distribution for RTT, jitter, and packet loss. Throughput satisfaction is the fraction of bytes successfully allocated, previously shown in Figure 8. Across all three service metrics, OTTER's periodic re-optimizing methods map a similar fraction of flows to paths with perfect satisfaction compared to GREEDY, but allocate far fewer flows to paths with extremely poor (<0.01) satisfaction. For RTT, PER+PATHPIN and PER+DSTPIN map approximately 47% of flows to paths with perfect RTT satisfaction, while GREEDY does so for 41% of flows. PER+PATHPIN and PER+DSTPIN allocate significantly fewer flows to paths that are entirely unsatisfactory (35% vs. 44%). Note that even with optimal allocation, OTTER still assigns at least 10% of flows to paths with poor RTT satisfaction (<0.01). Most of these flows belong to application profiles with service demands that are extremely difficult to meet alongside a large number of other flows.

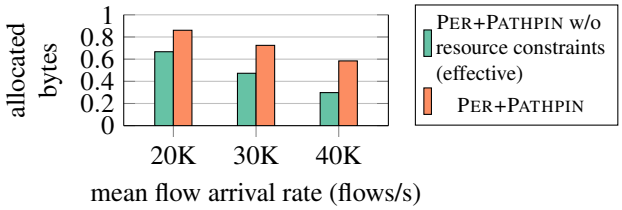

Figure 11: Impact of resource constraints on allocated bytes.

Best heuristic. Of the four realistic heuristics, we choose PER+PATHPIN for OTTER. It limits disruption of extremely performance sensitive flows, while still offering high allocated bytes and satisfaction.

Impact of edge resource constraints. In the disaggregated 5G network architecture, edge computing plays a central role in meeting service demands. However, TE systems do not account for the heterogenous availability of compute at edge sites, and may over-subscribe flows to destinations.

To demonstrate the value of explicitly considering destination resource capacities when routing 5G flows, we modify OTTER's Optimizer to ignore destination resource constraints (eliminating constraint $c4$ in Table 2). This effectively gives all destinations infinite resource capacity. The LP is restricted only by link capacities. While the unconstrained LP is seemingly able to allocate more bytes, the actual amount is much lower due to resource contention at destination sites. To estimate the amount of traffic that can actually be serviced, we reduce allocated bytes from flows that are assigned to over-subscribed destination sites. We follow random priority when de-allocating, *i.e.,* for each destination, we repeatedly select a flow at random and decrease the number of bytes allocated until the resource limitations are met. Figure 11 compares the effective fraction of bytes allocated between OTTER using PER+PATHPIN with and without edge resource constraints for different traffic loads. As we can see, ignoring destination resource constraints in the Optimizer formulation results in 23–50% fewer bytes allocated than PER+PATHPIN. This shows that the added complexity of integrating resource capacity constraints allows OTTER to better map flows to destinations that have the capacity to serve them, allowing more traffic to be supported.

8 Miscellany

Why does BGP not get in the way? Cellular network operators tend to be large ISPs that directly peer with public clouds in multiple locations. Our evaluation setup in §7 represents that, with both WANs directly peering and our use

of VPN gateways at the overlay layer. Not only do we expect 5G traffic to flow over direct connections, we expect 5G cloudification to spur operators to increase the quantity of peering. This has two implications for OTTER. First, many of the oddities of BGP in the wild do not apply here, where intermediate ASes enforce their policies between source and destination ASes. Second, we expect to see even more diversity of inter-domain paths that OTTER can exploit.

Why not optimize for WAN costs? OTTER does not explicitly incorporate monetary cost as an optimization criteria. Cloud compute and network costs tend to be uniform within countries. Most 5G network deployments are at national scales. Operators and clouds that they depend on use direct peering. Hence, optimizing for WAN costs is not a priority for OTTER and we leave that for future work.

Will OTTER negatitvely impact existing WAN TE? OTTER works within the confines of TE in both WANs — the routes available to OTTER are what the underlying TE has exposed to applications. OTTER then can only influence the traffic matrix, which TE systems effectively optimize over. If OTTER-induced demands are sufficiently high, TE systems can change the routes available to applications, including OTTER. OTTER will in turn adapt to these new routes and still pick the best ones for 5G workloads. While there is a feedback loop between OTTER and TE, it is not one that can be exploited for reducing the efficiency of existing TE. In Appendix H, we explore the value of using paths that underlying TE systems create but do not expose to applications.

9 Related Work

Overlay networks. Researchers have proposed overlay networks to improve underlying network availability, performance, or security [4, 5, 17, 22, 36, 59, 70, 77]. Recently, Skyplane [40] proposed a cloud overlay for inter-cloud bulk transfers between object stores, and selects routes that balance price and throughput. Routes and VMs are chosen using static throughput and cost measurements and participate in store-and-forward queuing. Hercules [29] is another bulk-transfer tool for overlays. CRONets [18] deploys overlay nodes on cloud networks and leverages MPTCP through overlay paths to improve throughput. CloudCast [72] focuses on latency improvement using cloud overlays.

OTTER also uses an overlay network to interconnect a 5G operator WAN and a cloud WAN. Unlike prior work, OTTER optimizes for various 5G NFs and applications, each of which can have different performance requirements, not just bulk data transfer. OTTER optimizes network paths online by using dynamic measurements for a wide range of metrics, including RTT, jitter, and loss. We achieve higher inter-cloud, per-VM throughput than prior work [40], in part because our security and privacy oriented topology design does not suffer from limits that some clouds impose on bandwidth to public IPs (Appendix B). OTTER also allocates both the path of flows as well as the compute destination.

Cloud TE. Existing cloud TE systems (such as Taiji [19], COPE [87], SWAN [39], B4 [41], BwE [46], OneWAN [45], Cascara [76], Espresso [94]) maximize network utilization or bandwidth fairness, or minimize cost for traffic grouped by coarse-grained priority classes. OTTER is not a replacement for existing TE, as underlay paths will still be subject existing TE. OTTER is an enhancement that can optimize at the granularity required for 5G applications by selecting overlay paths between multiple destinations across WANs. Additionally, OTTER performs dynamic flow placement and considers server resource capacities at endpoints, while TE periodically allocates batched traffic predictions and only considers network resource constraints. While some recent TE work [50] to optimize more fine-graned flows for applications, this optimization still takes place within a single WAN, and does not consider the multi-WAN setting of OTTER.

Multi-WAN collaboration. Unlike TE systems, OTTER optimizes traffic that spans two WANs. Prior work (Nexit [48], Wiser [47], P4P [90], Flow Director [68]) attempt to facilitate coordination between two independent entities by allowing them to exchange information while preserving privacy. Nexit and Wiser allow two ISPs to route traffic efficiently, despite competing interests. Nexit uses a negotiation-based approach, while downstream ISPs using Wiser tag routing advertisements with costs used by upstream ISPs. P4P improves peer-to-peer application performance by allowing ISPs to share performance and topology information with applications. Flow Director uses ALTO [2] to share information between ISPs and CDNs to optimize content placement. However, these works require negotiation to ensure mutually beneficial routing. OTTER makes use of the fact that, for 5G networks, these incentives are already aligned – operators pay to deploy resources on cloud networks to facilitate better QoS for 5G flows. OTTER does not require any buy-in from cloud platforms, so routing and resource placement can be done without coordination.

Better routing. Attempts to improve interdomain routing include multipath extensions to BGP [38, 92] and interdomain bandwidth reservation such as N-Tube [88]. New routing protocols that allow nodes to select paths that optimize multiple metrics include Routing on Multiple Optimality Criteria [78]. Such approaches may improve path diversity or even path selection. However, they must still optimize routing based on static metrics such as BGP AS path length or width, and cannot adjust based on dynamic metrics such as loss or latency. Deploying any of these technologies requires changes to BGP, which has proven to be a major practical impediment. SCION [95] is a novel Internet routing architecture that seeks to provide high security and availability. However, it requires ISP buy-in to deploy border routers to participate. RouteScout [7], PAINTER [43] and SCULP-

TOR [6] reroute traffic based on traffic performance degradation. However, such optimizations are performed locally or per prefix. In contrast, OTTER optimizes the entire overlay according to the performance demands of all flows, allocates per flow, and does not require deploying new devices.

Better path selection at the edge. In Tango [16], edge networks coordinate to expose more paths, enable better measurements, and route traffic efficiently. Rather than coordinate paths between edge networks, OTTER directly sets up overlay paths between the cloud provider and 5G operators by orchestrating resources on the cloud network. OTTER also routes traffic according to application-specific service demands and relies only on existing cloud network technologies. Other work [42] selects paths between a private WAN and the public Internet for video conferencing applications (e.g., Teams) based on extensive measurement data. Like OTTER, this work jointly optimizes the path and destination DC selection. However, unlike OTTER, it neither considers the general setting of 5G applications nor the coordination of paths among multiple ASNs. Any of these mechanisms that expose multiple paths to an endpoint could be utilized at the transport layer by multipath TCP.

Virtual Network Function (VNF) placement. Systems for VNF placement [62, 63, 82] optimize for metrics such as cost and CPU utilization of NFs. However, unlike OTTER, they do not consider the QoS needs of individual flows, and are evaluated on simulated setups. VNF placement systems periodically optimize for coarse-grained objectives, according to predicted future load, but OTTER dynamically places flows and resources, on-demand, according to customizable fine-grained service objectives.

10 Conclusions

The next generation of 5G networks includes new frequency bands and radio technology, equipping users with access links so fast that their E2E performance will become bottlenecked by inter-domain paths [91] rather than last mile access links. Moreover, next generation 5G networks will rely on hyperscalers to deploy software-based 5G NFs [61] and interactive applications. Thus, we need to improve the performance of paths across operator and cloud WANs.

We demonstrate the value of constructing such paths over two commercial WANs. OTTER achieves 13% higher average throughput or 6-10 Gbps in the maximum, RTT reduction as much as 42 ms within the US, jitter reduction by 45% on average, and 0.06% lower packet loss. We designed and implemented a scalable algorithm to jointly optimize the placement of workloads on available paths and compute resources. It allocates 26%–45% more bytes on the network than good baselines while also satisfying the service demands of more flows. While we focus on the urgency of 5G, our research contributions may be relevant in other upcoming access technologies such as 6G.

OTTER unlocks avenues of future work. Underlay paths that are private to one WAN can provide even more diversity in end-to-end path performance than we have shown – how can they be leveraged? How will OTTER work in topologies where a 5G operator relies on two or more hyperscalers?

A Multi-WAN US Topology

Figure 19 shows all the Azure and GCP cloud components (VMs, VPN gateways, etc.) and the connections between them on the continental US-wide topology we have deployed for evaluating OTTER. It is generated from the output of our Terraform deployment, using a Terraform visualizer called Rover. While difficult to read, the figure indicates the complexity and scale of our evaluation topology across 8 Azure and 8 GCP regions, as it contains many cloud components and connections between them.

Table 6 shows the 8 sets of VPN connections that we use in our evaluation topology. For example, the first row shows that GCP us-central1 is peered with Azure centralus. Each peering consists of 4 VPN connections, each with 2 tunnels, for improved throughput and resilience. This number can be increased or decreased as needed, or further augmented [30], but we have found that 8 tunnels gives us a good tradeoff

GCP Region name	GCP Region location		Azure Region name	Azure Region location
us-central1	Iowa	⟺	centralus	Iowa
us-east1	South Carolina	⟺	eastus	Virginia
us-east4	Virginia	⟺	eastus2	Virginia
us-east5	Ohio	⟺	northcentralus	Illinois
us-south1	Texas	⟺	southcentralus	Texas
us-west3	Utah	⟺	westcentralus	Wyoming
us-west2	California	⟺	westus	California
us-west4	Nevada	⟺	westus3	Arizona

Table 6: VPN connections between Azure and GCP regions.

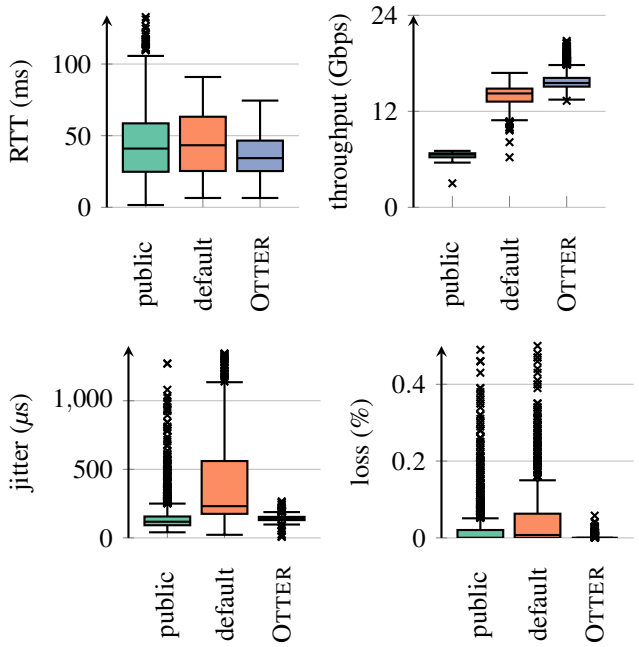

Figure 12: Network performance of paths available by different mechanisms. The jitter vertical axis is chopped at 1200 μs for clarity, and the loss vertical axis is chopped at 0.5%.

between cost and throughput. In picking which Azure region peers with which GCP region, our goal was to mimic how a 5G operator would peer with a cloud provider. Such peerings occur at carrier hotels or "meet-me" points, where two or more ASes may co-locate their routing equipment. Hence we strove to pick pairs of regions that were physically close to each other. Note that when we evaluated OTTER, there was one additional US region offered by both clouds, however we were unable to acquire sufficient compute capacity in those regions.

B Additional Analysis of OTTER Orchestrator Performance

Figure 12 summarizes the characteristics of the paths available by different mechanisms. The "default" box plots show the performance spread between all Src-Dst pairs in our topology (§7.1) across the 24 hour measurement period, when not controlling the path and allowing the two WANs to pick the path [32]. The "public" box plots show the performance spread without any of our security and privacy infrastructure (i.e., no private VNets, no VPN gateways, no VNet peering), where the source and destination use public IP addresses and nothing specified by us in between. The OTTER box plots show the best performing OTTER Orchestrator path for each Src-Dst pair for the relevant network performance metric.

We make several observations. Our secure, private, and scalable deployment topology offers far higher throughput than when using public routing. The {min, average, max} throughput for public is {3.0 Gbps, 6.5 Gbps, 7.1 Gbps}, while for default it is {6.3 Gbps, 14.0 Gbps, 16.8 Gbps}. As prior work [40] noted, some clouds such as GCP limit outbound transfers to 7 Gbps, but those limits do not apply to our use of private VNets and VPN connections. OTTER is able to further improve these numbers to {13.3 Gbps, 15.8 Gbps, 20.8 Gbps}. The median, 25th, and 75th percentile RTTs are slightly higher for default compared to public, but with far less spread above the 75th percentile. OTTER offers the lowest RTT at the 25th and higher percentiles. OTTER also offers the tightest jitter and lowest loss.

Figure 13 shows the performance improvement when comparing different mechanisms. "O-D" shows for every Src-Dst pair, for every round of measurements, the additional performance that the OTTER Orchestrator achieves compared to the default path on our topology. "O-P" provides OTTER's improvement over the public path when using public IP addresses and no private networking functions. "P-D" shows the improvement of the public path over the default private path. Figure 14 shows the same data, but as a percentage improvement. When considering the "O-D" boxes, all the values are 0% or higher, because the OTTER Orchestrator will never pick a path that has worse performance for the desired metric. The "O-P" and "P-D" boxes show that for RTT, jitter, and loss, the use of private networking functions introduces occasional performance regressions. We believe these functions are run by cloud providers in VMs, and that introduces small amounts of occasional jitter and packet loss as traffic goes up and down the software stack. Nonetheless, OTTER improves on this, by, for example, picking paths that

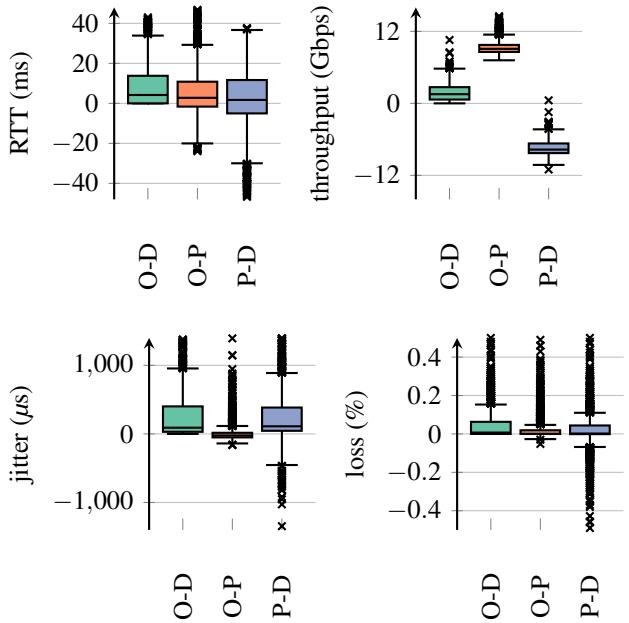

Figure 13: Improvement in network performance. On the horizontal axis, "O-D" shows the performance improvement of OTTER over default, "O-P" is OTTER over public, and "P-D" is public over default.

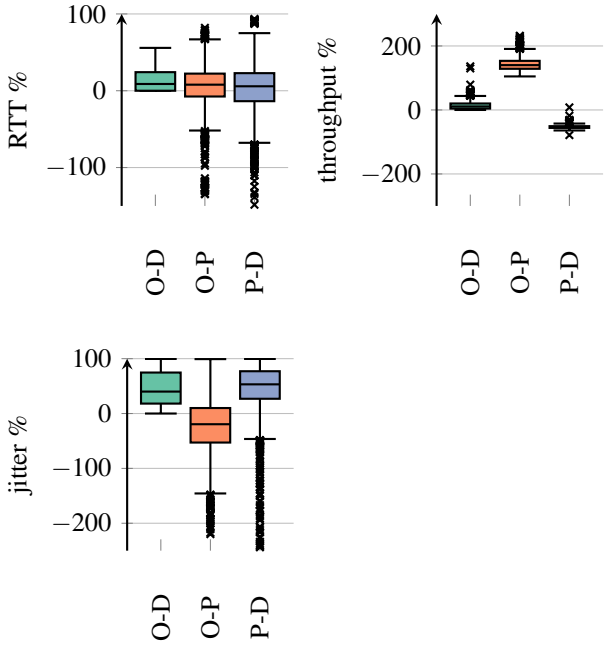

Figure 14: Percentage improvement in network performance. On the horizontal axis, "O-D" shows the performance improvement of OTTER over default, "O-P" is OTTER over public, and "P-D" is public over default. Loss is not presented because the large spread of outliers on small values makes the graph difficult to read.

go through other instances of VPN gateways that are not suffering from noise at the moment. This is seen in Figure 12, where on each metric of throughput, RTT, jitter, and loss, OTTER offers the best path.

C Evaluation of OTTER Optimizer on Different Mean Flow Durations

Table 7 summarizes the results of how well OTTER allocates flows of varying durations using the heuristics described in §7.2: GREEDY, PER+PATHPIN, PER+DSTPIN, PER, OPT+PATHPIN, OPT+DSTPIN, and OPT. These results, like results in §7.2, show that heuristics relying on a greedy allocation (GREEDY, PER+PATHPIN, PER+DSTPIN, PER) typically allocate less traffic, but are more practical for real-time decisions. We also see that with longer flow durations, the amount of bytes allocated per flow decreases for each algorithm. This is because, with longer flows, there are less resources available for later flows, because earlier flows are still active.

D Service Demand Generation

The traffic composition on 5G networks is dynamic and can evolve over time, making it difficult to predict what kinds of demands will be present. Applications will also have diverse service requirements across various performance metrics. To mimic 5G traffic in our evaluations, we generate flows by assigning them an "application profile" based on service guidelines from the 3GPP and other sources.

We selected a set of example applications outlined by the 3GPP standard [79] that represent a diverse range of performance demands that 5G networks are expected to support. These applications are listed in the first column of Table 5. In § 5.7.4 of the relevant 3GPP standard [79] are guidelines for the packet delay budget and packet error rate for each application, which we use to determine RTT and packet loss demands. These are shown in the latency and loss columns in Table 5. To obtain RTT demands, we double the one-way latency guidelines listed in that 3GPP standard. However, it does not provide information on throughput and jitter, so we infer them from other sources [1, 58, 66, 71, 83, 85]. In cases where the throughput demands are unclear or conflicting, we set a default of 1 Mbps for a single 4-tuple flow. We chose real-time gaming as one application with explicit jitter demands, doubling the 10 ms one-way jitter guideline from [71] to match the round-trip path attributes measured on our topology.

As mentioned in §4, OTTER models service demands as a vector of demand functions which map path performance characteristics to a tolerance coefficient in the range $(0, 1]$, where 1 is best. A demand function is able to capture com-

mean flow duration(s)	mean flow arrival rate (flows/s)	GREEDY	PER+PATHPIN	PER+DSTPIN	PER	OPT+PATHPIN	OPT+DSTPIN	OPT

60	30K	0.32	0.45	0.46	0.49	0.47	0.49	0.50
60	40K	0.21	0.32	0.33	0.35	0.34	0.35	0.36

Table 7: Fraction of allocated bytes across flows for varying mean flow durations.

plex service demands, which we believe will be necessary to capture the QoS characteristics expected by 5G applications. In our implementation, a demand function can be either a step, linear, or rational function, with inflection points randomly selected from within ±25% of the service guidelines mentioned above. For flows that are indifferent to the metric (*e.g.,* jitter), the demand function is constant at 1.

The service demand generation process is as follows: each flow is first randomly assigned an application profile. For each performance metric, we randomly assign a function type, then generate inflection points. For example, an augmented reality flow may have a step-type demand function for RTT that looks like the following:

$$\mathcal{D}_f^{rtt}(\sigma_p^{rtt}) = \left\{ \begin{array}{ll} 1, & \text{if } \sigma_p^{rtt} \leq 21.2\ ms \\ \varepsilon, & \text{if } \sigma_p^{rtt} > 21.2\ ms \end{array} \right\}$$

We then randomly select a value within ±25% of the application's guideline throughput demand.

E Evaluation of OTTER Optimizer on Different Flow Distributions

Table 8 summarizes the results of how well OTTER satisfies flow RTT requirements for varying distributions of flows, using the heuristics described in §7.2. We vary the proportion of flows with strict RTT requirements (RTT $\leq$ 60ms) and report the average RTT satisfaction for those RTT-sensitive flows. We find that for lower arrival rates, the proportion of RTT-sensitive flows does not affect their satisfaction, as there is less contention for resources. Like the results in §7.2, the GREEDY heuristic provides the lowest satisfaction. The heuristics that pin flows to either paths or destinations also provide less satisfaction than PER and OPT, as RTT-sensitive flows may get pinned to a high-RTT path, even as capacity on lower-RTT paths becomes available.

F Evaluation of OTTER Optimizer on Different Network Sizes

Table 9 summarizes the results of how well OTTER allocates flows on networks of various sizes using the same mean flow arrival rates and the heuristics described in §7.2: GREEDY, PER+PATHPIN, PER+DSTPIN, PER, OPT+PATHPIN, OPT+DSTPIN, and OPT. These results are qualitatively similar to those described in §7.2, with OPT being able to allocate more traffic compared to the other algorithms, but the PER heuristics scaling better with higher traffic load on the same network topology. We can additionally see that as we increase the number of paths between each Src-Dst pair, all algorithms are able to improve the amount of bytes allocated per flow. This is explained by the increase in path diversity, which gives more options for flows to be mapped to paths that better suit their service demands. The same effect can be seen as the number of sources and destinations increases. This increases the overall resource capacity of the network, since there are more links and compute resources for the same traffic load.

We also evaluate OTTER on larger topologies with larger flow arrival rates. We choose topology sizes to match the scale of contemporary TE systems, B4 [41] (approximately 30 DC sites globally) and SWAN [39] (evaluated with up to 40 DC nodes). In each topology, we set 75% of the destinations to be edge nodes, and set the rest to be DC nodes. We generate path, destination, and flow attributes (except flow arrival rates) using the values in Table 4. We scale up the flow arrival rates because as the topology grows, smaller arrival rates do not produce enough traffic to cause resource contention, and OTTER is able to achieve 100% allocation. We set the mean flow arrival rate to the number of source nodes times the number of destination nodes. The results are summarized in Table 10. The allocation from the OPT+PATHPIN, OPT+DSTPIN, and OPT heuristics are qualitatively similar to

% flows with RTT $\leq$ 60ms	mean flow arrival rate (flows/s)	GREEDY	PER+PATHPIN	PER+DSTPIN	PER	OPT+PATHPIN	OPT+DSTPIN	OPT
30	20K	0.34	0.38	0.48	0.77	0.50	0.57	0.85

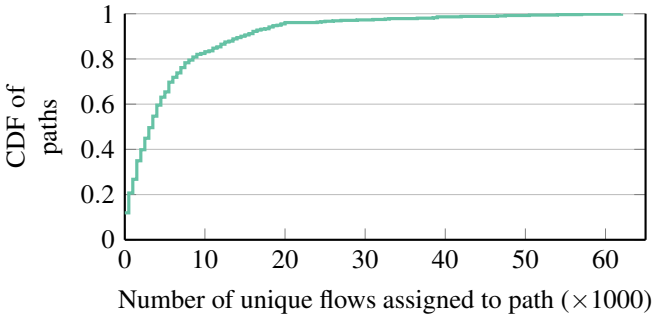

Figure 16: CDF of the number of unique flow aggregates assigned to each path in the network.

results in §7.2. As the flow arrival rate grows, there is a more significant gap between the PER+PATHPIN, PER+DSTPIN, and PER and the OPT heuristics. This is because the OTTER Optimizer has a longer runtime, which means the PER heuristics rely more on greedily allocating flows.

G OTTER's Path Usage

We present additional analysis results on the path usage of OTTER's allocation methods. This is in contrast to the service demand satisfaction and byte allocation metrics presented in the main body of the paper. We use this to demonstrate that the evaluated topologies have realistic capacity constraints and path metrics, and that the OTTER Optimizer does not simply assign the majority of flows to a single, particularly attractive, hypothetical path (*e.g.,* one that happens to have extremely low RTT, high throughput, and low loss).

Figure 15 shows the number of paths between each Src-Dst pair that is assigned at least one flow under the PER+PATHPIN allocation method. We use the default topology described in § 7.2, with eight sources, eight destinations, and eight paths between each Src-Dst pair. We can see that for more than half of all Src-Dst pairs, all eight paths are employed. In 75% of cases, at least seven paths are used. This demonstrates that OTTER does not simply favor a small number of well-provisioned paths, but that it balances traffic across those that are available to maximize satisfaction.

We further show in Figure 16 the distribution of the number of unique flows that are assigned to each path. We use a mean flow arrival rate of 40K flows per second for a period of 30 seconds from the time of the first flow. While there is a long tail in terms of number of flows assigned to each path, almost 90% of all paths in the network are allocated at least one flow within first 30 seconds.

H WAN Underlay Opportunity

The focus of OTTER is as an overlay, in setups which can be constructed by customers of public clouds without any special privileges. WANs, whether they be cloud WANs or 5G operator WANs, have a dedicated underlay network. This

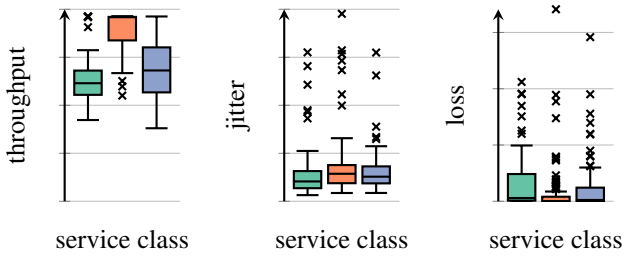

Figure 17: Relative network performance between two VMs across the US, with each box representing a different class of service. Jitter graph is chopped on vertical axis for clarity – outliers go up to 2X, 3X, 3X higher for each class from left to right.

underlay is typically comprised of layer 2 (such as MPLS or SONET) segments which are stitched together to form layer 3 links that interconnect various locations (DCs and/or PoPs). Some WANs maintain multiple paths in the underlay between any two locations [45], as well as different queues at the routers in the WAN. The combination of the two can be used to create different classes of service, with different properties (such as bandwidth, RTT, jitter, loss, reliability, cost). While typically not exposed to customers, we wonder if these underlay network capabilities could even further enhance the value of OTTER as part of a native offering by a WAN.

To briefly demonstrate the value of using these underlay capabilities, we show the relative network performance between two VMs, one in the US West coast and one in the US East coast, on a cloud WAN, over three different classes of service, on a two hour window in the middle of a US week day. We run approximately 100 iPerf3 measurements lasting 10 s each for each of UDP and TCP on each class of service.

Figure 17 shows that each class offers a different tradeoff. The class in the middle tends to offer more throughput but also slightly more jitter than the other two. The class on the right offers more throughput and less loss than the left, but more uncertainty in the throughput. As shown in Figure 18, these tradeoffs are not static, necessitating a dynamic approach to allocating traffic to underlay offerings. RTT is also different and time-varying between these classes – the

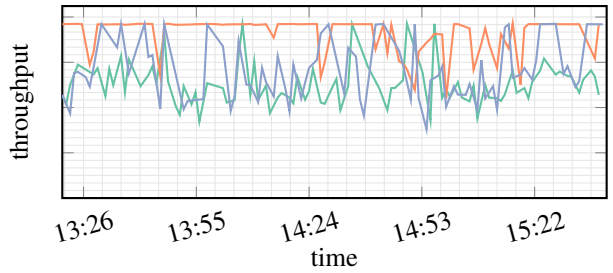

Figure 18: Relative throughput between two VMs in the US. Each line represents a different class of service.

minimum RTT is the same for all three, but the maximum is 1.7× higher for the middle class.

We have removed the units on the vertical axes on the graphs as these results are obtained from proprietary access to underlay paths that are not available to the public. However, the key takeaway is visible, that there are different underlay paths offering different tradeoffs in network performance. As future work, we are considering how to construct hybrid paths across one WAN with only overlay paths and another WAN with access to underlay paths.

Verifying maximum link loads in a changing world

Abstract

To meet ever more stringent requirements, network operators often need to reason about worst-case link loads. Doing so involves analyzing traffic forwarding after failures and BGP route changes. State-of-the-art systems identify failure scenarios causing congestion, but they ignore route changes.

We present Velo, the first verification system that efficiently finds maximum link loads under failures *and* route changes. The key building block of Velo is its ability to massively reduce the gigantic space of possible route changes thanks to (i) a router-based abstraction for route changes, (ii) a theoretical characterization of scenarios leading to worst-case link loads, and (iii) an approximation of input traffic matrices. We fully implement and extensively evaluate Velo. Velo takes only a few minutes to accurately compute all worst-case link loads in large ISP networks. It thus provides operators with critical support to robustify network configurations, improve network management and take business decisions.

1 Introduction

Link loads—how much traffic crosses each link—are a key indicator of network performance. High link loads, in particular, increase the likelihood of congestion, packet drops, and inflated delays. To meet stringent service-level agreements, operators often need to reason about the worst-case load that every link can realistically experience during network operation – e.g., to check that all loads are below a safety threshold, and adapt routing configurations if they do not.

Identifying worst-case link loads is hard, though. Operators often have tools to measure traffic and model traffic patterns, even long term [26, 35]. However, determining worst-case loads requires to scrutinize traffic forwarding for a *huge range of possible events*. During network operation, links and nodes fail, and BGP routes for external destinations appear, disappear and change. Even a single failure or 3-4 route changes at specific border routers can overload links, as our case study on a real ISP network shows (§7).

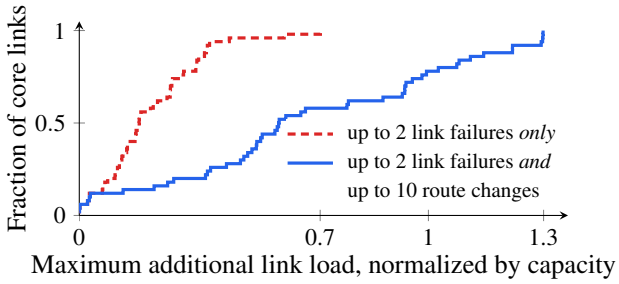

Figure 1: Additional link loads can double due to route changes compared with link failures only. This plot shows the additional traffic on all the core links of an ISP network.

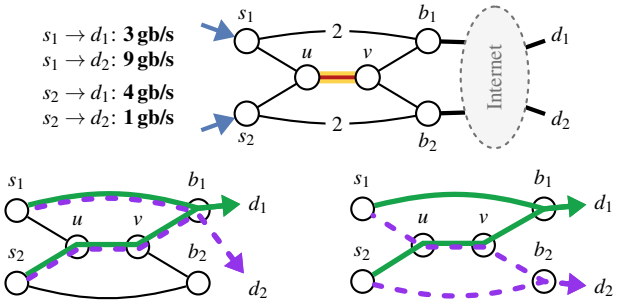
Reasoning about link loads is beyond the capabilities of existing network verifiers. Most of them [1, 4, 14, 39, 40, 42, 45, 50] do not support *performance* requirements such as maximum link loads, but restrict to *functional* requirements, such as the absence of blackholes and forwarding loops.

A couple of recent contributions [7, 27, 44] focus on assessing properties on link loads. Yet, they only consider network failures and assume fixed external routes, fitting controlled network environments such as data centers. For most Internet-connected networks, *both* failures and route changes must be considered, *jointly*, to provide guarantees on link loads. As an illustration, Figure 1 depicts the additional load on the core links of a real ISP network, when simulating all one and two link failures. In the presence of up to ten route changes (solid curve), most links reach higher load than without route changes (dashed curve), and their load can be twice as big. In other words, ignoring route changes leads to vastly underestimating maximum link loads.

This paper presents Velo, the first verification system that efficiently computes the individual worst-case loads of *all* links for arbitrary link failures and external route changes. Velo does not depend on how paths are computed, and hence it works in both traditional (e.g., IGP/BGP-based) and SDN networks; it also supports typical traffic engineering technologies such as ECMP and tunnelling (e.g., MPLS).

In each run, Velo takes as input: router configurations, BGP routes, and a traffic matrix. The traffic matrix captures the specification (such as the worst-case pattern seen in the past, or the expected future traffic) for that run. Different traffic scenarios can be verified in separate runs. As in [44], operators can also input the maximum traffic volume additional to the given matrix, e.g., to model uncertainty. Further, Velo can limit its computations to user-defined subsets of failures and route changes that model realistic scenarios. For example, operators can specify a maximum number of simultaneous route changes, and define per-network and per-router stable destinations, for which route changes are not allowed.

As such, Velo supports many practical use cases including: *(i)* verification of configurations before deployment; *(ii)* adaptation of BGP preferences to make the worst-case routing states less likely; *(iii)* fine-tuning of network monitors to raise alerts only when there is a significant risk of congestion; *(iv)* support for business decisions and routing policies. Our case study (§7) exemplifies some of these use cases.



Challenge It is infeasible to iterate over all possible route changes and failure scenarios. For each destination, external networks may advertise new routes, modify existing ones, or completely withdraw them. New and modified routes have attributes (e.g., AS path or BGP communities) with a very large set of possible values. When factoring in possible failures, not only does the search space grow, but it also becomes more challenging to navigate. Indeed, failures generally affect paths to multiple destinations, hence destinations cannot be treated as independent from each other across failures. This also prevents us from extending prior verification work [4, 15, 45, 50].

Solution We greatly reduce this search space in three steps.

First, we provide a compact abstraction for capturing route changes. We do not explicitly model possible external routes, e.g., symbolically as in [4]. Instead, we model possible routes for a destination as *sets of egress routers*. Each set captures the many equivalent routes inducing the same link loads.

Second, we design Velo to explore a *minimal* set of states guaranteeing correctness. We prove that for common intra-domain routing schemes (e.g., shortest-path routing), each link is maximally loaded when only one egress router is used per destination. This enables Velo to compute all the worst-case link loads in *polynomial* time. In the presence of paths deviating from the above schemes (e.g., for traffic engineering), Velo extends its search to *minimal* sets of egress routers, ensuring limited impact on Velo's efficiency.

Third, we propose an efficient technique to approximate the input traffic matrix by combining destinations with similar traffic patterns, while also providing strong accuracy guarantees. We formalize the traffic matrix approximation as a clustering problem, and prove that the clustering error bounds the approximation error of the worst-case link load.

(a) Both destinations d_1 and d_2 are advertised only to b_1.

(b) Destination d_1 is advertised to b_1 and d_2 is advertised to b_2.

Figure 2: Network that routes traffic along the shortest paths. Subfigures (a) and (b) show the forwarding paths for two possible routing advertisements of destinations d_1 and d_2. All link weights are 1, except those from s_i to b_i are 2.

Results We implement a prototype of Velo and make it publicly available[1]. Our evaluation on real network topologies shows that Velo computes the worst-case load of every link in large networks and the entire BGP routing table, *within minutes*, even considering up to two simultaneous link failures. Velo's computed maximum loads are also highly accurate, within 1% of the actual ones, and this across a wide range of traffic matrices, from heavy-tailed to almost-uniform.

2 Overview

Velo finds the worst-case load for each link by exploring the input space of failures and route changes. Consider the example in Figure 2. Routers s_1 and s_2 receive traffic for two remote destinations d_1 and d_2. Depending on the received BGP routes, d_1 and d_2 can be reached via either b_1 alone, b_2 alone, or both simultaneously. Both s_1 and s_2 send packets to the closest egress among b_1 and b_2 that can reach the destination (i.e., implementing hot-potato routing).

Let's initially focus on the link (u,v), assuming no failures. The link load depends on the BGP routes received by b_1 and b_2. For example, if only b_1 receives BGP routes for d_1 and d_2, packets from s_2 crosses (u,v) but those from s_1 do not, resulting in a total load of 5 gb/s—see Figure 2a.

To compute the worst-case link load, we conceptually need to check all the combinations of each destination being reachable from b_1, b_2, or both. For example, if b_2 receives the same BGP route as b_1 for d_1 and still no route for d_2, the load of (u,v) decreases, because the traffic from s_2 to d_1 is moved to the path (s_2,b_2). Figure 2b shows the worst-case scenario: when d_1 is only reachable from b_1 and d_2 only from b_2, then 13 gb/s are sent over (u,v) since both demands $s_1 \to d_2$ and $s_2 \to d_1$ cross that link.

[1] Available at https://github.com/nsg-ethz/velo (GPLv3 license)

Consider now any other link, for example, (s_2, b_2). Clearly, Figure 2b is not the worst-case scenario for (s_2, b_2); its load is higher if s_2 uses b_2 as next hop for both d_1 and d_2.

Real networks are much bigger than Figure 2, and typically have many more border routers and millions of destinations, making the problem challenging to solve. For example, iterating over all the possible BGP routes received by any border router for each destination does not scale. Worse yet, every possible failure affects the network topology, and so requires to re-assess the impact of each possible route change.

2.1 Problem Statement

We now describe Velo's problem and provide the intuition of how Velo manages to accurately and efficiently solve it. We refer to any router that sends traffic outside the network as *egress router*. For example, in Figure 2b, b_1 is the only egress router for d_1, and b_2 is the only egress router for d_2. An *egress change* occurs when the set of egress routers for one destination changes, such as between Figure 2a and Figure 2b.

Problem: Given *(i)* the network configuration, *(ii)* current BGP routes, *(iii)* traffic per destination, *(iv)* constraints on route changes, and *(v)* a space of failure scenarios, find the worst-case load for each link in the network, along with the egress changes and the failure scenario causing such loads.

We provide more details on Velo's inputs in the following.

Network configuration We define a network configuration as the network topology and the collection of all router configurations. We support a wide range of networking paradigms and protocols and present an abstraction in §3. Operators can provide either the *current* topology and router configurations as input, or alternative ones (e.g., for what-if analyses).

BGP routes Velo takes the current BGP routes as input. We define a BGP route as a BGP advertisement from an external network concerning a single destination and including its BGP attributes. Routes generally change over time.

Yet, not all route changes are equally likely, and some are not worth considering in practice. For example, at operational timescales, receiving new routes for a few destinations is more likely than the same occurring for all Internet prefixes.

For this reason, Velo allows to limit the set of route changes verified in any Velo's run. Operators can specify the maximum number k of egress changes, where the *number of egress changes* is the number of destinations featuring one or more egress changes. Operators can also provide constraints on specific destinations (e.g., high-volume IP prefixes) for which routes can or cannot change, and on the possible egress routers per destination (e.g., enforcing that BGP customers always advertise only their own prefixes).

Failure scenarios Contrary to route changes, network failures typically affect many forwarding paths for many (if not all) destinations. Velo takes as input a description of the space of failure scenarios to explore. This can be the set of up to l simultaneous link or node failures [42, 44], and can include Shared Risk Link Group (SRLG) information [53]. The only constraint here is that for each failure scenario, Velo can derive a new topology from the original one.

Traffic In each run, Velo takes a traffic matrix as input. Previous work often defines a traffic matrix as the traffic volumes per pair of ingress and egress routers, describing where traffic enters and exits the network. We instead define a traffic matrix as traffic volumes for each pair of ingress router and destination prefix. We do so because we are interested in assessing the impact of BGP routes which are per-destination.

While Velo accepts a single matrix as input, operators can specify the current traffic matrix, or, for more conservative analyses, they can provide Velo with a matrix derived from one or multiple congestion events recorded in the past. They can also run Velo multiple times on different matrices.

Velo models uncertainty on inter-domain traffic in the same way as QARC [44]. It indeed allows operators to specify the total amount of traffic, across all the destinations, that may need to be forwarded in addition to the input traffic matrix.

2.2 Velo in a nutshell

Verifying link loads requires exploring a gigantic search space. Besides the sheer number of routes and route attributes, link failures prevent destinations from being verified independently (i.e., one at the time). Velo addresses these challenges by massively reducing both the search space and the number of destinations. We now provide the intuition of how it does so, referring to the following sections for details.

Reducing the search space In §4, we prove that the worst-case link loads occur when for each destination, all the network routers select the same BGP route. Indeed, the worst-case load for (u, v) in Figure 2 occurs when all routers select b_1's route for d_1, and b_2's route for d_2. This key insight enables us to explore, for each failure scenario, only $|P| \cdot |N_B|$ different states, where P is the set of destinations and N_B is the set of egress routers—a polynomial search space instead of an exponential one.

The above property holds for all strictly isotone routing protocols (such as shortest path routing) that usually govern intra-domain routing. We further extend our technique to support exceptions to strict isotonicity, such as MPLS tunnels for traffic engineering, by computing the minimal set of additional states to explore in these cases (§4.1.2).

Velo iterates over all the input failure scenarios, one by one. We experimentally show (§6) that Velo is anyway more efficient than approaches attempting to prune failure scenarios, like QARC, even when considering combinations of up to 3 or 4 simultaneous failures. Intuitively, this happens because our search space reduction enables Velo to analyze any failure scenario *very* quickly.

Reducing the number of destinations In §5, we show that we can combine destinations with *similar* traffic distributions across the same ingress routers, and obtain an approximated traffic matrix that contains much fewer destinations. This approximation significantly improves Velo's running time at the expense of potentially degrading its accuracy. Yet, we present a modified k-means clustering algorithm that computes an approximated traffic matrix with provable bounds on the accuracy loss. In §6.2, we experimentally show that the approximation is highly accurate for both realistic (heavy-tailed) and unrealistic (almost-uniform) traffic matrices. We show that this clustering technique is more efficient and general than a simple approach based on heavy-hitters, as it achieves tighter error bounds by considering fewer destinations for all the traffic matrices used in our experiments.

To illustrate our approximation, consider a third destination d_3 in Figure 2 with traffic $s_1 \to d_3$ of 0.4 gb/s and $s_2 \to d_3$ of 0.3 gb/s. d_3 is also reachable via b_1, b_2, or both. The traffic for d_1 (3 gb/s from s_1 and 4 gb/s from s_2) is ten times larger than for d_3, but their distributions are similar. Considering d_1 and d_3 jointly would yield a maximum load on link (u,v) of 13.3 gb/s instead of 13.4 gb/s when analyzing d_1 and d_3 individually. Velo accurately bounds the error to 0.1 gb/s.

Dealing with traffic variability Velo's input can include an amount y of traffic additional to the input traffic matrix. There are infinite traffic matrices compatible with any given y; obviously, we cannot analyze all of them. Two key observations instead inspire Velo's approach. First, allowing y additional traffic increases the worst-case load of any link by up to y compared to its maximum load for the input traffic matrix. Second, for any link, its maximum load increases exactly by y whenever a router r sends *all* its traffic to a destination d across that link: in this case, indeed, increasing the traffic from r to d by y increases the load on that link by y.

Based on these observations, Velo accounts for y additional traffic by first computing the maximum link loads for the input traffic matrix, and then increasing the maximum link loads by y. This approach may overestimate the maximum load of a link if no router forwards all its traffic for any single destination over that link in the worst-case scenario for that destination. This tends to occur rarely in practice (less than 0.1% in our experiments in §6), implying that Velo is fully accurate in the vast majority of scenarios.

3 Model and Notation

We model the network as a graph $G = (N, E)$ with routers N connected by edges E. Border routers $N_B \subset N$ are connected to external networks that advertise BGP routes to destinations P, that is, remote IP prefixes populating the routing tables of the routers. For each destination, the network selects a set of *preferred routes*, corresponding to a set $B \subseteq N_B$ of border routers that will be used as *egress routers* (i.e., to forward traffic towards that destination). This selection can be done by a central controller [10] or in a distributed fashion using iBGP [37]. In the case of iBGP, we assume that *(i)* BGP attributes that affect routes' preference are not modified on any iBGP session, and *(ii)* all routers eventually learn their preferred routes. Several techniques are available to avoid iBGP visibility problems [36, 47, 48] or to prove the absence thereof [4, 16, 45, 49].

By focusing on egress routers per destination, we hide most of BGP's low-level details (e.g., its decision process). For any given destination d, we must only consider *(i)* the border routers that *can* receive a route for d, and *(ii)* the possible subsets of border routers that can receive *preferred* routes for d. For the former, we check whether configured eBGP ingress route maps discard all routes for d. For the latter, we analyze the attributes modified by ingress route maps, mainly the Local Preference, that affect the BGP decision process. Other attributes like the AS path can take arbitrary values, including those that result in a tie during route selection.

We denote the input traffic matrix as $\mathbf{M}$. Each element $\mathbf{M}_{s,d}$ is the ingress traffic that enters the network at router $s \in N$ with destination $d \in P$. We define a column $\mathbf{M}_d$ of $\mathbf{M}$ as the total traffic for destination d, as sourced from all ingress routers in N. The network sends traffic $\mathbf{M}_d$ for d over the computed paths for egress routers in B, resulting in load $load(e, \mathbf{M}_d, B)$ on any link $e \in E$.

Intra-domain routing Forwarding paths are computed from each router to its selected egress router. Many intra-domain routing approaches exist. Some rely on a central controller [18, 20], while others use distributed Interior Gateway Protocols (IGPs) [33, 34]. Static routes, source routing or tunnelling can also be used to forward traffic [26].

We model the intra-domain path computation using routing algebra [41], consisting of weights W, a binary operation $\oplus$ and an order relation $\succcurlyeq$. For example, the commonly used shortest-path-based IGPs [33, 34] are modeled with weights corresponding to per-link IGP costs, a binary operation that adds costs, and a binary relation that selects the shorter path.

We write link weights as $w : E \mapsto W$. We denote the optimal s-t path in the routing algebra as $p^*_{s,t} = (s, n_1, \ldots, n_i, t)$ with path weight $w_{s,t} = w(s,n_1) \oplus \cdots \oplus w(n_i,t)$. We assume that traffic is split equally across all next-hops of each router, i.e., the first hops of its optimal paths. This is consistent with traffic distribution in the presence of ECMP [26].

Link weights W are *strictly isotone* if $a \succ b$ implies both $a \oplus c \succ b \oplus c$ and $c \oplus a \succ c \oplus b$ for any $a, b, c \in W$. This property is both necessary and sufficient to ensure that any sub-path of an optimal path is itself optimal, allowing the paths to be computed using a generalized Dijkstra algorithm (if they exist) [41]. Note that strict isotonicity is common in intra-domain routing regardless of the forwarding paradigm (e.g., hop-by-hop vs. source routing vs. SDN).

Strictly isotone weights offer limited flexibility to achieve traffic engineering [13], so operators sometimes configure *exception paths* (e.g., MPLS RSVP-TE tunnels [3]) that carry packets over manually defined sequences of edges. We denote the set of exception paths as ρ that take precedence over shortest paths.

4 Finding Maximum Link Loads

We achieve scalability thanks to a highly efficient algorithm for finding the worst-case link load in any input topology, allowing us to iterate over a large number of failure scenarios. For any given topology, the worst-case load of a link is the sum of its worst-case loads for each destination considered independently: this is because BGP routes are specified per destination, and so are forwarding paths. To find the worst-case link loads in each topology, we thus search for the worst-case egress routers per destination, one destination at a time. Hereafter, we explain how Velo performs such a search for a given topology and a single destination.

4.1 Per-Destination Worst-Case Link Loads

The basic building block of our approach is to efficiently find the set of egress routers for a single destination that maximizes the load of a specific link. Reasoning on the worst-case egress routers per destination compared to the huge and possibly infinite space or BGP routes and their attributes is already a massive optimization. Yet, naively exploring the space of egress routers still requires exploring $O(2^{|N_B|})$ states.

In the following, we explain how we reduce our search space to $O(|N_B|)$ states whenever internal paths are computed from strictly isotone weights (§4.1.1), and slightly more states in the presence of a few exception paths (§4.1.2).

4.1.1 Strictly Isotonic Routing

Let $G = (N, E)$ be a network routing traffic matrix $\mathbf{M}$ according to protocol $(W, \oplus, \succcurlyeq)$ where W is strictly isotone. We focus on one destination d and the maximal load on link e.

Theorem 1 *For any non-empty set of egress routers $B \subseteq N_B$ and any link $e \in E$, there exists a single egress $b \in B$ that, if chosen as the unique egress for destination d, causes at least the same load on e as the set B. Formally:*

$$\forall e \in E : \exists b \in B \text{ s.t. } load(e, \mathbf{M}_d, B) \leq load(e, \mathbf{M}_d, \{b\})$$

Algorithm 1: Find the worst-case link load for all links simultaneously if all traffic is forwarded along optimal paths.

Data: Graph $G = (N, E)$, border routers $N_B \subseteq N$, link weights $w : E \mapsto \mathbb{R}$, traffic $\mathbf{M}_d$
Result: maximum link loads $y[e]$ for all links $e \in E$

$y[u, v] \leftarrow 0 \; \forall (u, v) \in E$
for $b \in N_B$ **do**
  $l[s] \leftarrow \mathbf{M}_{s,d} \; \forall s \in N$
  $G_{dag} \leftarrow ForwardingDAG(G, w, root = b)$
  for $u \in TopoSort(G_{dag})$ **do**
    $d_{out} \leftarrow |out(G_{dag}, u)|$
    for $v \in out(G_{dag}, u)$ **do**
      $l[v] \leftarrow l[v] + l[u]/d_{out}$
      $y[u, v] \leftarrow \max(y[u, v], l[u]/d_{out})$

Intuitively, Theorem 1 holds by the main property of strict isotonic routing protocols; the sub-path of any optimal path is also optimal. All traffic crossing the edge $e = (u, v)$ must follow a path that is also optimal for v, allowing us to reduce the set of egresses to the one selected by v. In case a router splits its traffic equally among multiple paths, we show that the fraction of traffic it sends across the edge e will not decrease.

Proof of Theorem 1. Consider any edge $e = (u, v)$, and let $N_e \subseteq N$ be the set of all nodes that forward traffic along e. Further, let b be an egress router preferred by v, and pick any router $n \in N_e$.

First, observe that the weight of n's optimal path towards any egress router in B, namely $w_{n,B}$, is equal to the weight of its path to b via e, i.e., $w_{n,b} = w_{n,u} \oplus w(e) \oplus w_{v,b}$. Hence, $w_{n,B} = w_{n,b}$ due to the strict isotonicity.

We now show that the total amount of traffic n sends across edge e cannot decrease when only egress b is available. We show this by comparing n's next-hops for egresses B, i.e., $nh_{n,B}$, with those for the single egress b, i.e., $nh_{n,b}$. First, we argue that $nh_{n,b} \subseteq nh_{n,B}$, and thus, the traffic n sends to any next-hop in $nh_{n,b}$ does not decrease. This follows from the fact that any optimal path of n for b is also optimal for B.

Second, we show that $nh_{n,b} \cap N_e = nh_{n,B} \cap N_e$, proving that the fraction of traffic n sends across the edge e cannot decrease. Consider any next-hop $x \in nh_{n,B} \cap N_e$: n can still reach the destination d via egress b on an optimal path via x. This is because $x \in N_e$, and thus, $w_{x,B} = w_{x,b}$. □

Theorem 1 implies that the worst-case load of any link for any destination is obtained when the entire network chooses a single egress router. More formally,

$$\max_b load(n, \mathbf{M}_d, \{b\}) = \max_B load(n, \mathbf{M}_d, B).$$

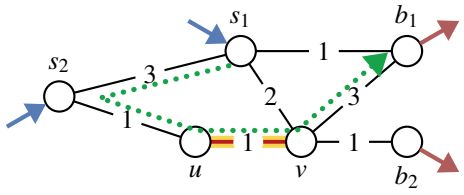


Figure 3: Example where considering less combinations of egress routers than Velo in the presence of exception paths leads to underestimating maximum link loads.

This observation directly enables us to reduce the number of explored states to $O(|N_B|)$. Indeed, Velo iterates over the border routers in N_B. For each border router b, Velo creates the forwarding graph rooted at b, which is a directed acyclic graph (DAG). It then computes the corresponding link loads by traversing the DAG in topological order and pushing traffic from each node to its outgoing edges. At the end of the iteration, it reports the worst-case scenario for each link.

Algorithm 1 shows our pseudo-code. Note, that the second-to-last line ensures traffic is split equally among next-hops, i.e., implementing ECMP. Its computational complexity is $O(|N|^2 \log|N| + |N||E||P|)$, because the two most expensive operations are (i) computing $|N_B|$ forwarding DAGs with Dijkstra's algorithm [41], and (ii) traversing a DAG in topological order for each destination prefix $d \in P$.

4.1.2 Exception Paths for Traffic Engineering

Theorem 1 does not hold in the presence of exception paths. Take the example depicted in Figure 3, with two egresses b_1 and b_2, and two ingress routers s_1 and s_2. Shortest-path routing is always used, except s_1 forwards traffic for b_1 on the path (s_1, s_2, u, v, b_1), drawn as a dotted line. The load on link (u,v) is maximized when both b_1 and b_2 are egress routers. Indeed, shortest paths are such that s_2 bypasses (u,v) if b_1 is the only egress, and s_1 bypasses (u,v) if b_2 is the only egress.

To deal with exception paths for destination d, we explore all single egress routers plus all the combinations of the border routers terminating any exception paths configured for d. The example in Figure 3 demonstrates that considering less egress routers can lead to incorrect results. We now show that considering only these combinations is sufficient to find the worst-case link loads. Let ρ_d be the exception paths configured for d, and let $T = \{b \mid (s, \cdots, b) \in \rho_d\}$ be the set of egress routers ending any path in ρ_d.

Theorem 2 *For any non-empty set of egress routers $B \subseteq N$ and any link $e \in E$, there exists a subset $B' = \{b\} \cup T'$, where $T' = T \cap B$, that causes at least the same load on e than the set B. Formally, for every link $e \in E$,*

$$\exists b \in B \text{ s.t. } load(e, \mathbf{M}_d, B) \leq load(e, \mathbf{M}_d, \{b\} \cup T \cap B)$$

Intuitively, Theorem 2 holds as nodes either forward via optimal paths, in which case Theorem 1 applies, or via exceptional path that are still available with the reduced subset of egress routers. We provide a proof in Appendix A.1.

Theorem 2 allows us to find the worst-case link loads by iterating over all subsets $T' \subseteq T$ and one other egress router in $N_B \setminus T$. We filter out combinations of egresses that cannot receive equally preferred routes due to BGP policies.

For each set B of egress routers computed as above, we construct the corresponding forwarding DAG by combining the forwarding DAGs rooted at all egresses in B. We then find the load resulting from traffic routed along exception paths, and push the remaining traffic through the DAG as in Algorithm 1. We provide a pseudo-code in Appendix A.2.

Computing link loads in the presence of exception paths has complexity $O(|N|^2 \log|N| + 2^{|T|}|N||E||P|)$, similarly to the complexity of Algorithm 1 but for the larger search space.

4.2 Restricting the Number of Route Changes

So far, we have discussed finding the worst-case link loads considering any set of route changes. However, part of Velo's input is the maximum number k of egress changes. Hence, for each link, we must find the k destinations that cause the highest increase of its load. To that end, we maintain for each link a heap of size k with the largest difference between the worst-case and current-state link loads. Maintaining the heap has a time complexity of $O(|E| \cdot |P| \cdot \log k)$ which is negligible with respect to the total time of the algorithm.

5 Approximating the Traffic Matrix

The algorithms presented in §4 scale linearly in the number of destinations. It is not rare that real routers have order of a million entries [19, 26], so finding the worst-case link load for so many destinations would be a limiting factor.

We greatly reduce the number of destinations by combining those with similar traffic patterns. Specifically, we approximate the input traffic matrix with a smaller one, leveraging the low effective rank that traffic matrices typically exhibit [6, 31].

We formulate this traffic matrix approximation problem as a clustering problem, and find that the clustering error bounds the *approximation error* δ; by how much the link loads differ when computed on the original and approximated traffic matrices. We envision that our approximation technique can be useful within other networking problems for which the size of traffic matrices limits scalability.

Approximation problem Given a traffic matrix $\mathbf{M} : |N| \times |P|$, we aim to find a clustering C of the destinations that reduces the size of $\mathbf{M}$ while also bounding the error induced by that reduction. More formally, we aim to compute a partition C of P, an approximate traffic matrix $\mathbf{A}$ of size $|N| \times |C|$, and

an *error bound* ε for the approximation error δ, such that

$$\delta = \max_{e \in E} |max\,load(e, \mathbf{M}) - max\,load(e, \mathbf{A})| \leq \varepsilon, \quad (1)$$

where $max\,load(e, \mathbf{M})$ is the maximum load of link e for $\mathbf{M}$.

We take the number of clusters $|C|$ as input. Increasing $|C|$ reduce both ε and δ at the cost of running time. Operators can tune $|C|$ to find a balance between accuracy and running time.

We must however be careful to cluster together only destinations for which the routing and forwarding states are equivalent. For example, we must not aggregate destinations with different intra-domain paths for the same egress point. To this end, we provide a custom definition of *Equivalence Class*, and only cluster destinations in the same equivalence class. We distribute the available clusters $|C|$ across all equivalence classes proportional to the amount of traffic they carry. Specifically, any pair of destinations in an equivalence class must satisfy the following two conditions:

1. The same egress routers are used for both destinations in the current routing state.
2. The forwarding paths for both destinations are always equal for the same set of preferred egress routers.

In the following, we detail our clustering algorithm for destinations in the same equivalence class.

Normalized clustering algorithm We cluster together destinations with similar traffic distribution across ingress routers, i.e., if similar fractions of traffic for two destinations enter from the same routers. Such destinations *likely* produce worst-case link loads for the same routing inputs.

We define the traffic distribution $\mathbf{M}_d/|\mathbf{M}_d|$ of destination d as the fraction of traffic from each ingress compared to d's total traffic load $|\mathbf{M}_d|$. We then use the L1 norm [24] to measure the similarity of two distributions, as the L1 norm quantifies their absolute difference. We run an *adaptation* of the k-means clustering algorithm on the traffic distributions: instead of minimizing the L1 distances within a cluster c_i, we weighten the distance between its cluster centroid $\mathbf{A}_i$ and a destination d according to d's total traffic. Thus, the computed clusters accurately resemble high-traffic destinations. Cluster centroids $\mathbf{A}_i$ and the clustering error ε are defined as follows.

$$\mathbf{A}_i = \sum_{d \in c_i} \mathbf{M}_d \qquad \varepsilon = \frac{1}{2} \sum_{c_i \in C} \sum_{d \in c_i} |\mathbf{M}_d| \cdot \left| \frac{\mathbf{M}_d}{|\mathbf{M}_d|} - \frac{\mathbf{A}_i}{|\mathbf{A}_i|} \right|. \quad (2)$$

Finally, Velo constructs the approximate traffic matrix $\mathbf{A} = [\mathbf{A}_1, \mathbf{A}_2, \cdots]$ directly from the cluster centroids.

Our clustering approach guarantees that the approximation error δ is bounded by the clustering error ε. Intuitively, this is because *(i)* ε is the amount of traffic in $\mathbf{M}$ that the approximation $\mathbf{A}$ does not account for, and *(ii)* ε is also the amount of additional traffic in $\mathbf{A}$ that is not part of the original matrix $\mathbf{M}$. Consequently, $max\,load(e, \mathbf{A})$ can differ from $max\,load(e, \mathbf{M})$ by at most ε. We provide a formal proof in Appendix B.

6 Evaluation

We now evaluate Velo's performance in terms of scalability (running time) and accuracy. Its correctness is instead guaranteed by our theorems in §4 and §5.

In §6.1, we discuss aspects that influence Velo's running time. We show that Velo can find the maximum loads for all the links in large networks (with close to 2 000 links) within a few hours, considering up to two simultaneous failures and up to ten changes of any external routes. As baseline, we also compare Velo against its closest related work, QARC [44], in scenarios where external routes do not change. We find that Velo runs much faster than QARC for scenarios considering up to two simultaneous failures (the most practical ones).

In §6.2, we evaluate the impact of the traffic matrix on Velo's accuracy. We show that Velo's approximation error is less than 1% even for unrealistic traffic matrices that are hard to approximate.

Implementation We implement a prototype of Velo in $\approx$ 7 000 lines of Rust,[2] including an optimized version of both Algorithms 1 and 2, and our modified k-means clustering algorithm. We run the evaluation on a server with 96 CPU threads and 384 GB of memory.

Networks We study the 75 largest networks from Topology-Zoo [23], ranging from 40 to 754 nodes with 80 to 1 790 links. For each network, we study the effect of increasing the number of border routers by randomly connecting external peers that can advertise a route for any destination to internal routers. We assign random IGP weights (between 10 and 100) to each link. To study the impact of non-shortest paths routing, we setup exception paths (i.e., traffic-engineered paths that do not follow the shortest paths) for given destinations by computing alternative paths using permuted link weights.

Traffic matrices We obtain real traffic matrices from a research network. We also generate synthetic traffic matrices following the gravity model [9, 31]. This enables us to control and vary traffic characteristics to evaluate Velo's sensitivity to different traffic patterns.

6.1 Running Time

The following factors affect Velo's running time: network size, number of simultaneous failures l, maximum number of external route changes k, number of clusters $|C|$, number of border routers $|N_B|$, and number of exception paths $|\rho|$. The specification of traffic additional to the traffic matrix instead has no noticeable impact, consistently with the inexpensive approach to deal with it in Velo (see §2).

[2] Available at https://github.com/nsg-ethz/velo (GPLv3 license).

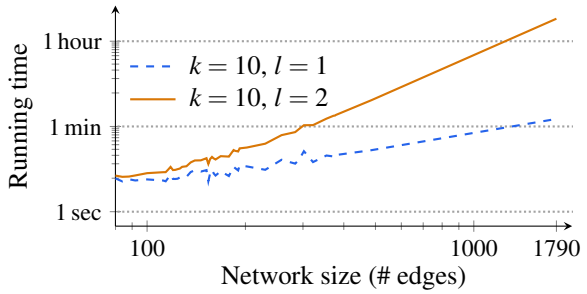

Figure 4: Velo can scale to large networks of over 1 000 links while exploring up to two simultaneous link failures. This log-log plot shows the running time of Velo for the 75 largest topologies in TopologyZoo with up to one and two simultaneous link failures l running on 96 parallel threads.

We find that the network size and the number of failures have the biggest impact on Velo's running time. We therefore divide our experiments in two sets: a fist set considering only these two factors, and another set considering the others.

Following these experiments, we compare Velo's running time against QARC [44], a state-of-the-art approach to find link load violations under varying scenarios, albeit assuming fixed external routes.

Network size and link failures In the first set of experiments, we analyze the impact of network size and maximum number of failures on Velo's efficiency across all the topologies in our dataset. We set a relatively low number of simultaneous failures ($l \leq 2$) and route changes ($k = 10$), as it is unlikely for many more links to fail and many more external routes to change at the same time [42]. We also set $|C|$ to 300, which empirically provides a good accuracy-performance tradeoff (see Appendix D.3). We finally configure 30 border routers per topology, and no exception path.

Figure 4 shows a log-log plot of Velo's running time. Varying the network size from 100 to 1 790 increases the running time by about four orders of magnitude. A similar effect is caused by considering all combinations of two link failures ($l = 2$) rather than single link failures ($l = 1$).

Yet, our results show that Velo is practical for all the TopologyZoo networks. For the largest one, Velo finds the worst-case load for all its 1 790 links within one minute for single link failures, and within three hours for two link failures. For all the other networks, Velo finds all the worst-case loads for $l \leq 2$ within two minutes.

We further break down Velo's efficiency according to its two main phases: clustering and analysis. The clustering phase dominates the running time for small networks (up to 200 edges), while the analysis phase is the dominant one for bigger networks. The asymptotic growth of the analysis time, and hence of the overall running time, is roughly cubic for $l = 2$. Full results are shown in Appendix D.2.

Finally, we approximate the running time improvement gained from reducing the search space of route changes. With 30 border routers, the naive approach requires exploring 2^{30} states—seven orders of magnitudes bigger than Velo's search space. Analyzing a network of only 80 links without the state reduction would take roughly one year for $l = 2$.

Other factors To measure the impact of the other factors, we focus on Cogent, one of the largest networks in Topology Zoo, and vary each factor, one at a time.

The number of route changes k has a small effect on Velo's efficiency. This is because for each link, we always need to compute the worst-case routing input for *all* destinations, before picking the k destinations causing the highest load on that link. Increasing k from 10 to 100 still increases the running by 1.3× but only because the algorithm must maintain larger heaps. We however note that allowing all routing inputs to change (i.e., $k = |P|$) *reduces* the running time by 2.9×, as Velo needs to maintain less state.

Increasing the number of clusters $|C|$ affects the running time, as Algorithms 1 or 2 are called for each cluster. Increasing $|C|$ from 300 to 600 or 1 000 increases the running time by 1.3× or 1.6×, respectively. Similarly, decreasing $|C|$ to 100 improves Velo's performance 1.2×. As a reference, deactivating clustering would take Velo roughly 1 000× longer to complete, assuming around 1 million destinations.

The number of border routers $|N_B|$ affects the number of states to be explored. Yet, increasing $|N_B|$ from 30 to 100 only increases Velo's running time by 1.7×.

Finally, adding exception paths forces Velo to explore additional states. Indeed, Velo must explore all combinations of distinct egress routers of these paths. Such paths are usually configured manually, and they are often used only for traffic-heavy destinations. A total of 30 or 50 exception paths increases the running time by respectively 1.4× or 3.2×.

Comparison to QARC QARC does not support changes in routing inputs. We thus compare Velo against QARC when both systems are asked to analyze link loads under l link failures. We rerun the same experiments as in [44] with the author's implementation. These experiments involves the specification of traffic between all pairs of routers, and 10% additional traffic. For Velo, we extract the traffic matrix by attaching one destination per egress router, and set $k = 0$: this effectively disables Velo's clustering algorithm, since no destinations fall in the same equivalence class (see §5).

The results for up to two simultaneous link failures are shown in Figure 5. Velo is several orders of magnitude faster in computing maximum link loads than QARC, achieving sub-second computation on all topologies. We believe that such a performance gap is mainly due to the different approaches at the core of the two systems: QARC solves an Integer Linear Program, while Velo relies on Dijkstra's algorithm.

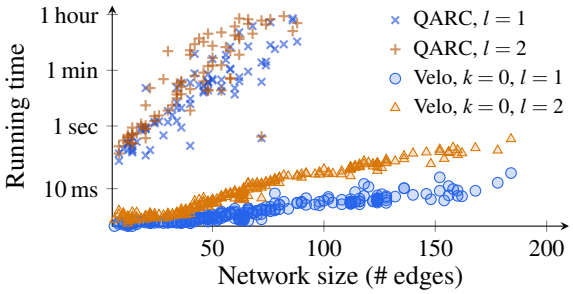

Figure 5: For small $l < 3$, Velo outperforms QARC when comparing only the current state, i.e., with $k = 0$. This figure compares the running time of Velo and QARC [44] to find link load violations for networks from TopologyZoo.

Velo is 10-100× faster than QARC even for $l = 3$ and $l = 4$ (see Figure 7). However, the performance gap between the two systems seems to progressively decrease when increasing l. We expect QARC to outperform Velo for large values of l.

In fairness, QARC guarantees exact computation of link loads, while Velo theoretically doesn't. However, in the absence of clustering, Velo is fully accurate, except possibly overapproximating additional traffic (see §2.2). This is a rare case that does not occur in these scenarios—Velo has *no approximation error* in any of these experiments.

Takeaways Velo finds the worst-case loads of all links within minutes for the most likely and practical scenarios with up to two link failures and a limited number of route changes. Because it is mostly polynomial in the network size, Velo scales to large networks with close to 2 000 links.

6.2 Accuracy

Velo's accuracy depends on the input traffic matrix, which indeed impacts the effectiveness of our clustering. We evaluate Velo's accuracy on both real inter-domain traffic data and synthetic traffic matrices, using the latter ones to measure the effects of traffic characteristics on our clustering algorithm.

We measure both the error bound ε as defined in Equation (2) and the approximation error δ from Equation (1), i.e., maximum difference in worst-case link loads between the approximate and the original traffic matrix.

We further compare our clustering algorithm with the simpler approach of picking the destinations carrying the most traffic, in the following called *Top-X*. We determine how many such destinations are needed to provide the same guarantees as Velo. That is, we find the smallest X such that the amount of traffic disregarded by Top-X equals our error bound ε. We report the ratio between this smallest X and $|C|$: such ratio relates directly to Velo's running time, given that its efficiency scales linearly with the analyzed destinations.

We represent real and synthetic traffic matrices according to the gravity model, a common technique in network traffic synthesis [38]. In the gravity model, a traffic matrix is parametrized by three distributions:

$$\mathbf{M}_{s,d} \propto \mathit{repulsion}(s) \cdot \mathit{attraction}(d) \cdot \mathit{friction}(s,d).$$

The *attraction* describes the distribution of the traffic towards the destinations: a heavy-tailed attraction results in a few destinations attracting most traffic. The *repulsion* describes the distribution of traffic originating from each ingress, symmetrically to the attraction. The *friction* describes traffic similarity across source-destination pairs: a heavily tailed friction yields a sparse matrix, where many entries are zero.

Related work has shown that all the three distributions are heavy tailed in practice [31]. Our real measurements confirm this: traffic per destination (i.e., the attraction), traffic per source (i.e., the repulsion), and traffic similarity across destinations (i.e., friction) are similar to LogNormal distributions. We thus characterize traffic matrices according to the σ parameter of attraction, repulsion and friction: σ indeed measures the skeweness of LogNormal distributions. We provide more details in Appendix C.1.

In all experiments, we pick $|C| = 300$ clusters, as we find this to be a good compromise between accuracy and running time, but we evaluate different values of $|C|$ in Appendix D.3.

Real traffic data We obtain Netflow data for four 5-minute slices from the Swiss research network Switch. These measurements include byte counters per ingress link and per destination IP, aggregated by /24 IPv4 or /48 IPv6 prefixes. The data is extremely skewed; 95% of all traffic is towards 0.23% of all destinations. We stress that this does not seem to be common in the Internet [11, 31]. For example, the top 15% destinations are reported to account for 95% of the traffic in the real traffic matrices studied in [31]. This difference might be an artifact of the destination granularity (i.e., we cannot reconstruct traffic for prefixes less specific than /24), or due to the specificities of the research network originating our data.

Both addresses and ingress links are anonymized, forcing us to randomly assign links to routers. We analyze 100 such random assignments to confirm that this has little impact on the results. We refer to Appendix C.2 for more details.

The first four rows in Table 1 show the results for all such traffic matrices. Velo achieves an error bound ε of around 5% and an approximation error δ of around 0.5%. Appendix D.4 expands on the relationship between ε and δ. Further, Velo is ≈ 3.4× more efficient that top-X despite the extreme skeweness of the data; a property that favors Top-X.

Synthetic data Based on our real traffic matrices, we synthesize matrices with similar characteristics using the gravity model with 30 equivalence classes, cf. §5. Starting from the average parameters of the real matrices, we evaluate how

real	repulsion	attraction	friction	error bound ε (0 … 10%)	approx. error δ (0 … 1%)	efficiency w.r.t. Top-X (1 … 60×)
yes	**2.79**	**2.99**	**3.99**	5.63%	0.68%	4.3×
yes	**2.82**	**2.93**	**3.96**	5.34%	0.68%	3.7×

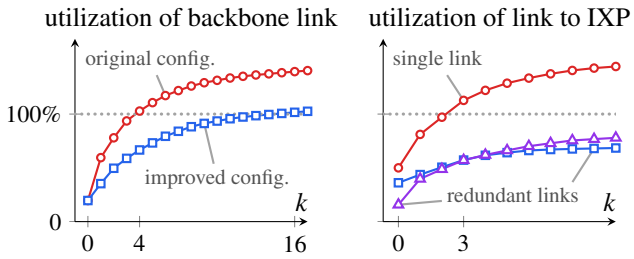
Table 1: Velo's accuracy is affected by the tail distribution over per-destination traffic, i.e., the attraction, and the variation between traffic distributions, i.e., the friction. This table shows both the error bound ε and the approximation error δ, the latter on a smaller scale. The box represents the 25 and 75 percentiles, with the mean indicated by the red line. The whiskers show the minimum and maximum values. The number right to the upper whisker show the maximum number.

changing the skewness in all three dimensions affects Velo's accuracy, one at a time. We do so for six large topologies from TopologyZoo (with 140–200 nodes). For each topology and set of parameters, we generate 20 random traffic matrices.

Table 1 demonstrates that clustering is an excellent fit for approximating traffic matrices. The error bound ε is mostly below 10%, and the actual approximation error δ is always <1%. Clustering is also 5x-50x more efficient than Top-X.

As expected, decreasing traffic skeweness (for any parameter) increases both ε and δ, because it causes traffic to be more evenly spread across more sources or destinations, making it harder to capture all traffic with a fixed amount of clusters. Yet, $|C| = 300$ clusters accurately approximate unrealistic traffic matrices where traffic distributions are not very skewed at all. In contrast, Top-X needs a lot more destinations to achieve the same error bound, especially if the attraction has a less significant tail. We conclude that Velo's clustering is more effective and more general than Top-X.



The number of clusters $|C|$ also affects the accuracy of Velo, reducing the error when increasing $|C|$. Doing so, however, also increases the running time, as discussed in §6.1. We find that Velo with $|C| = 300$ is sufficiently accurate for all matrices we evaluated, and increasing it to 1000 clusters only yields minor gains in accuracy (reducing the error bound from ≈3.5% to ≈1.8%). Appendix D.3 shows more results.

Traffic Variability We finally evaluate Velo's accuracy when traffic volumes additional to the traffic matrix is given as input (see §2). Across all the experiments described in Figure 4, Velo computes the correct maximum link loads in over 99.9% of all links, for any value of additional traffic.

Takeaways Velo is very accurate in approximating the worst-case link loads, even when using only $|C| = 300$ clusters. In all our experiments, Velo's approximation error is below 1% of the total traffic volume. Further, Velo guarantees error bounds below 12% even for unrealistic traffic matrices that are challenging to approximate.

7 Case Study

We experiment with an ISP that provides connectivity to around 100 universities and research institutions. The ISP manages 126 routers connected by 376 links. Ten routers are connected to either providers or IXPs. We generate a traffic matrix with 100 000 prefixes according to the gravity model [32] to match reported characteristics [31]. Customers only announce their respective prefixes, while all the other prefixes are reachable through neighboring providers or IXPs. In the initial network state, all links are utilized below 50%—the ISP upgrades links that maintain load above that threshold.

(a) Configuration fine-tuning (b) Network upgrade

Figure 6: Our case study demonstrates that Velo helps improving network robustness.

We run Velo on the relevant parts of the router configurations, the generated traffic matrix, and an increasing k. Within a few seconds, Velo finds that the current configuration and topology is worryingly fragile to specific egress changes: two links would exceed their capacities if egresses of only four destinations change. We now show three ways in which Velo's insight can be leveraged by operators.

Robustifying configurations One of the two fragile links is part of the ISP backbone: this link would be congested by specific egress changes for four (large) destinations. We use this insight to assess an alternative configuration with three additional MPLS paths to effectively shift traffic to underutilized links. The alternative configuration would prevent congestion on any link for up to 16 arbitrary egress changes – a much less likely scenario than 4 egress changes. Figure 6a compares the robustness of the initial and alternative configurations.

Aiding strategic decisions The second fragile link connects the ISP to an IXP. The link would be congested if traffic to just three specific destinations is sent to that IXP. Operators may think about upgrading that link; however, Velo's output highlights that other links within the ISP would also need to be upgraded to sustain the additional traffic. A better alternative is to add a link from the IXP to another, geographically close backbone router. Re-running Velo on the alternative topology reveals that $\approx 1\,000$ prefixes must be advertised at that IXP to congest either of the two links – see Figure 6b.

Velo can also guide operators' peering decisions, predicting possible configuration and infrastructural changes required by new BGP peerings.

Improving network management Velo identifies 64 pairs of prefixes and egress routers; link loads significantly increase if any such prefix is routed via the corresponding egress. This information is highly valuable for network management and operation. For example, it enables monitoring systems to focus only on those 64 pairs of prefixes and egress routers, alerting operators only for the small subset of critical events.

Velo's output can also improve automated management systems. For example, it enables traffic engineering systems (e.g., [8, 18, 20]) to optimize paths *before* link load requirements are violated. Consider the above case of the backbone link congested after four BGP egress changes. When any three egress changes are observed out of these four, an emergency recomputation of internal paths can be triggered immediately, *preventing* congestion without waiting for data-plane measurements typically collected every few minutes [20].

8 Related Work

Velo focuses on verifying link load properties, e.g., to help improving network robustness to external events. As such, it is related to prior work in network verification and routing.

Network verification Many verification systems have recently been proposed. Among them, data-plane ones [12, 21, 22, 43] target properties based on packet headers for fixed forwarding states, basically ignoring traffic and routing.

Control-plane verification systems [1, 4, 5, 14, 15, 45, 46, 54] are more related to Velo, as they admit different network settings (e.g., failures). Almost all of them however focus on properties, such as forwarding paths and routes' propagation, that cannot be directly translated into link loads. Prior works cannot be easily extended to verify link load properties, because they verify one destination at the time. As failures break the independence of destinations, thousands of destinations must be considered jointly for link load properties. Doing so with prior approaches would simply not scale: for techniques like [15], it would inflate SMT formulas by $|P|\times$, where P is the number of destinations, hence hundreds of thousands.

The few existing checkers of link load properties *do not support BGP route changes*. Jingubang [26] is a flow-level simulation tool that computes link loads for specific failure scenarios and traffic matrices. YU [27] extends the above simulator to deal with k arbitrary link failures: it still works at the per-flow level. NetDice [42] implements probabilistic verification of properties including link load ones; however, for link load properties, NetDice's approach does not scale beyond a dozen ingress-destination pairs [42]. The framework presented in [7] allows to check link utilization under arbitrary failures for network designs where configurations (e.g., routing) can be changed. Our closest related work is QARC [44], that verifies link load *violations* (without computing all link loads) upon link failures. We experimentally compare Velo against QARC in §6.1.

Routing systems Optimizing link loads has been the focus of a large body of work [2, 30, 51], especially in the area of traffic engineering (TE). TE approaches typically optimize paths based on the *current* traffic and BGP routes or, at best, variations of them [17, 25, 35]. Some of these

approaches [7, 28, 52] rely on robust optimization to *approximate* the impact of failures. Future work may try robust optimization techniques for link-load verification, although it's unclear how these techniques would guarantee accuracy and scalability when analyzing both failures and route changes.

Real-world TE systems [18, 20] update forwarding upon detecting a failure, and react to BGP route changes by re-optimizing paths according to load measurements collected every few minutes. By anticipating the most impactful failures and route changes, Velo can be integrated into TE systems to prevent excessive link loads or react faster to them, see §7.

Information on current and future traffic is key for intra-domain traffic engineering. Recently, systems (e.g., [29]) have been proposed to predict changes in incoming traffic caused by specific BGP routes *announced to* external neighbors. We envision that such systems can be used by operators to compute traffic matrices they want to verify with Velo.

9 Discussion

In this section, we discuss some of the design choices we made in Velo alongside the generality of the approach.

Why *not* modeling congestion? For each link, Velo computes the load by simply summing the amount of traffic routed over it. In practice, though, no link load could exceed its capacity: traffic would be dropped instead. This also means that the amount of traffic forwarded through the network immediately decreases for the links downstream of the congested one. Hence, when any link is congested, the link loads reported by Velo do not reflect the actual traffic volumes crossing links.

Despite this simplification, Velo's approach is practical for at least two reasons. First, Velo correctly identifies *all* the links that cannot sustain the input traffic. Second, it correctly estimates the amount of exceeding traffic, and it therefore helps quantifying how much traffic needs to be rerouted, or by how much links' capacity should be upgraded.

What protocols and features can Velo model? Despite hiding most of the complexity of BGP and intra-domain routing protocols, Velo's model is powerful enough to capture common routing architectures, including iBGP and SDN (see §3). In fact, our model only imposes two constraints on intra-domain routing. First, all routers must be able to select any of the egress routers, which means that there must be no iBGP visibility problems. Several existing techniques avoid these problems [36, 47, 48]. Second, destinations must be independent, which requires the de-activation of intra-domain routing features that tie different destinations together, such as route aggregation or conditional advertisements. The use of these features is discouraged in iBGP [37]. Additionally, we think that Velo can be extended to jointly reason about egresses of dependent destinations, if needed.

Data-plane filters like ACLs do not influence routing, and thus, Theorem 1 still applies. In their presence, Algorithms 1 and 2 can be easily extended to apply such filters by dropping (some) traffic instead of propagating it. Doing so would ensure that the worst-case link loads computed by Velo would be consistent with both routing inputs and data-plane filters.

What route changes does Velo support? Velo computes the worst-case link loads for route changes affecting subsets of destinations. In §3, we have defined destinations as the IP prefixes in the routing tables. This allows Velo to cover BGP route changes for any of these IP prefixes.

In reality, the set of IP prefixes learned via BGP can change over time. For example, at any time, the remote network owning an IP prefix, say 1.0.0.0/8, can start announcing a more specific prefix, such as 1.0.0.0/16. If this happens, BGP propagates two distinct and independent routes – e.g., one for 1.0.0.0/8 and the other for 1.0.0.0/16.

Since Velo learns the destinations from the input traffic matrix, it supports some analyses of route changes affecting the set of known destinations, provided that enough information is specified by operators. For instance, Velo can handle the previous example if the input matrix includes traffic volumes for 1.0.0.0/16 and (separately) for the other subnets in 1.0.0.0/8. This information is anyway necessary to compute link loads with distinct routes for 1.0.0.0/16 and 1.0.0.0/8.

In contrast, Velo does not currently support systematic explorations of route changes affecting the set of destinations, e.g., announcements of *any* possible sub-prefix of a current destination. We leave this direction for future work.

10 Conclusions

Velo demonstrates the feasibility of verifying worst-case link loads in large networks, despite the need to navigate a gigantic space of possible failures and route changes. Our evaluation shows that Velo is both scalable and accurate across a wide range of topologies, settings, constraints and traffic matrices.

Velo focuses on maximum link loads due to their straightforward practical relevance in assessing network performance. As our case study demonstrates, Velo readily supports operators in complex tasks ranging from improving configurations to network design and aiding business decisions.

We also see Velo as a stepping stone towards the broader goal of verifying network performance. We believe that exploring other performance aspects, such as delay or bandwidth guarantees, is an interesting avenue for future research.

Acknowledgments The research leading to these results was supported by an ERC Starting Grant (SyNET) 851809. We thank João Luís Sobrinho, our shepherd Siva Kakarla and all anonymous reviewers for their valuable feedback. We also thank Simon Leinen and Switch for providing traffic data.

A Exception Paths

In the following, we first proof Theorem 2 that pretains to we handle exception paths. We then present the algorithm that relies on Theorem 2 to find the worst-case link loads under optimal and exception paths.

A.1 Proof of Theorem 2

Proof. Consider edge $e = (u,v)$, and let $b \in B$ be an egress router preferred by v. Now, take any node $n \in N_e$ that forwards traffic along the edge e for destination d. We distinguish two cases:

1. Paths of n that traverse e are optimal (i.e., are not exception paths), and by Theorem 1, n will not decrease the traffic it sends along edge e.
2. n forwards traffic along exception paths in ρ_d. Then, n will use the same forwarding paths for egresses $\{b\} \cup T \cap B$ as all destinations of n's forwarding paths are within T and B. Thus, n will still forward the same amount of traffic over link e.

It follows that the traffic on e cannot decrease for egresses $\{b\} \cup T \cap B$, proving Theorem 2. □

A.2 Algorithm for Exception Paths

Algorithm 2 shows the algorithm for finding the worst-case loads for all network links in the presence of exception paths, i.e., paths that don't follow the optimal paths according to the strictly isotone routing protocol.

The function `selected_combinations` iterates over all combinations of egress routers within T and all individual routers in $N_B \setminus T$. It further, checks whether there exists a set of advertisements for all egresses to be selected simultaneously based on the `LocalPref` values.

Algorithm 2: Find the worst-case link load for all links for optimal or exception paths.

Data: Graph $G = (N,E)$, border routers $N_B \subseteq N$, link weights $w : E \mapsto \mathbb{R}$, traffic $\mathbf{M}_d$, paths ρ_d
Result: maximum link loads $y[e]$ for all links $e \in E$

$T \leftarrow \{b \mid (s, \cdots, b) \in \rho_d\}$
$y[u,v] \leftarrow 0 \; \forall (u,v) \in E$
$G_{dag}[b] \leftarrow \mathit{ForwardingDAG}(G, w, root = b) \; \forall b \in N_B$
for $B \in$ `selected_combinations`(N_B, T) **do**
  $y'[u,v] \leftarrow 0 \; \forall (u,v) \in E$
  $l[s] \leftarrow \mathbf{M}_{s,d} \; \forall s \in N$
  $G_{fw} \leftarrow \mathit{merge}(G_{dag}[b] \; \forall b \in B)$
  for $path = (s, n_1, \cdots, n_i, b) \in \rho_d$ **do**
    if *s forwards to b in* G_{fw} **then**
      $y'[u,v] \leftarrow y'[u,v] + l[s] \; \forall (u,v) \in path$
      $l[s] \leftarrow 0$
  for $u \in \mathit{TopoSort}(G_{dag})$ **do**
    $d_{out} \leftarrow |\mathit{out}(G_{dag}, u)|$
    for $v \in \mathit{out}(G_{dag}, u)$ **do**
      $l[v] \leftarrow l[v] + l[u]/d_{out}$
      $y'[u,v] \leftarrow y'[u,v] + l[u]/d_{out}$
      $y[u,v] \leftarrow \max(y[u,v], y'[u,v])$

B Clustering Error Bounds

In the following, we formally proof that the clustering error bounds the approximation error of the worst-case link load. To that end, we first introdoce two lemmas the pertain to linearity and the superposition of maximum link loads before proofing Theorem 3.

Lemma 1 *$\mathit{max\,load}(e, \mathbf{M})$ is linear in terms of $\mathbf{M}$, i.e.,*

$$\forall a \geq 0 : a \cdot \mathit{max\,load}(e, \mathbf{M}) = \mathit{max\,load}(e, a \cdot \mathbf{M})$$

Proof. Intuitively, Lemma 1 holds, because scaling the traffic matrix does not affect the worst-case routing state, and thus, the forwarding paths in the worst case and the link loads remain unchanged. More formally, the worst-case routing state is obtained using a set of inequalities over sums of traffic volumes (see Algorithm 1). Scaling each entry in the traffic matrix does not influence these inequalities. The link loads in that routing state are computed by adding individual entries in the matrix, which itself is a linear operation. Thus, *max load* is linear in terms of $\mathbf{M}$. □

Lemma 2 *$\mathit{max\,load}(e, \mathbf{M})$ is equal the superposition of the maximum link loads for all columns of $\mathbf{M}$. In other words,*

$$\mathit{max\,load}(e, \mathbf{M}) = \sum_d \mathit{max\,load}(e, \mathbf{M}_d)$$

Proof. Lemma 2 is intuitively true because the forwarding decision for one destination is independent of the routing state of another destination. In other words, we can tweak the worst-case routing input for destination d_1 independently of d_2 to obtain the maximum load on link e for destinations d_1 and d_2. Then, the load on link e is equal to the sum of all traffic for all individual destinations, including d_1 and d_2. □

Theorem 3 *The approximation error δ of computing the maximum link loads for the approximated traffic matrix $\mathbf{A}$ is bounded by ε. More formally,*

$$\delta = \max_{e \in E} |\mathit{max\,load}(e, \mathbf{M}) - \mathit{max\,load}(e, \mathbf{A})| \leq \varepsilon. \quad (3)$$

Proof. We prove Theorem 3 by considering each individual destination d and its contribution to both the clustering and the approximation error. To that end, we define $\overline{\mathbf{M}}_d$ as the approximation of d's traffic $\mathbf{M}_d$, and express both the approximation error δ and the clustering error ε in terms of $\overline{\mathbf{M}}$.

Since the approximated matrix $\mathbf{A}$ is of a different shape than $\mathbf{M}$, we first describe how to relate the contribution of any destination $d \in c_i$ to its cluster centroid $\mathbf{A}_i$. To that end, we define $\overline{\mathbf{M}}_d = |\mathbf{M}_d| \cdot \mathbf{A}_i / |\mathbf{A}_i|$ as the approximated traffic for destination d. Notice, that the clustering error ε, defined in Equation (2), can be rewritten as:

$$\varepsilon = \frac{1}{2} \sum_{c_i \in C} \sum_{d \in c_i} \left| \mathbf{M}_d - |\mathbf{M}_d| \frac{\mathbf{A}_i}{|\mathbf{A}_i|} \right| = \frac{1}{2} \sum_{d \in P} \left| \mathbf{M}_d - \overline{\mathbf{M}}_d \right|.$$

Further, the maximum link load $\mathit{max\,load}(e, \mathbf{A})$ can expressed in terms of $\overline{\mathbf{M}}$ by relying on the definition of $\mathbf{A}_i$ in Equation (2), and the linearity and decomposition of maximum link loads. We prove both properties in Appendix B.

$$\begin{aligned} \mathit{max\,load}(e, \mathbf{A}) &= \sum_{c_i \in C} \mathit{max\,load}(e, \mathbf{A}_i) \\ &= \sum_{c_i \in C} \sum_{d \in c_i} \mathit{max\,load}(e, \mathbf{A}_i) \cdot |\mathbf{M}_d| \,/\, |\mathbf{A}_i| \\ &= \sum_{d \in P} \mathit{max\,load}(e, \overline{\mathbf{M}}_d) \end{aligned}$$

Now, let's focus on the maximum link load for $\mathbf{M}_d$ and $\overline{\mathbf{M}}_d$ on link e. To that end, we consider traffic x_d^+ that is part in the approximation $\overline{\mathbf{M}}_d$ but not in the original $\mathbf{M}_d$, and traffic x_d^- of $\mathbf{M}_d$ that is not part in $\overline{\mathbf{M}}_d$:

$$x_d^+ = \sum_s \max(0, \overline{\mathbf{M}}_{s,d} - \mathbf{M}_{s,d}) \quad x_d^- = \sum_s \max(0, \mathbf{M}_{s,d} - \overline{\mathbf{M}}_{s,d})$$

Let's first focus on x_d^+, but the argument for x_d^- is symmetrical by swapping $\mathbf{M}$ and $\overline{\mathbf{M}}$. The difference of maximum link loads for $\overline{\mathbf{M}}_d$ and $\mathbf{M}_d$ is at most the additional traffic x_d^+ of $\overline{\mathbf{M}}_d$, i.e., $\mathit{max\,load}(e, \overline{\mathbf{M}}_d) - \mathit{max\,load}(e, \mathbf{M}_d) \leq x_d^+$. That is because $\mathit{max\,load}(e, \mathbf{M}_d)$ by definition is the maximum load achievable on link e, and adding traffic x_d^+ cannot increase that maximum by more than x_d^+. Therefore, $\delta \leq x_d^+$ and $\delta \leq x_d^-$.

Finally, we show that $\sum_d x_d^+ = \sum_d x_d^- = \varepsilon$. This is because, by definition of the L1 norm, $x_d^+ + x_d^- = \left| \overline{\mathbf{M}}_d - \mathbf{M}_d \right|$, and that the centroid $\mathbf{A}_i = \sum_{d \in c_i} \overline{\mathbf{M}}_d$ contains equal positive and negative errors, i.e., $x_d^+ = x_d^-$. This proves Theorem 3. □

C Methodology for Table 1

The following elaborates on the Methodology for Table 1. Specifically, we detail how we find the attraction, repulsion, and friction parameters from a (real or synthetic) traffic matrix, and our processing that was required to obtain the real traffic matrices from aggregated netflow statistics.

C.1 Characterizing a Traffic Matrix

We characterize a traffic matrix according to the three distributions of the gravity model. Specifically, we assume the matrix was generatred from a gravity model, with repulsion, attraction, and friction sampled independently from LogNormal distributions. We then obtain the most likely σ parameter.

To characterize the attraction, we compute the total traffic to each destionation d, normalized to have a mean of 1:

$$\forall d \in P: \ \overline{\mathbf{M}}_d = \frac{|P|}{|\mathbf{M}|} \sum_s \mathbf{M}_{s,d}.$$

We then assume $\{\overline{\mathbf{M}}_d \mid d \in P\} \sim \mathit{LogNormal}(\sigma, \mu = 0)$ to be sampled from a LogNormal distribution with $\mu = 1$ (the expected value in log-space) and find the most likely σ parameter. Similarly, we repeat the same process for the repulsion, but with traffic from each ingress router:

$$\forall s \in N: \ \overline{\mathbf{M}}_s = \frac{|N|}{|\mathbf{M}|} \sum_d \mathbf{M}_{s,d}.$$

For the friction, we use the traffic from each source and to each destination to find the variance for each element in the matrix. In other words, we find find the most likely σ assuming $\{\overline{f}_{s,d} \mid (s,d) \in N \times P\} \sim \mathit{LogNormal}(\sigma, \mu = 0)$ with

$$f_{s,d} = \frac{\mathbf{M}_{s,d}}{\overline{\mathbf{M}}_s \cdot \overline{\mathbf{M}}_d}, \quad \overline{f}_{s,d} = \frac{|N| \cdot |P|}{\sum_{s,d} f_{s,d}} f_{s,d}.$$

By dividing each element $\mathbf{M}_{s,d}$ by the total traffic from source s to destination d, we are left with the variation factor $\mathit{friction}(s,d)$ from the gravity model.

C.2 Real Traffic Matrices

The ISP samples traffic on all links towards external peers and providers, but not on links to their customers. The collected netflow data consists of byte counters aggregated by souce and destination IP addresses (either /24 or /48), and the specific egress link on which the packet was sampled, including its direction (whether it leaves or enters the ISP).

To construct the inter-domain traffic matrix (i.e., byte counters per ingress router and destination prefix), we must associate destination addresses of ingress traffic (and source addresses of egress traffic) to the customer associated with that prefix. Together with the operators, we constructed a mapping from prefixes to customers. Unfortunately, this mapping is neither complete nor unique. Some prefixes are related to multiple customers that did not obtain full /24 or /48 prefixes. Further, some prefixes could not be assigned to customers due to time constraints. This affects around 30% of the total traffic volume[3].

[3] We plan to improve this mapping for the final version.

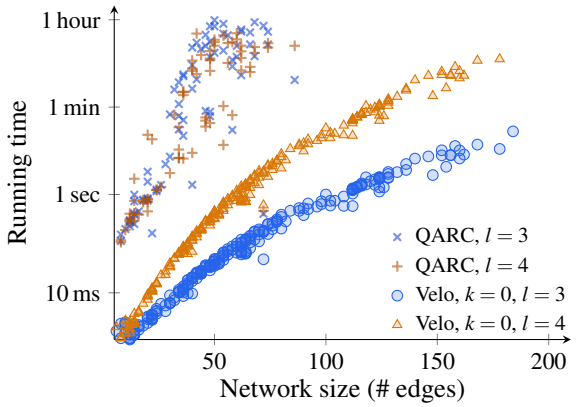

Figure 7: For $l = 3$ and $l = 4$, Velo still outperforms QARC, yet the performance gap decreases.

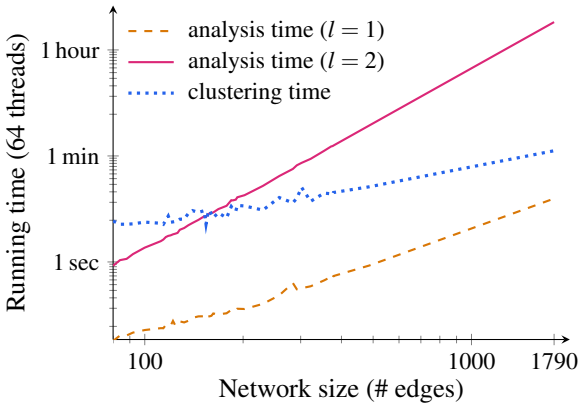

Figure 8: The running time of Velo in terms of the time to perform the clustering and the time to find the worst-case link failures.

The data further allows us to reconstruct the routing state (i.e., the selected egress routers) at time of measurement. For ingress traffic, the traffic is always routed towards the respective customer. For egress traffic, the egress interface on which the traffic is observed is the selected egress point.

D Supplementary evaluation

We provide additional measurements to support §6.

D.1 Comparison with QARC

Figure 7 compares the running time of Velo with QARC for finding worst-case link loads under three and four simultaneous link failures. In 15% of these scenarios, QARC timeouts after running for one hour, while Velo can find the worst-case within 20 minutes for networks up to twice as large.

D.2 Clustering Time vs. Analysis Time

Velo's total running time can be separated into the *clustering time* to find the approximate traffic matrix and the time to find the maximum link loads, which we call the *analysis time*. Figure 8 shows both the clustering and the analysis time for the largest 75 networks on a log-log plot, for both $l = 1$ and $l = 2$. We use the same parameters as described in §6.1. We find that the clustering time dominates the running time for small networks, while it can be neglected for large networks. Further, both the analysis time and the clustering time appear as straight lines in the log-log plot, indicating they scale polynomially in the network size. The analysis time scales roughly quadratically for $l = 1$ and cubic for $l = 2$, as Velo considers $|E|$ additional failure scenarios. Finally, the clustering time scales linearly in the network size which corresponds to the dimensionality of the clustering problem.

Table 2: Velo's accuracy and running time for varying number of clusters

		error bound ε	approx. error δ
$\|C\|$	time	0 **20%**	0 **3%**
100	178 s	16.23%	2.66%
300	210 s	7.34%	0.88%
600	268 s	4.95%	0.39%
1000	343 s	3.71%	0.22%

D.3 Performance–Accuracy Tradeoff

Velo can be configured to an arbitrary number of clusters. Increasing the number of clusters will yield more accurate results at the expense of longer running times, as Algorithm 1 is executed for each cluster.

To evaluate the performance–accuracy tradeoff, we run Velo on the same 6 topologies as in §6.2, choose the traffic matrix using the same baseline distributions, and choose $l = 2$, $k = 10$, and $|N_B| = 30$.

Table 2 shows both Velo's running time and accuracy for 100, 300, 600, and 1 000 clusters. We identify a substantial improvement in accuracy when increasing $|C|$ from 100 to 300, especially in terms of the error bounds. However, increasing $|C|$ to 1000 yields a much smaller accuracy improvement at the expense of a 1.6× increase in running time.

Based on the results in Table 2, we choose $|C|$ as a reasonable tradeoff between accuracy and running time. Yet, the number of clusters can be tuned to the operator's use case to either reduce the running time or improve the accuracy.

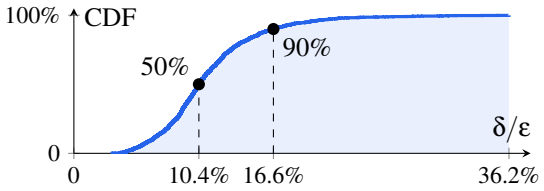

Figure 9: The approximation error δ is typically over $100\times$ smaller than the error bounds ε. This plot shows the CDF of the fraction δ/ε, a measure of how "tight" ε bounds δ.

D.4 Tightness of error bounds.

Table 1 shows that the clustering error ε typically 10 times larger than the approximation error δ. This demonstrates how our error bounds is pessimistic, as it *sums* the absolute values of all the clustering errors as if all the traffic would traverse every single link. In practice, however, differences in a single destination's traffic distribution do not necessarily cause the worst-case routing state for that destination to change. Further, if a few destinations in that cluster have different worst-case routing state, their impact on the resulting load can be both positive or negative, likely canceling each other out.

Figure 9 displays the CDF of the approximation error δ divided by the error bounds ε to visualize how tight the theoretical and real errors are. In 50% of our experiments, the approximation error δ is within 10.4% of the error bounds ε. In 90%, it is within 16.6%.

A Layered Formal Methods Approach to Answering Queue-related Queries

Divya Raghunathan

Princeton University

Aarti Gupta
Princeton University

Abstract

Queue dynamics introduce significant uncertainty in network management tasks such as debugging, performance monitoring, and analysis. Despite numerous queue-monitoring techniques, many networks today continue to collect only per-port packet counts (*e.g.,* using SNMP). Although queue lengths are correlated with packet counts, deriving the precise correlation between them is very challenging since packet counts do not specify many quantities (*e.g.,* packet arrival order) which affect queue lengths.

This paper presents QUASI, a system that can answer many queue-related queries using only coarse-grained per-port packet counts. QUASI checks whether there exists a packet trace that is consistent with the packet counts and satisfies a query. To scale on large problem instances, QUASI relies on a layered approach and on a novel *enqueue-rate* abstraction, which is lossless for the class of queries that QUASI answers. The first layer employs a novel and efficient algorithm that generates a *cover-set* of abstract traces, constructs *representative* abstract traces from the cover-set, and efficiently checks each representative abstract trace by leveraging a known result on $(0,1)$-matrix existence. The first layer guarantees no false negatives: if the first layer says "No", there is no packet trace consistent with the observed packet counts that makes the query true. If it says "Yes", further verification is needed, which the second layer resolves using an SMT solver. As a result, QUASI has no false positives and no false negatives.

Our evaluations show that QUASI is up to 10^6X faster than state-of-the-art, and can answer non-trivial queries about queue metrics (*e.g.,* queue length) using minute-granularity packet counts. Our work is the first step toward more practical formal performance analysis under given measurements.

1 Introduction

Many challenging network management tasks can be reduced to queue-related queries, as queuing delays often represent the most significant source of uncertainty for a packet on its journey [21]. For instance, a network operator can verify a latency Service Level Objective (SLO) for a path by querying the bounds for each queue's length on that path. Similarly, a decision about whether to increase the size of on-chip buffers or whether to allow certain applications to share a switch could be informed by querying how often multiple queues of the same device experience bursts concurrently [1, 2].

While there are various techniques for measuring queue behavior, fine-grained queue monitoring is often costly to collect, store, and analyze, and it may even require specialized hardware [6, 9, 16, 18, 20]. As a result, commodity data centers, ISPs, and enterprise networks often rely on simpler, always-on packet count monitors that track the number of incoming and outgoing packets at each port (*e.g.,* SNMP [7, 12, 19, 23, 25, 26]). These per-port packet counts are highly scalable and are typically collected at coarse-grained intervals, such as every few minutes. They are useful for estimating average utilization and identifying traffic patterns, but the widely held assumption is that they cannot be used for answering queue-related queries.

Upon closer examination, this assumption appears flawed. Per-port packet counts are actually closely correlated with queue lengths and can impose significant constraints on queue dynamics, hence helping answer queue-related queries. For instance, multiple packets are required for a queue to form, and bursts only occur when multiple ports simultaneously send to the same queue (fan-in). Additionally, there should be a limit to the number of concurrent bursts a symmetric device can handle. These observations motivate the question this paper seeks to answer: *Can we answer queue-related queries using only coarse-grained packet counts?*

At first glance, this task appears impossible. The first hurdle lies in the discrepancy between the query metric (queue length) and the available data (per-port packet counts). Although these two are closely related, establishing a closed-form relationship between them is not straightforward. The counts only provide the total number of packets received and sent at each port, without information on their timing, sequences, or routing (i.e., which input port's packet was forwarded to which output port and when). This information defines a *packet trace* and are

crucial for deducing queue lengths. Hence, to answer queries about queue lengths, one would need to consider a vast number of packet traces, identify those consistent with the given per-port counts, and then determine the answer based on these traces. The search space expands significantly as the monitoring interval duration increases. An alternative approach would be to leverage FPerf [4], a system that models network components and their queues in logic, and synthesizes workloads that satisfy a given query. FPerf solves a different performance analysis problem, so we modified FPerf to check if there exists a packet trace consistent with given measurements (specified as constraints over a workload) that satisfies a given query. However, FPerf does not support output and dropped packet count measurements, and quickly becomes unscalable (§7.4).

Layered approach. To navigate the search space of packet traces more efficiently, we have developed a layered approach called QUASI (**Que**ue **A**nalysis from **S**NMP **I**nformation), drawing inspiration from the abstraction-refinement paradigm [10], which has seen tremendous success in the formal methods community [8, 17]. At its core, QUASI provides Boolean answers to queries (*e.g.,* answer yes or no: could this queue have n packets?). QUASI can also handle quantitative queries by running multiple Boolean queries (*e.g.,* to answer: what is the maximum length this queue could have reached?). The first layer of QUASI performs an efficient over-approximate analysis using representations of packet traces as $(0,1)$-matrices, such that a negative result is conclusive and does not require further analysis – we prove that QUASI's first layer will not incorrectly answer a query negatively. If this first layer is inconclusive, QUASI progresses to a second layer that utilizes an exact but less scalable analysis based on use of a Satisfiability Modulo Theories (SMT) solver [5, 11]. This layered strategy allows QUASI to balance efficiency and accuracy, reserving the use of more computationally intensive methods for situations where they are genuinely necessary.

Novel abstraction. QUASI is centered around a novel, powerful, and lossless abstraction that we call *enqueue-rate*. The enqueue-rate abstraction enables QUASI to reason about multiple packet traces simultaneously, thereby improving efficiency without any loss of accuracy. This abstraction is based on the insight that the exact routing of packets between input and output ports is not relevant for answering the queue-related queries supported by QUASI.

Efficient over-approximate analysis. QUASI's first layer leverages the enqueue-rate abstraction and incorporates three key innovations that result in high efficiency. First, QUASI derives necessary conditions from the query, represented as a disjunction of concise representations of sets of abstract traces; each set can be investigated independently or in parallel with others. Second, we show that for each such set of abstract traces, we can construct a special abstract trace — termed the *most-uniform* abstract trace — that serves as a representative of all abstract traces in the set. In particular, we prove that it is enough to check just the representative abstract trace for each set. Finally, we show that we can efficiently check each representative abstract trace using a known result from combinatorics, specifically the Gale-Ryser theorem [13, 24].

Exact Analysis. QUASI's second layer also uses the enqueue-rate abstraction, using an SMT solver to precisely model the *exact* (rather than necessary) conditions for an abstract trace to be consistent with the given measurements and the query.

Summary of results. We evaluate QUASI on simulated data and compare it against a heuristic baseline and FPerf [4] on a variety of queries (both Boolean and quantitative). Our results show that QUASI is useful: QUASI's first layer finds upper bounds on maximum queue length and buffer occupancy up to 58% tighter than bounds found by a heuristic analysis within one second; QUASI's second layer finds the exact value in 25 minutes. QUASI is 10^6x faster than FPerf and supports an important class of burst-related queries that FPerf does not support. QUASI scales to realistic monitoring intervals (5 mins/300 million time steps) for queue length queries.

2 Motivation

In this section, we start by describing use cases that showcase the usefulness of provably answering queue-related queries, especially when done with coarse-grained per-port packet count measurements. Then, we explain the shortcomings of existing approaches to measuring and inferring queue dynamics.

2.1 Why are Queue-related Queries Useful?

Having visibility on queue lengths in a network (through direct or indirect measurements) is critical for multiple network management tasks. We discuss use cases related to root-cause analysis, provisioning, and performance guarantees.

First, visibility over queue lengths makes debugging network incidents easier. Consider, for example, an operator debugging an incident of packet drops on a particular network device. The operator would benefit from learning whether the drops could have been caused by buffer pressure (*i.e.,* excessive buffering on ports distinct from the one dropping), or whether they could have been from a bursty application. The operator could learn this by looking at the queue-length time series of each queue on the device. Yet access to such data via monitoring alone would require an always-on tool that monitors all queues of all devices at a millisecond (at least) granularity. Considering the cost, a tool that would *provably* answer at least some such queries using cheap coarse-grained packet counts would be useful.

Second, visibility over queue lengths simplifies network planning. Consider an operator that aims to place applications in their network avoiding bursty applications sharing the same device, or an operator investigating whether they need to upgrade on-device buffers. Observe that such a query needs to run over historical queue length data spanning a good amount

of time to contain various applications. Even if these data were collected in the past at ms granularity, it is unlikely that they would be currently available. Hence, a tool that would "piggyback" queries about queues on coarse-grained packet counts that are used for other tasks (*e.g.,* predicting utilization, traffic matrices) and hence are more likely to be available, would be very useful.

Finally, answering queue-related queries could be useful for verification. Queue management in high-speed switches involves intricate mechanisms for flow control across multiple queues on different ports. Implementation errors by equipment manufacturers can result in counterintuitive outcomes, such as high packet loss and delays even during periods of low link utilization. Investigating whether the device's working is consistent with the specification is very challenging. Accurate and fine-grained queue length monitoring would be useful but might not be reliable. Hence, it would help to cross-check those measurements with coarse-grained packet counts. In this case, a tool that can provably answer queries about what queue length values are possible given the packet counts would be useful.

2.2 Limitations of Inferring Queue Lengths

Directly measuring and storing queue lengths at a fine-grained granularity (e.g., nanosecond level) in an always-on manner is impractical [15], leading to the development of various inference methods such as Zoom2Net [15] and SIMON [14]. While these methods are innovative in that they do not require additional resources or hardware, they lack correctness guarantees. For example, Zoom2Net generates fine-grained telemetry guaranteed to satisfy selected constraints enforcing consistency with coarse-grained measurements and switch operation. However, these constraints are not sufficient, so the generated fine-grained telemetry might be impossible in practice. Also, it cannot prove, *e.g.,* that a certain queue length could not have occurred. This limitation becomes particularly problematic when an operator needs to understand the worst-case scenario or is concerned about a specific set of scenarios with some property. Consider an operator troubleshooting an incident of increased end-to-end latency: knowing the worst-case queuing delay for each device on-path (or that the delay has not exceeded some threshold) would help her safely narrow down the search to a smaller set of devices. However, if the inferred queueing delay is an underestimate, it can mislead the operator, complicating the debugging process. Beyond these limitations, both works assume access to coarse-grained measurements of queue length/delay. Zoom2Net considers periodic and maximum queue lengths (along with packet counts), and SIMON assumes end-to-end queueing delay.

3 Overview of QUASI

After formally defining our problem (§3.1), we introduce a running toy example that shows how leveraging coarse-grained packet counts can be useful in deducing queue dynamics

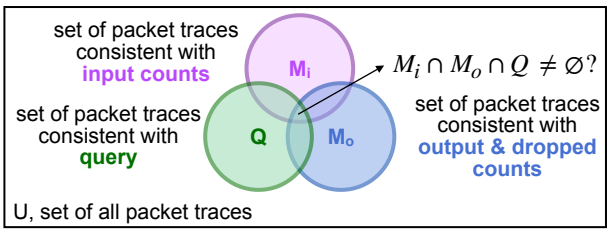

Figure 1: We recast the problem of answering a queue-related query under given measurements into the problem of checking whether the intersection of M_i, M_o, and Q is non-empty.

(§3.2). More importantly, the example showcases that even in such a seemingly simple example, answering a queue-related query is nontrivial. We use this example to illustrate the key steps in how QUASI answers queue-related queries in §4.4, after we have introduced key concepts in §4.3.

3.1 Problem Definition

We are given packet counts of received (input), sent (output), and dropped packets for each port of a switch, aggregated over a monitoring interval. We are also given a query describing an incident/property or value depending on one or more queues during the interval which can be answered positively or negatively.

Goal. Our goal is to build a system that can answer positively if there exists some sequence of packets (called a *packet trace*) which, if arrived at the switch during the interval, would be consistent with input, output, and dropped counts, and would satisfy the query. The system should answer negatively if such a packet trace does not exist. The exact syntax of the query language is shown in Fig. 4 (§4.2).

More concretely, we formulate the problem of answering a queue-related query as determining whether the intersection of three sets is non-empty, as shown in Fig. 1:

M_i : set of all packet traces consistent with the per-port input counts of all ports of a switch.

M_o : set of all packet traces consistent with the per-port output and dropped counts of all ports of a switch.

Q : set of all packet traces that make the query true.

There exists a packet trace consistent with the measurements that makes the query true if and only if $M_i \cap M_o \cap Q \neq \emptyset$.

3.2 Motivating Example

Consider a cloud operator who receives a complaint from a customer claiming that the latency between her silicon servers violated the service level objective (SLO) at some point between 9 am and 10 am on a given day. Since the customer's servers are connected through a single switch (shown in Fig. 2), the operator deduces that the only way the cloud provider might be liable is if the queueing latency at the switch exceeded a threshold close to the SLO during that time. Consider that the operator lacks access to fine-grained queue-length measurements, either because the hardware

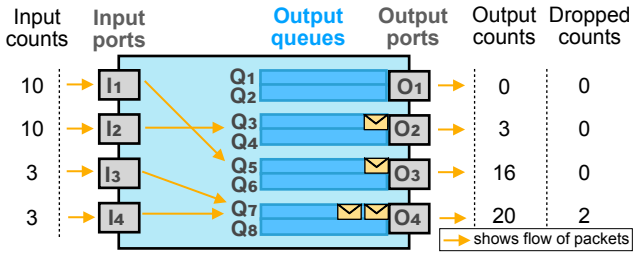

Figure 2: Output-queued switch with per-port packet counts.

does not support such fine-grained monitoring or because collecting and storing these measurements is only available on-demand due to its high cost. Instead, the operator has access to SNMP [12] packet counts *i.e.,* per-port packet counts aggregated over a monitoring interval of 20 time steps, where each time step represents either a packet received or sent.[1]

Fig. 2 shows an output-queued switch with 4 ports. Packets are received through input ports, forwarded to output queues, and sent through output ports. Each port receives/sends at most one packet in a time step, and multiple input ports can simultaneously forward packets to the same output queue. We assume packet forwarding takes negligible time. Packets are dropped if the destined queue is at its maximum size (10 packets in our example). Fig. 2 shows per-port input, output, and dropped counts, *i.e.,* the number of packets received, sent, and dropped respectively during a single interval of 20 time steps. Note that queues could store packets at the start of the monitoring interval, so the total count of sent and dropped packets can exceed the total count of received packets. The operator's query is: "Could port O_2's queues have a combined queue length of 7 packets at any time during this interval?" The operator would need to ask this query for every interval between 9 and 10 am. Next, we focus on the query for a single interval. The query is expressed in our query language as

$$\exists t \in [0,T].\ \sum_{q \in O_2} qlen(q,t) \geq 7 \qquad (1)$$

A naive observer would answer the query positively. If one were to consider port O_2 in isolation from the rest of the ports, one might think that there is a packet trace which results in a queue length of 7 packets and is consistent with its packet counts during the interval. Fig. 5 shows such a packet trace P_1, represented as a 2-D matrix with $P_1[q][t]$ showing the packets enqueued at queue q at time t, with packet colors denoting the input port each packet came from; blank entries denote no packets enqueued.

In this packet trace, O_2 receives no packets until the last 3 time steps, when it receives a sequence of 4, 4, and 2 packets. This causes the queue length to increase by 3, 3 and 1 in each time step since the port dequeues one packet per time step and the remaining packets are queued. Assuming port O_2 is initially empty, at the end of the interval, it has $3+3+1=7$ packets queued, satisfying the query. In addition, since O_2 receives packets only in the last 3 time steps, it dequeues a total of 3 packets during the interval, matching its sent count. Since port O_2 never reaches the maximum queue size of 10, it does not drop any packets, thereby matching its dropped count. However, this naive reasoning is erroneous.

[1] we have scaled down the interval to make the example easier to follow, but we have evaluated QUASI on an interval with 300 million time steps (§7.1).

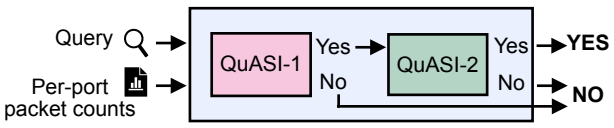

Figure 3: QUASI architecture.

The correct answer to the query is negative. In fact, there is no packet trace consistent with the observed measurements that will make the query true, *i.e.,* O_2's queue length is always less than 7 during the monitoring interval. The reason that the correct answer is negative though it appears positive at first glance is that the packet counts of other ports constrain the number of packets that could have been enqueued at O_2.

At a high level, answering queue-related queries is challenging because the queries involve quantities that are not directly measured and cannot be inferred by a simple analysis of the measurements. While a query metric (*e.g.,* queue length) is correlated with measured signals (packet counts) it also depends on information absent in packet counts, namely on the arrival sequence of packets entering the switch, and to which output queue each packet is forwarded.[2] This information is present in a packet trace, which specifies which port's packet was forwarded to which port and when. However, a huge number of packet traces could be consistent with given packet counts, and reasoning about all these packet traces is computationally expensive.

4 QUASI Design

This section describes the key concepts QUASI relies on and demonstrates their usefulness on the running example (§3.2).

4.1 QUASI's Layered Architecture

Due to the scalability limitations of an exact analysis, we use a layered approach consisting of two layers, QUASI-1 and QUASI-2, as shown in Fig. 3. QUASI-1 is a fast, over-approximate analysis which is guaranteed to never report a false negative. Hence, if QUASI-1 answers "No", QUASI reports "No" and terminates. If QUASI-1 answers "Yes", it could be a false positive, so the analysis proceeds to QUASI-2 which is a more expensive, exact analysis that reports the correct answer. QUASI's first layer is accurate enough to conclusively answer non-trivial queries in a fraction of a second, as we demonstrate in the evaluations (§7). By running the more expensive

[2] For context, Zoom2Net [15] does not deal with this challenge – it assumes there is a coarse-grained version of the signal of interest.

$$
\begin{aligned}
query &::= \{\exists|\forall\}\ t \in [T_1, T_2].\ cmp \\
cmp &::= lhs\ ?\ rhs \mid \bigwedge lhs\ ?\ rhs \\
lhs &::= \{\exists|\forall\} q \in Qs.\ m(q,t) \mid \textstyle\sum_{q\in Qs} m(q,t) \\
&\quad \mid m(Q_1,t) - m(Q_2,t) \\
m(q,t) &::= enq(q,t) \mid cenq(q,t) \mid qlen(q,t) \\
rhs &::= K \mid K.t
\end{aligned}
$$

Figure 4: Query language. T_1, T_2, K are constants, ? denotes a comparison operator, and Q_1, Q_2 denote queues in a switch.

second layer only on queries that cannot be answered conclusively by the fast first layer, QUASI can scale to *tens of thousands* of time steps. This is well beyond the capabilities of existing tools [4], which take several hours even for 10 time steps.

4.2 Query Language

A query in QUASI is a comparison (or conjunction of comparisons) involving a metric over one or more queues in a switch; Fig. 4 shows the syntax. We consider metrics (1) $enq(q,t)$: number of packets received by queue q at time step t, (2) $cenq(q,t)$: total number of packets received by queue q until time step t, and (3) $qlen(q,t)$: queue length (in packets) at queue q at time step t. Queries allow quantification over (bounded) time steps as well as queues. Our query language is expressive enough to allow interesting questions related to bursts, queue lengths, and buffer occupancy, including some queries that FPerf [4] does not support, *e.g.,* the Burst query used in our evaluation (§7). Our query language can be extended with interfaces to languages like Python or SQL to make it easier to use for operators unfamiliar with logic.

QUASI currently supports single-switch queries, but can also be used to answer some queries over multiple switches. For example, we can find the maximum queueing latency along a given network path using QUASI to find the maximum queueing latency at individual switches on the path and adding up these values. Using only QUASI-1, the answer will be an upper bound on the maximum latency along the path while QUASI-2 will report the true maximum latency.

4.3 Key Concepts

We present key concepts required to understand our approach.

Packet trace. A packet trace P is a $N_q \times T \times N$ $(0,1)$-matrix with entry $P[q][t][i]$ equal to 1 if input port i forwards a packet to queue q at time step t, and 0 otherwise. N denotes the number of switch input ports, N_q denotes the total number of output queues, and T denotes the number of time steps in the monitoring interval. Fig. 5 shows packet trace P_1 as a 2-D matrix with packet color denoting the input port it came from; blank entries are 0.

Enqueue-rate abstraction. We target queries that do not distinguish between packets in a queue based on their origin input ports. Thus, it is safe to ignore input port information in a packet trace. Our enqueue-rate abstraction defines an *abstract* packet trace that represents the *enqueue-rate*, the number of packets enqueued to each queue at each time step, ignoring the input port each packet came from. An abstract trace represents a set of packet traces, one packet trace for each labelling of packets with input ports. QUASI-2 uses the enqueue-rate abstraction to reduce the number of variables in its SMT formulation without any loss of precision due to abstraction, since our query language (Fig. 4) treats all packets in a queue as identical.

Abstract trace. An abstract trace A is a $N_q \times T$ matrix with entry $A[q][t]$ denoting the number of packets enqueued to queue q at time step t. An abstract trace represents a set of packet traces. We say packet trace P is "contained" in A iff $\forall q, t.\ \sum_{1\le i\le N} P[q][t][i] = A[q][t]$. Fig. 5 shows an abstract trace A_1 which contains both packet traces P_1 and P_2, which differ in the input ports of some packets but have the same number of packets enqueued at each queue at each time step.

Cover-set F_C. In QUASI-1, we use the enqueue-rate abstraction at a coarser granularity than in QUASI-2. The first module of QUASI-1 generates a cover-set $F_C = F_C^1 \vee \ldots \vee F_C^k$, a finite disjunction of *components* $F_C^1, \ldots, F_C^k$, formulas representing *sets* of abstract traces. Each component F_C^j is a conjunction of constraints involving enqueue-rate (enq); we do not enumerate the abstract traces satisfying F_C^j. A cover-set represents all packet traces consistent with the query and output counts and dropped counts, *i.e.,* $M_o \cap Q \subseteq C$, where C denotes the set of packet traces satisfying the cover-set formula F_C. Fig. 5 shows the cover-set that QUASI generates for our motivating example; it has only one component F_C^1 (*i.e.,* $k=1$).

Representative abstract trace. Each (non-empty) component F_C^j in a cover-set F_C has a representative abstract trace R_j that is "most-uniform" in the set of abstract traces C_j satisfying F_C^j. We prove that if R_j does not contain a (concrete) packet trace consistent with input counts, then the entire C_j has no packet trace consistent with input counts (Theorem 5.3). Representative abstract traces provide a correctness-preserving *reduction* in the search space: it is enough to consider only the representative R_j in each component. The second module of QUASI-1, MUC *constructs* a representative abstract trace R_j for a given F_C^j. For our motivating example, Fig. 5 shows the representative abstract trace R_1 for F_C^1.

Abstract trace consistency. We say abstract trace A is consistent with input counts (or is *input-consistent*) if there exists a labeling function Lbl that maps each packet in A to an input port such that: (1) packets at the same time step are assigned different input ports (an input port can forward at most one packet in a time step), and (2) each input port label i is used exactly $rcv[i]$ times, where $rcv[i]$ is port i's input count. We efficiently check input-consistency of each representative abstract trace by reducing it to checking the existence of a $(0,1)$-matrix with given row sums and column sums (Theorem 5.4) and using a known combinatorics result (Gale-Ryser theorem [13, 24]).

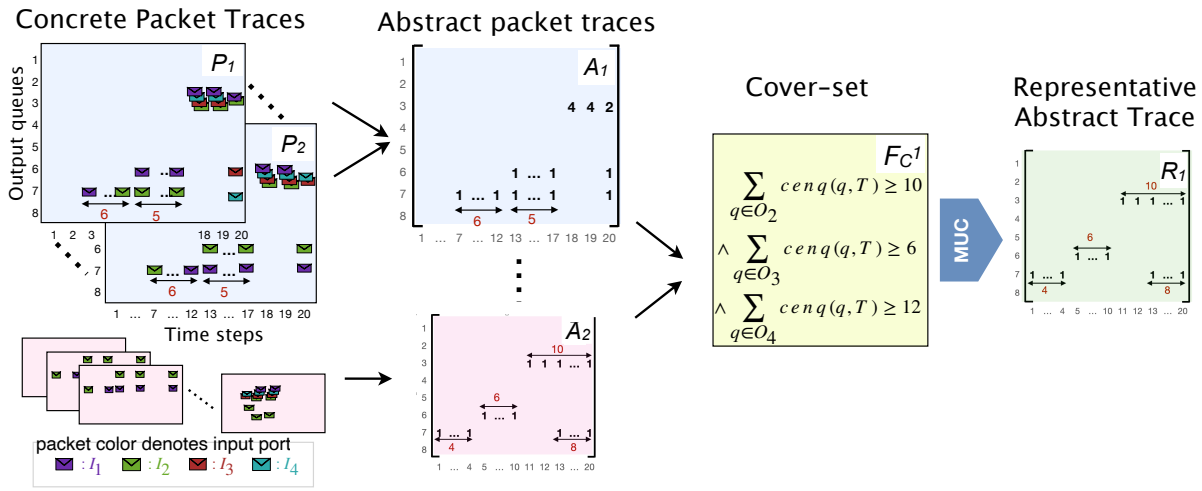

Figure 5: Multiple concrete packet traces (*e.g.,* P_1 and P_2) are mapped through the enqueue-rate abstraction to an abstract trace (*e.g.,* A_1). Multiple abstract traces (*e.g.,* A_1 and A_2) are represented by a cover-set (*e.g.,* F_C^1 with number of components $k=1$). The MUC constructs a most-uniform abstract trace which can be used as a representative in F_C^1 for checking input-consistency. For their analysis, QUASI-1 uses cover-sets and representative abstract traces, while QUASI-2 uses abstract traces.

4.4 QUASI on Motivating Example

We illustrate the key steps of QUASI on our motivating example (§3.2). While QUASI is composed of two layers, it reaches a conclusive negative answer already at the first layer, which is guaranteed to be correct. QUASI's first layer generates a formula F_C (the cover-set) that represents a set C containing all packet traces consistent with output counts, dropped counts, and the query, *i.e.,* $M_o \cap Q \subseteq C$.

$$F_C = \sum_{q \in O_2} cenq(q,T) \geq 10 \wedge \sum_{q \in O_3} cenq(q,T) \geq 6 \wedge \sum_{q \in O_4} cenq(q,T) \geq 12 \quad (2)$$

Eqn. (2) shows F_C in terms of the cumulative enqueue-rate $cenq(q,t)$, the number of packets enqueued at a queue q until time step t. F_C states that during the monitoring interval, output port O_2 must receive at least 10 packets, output port O_3 must receive at least 6 packets and output port O_4 must receive at least 12 packets.

Next, QUASI needs to determine whether each component F_C^i in F_C is consistent with input counts (here, $F_C = F_C^1$ with $k=1$), *i.e.,* whether $F_C^1 \cap M_i = \emptyset$. Note that F_C^1 itself represents a large set of packet traces, so checking each individual packet trace is impractical. QUASI constructs one representative abstract trace, denoted R_1, which satisfies F_C^1. R_1 specifies the number of packets enqueued over time at each queue (or each port, depending on the query). We prove that it suffices to check *only* R_1 for consistency with input counts: if R_1 does not contain a packet trace that is input-consistent, then no other abstract trace satisfying F_C^1 will contain a packet trace that is input-consistent (Theorem 5.3). Fig. 5 shows R_1 for our example.

To check R_1 for consistency with input counts, QUASI first checks if the total number of packets in R_1 exceeds the total number of packets received by the switch. If yes, R_1 is inconsistent with input counts; otherwise, QUASI proceeds to run an efficient matrix-based consistency check. For our example, the total number of packets in R_1 is 28, which is more than the total number of packets received (26). Hence, QUASI answers the query negatively, which is the correct answer for this example.

5 QUASI: Layer 1

QUASI-1 consists of three modules (Fig. 6):

1. **Cover-set generator (CSG)** generates a cover-set $F_C = F_C^1 \vee \ldots \vee F_C^k$ which represents all packet traces consistent with output and dropped counts that make the query true, *i.e.,* $M_o \cap Q \subseteq C$, where C denotes the set of packet traces satisfying F_C. Fig. 6 shows C with $k=4$ as a yellow circle superimposed on a Venn diagram showing the sets M_i, M_o, and Q from our problem formulation (§3.1).
2. **Most-uniform Abstract Trace Constructor (MUC)** constructs a representative abstract trace R_j (shown as a small red square in Fig. 6) that is *most-uniform* for each component F_C^j. We prove that it is enough to check *only* each R_j for consistency with input counts (Theorem 5.3).
3. **Matrix-based Consistency Checker (MCC)** determines whether a given representative abstract trace contains a packet trace that is input-consistent, *i.e.,* whether R_j intersects with M_i. We reduce this problem to checking the existence of a $(0,1)$-matrix with given row sums and column sums (Theorem 5.4) and use the Gale-Ryser theorem [13, 24] to solve it efficiently.

If some representative abstract trace R_j is found to be consistent with input counts, QUASI-1 answers the query positively. QUASI-1 answers the query negatively if every R_j is inconsistent with input counts.

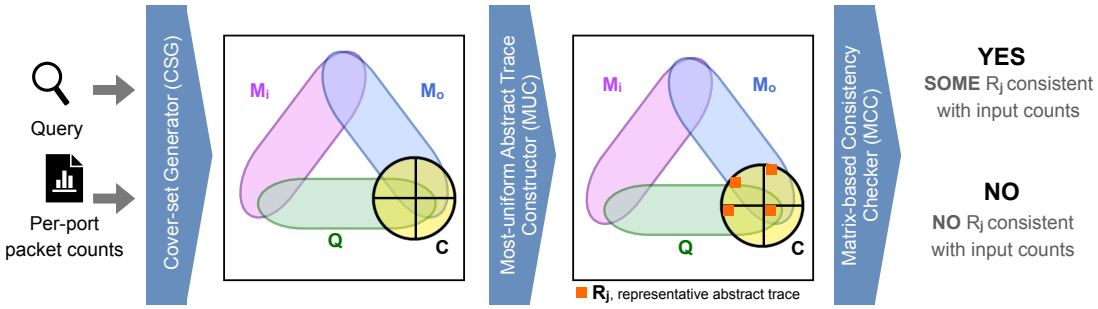

Figure 6: QUASI-1 design: (1) CSG generates a cover-set formula F_C representing a set $C = C_1 \cup ... \cup C_4$, with $C \supseteq M_o \cap Q$, (2) MUC constructs a representative R_j for each C_j, (3) MCC checks if $R_j \cap M_i = \emptyset$ for each R_j; if true, QUASI-1 reports "No", otherwise "Yes".

Theorem 5.1 (QUASI-1 correctness)**.** *If* QUASI-*1 answers a query negatively, there is no packet trace consistent with the measurements that makes the query true,* i.e., QUASI-*1 will never report a false negative.*

Proof. Assume QUASI-1 answers a query Q negatively. This means the MCC determined that each representative abstract trace R_j (for C_j) does not contain a packet trace that is consistent with input counts, *i.e.,* $R_j \cap M_i = \emptyset$. For each C_j, by Theorem 5.3, no other abstract trace in C_j is consistent with input counts, *i.e.,* $C_j \cap M_i = \emptyset$. Hence, there is no packet trace in $C = C_1 \cup ... \cup C_k$ which is consistent with input counts, *i.e.,* $C \cap M_i = \emptyset$. By Lemma 5.2, C contains all packet traces consistent with output and dropped counts that make the query true, *i.e.,* $M_o \cap Q \subseteq C$. Since $C \cap M_i = \emptyset$, it follows that $M_o \cap Q \cap M_i = \emptyset$. Hence, there exists no packet trace consistent with the measurements that makes the query true. □

Our proof depends on Lemma 5.2 and Theorem 5.3 – these are discussed in the related subsections.

False positives. If QUASI-1 answers a query positively, it is possible that no trace exists which is consistent with the measurements and query. This is because the cover-set generated by the CSG is an *over-approximation*, *i.e.,* it could include additional packet traces not consistent with output and dropped counts and/or the query. If one of these extra packet traces is consistent with input counts then QUASI-1 could incorrectly answer the query positively.

5.1 Generating a Cover-set

The CSG constructs symbolic representations (as formulas) of two sets: (1) Q', which contains all packet traces satisfying the query ($Q \subseteq Q'$) and (2) M'_o, which contains all packet traces consistent with output and dropped counts (*i.e.,* $M_o \subseteq M'_o$). It returns $F_C = F_C^1 \vee ... \vee F_C^k$, obtained by performing standard syntactical transformations on the formula for $M'_o \cap Q'$.

M'_o, necessary conditions for consistency with output and dropped counts. Each output port O_i must receive a minimum number of packets (across all its output queues) during the monitoring interval to be consistent with its output count (deq_i) and dropped count (drp_i).

$$\forall 1 \le i \le N. \sum_{q \in O_i} cenq(q,T) \ge deq_i + drp_i - ilen_ub_i \quad (3)$$

$ilen_ub_i$ is an upper bound on $ilen_i$, the number of packets queued at port O_i at the start of the interval. Note that $ilen_ub_i \le deq_i$ otherwise port O_i would dequeue more than its output count. Also, $ilen_ub_i \le L$, the maximum number of packets that can be queued at a port. Hence, we set $ilen_ub_i = min(L, deq_i)$. We can improve this bound further depending on the query, *e.g.,* if the query asks if the queue length can be always below some K.

Equation (3) is obtained from conservation of packets at an output port, assuming that output and dropped counts hold. By conservation of packets, the number of packets queued in the port at the end of the monitoring interval ($flen_i$) is equal to the difference between the number of packets received (or were queued initially) at the port during the interval and the number of packets that left the port (or were dropped) during the interval. Formally,

$$flen_i = ilen_i + cenq(O_i,T) - cdeq(O_i,T) - cdrp(O_i,T) \quad (4)$$

where $cenq(O_i, T)$, $cdeq(O_i, T)$ and $cdrp(O_i, T)$ denote the total number of packets enqueued, dequeued, and dropped respectively at port O_i from time step 0 until T. By consistency with output counts, $cdeq(O_i, T) = deq_i$; by consistency with dropped counts, $cdrp(O_i, T) = drop_i$. Using $flen_i \ge 0$ and rearranging, we get $cenq(O_i,T) \ge deq_i + drp_i - ilen_i \ge deq_i + drp_i - ilen_ub_i$. Observing that $cenq(O_i,T) = \sum_{q \in O_i} cenq(q,T)$, we get eqn. (3).

Q', necessary conditions to satisfy query.

Case 1: Query metric is *enq* or *cenq*. For queries involving the metrics enqueue-rate (*enq*) or cumulative enqueue-rate (*cenq*) the query Q is translated into an equivalent quantifier-free formula by eliminating quantifiers over queues and time steps to get Q', which is semantically equivalent to Q. Existential quantifiers are eliminated using disjunctions and universal quantifiers are eliminated using conjunctions.

Case 2: Query metric is *qlen*. Our necessary conditions need to use a different metric (*enq* or *cenq*) from the metric in

the query, so we cannot obtain Q' just by eliminating quantifiers as in the previous case. To relate queue length to enqueue-rate, we use conservation of packets (5) at the queue(s) in the query, setting $qlen(q,t)$ to an appropriate value depending on the query. We explain how we construct our necessary conditions for the query $QgeK : \exists t \in [st,end].qlen(q,t) \geq K$ which asks if queue q can have at least $K > 0$ packets at some time step $t \in [st,end]$; other queries are handled similarly.

By conservation of packets, the number of packets in the queue at time step t ($qlen(q,t)$) is equal to the difference between the number of packets received (or were queued initially) at the queue and the number of packets that left the queue (or were dropped) until t:

$$qlen(q,t) = il(q) + cenq(q,t) - cdeq(q,t) - cdrp(q,t) \quad (5)$$

where $il(q)$ denotes the number of packets in the queue at the start of the monitoring interval; and $cenq(q,t)$, $cdeq(q,t)$, $cdrp(q,t)$ denote the number of packets enqueued, dequeued, and dropped, respectively, at queue q from time step 0 until t. For the query to be true, $qlen(q,t) \geq K$ for some $t \in [st,end]$; substituting this in eqn. (5) we get

$$il(q) + cenq(q,t) - cdeq(q,t) - cdrp(q,t) \geq K$$
$$cenq(q,t) \geq K - il(q) + cdeq(q,t) + cdrp(q,t)$$

We replace each term on the right-hand-side by a lower/upper bound as appropriate: an upper bound for $il(q)$, and lower bounds for $cdeq(q,t)$ and $cdrp(q,t)$.

Upper bound on initial queue length. Note that $il(q) \leq L_q$, the maximum queue size. In some cases, we impose further constraints on the initial queue length to ensure consistency with the output count deq for q's port. For example, when $deq < T$, the number of time steps in the interval, and the output port has a single queue, the initial queue length must not exceed deq. Otherwise, the queue would dequeue more than deq packets, conflicting with the observed output count.

Lower bound on number of packets dequeued until t. We calculate the minimum number of packets that q will dequeue until t, assuming the query is true. For our example query $QgeK$ to be true, queue length at t must be at least $K > 0$. Depending on the value of K, the queue length must be non-zero for some minimum number of time steps $nz(K)$ before t, during which time it will dequeue at its minimum dequeue rate mdr. Hence, $cdeq(q,t) \geq nz(K) * mdr$. We calculate $nz(K)$ assuming the queue receives packets at the maximum possible rate (according to the input packet counts) for as long as possible until it reaches a queue length of K. We consider two (exhaustive) cases to determine the initial queue length (1) queue has a packet to send at every time step before t (queue length must become at least K at t starting from the maximum possible value of $il(q)$) and (2) queue has no packet to send at some time step before t (in this case, queue length must become at least K at t starting from a queue length of zero.)

Lower bound on number of packets dropped until t. We use $cdrp(q,t) \geq 0$. We use a tighter lower bound if the query specifies $st = end = T$ (which makes $t = T$) and queue q is the only queue in its port; then, $cdrp(q,T) = drp_i$, where drp_i is the dropped packet count for q's port.

Lemma 5.2 (CSG correctness)**.** *CSG returns a formula F_C representing a set C that contains all packet traces consistent with the query, output counts, and dropped counts,* i.e., $M_o \cap Q \subseteq C$.

Proof sketch. The set C represented by formula F_C is equivalent to $M'_o \cap Q'$ (by construction). M'_o is obtained from the packet conservation equation (4) assuming consistency with output and dropped counts, so any packet trace consistent with output and dropped counts will satisfy M'_o, *i.e.,* $M_o \subseteq M'_o$. For queries over *enq* or *cenq* metrics, Q' is obtained by eliminating quantifiers in the query Q to obtain an equivalent formula, so $Q' = Q$ in this case. For queries over $qlen$, Q' is derived starting from the packet conservation equation (5) (which is true for all packet traces) and enforcing bounds on terms assuming that the query is true. Hence, any trace that satisfies the query will also satisfy Q'. For all three metrics, $Q \subseteq Q'$. Since $M_o \subseteq M'_o$ and $Q \subseteq Q'$ it follows that $M_o \cap Q \subseteq M'_o \cap Q'$, so $M_o \cap Q \subseteq C$.

5.2 Computing Representative Abstract Traces

For each component F_C^j in the cover-set $F_C = F_C^1 \vee ... \vee F_C^k$ generated by the CSG, the MUC constructs a representative abstract trace R_j that satisfies F_C^j.

Representative is most-uniform. We characterize a representative abstract trace R_j satisfying F_C^j as being "most-uniform" among all abstract traces satisfying F_C^j. A most-uniform abstract trace has packets in columns of lowest possible *height* subject to satisfying F_C^j, where height of a column denotes the sum of its entries. Formally, for all $i \geq 1$, the total height of the i highest columns in R_j must be no more that the total height of the i highest columns in an arbitrary abstract trace A satisfying F_C^j.

Algorithm 2 (shown in Appendix A) takes as input F_C^j, a conjunction of constraints of three types: LB ($enq(q,t) \geq lb$), CLB ($cenq(q,t) \geq lb$), and CUB ($cenq(q,t) \leq ub$). It constructs an abstract trace R_j that is most-uniform by starting with the null matrix (with all entries 0) and incrementing appropriate matrix entries in order to satisfy the constraints. The procedure can be thought of as placing packets at appropriate time steps and queues in order to satisfy the given constraints. Importantly, the algorithm places each packet in a time step with lowest height (*i.e.,*, with minimum number of packets in total across all output queues) subject to upper bound constraints. This allocation strategy prioritizes placing packets in time steps that have few packets, making the resultant arrangement as uniform as possible subject to satisfying the given constraints.

Theorem 5.3 (Reduction via representative abstract trace)**.** *If the representative abstract trace R_j of a component F_C is not input-consistent, then every abstract trace A satisfying F_C^j is not input-consistent.*

Proof sketch. Consider an arbitrary A satisfying F_C^j. We show that if A is consistent with input counts then the output of Algorithm 2, R_j, must be consistent with input counts. Since A is consistent with input counts, by the definition of input-consistency, there exists some labeling function mapping each packet in A to an input port such that each input port i is used exactly $rcv[i]$ times (where rcv denotes the input packet counts) and packets at the same time step in A are mapped to different input ports. We show that is possible to transform A to R_j by shifting packets from one time step to another so that packets at the same time step continue to be mapped to different input ports after each shift. After performing all these shifts to reach R_j, the labels of packets in R_j will be a valid labeling; hence, R_j is consistent with input counts. The full proof is in Appendix B.

5.3 Checking Consistency with Input Counts

The Matrix-based Consistency Checker (MCC) checks if a given representative abstract trace R_j contains a packet trace that is consistent with input packet counts rcv. Recall that an abstract trace does not specify the input port each packet came from, and represents a set of packet traces, one packet trace for each labeling of packets with input ports.

There could be a huge number of possible labelings of packets in an abstract trace so it is impractical to iterate through all labelings to check if one is consistent with input counts. Constraint solving approaches will also have scalability limitations due to the large search space of labelings.

Reduction to $(0,1)$-matrix existence. We reduce the problem of determining if an abstract trace R_j contains a packet trace consistent with input counts to checking the existence of a $(0,1)$-matrix with given row sums and column sums. We leverage a known combinatorics result (the Gale-Ryser theorem [13, 24]) on matrix existence to solve it efficiently. The idea behind this reduction is that an abstract trace can be equivalently represented as a $(0,1)$-matrix with a row for each input port and a column for each time step. The given abstract trace R_j fixes the sum of each column and the input counts rcv fix the sum of each row of this $(0,1)$-matrix. R_j is consistent with input counts iff such a $(0,1)$-matrix exists for input counts rcv. We prove this in Appendix C.

Theorem 5.4 (Abstract Trace Consistency)**.** *An abstract trace R_j ($N_q \times T$ matrix) is consistent with input counts rcv iff There exists an $N \times T$ $(0,1)$-matrix X s.t.*

$$\forall i.\ rsum(X,i) = rcv[i] \text{ and } \forall t.\ csum(X,t) = csum(R_j,t)$$

where $rsum(X,\ i)$ and $csum(X,\ t)$ denote the sum of entries in row i and column t respectively of matrix X.

Algorithm 1 checks input-consistency of an abstract trace using the Gale-Ryser theorem [13, 24]. The Gale-Ryser theorem [13, 24] states that there exists a $(0,1)$-matrix with column sums c and row sums r, where c and r are partitions of a positive integer, if and only if r is dominated by c', where c' is the conjugate partition [3] of c.

Algorithm 1: Matrix-based consistency check

Input : R_j, abstract trace ($N_q \times T$ matrix)
rcv, input counts ($1 \times N$ matrix)
Output : True iff R_j has a packet trace satisfying rcv

```
1  Function check_consistency(R_j, rcv):
2      rt : 1 × T // Aggregate rate of R_j
3      for t = 0; t < T; t++ do
4          rt[t] ← Σ_{q∈N_q} R_j[q][t] // column sums
5      rt.sort(); rcv.sort()// descending
6      return matrix_exist(rcv, rt)
7  Function matrix_exist(r, c):
8      rsums[0] = r[0]// cumulative row sums
9      for i = 0; i < r.size(); i++ do
10         rsums[i] = rsums[i−1] + r[i]
11     c' ← conj(c)// conjugate partition of c
12     csums[0] = c'[0] // cumulative sums of c'
13     for i = 0; i < c'.size(); i++ do
14         csums[i] = csums[i−1] + c'[i]
15     for i = 0; i < r.size(); i++ do
16         if rsums[i] > csums[i] then
17             return False // c doesn't dominate r
18     return True
```

6 QUASI: Layer 2

QUASI-2 models switch operation at each time step using Satisfiability Modulo Theories (SMT) [5] constraints, with additional constraints enforcing the observed packet counts and the query. It uses the Z3 [11] solver to check if these constraints are satisfiable. If satisfiable, the query is true for some packet trace consistent with measurements; otherwise, the query can never be true for the given measurements.

Enqueue-rate abstraction enables N times fewer variables. QUASI-2 models a symbolic abstract trace which specifies the number of packets entering each output queue at each time step, requiring $O(N_qT)$ variables. In contrast, a symbolic packet trace (without enqueue-rate abstraction) specifies which input port sends a packet to which output queue at which time step and requires $O(NN_qT)$ variables.

Enqueue-rate abstraction is lossless for our query language, guaranteeing correctness of QUASI-2. Although the enqueue-rate abstraction ignores input ports of packets, it does not lose any information since our queries do not distinguish between packets in an output queue based on their input ports.

7 Evaluation

Our evaluation demonstrates QUASI 's usefulness by showing that QUASI can conclusively answer queries that cannot be

answered by our baseline, *i.e.,* a conservative heuristic analysis of the measurements. We go further than answering yes/no queries, extracting quantitative bounds on metrics like queue size and buffer occupancy from per-port packet counts. We show that QUASI 's bounds are significantly tighter than the bounds inferred by our baseline, demonstrating that QUASI can infer useful information about metrics (like queue size) that are not directly measured. We study how QUASI scales with the number of time steps in a monitoring interval and compare it with an existing performance analysis tool, Fperf [4].

Our measurements admit interesting scenarios. We collect per-port packet counts using the ns-3 simulator [22] with a star topology consisting of a switch with 8 ports, with hosts sending randomized UDP traffic. Each switch output port can queue a maximum of 250 packets and the total buffer size is 2000 packets. We ensure our collected measurements allow the possibility of packets accumulating in queues, which leads to interesting performance scenarios like bursts and increased queueing latency. We evaluate QUASI on a set of 25 monitoring intervals of duration 100 time steps, each interval corresponding to a different set of measurements. We use *example* to refer to one monitoring interval. We use a smaller interval ($T = 10$) for comparison with FPerf, and several intervals of increasing duration to evaluate QUASI's scalability.

We select relevant, non-trivial queries. Our queries are drawn from real-world use cases: (1) BurstOccurrence ("Could a burst of rate R and duration D occur sometime during the interval?") is useful for troubleshooting poor application performance, (2) QlenK ("Could the queue length at port O_i be at least K?") is useful for checking latency SLO compliance, (3) MaxQlen ("What is the maximum queue length at port O_i during the interval?") is useful for estimating queueing latency, and (4) MaxBuff ("What is the maximum buffer occupancy during the interval?") is useful for buffer provisioning. Our queries involve multiple performance metrics (queue length and enqueue-rate) and the MaxBuff query involves multiple queues. We demonstrate that our selected queries cannot be easily answered by a heuristic analysis of the measurements, implemented in our HEURISTIC baseline: HEURISTIC fails to answer many queries that QuASI conclusively answers.

We use a strong baseline. As a baseline, we implement a conservative analysis, HEURISTIC, that answers a query negatively if it conflicts with a set of heuristics/rules that must always hold. HEURISTIC incorporates several non-trivial rules based on switch operation, including accounting for ports not included in the query. For burst queries, it uses rules: (1) number of packets in burst cannot exceed total number of packets received by the switch, (2) rate of incoming packets to an output queue cannot exceed the number of input ports that receive packets during the interval, and (3) a burst cannot occur in an output port if the minimum number of packets it dequeues is larger than the port's output count. Note that HEURISTIC will never report false negatives but could report false positives.

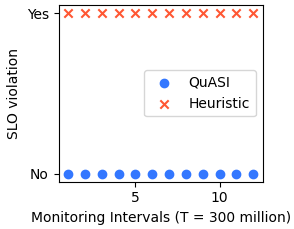

Figure 7: QUASI proves latency SLO compliance in each interval while HEURISTIC incorrectly reports an SLO violation.

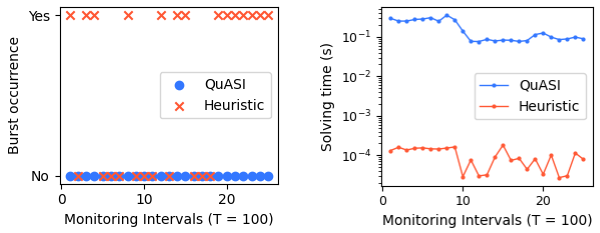
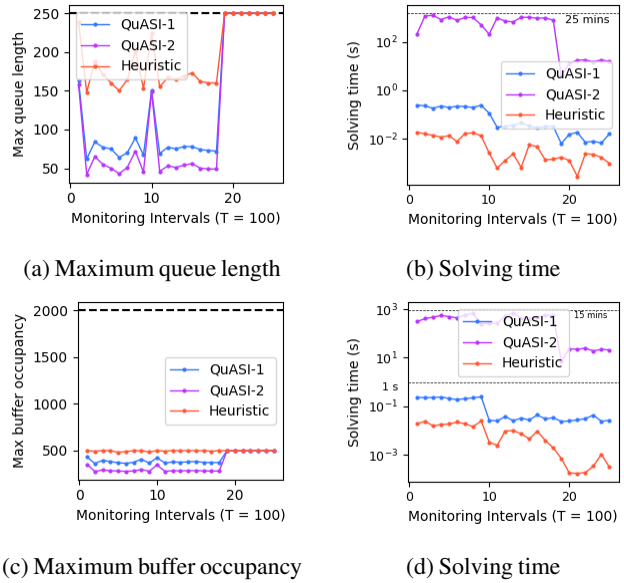
7.1 Case Study: Checking SLO Compliance



Consider, as in §3.2, a cloud operator who receives a complaint from a customer claiming the latency between the customer's servers, connected by a single switch, violated the Service Level Objective (SLO) of 289μs between 9 am and 10 am on a given day. The operator has SNMP [12] per-port packet counts over 5-minute intervals, which we collect via simulation using a switch with 8 ports, 8Gbps bandwidth, and no more than 2500 packets queued per output port. We generate randomized traffic using 1KB packets. Packet transmission time is 1μs, so a 5-minute interval has 300 million time steps.

To check for an SLO violation, we use the QlenK query which asks if a port could queue at least K packets, with K set to 290 (the SLO specifies no more than 289 queued packets). We run QUASI and HEURISTIC on each 5-minute interval in the specified hour. The results are shown in Fig. 7. HEURISTIC reports that the queue length was at least 290 packets during each interval, failing to prove SLO compliance. In comparison, QUASI reports that the queue length was always below 290 packets during each interval, thereby proving SLO compliance. QUASI-1 answers each query negatively so QUASI-2 is not run. QUASI took only 0.03s in total to prove SLO compliance, demonstrating that QUASI can scale to realistic (minute-granularity) monitoring intervals.

7.2 Burst Occurrence



We evaluate QUASI on the BurstOccurrence query which asks if a burst of given rate and duration could occur in an interval. Fig. 8a shows the reported answer, with "yes" denoting a burst could have occurred and "no" denoting a burst is impossible. We have purposefully only included queries that could not have happened to see how often QUASI-1 would have a false positive and how long it would take for QUASI-2 to solve. Fig. 8b shows the solving time.

QUASI proves the absence of bursts in all intervals. QUASI-1 answers the query negatively for all examples, so we do not run QUASI-2 (since QUASI-1 will never report a false negative). HEURISTIC incorrectly reports that a burst is possible for 14 out of 25 examples, demonstrating that QUASI can conclusively negatively answer queries that a heuristic analysis cannot. Fig. 8b shows that QUASI is

(a) Burst occurrence (b) Solving time

Figure 8: QUASI proves the absence of bursts within 1s, while HEURISTIC incorrectly reports some bursts are possible.

(a) Maximum queue length (b) Solving time

(c) Maximum buffer occupancy (d) Solving time

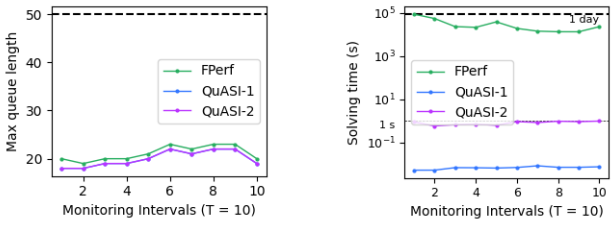


Figure 9: HEURISTIC results are consistently looser compared to QUASI. Even QUASI-1 (*i.e.,* the first layer alone) can provide tighter bounds within a fraction of a second.

efficient: QUASI-1 takes less than 1s for each example. Here we observe the benefit of a layered approach. Having a less accurate but much more scalable first layer removes the need for running the exact (but less scalable) analysis here.

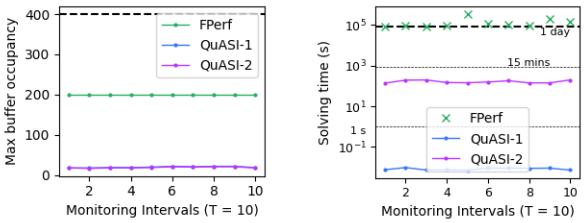
7.3 Max Queue Length and Buffer Occupancy

We evaluate QUASI on queries MaxQlen and MaxBuff which ask the maximum queue length and buffer occupancy respectively during a monitoring interval.

Using QUASI to estimate quantitative bounds. We implement a binary search over the value of the metric (queue length/buffer occupancy), issuing a sequence of parameterized Boolean queries, each query asking if the value of the metric can be no less than a constant K. For MaxQlen, we use the Boolean query "$\exists t \in [1,T] \sum_{q \in O_i} qlen(q,t) \geq K$?, which can be read as "Can port O_i ever have at least K packets queued at some time during the monitoring interval?", where O_i is a specified port and K is a parameter. We initialize K to L_i, the maximum

(a) Maximum queue length (b) Solving time

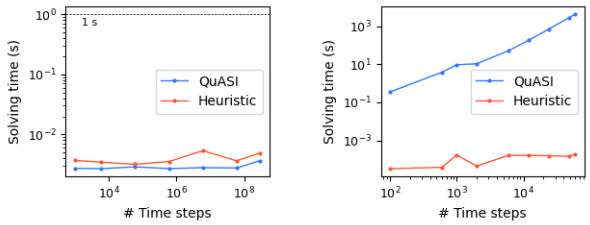
Figure 10: QUASI is up to 10^6x faster than FPerf for MaxQlen.



queue size at port O_i. The answer reported by QUASI (yes/no) determines how K is varied (increased or decreased) in the next Boolean query. If QUASI says "No", it means the queue length is always below K during the interval. Hence, we decrease the value of K in the next query. This process continues until the binary search terminates (QUASI zeroes in on a single value of K) or the minimum/maximum limit of the metric is reached. The final value of K is returned as QUASI's estimate of the maximum possible value of the metric for the given packet counts.

As QUASI-1 will never report a false negative, but could report a false positive, it over-estimates the value so that the final answer is an upper bound on the true maximum value. QUASI-2, which is an exact analysis, will report the correct answer to each Boolean query, so its final answer will be the true maximum value. We use the answer returned by QUASI-2 as ground truth to evaluate the accuracy of QUASI-1.

Fig. 9 shows the reported estimates of maximum queue length and buffer occupancy (lower is better as the estimates are upper bounds) and solving time for 25 monitoring intervals (each interval is a new set of measurements). We independently evaluate QUASI's two layers to show their difference in running time and the effect of false positives in QUASI-1.



QUASI finds upper bounds within a second and the exact answer within 25 minutes for both metrics. Thanks to its layered approach, QUASI quickly finds upper bounds for both metrics (with avg. relative error of 0.25) within a second for each interval. QUASI finds the true maximum value over each interval within 25 minutes for queue length, and within 15 minutes for buffer occupancy.

QUASI-1 finds bounds up to 58% tighter than bounds found by HEURISTIC. Figs. 9a and 9c show that for both metrics, QUASI-1 reports bounds (shown in blue) that are consistently lower than bounds found by HEURISTIC (shown in orange), demonstrating that QUASI's approximate layer provides valuable insights that cannot be obtained by a heuristic analysis of the measurements. Our implementation of HEURISTIC is fair: its estimates are significantly below the trivial upper bounds of maximum queue size (250) and total buffer size (2000) shown by black dashed lines in Figs. 9a and 9c.

(a) Maximum buffer occupancy (b) Solving time

Figure 11: FPerf fails to compute the maximum buffer occupancy within a day while QUASI takes less than 15 minutes.

(a) QlenK (b) BurstOccurrence

Figure 12: QUASI takes almost constant time for QlenK and scales quadratically with interval size for BurstOccurrence.

7.4 Comparison with FPerf

To evaluate FPerf on our problem, we disable its workload synthesis step and stop after FPerf checks if some trace consistent with the base workload satisfies the query. We specify a base workload that enforces input packet counts (FPerf does not allow constraints over dequeued packets, so we do not use output and dropped packet counts). We extend FPerf to answer our quantitative queries MaxQlen and MaxBuff. FPerf does not support our BurstOccurrence query. We reduce the monitoring interval to just 10 time steps (from 100 steps in preceding subsections) so that Fperf terminates sometimes. We report FPerf's estimates after running it up to $\approx$ 1 day for each interval.

QUASI computes the maximum queue length 10^6X faster than FPerf. FPerf takes an average of 8.5 hours to find the maximum queue length while QUASI takes less than a second. The answers reported by FPerf and QUASI match when FPerf terminates within a day (*i.e.,* for 9 out of 10 intervals); the difference of 1 in Fig. 10a is because FPerf calculates queue length before dequeueing a packet rather than after.

FPerf does not complete all per-interval required queries in 1 day, reporting an upper bound $\approx$9 times larger than the true maximum buffer occupancy; QUASI finds the exact answer in under 15 minutes. We left FPerf running for more than 2 days for one example but that did not improve its estimate. As shown by the green curve in Fig. 11a, FPerf finds a very loose upper bound; the purple curve shows the exact answer found by QUASI-2. QUASI-1 is 100% accurate on all these examples, reporting the same answer as QUASI-2 (which we regard as ground truth).

7.5 Scalability

QUASI 's verification time increases as the number of time steps in the monitoring interval increases. This is because a larger number of time steps leads to larger abstract trace matrix dimensions in QUASI-1 and more variables in QUASI-2's SMT encoding. Increased switch bandwidth (which decreases packet transmission time) and longer monitoring intervals both lead to more time steps in the monitoring interval. We evaluate QUASI's scalability with the number of time steps in the monitoring interval for two queries: QlenK and BurstOccurrence; and report solving time in Fig. 12. QUASI-1 answers all queries negatively, so QUASI-2 does not run.

QUASI's solving time scales quadratically with number of time steps for BurstOccurrence. For the BurstOccurrence query, QUASI generates a cover-set with $O(T)$ components, and takes about 75 minutes for 60,000 time steps. For QlenK, QUASI's solving time remains about the same as the monitoring interval size is increased, answering queries for intervals with millions of time steps within 1 sec. This is because CSG detects that the generated cover-set does not contain any packet traces, so subsequent components in QUASI-1 are skipped. These queries are not trivial: HEURISTIC incorrectly answers all of them positively.

QUASI scales to realistic monitoring intervals (5 mins) for queue length queries. QUASI answers the queue length query negatively within a second for an interval with 300 million time steps (*i.e.,* 5 minutes, as packet transmission time is 1μs). HEURISTIC answers the query positively, showing again that QUASI can quickly answer non-trivial queries.

8 Conclusion

This paper presents QUASI, a layered approach to answering queue-related queries using coarse-grained packet counts. QUASI is centered around the novel and lossless enqueue-rate abstraction. The first layer of QUASI performs an over-approximate analysis using representations of packet traces as $(0,1)$-matrices. The second layer utilizes an exact but less scalable analysis based on use of an SMT solver. QUASI is 10^6X faster than state-of-the-art while answering non-trivial queries about queue metrics.

Acknowledgments

We would like to thank the NSDI reviewers and our shepherd for their comments. We are grateful to Prof. Matt Weinberg for helpful feedback in the early stages of this work. This work was supported in part by NSF Grants CNS-2319442 and CNS-2312539.

A MUC Algorithm

The MUC uses Algorithm 2 to construct a most-uniform abstract trace for a given cover-set component.

Algorithm 2 takes as input a cover-set component, consisting of three types of constraints, and the total number of packets received in the interval (P). It then constructs a representative abstract trace starting from an empty abstract trace (with no packets) and iteratively placing packets to be enqueued at appropriate output queues at specific time steps in order to satisfy the given constraints.

First, lower bound (LB) constraints are satisfied (lines 2 to 4); the **get_lb** function returns the lower bound lb given queue q and time step t. The algorithm sets $R[q][t]$ to lb; this is the minimum number of packets needed to satisfy this constraint.

Second, cumulative lower bound (CLB) constraints are satisfied (lines 6 to 11). Note that there are many ways to distribute packets in an interval $[1,t]$ to satisfy such a constraint of the form $cenq(q,t) \geq lb$. Algorithm 2 uses the **fill** function, which places packets until the given lower bound constraint is satisfied, or until upper bound constraints prevent filling additional packets. Each packet is placed at time step $place \in ts$ which has the minimum number of packets in total (across output queues); ts is the set of time steps in $[1,t]$ that can take at least one packet without violating upper bounds. This allocation strategy prioritizes placing packets in time steps that have few packets, making the resultant arrangement as uniform as possible subject to satisfying the given constraints.

If the **fill** function returns abstract trace R that does not respect the lower bound lb, it means the upper bound constraints did not allow placing any more packets. In this case, there is no way to satisfy the lower bound constraint while respecting the upper bound constraints, so allocation fails and the algorithm returns *False*.

Algorithm 2: MUC

```
Input  : LB, lower bounds at given time steps
         CLB, lower bounds until given time steps
         CUB, upper bounds until given time steps
         P, total number of packets received
Output : R_j, most-uniform abstract trace
         for given constraints; False if it does not exist
1  int R[N_q][T] // Empty abstract trace
2  for t,q ∈ LB do
3      lb ← get_lb(LB,t,q)
4      R[q][t] ← lb
5  time_pts ← get_sorted_time_pts(CUB,CLB)
6  for t in time_pts do
7      for q ∈ [1,N_q] do
8          lb ← get_lb(CLB,t,q)
9          R ← fill(R,t,q,lb,CUB,N)
10         if tot(R,t,q) < lb then
11             return False
12 R ← fill(R,T,any_q,P,CUB,N)
13 if tot(R,T) > P then
14     return False
15 return R
16 Function fill (R, end, q, lb, CUB, N):
       // Ensure Σ_{t=1}^{end} R[q][t] ≥ lb
17     while tot(R,end,q) < lb do
18         ts ← ts_with_space(R,end,CUB)
19         if |ts| = 0 then
20             break
21         place ← minHeightIndex(ts)
22         R[q][place] ← R[q][place] + 1
23     return R
```

After satisfying CLB constraints, the algorithm fills any remaining packets to make the total number of packets in R equal to P (line 12); the argument any_q indicates the packets can be filled in any queue subject to satisfying the upper bound (CUB) constraints. If the total number of packets exceeds P, there are insufficient packets to satisfy the constraints and the algorithm returns *False* (line 14). Otherwise, R is returned.

If Algorithm 2 returns an abstract trace, it is most-uniform. The algorithm ensures that its output R satisfies the given constraints (*i.e.,* the cover-set component). The **fill** function always places a packet in a time step with the fewest possible packets subject to satisfying the constraints, hence ensuring the output R is most-uniform. The algorithm does not return an abstract trace if the given cover-set component is unsatisfiable, *i.e.,* if the lower bound constraints cannot be satisfied along

with the upper bound constraints or if the number of packets received P is insufficient to satisfy the given constraints.

B MUC Correctness

We present the proof of Theorem 5.3, which states that if the representative abstract trace R_j of a component F_C is not input-consistent, then every abstract trace A satisfying F_C^j is not input-consistent.

We begin by defining some notation. For an abstract trace A, $csum(A, t_1)$ denotes the sum of entries in column t_1 of A. We will also use the term "height of t" to mean the sum of entries at column t. We use R_j to denote the most-uniform abstract trace returned by Algorithm 2 for constraints F_C^j. For an abstract trace A, $ht_A \in \mathbb{N}^T$ denotes the row vector of column heights (where height of a column is the sum of its entries), sorted in non-increasing order, *i.e.,* $ht_A[1] \geq ... \geq ht_A[T]$. We use ht_{R_j} to denote the vector of sorted column heights for R_j. We use $v[:i]$ to denote the vector of the first i entries of v; and $\sum v[:i]$ to denote the sum of the first i entries in v.

Next, we define a transformation of an abstract trace, called a balancing shift, which preserves input-consistency.

Definition B.1 (Balancing shift)**.** *For an abstract trace A, a balancing shift moves a packet from time step t_1 to time step t_2 where $csum(A, t_1) > csum(A, t_2)$.*

A balancing shift moves a packet from a column of higher height to a column of lower height. A balancing shift from t_1 to t_2 requires that the height of t_1 is larger than the height of t_2, and will never increase the height difference between t_1 and t_2.

Lemma B.2 (Balancing shifts preserve input-consistency)**.** *For any abstract trace A, let A' be the abstract trace obtained by performing a balancing shift on A. If A is input-consistent, then A' must also be input-consistent.*

Proof. Assume that A is input-consistent. Then there is a labeling Lbl that associates each packet in A with an input port such that packets at the same time step in A are mapped to distinct input ports. Let the balancing shift be from t_1 to t_2 where $csum(A, t_1) > csum(A, t_2)$. Since column t_1 has at least one more packet than column t_2 and packets at the same time step are mapped to different input ports, it is always possible to choose a packet p at t_1 that has an input port distinct from all packets at t_2. (If this were not the case, it would mean that at least two packets at t_1 were mapped to the same input port, which is a contradiction). Shift packet p from t_1 to t_2 to obtain abstract trace A'. The balancing shift did not change the number of input port labels, so A' will have each input port label appearing as many times as the port's input count. Moreover, A' has packets at each time step mapped to distinct input ports by Lbl, so A' is input-consistent. □

We now show that the abstract trace R_j returned by Algorithm 2 is the "most-uniform" in C_j, the set of abstract traces satisfying a cover-set component F_C^j.

Lemma B.3. *The abstract trace R_j returned by Algorithm 2 is the most-uniform in C_j,* i.e.,*for any abstract trace $A \in C_j$, the total height of the i largest columns in R_j must be no more than the total height of the i largest columns in A, for any $i \geq 1$.*

$$\forall A \in C_j.\ \forall i \geq 1.\ \sum ht_{R_j}[:i] \leq \sum ht_A[:i] \tag{6}$$

Proof. The proof is by contradiction. Assume R_j is not most-uniform (*i.e.,* eqn. (6) does not hold). Then, there exists some $A \in C_j$ and some $i \in [1,T]$ such that

$$\begin{aligned} &\sum ht_{R_j}[:i] > \sum ht_A[:i]\ \text{, and} \\ &\forall k < i.\ \sum ht_{R_j}[:k] \leq \sum ht_A[:k] \end{aligned} \tag{7}$$

Note that $ht_{R_j}[i] > ht_A[i]$; otherwise, $\sum ht_{R_j}[:i]$ could not be greater than $\sum ht_A[:i]$. Let h denote the value of $ht_A[i]$. Consider the total number of packets that A and R_j pack in columns of height no more than h.

Let P denote the total number of packets in A and R_j.

$$P = \sum ht_A = \sum ht_{R_j} \tag{8}$$

Then, A packs more than $P - \sum ht_A[:i]$ packets in columns of height $\leq h$. Since $ht_{R_j}[i] > ht_A[i]$ and ht_{R_j} is sorted in non-increasing order, R_j packs no more than $P - \sum ht_{R_j}[:i]$ packets in columns of height $\leq h$. From eqn. (7), $\sum ht_{R_j}[:i] > \sum ht_A[:i]$, so R_j packs fewer packets than A in columns of height $\leq h$. Algorithm 2 constructs R_j by placing each packet at the minimum possible height subject to satisfying the given constraints. This allocation strategy packs as many packets as possible in columns of low height. Since A satisfies the constraints F_C^j, the total number of packets in columns of height $\leq h$ in A must be no more than the corresponding number of packets in R_j. Assuming there exists an $A \in C_j$ such that R_j is less uniform than A (eqn. (7)) implies that A packs strictly more packets than R_j in columns of height $\leq h$, which is a contradiction. □

We now present the proof of Theorem 5.3. We show that if some $A \in C_j$ is input-consistent, then the most-uniform abstract trace R_j must also be input-consistent. We define a procedure `Relabel` that transforms the labeling function f_L for A to construct a valid labeling function for R_j, thereby showing that R_j is input-consistent.

Proof. Assume there is some $A \in C_j$ which is input-consistent. Let f_L denote the labeling function which assigns each packet in A to an integer denoting an input port. Function f_L satisfies two conditions: (1) number of input port labels is equal to the port's input count; and (2) packets at the same column in A are mapped to distinct input port labels.

We define a procedure `Relabel` which transforms the labeling function f_L into a valid labeling function f'_L for the most-uniform abstract trace R_j. `Relabel` operates on the sorted height vectors ht_A and ht_{R_j} for A and R_j respectively.

`Relabel` consists of T steps. In step i, `Relabel` sets entry i of ht_A equal to entry i of ht_{R_j}; we use $ht'_A[i]$ to denote the value of $ht_A[i]$ after modification. At each step, `Relabel` stores the number of extra packets $excess[i] = \max(0, ht_A[i] - ht_{R_j}[i])$. If $ht_A[i] < ht_{R_j}[i]$ it uses the extra packets so far to make $ht_A[i]$ equal to $ht_{R_j}[i]$ (we will show that there will always be enough extra packets). After T steps, each entry of ht'_A will be equal to the corresponding entry of ht_{R_j}, *i.e.,* $ht'_A = ht_{R_j}$ at the end of the procedure.

We will now show that `Relabel` transforms ht_A into ht_{R_j} by only using balancing shifts.

By Lemma B.3, $\sum ht_{R_j}[:i] \leq \sum ht_A[:i]$ for all $i \in [1,T]$. In step 1, we will not have a deficit of packets since $ht_{R_j}[1] \leq ht_A[1]$.

Consider any step $i \geq 2$ in which there is a shortage of packets in ht_A, *i.e.,* where $ht_A[i] < ht_{R_j}[i]$. Since $\sum ht_A[:i] \geq \sum ht_{R_j}[:i]$ and $\sum ht_A[:i-1] \geq \sum ht_{R_j}[:i-1]$, it is guaranteed that the total excess packets so far, $ht_A[:i-1] - \sum ht_{R_j}[:i-1]$, is no less than the deficit at i, $ht_{R_j}[i] - ht_A[i]$.

$$\sum ht_A[:i] \geq ht_{R_j}[:i] \tag{9}$$

$$\sum ht_A[:i-1] + ht_A[i] \geq ht_{R_j}[:i-1] + ht_{R_j}[i] \tag{10}$$

$$\sum ht_A[:i-1] - \sum ht_{R_j}[:i-1] \geq ht_{R_j}[i] - ht_A[i] \tag{11}$$

Hence, we will be able to make entry $ht_A[i]$ equal to $ht_{R_j}[i]$ by using some of these extra packets.

Any extra packet is from some entry $t < i$ where $ht_A[t] > ht_{R_j}[t]$ originally (*i.e.,* before `Relabel` changes ht_A). Given that there is a deficit at entry i in A and both ht_A and ht_{R_j} are sorted in non-increasing order,

$$ht_A[t] > ht_{R_j}[t] \geq ht_{R_j}[i] > ht_A[i] \tag{12}$$

which implies that $ht_A[t] > ht_A[i]$. Hence, shifting an extra packet to i is always from a column with greater height to a column of lower height, *i.e.,* it is always a balancing shift.

Since the only moves that `Relabel` uses are balancing shifts, by Lemma B.2, it is always possible to choose an extra packet to shift from entry t to entry i such that entry i will have each packet mapped to a distinct input port. After `Relabel` terminates, the resultant vector ht'_A will have each entry i mapped to $ht'_A[i]$ distinct input port labels. Since a balancing shift does not change any input port label (it just moves labeled packets), ht'_A will be labeled with each input port a number of times equal to the port's input count. Since $ht'_A = ht_{R_j}$, each entry in ht'_A corresponds to some column in matrix R_j. Using the labeling over ht'_A, associating each entry with its corresponding column in R_j, we obtain a labeling that associates each packet in abstract trace R_j with an input port label satisfying the requirements of a valid labeling function. Hence, R_j is input-consistent. □

C MCC Correctness

We present the proof of Theorem 5.4, which reduces the problem of checking input-consistency of an abstract trace to checking the existence of a $(0,1)$-matrix with given row sums and column sums.

Proof. $\Rightarrow$: Assume abstract trace R_j is consistent with input counts rcv. Then, there exists some labeling Lbl that associates each packet in R_j with an input port. We construct a $N \times T$ $(0,1)$-matrix X from R_j and Lbl with each entry $X[i][t]$ defined as follows:

$$X[i][t] = \begin{cases} 1 & \text{if } Lbl \text{ uses port } i \text{ at } t \\ 0 & \text{otherwise} \end{cases} \tag{13}$$

Since Lbl uses each port i exactly $rcv[i]$ times, X will have exactly $rcv[i]$ 1s in row i, *i.e.,* the sum of row i will be $rcv[i]$ for all $i \in [1,N]$. Since Lbl labels all packets at the same time step in R_j with different ports, for each $t \in [1,T]$ the t^{th} column of X will have $csum(R_j, t)$ 1s, *i.e.,* $csum(X, t) = csum(R_j, t)$. Hence, R_j being input-consistent implies there exists a $(0,1)$-matrix X with its row sums determined by rcv and its column sums determined by R_j.

$\Leftarrow$: Assume there exists a $(0,1)$-matrix X with its row sums equal to the input counts rcv and its column sums equal to the column sums of abstract trace R_j. We construct a function Lbl from X. Let $AvlPorts(t)$ denote the set of indices of rows which have 1 in the t^{th} column of X. For each $t \in [1,T]$, let Lbl pick any $1-1$ mapping from $AvlPorts(t)$ to packets in the t^{th} column of R_j. Since $csum(X,\ t) = csum(R_j,\ t)$, $|AvlPorts(t)| = csum(R_j,\ t)$ so each packet enqueued at t can be labeled with a distinct input port. Since Lbl only uses ports from $AvlPorts(t)$ in each time step t (*i.e.,* only ports corresponding to entries of 1 in X for that time step), Lbl will use port i the number of times row i has entry 1 in X. Since $rsum(X,\ i) = rcv[i]$ for all $i \in [1,N]$ Lbl will use each port i exactly $rcv[i]$ times. Since Lbl satisfies the required properties in the definition of input-consistency and labels each packet in R_j, R_j is consistent with input counts rcv. □

Runtime Protocol Refinement Checking for Distributed Protocol Implementations

Ding Ding, Zhanghan Wang, Jinyang Li, Aurojit Panda
NYU

Abstract

Despite significant progress in verifying protocols, services that implement distributed protocols (we refer to these as DPIs in what follows), e.g., Chubby or Etcd, can exhibit safety bugs in production deployments. These bugs are often introduced by programmers when converting protocol descriptions into code. This paper introduces *Runtime Protocol Refinement Checking* (RPRC), a runtime approach for detecting protocol implementation bugs in DPIs. RPRC systems observe a deployed DPI's runtime behavior and notify operators when this behavior evidences a protocol implementation bug, allowing operators to mitigate the bugs impact and developers to fix the bug. We have developed an algorithm for RPRC and implemented it in a system called Ellsberg that targets DPIs that assume fail-stop failures and the asynchronous (or partially synchronous) model. Our goal when designing Ellsberg was to make no assumptions about how DPIs are implemented, and to avoid additional coordination or communication. Therefore, Ellsberg builds on the observation that in the absence of Byzantine failures, a protocol safety properties are maintained if all live DPI processes correctly implement the protocol. Thus, Ellsberg checks RPRC by comparing messages sent and received by each DPI process to those produced by a simulated execution of the protocol. We apply Ellsberg to three open source DPIs, Etcd, Zookeeper and Redis Raft, and show that we can detect previously reported protocol bugs in these DPIs.

1 Introduction

Distributed protocols, implemented in lock services [11, 21, 100], distributed databases [85, 99], etc., lie at the heart of all fault-tolerant applications. Ensuring that these services, which we refer to as *distributed protocol implementations* (DPIs), correctly implement distributed protocols remains challenging. Popular DPIs have shipped with application visible bugs: *e.g.,* prior versions of Etcd [21] would return stale values in some scenarios due to a bug [25] in its implementation of a linearizable read protocol [95]. Similarly, prior versions of Zookeeper [100] would, in some scenarios, lose updates during leader elections due to a protocol implementation bug [101]. Both systems are widely used, and both bugs can result in application bugs such as data corruption.

In this paper we develop an approach, *runtime protocol refinement checking* (RPRC), that notifies administrators when bugs such as the ones above occur, allowing administrators to mitigate the bug's effects and programmers to fix the bug. We started developing RPRC because we observed that despite the widespread use of verification tools [3, 4, 10, 41, 42, 55, 60, 65, 68, 90–92, 94] that prove the safety of distributed protocols, and testing tools [6, 15, 35, 41–43, 48, 66] that check implementation correctness, deployed DPIs continue to exhibit bugs. This is because ensuring that programmer correctly implements a verified protocol is challenging, and detecting (and eliminating) all bugs with testing is infeasible. Recently, IronFleet [34], Verus [47], Goose [12] and others, have proposed using static refinement proofs to connect verified protocols to implementations. However, to ensure feasibility (of refinement proof generation and checking) these frameworks must limit how code is written, making it hard for developers to produce verified, high-performance DPIs.

RPRC provides an alternate approach for connecting statically verified protocols to an implementation: RPRC systems observe a DPI's runtime behavior, and notify administrators when the implementation's behavior deviates from what is required by the protocol. Analyzing runtime behavior allows RPRC tools to avoid making assumptions about how the protocol is implemented or what libraries are used. Indeed, *Ellsberg*, the RPRC system described in this paper, treats the DPI as a blackbox, assumes no access to the DPI's internal state, and does not impose any limits on how DPIs are implemented. Note, RPRC systems do not replace static protocol and implementation verification [10, 34, 47, 49, 55, 68, 88, 91, 92] (they cannot statically generate proofs to show that a protocol is correct, or that an implementation refines the protocol) and fuzz testing tools [6, 41–43, 48, 66] (they do not try to maximize coverage and find all bugs before an implementation is deployed), but rather complement them.

This paper describes an RPRC algorithm that we have implemented in a system called Ellsberg. We designed Ellsberg to work with existing unmodified DPIs, to minimize communication and processing overheads, and to ensure that it had no effect on a DPI's failure guarantees. These design goals allow Ellsberg to be used in deployment and to find bugs that were missed during testing.

Ellsberg (Figure 1) consists of a set of co-located instances that run alongside (that is, co-located with) each DPI process. An Ellsberg instance has access to a trace of incoming and outgoing messages sent by its colocated process, but has no access to its internal state. Furthermore, Ellsberg instances are designed to work without communicating

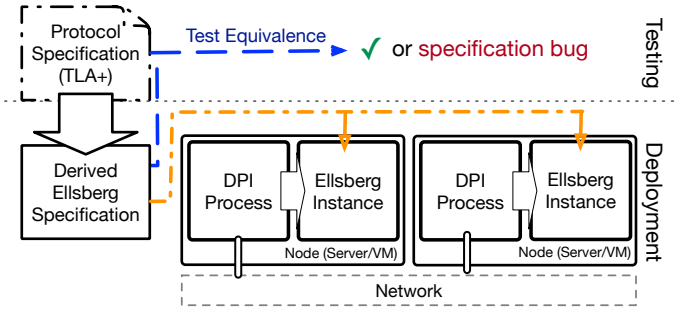

Figure 1: *An overview of* Ellsberg*, which runs an instance colocated with each DPI process, and compares the colocated process's behavior to a correct protocol implementation. We assume the TLA+ protocol specification is provided by the protocol designer, and programmers derive a* Ellsberg *specification from this specification.*

with each other: each instance processes the trace produced by its colocated process and can independently generate a notification when it observes an implementation bug. Our design builds on the observation that a DPI correctly implements a distributed protocol if and only if all processes executing the DPI have correctly implemented the protocol, allowing us to check implementation correctness without requiring additional communication or coordination. In cases where the protocol has been proven to maintain global safety properties (*e.g.,* agreement or linearizability), Ellsberg's local checks are sufficient to ensure that administrators are notified when these properties are violated.

Administrators and programmers use Ellsberg (Figure 1) as follows: before deployment, the administrator (or DPI programmer) translates the protocol the DPI purportedly implements into an Ellsberg specification and tests it (§4) to check correctness. When deploying the DPI, the administrator colocates an Ellsberg instance, configured with protocol specification, with each DPI process, and configures the DPI process so that the colocated instance has access to a trace of all messages received or sent by the process (§3.1). Each instance uses the specification and trace to simulate a correct implementation of the protocol and reports a bug if the process's behavior diverges from the simulated behavior.

We needed to address two challenges when developing Ellsberg: (a) **Concurrency within DPI processes.** Many DPI implementations are concurrent, and to avoid false notifications, Ellsberg needs to ensure that its simulation state corresponds to the DPI's protocol state. However, the DPI's protocol state depends on the order in which messages are processed, and the trace available to Ellsberg does not reveal this order. Consequently, Ellsberg instances need to consider all simulation states reachable by reordering messages in the trace, which can grow exponentially over time. Therefore, to be feasible Ellsberg needs to efficiently explore the set of reachable states; and (b) **Incremental checking,** by which we mean the ability to check DPI correctness without needing to process the entire trace or requiring access to messages sent or received in the future. Incremental checking prevents us from using existing approaches for efficiently processing multiple simulation states: these approaches assume access to a complete trace (including future messages), or assume that messages are annotated with a vector clock [78, 80] that records processing order.

Ellsberg addresses these challenges using a novel incremental RPRC algorithm (§3.4): each Ellsberg instance maintains the set of simulation states the associated DPI process can be in, and uses breadth first search to update the instances states and check DPI correctness. We use two optimizations to speed up breadth first search: we prune branches whose execution produces a simulation state that is guaranteed, based on the observed trace, to differ from the DPI's protocol state; and we identify messages whose effect will not change after being reordered with future messages and apply them immediately.

We have evaluated Ellsberg using three open-source DPIs: Etcd and ZooKeeper, which are consistent key-value stores that are used by projects such as Kubernetes for configuration and state management; and Redis Raft, an extension of the Redis key-value store that adds fault-tolerance. Etcd and Redis Raft implement the Raft [64] consensus protocol, and ZooKeeper implements the Zab [38] atomic broadcast protocol. Our evaluation (§6) shows that Ellsberg can detect bugs in these systems, that it can do so with minimal impact on response latency (we observed a worse case impact of 11% on the 99th percentile latency), no impact on throughput, and has modest processing and memory requirements.

Although the RPRC approach is general, and can be used with any distributed protocol that assumes fail-stop behavior and the asynchronous (or partially synchronous) model, it has an important limitation: it only suffices to detect protocol bugs that lead to changes in either the content or order of messages sent or received by a DPI process.We cannot detect several important classes of bugs, including ones that lead to livelock or deadlock, corrupt stored data, or degrade performance, and must rely on tools developed by prior work (§2.1) to detect these bugs. Nevertheless, as our evaluation (§6) shows, safety bugs of the kind we find do occur in practice.

2 Current Approaches and Related Work

Our goal is to catch protocol bugs in deployed DPIs that can lead to violations of safety properties. Before describing our approach, RPRC, we first review existing approaches, focusing on those that prevent or detect safety bugs. We categorize these work into five classes:

Trace Validation. A recently developed approach [15, 35] validates totally ordered traces generated during the testing against a TLA+ specification. This approach seeks to check protocol refinement at test time. However, it can only check execution traces generated by tests and, consequently can miss bugs. By contrast, Ellsberg is designed to minimize overheads, allowing it to be used in deployment and uncover bugs that were not found during testing. As a result, both approaches are complimentary: trace validation identifies bugs before deployment, while Ellsberg identifies bugs in

deployment.

Trace-validation also makes different assumptions than Ellsberg. It assumes that there is a close correspondence between implementation and specification, assuming that the the implementer used the TLA+ specification as a blueprint when writing code ([15, §1]) or that the specification was reverse engineered from the implementation. For DPI implementations, this requirement means that the DPI must log all changes to state variables, and log 'linearization points' that correspond to TLA+ state transitions. Thus, in contrast to our approach, DPIs must be implemented (or updated) for use with trace validation. Howard et al [35, §6.1] report that they needed to add 15 additional log statements to capture linearization points, which requires understanding both the protocol specification and the implementation. Similarly, for specifications, requiring close correspondence between implementation and specification means that specifications must be changed as applications are optimized or changed, and cannot necessarily be reused across applications. Indeed, the CCF effort had to develop a new detailed Raft specification [35, §4, §5] to use trace validation. By contrast, Ellsberg does not require close correspondence between the specification and the traces, and in our evaluation, we reuse the same Raft specification (modulo a few changes to account for the use of different reconfiguration protocols) for both Etcd and Redis Raft.

Furthermore, the trace-validation algorithm relies on two assumptions that make it challenging to use this approach in deployment: It assumes that (a) checks are run after the test has terminated; and (b) the test produces a totally ordered output. These assumptions require additional coordination – *e.g.,* Microsoft CCF [35, §6.1] uses a test driver to serialize node execution and a synchronized global clock to order process logs, and to decide when a test has completed – which affects a DPI's fault tolerance guarantees and performance.

Protocol Verification. Prior work has described several strategies to prove a distributed protocol's safety properties. Verdi [88], Diesel [81] and others [89] provide frameworks that make it easier for users to write proofs that can be mechanically checked by a proof assistant (*e.g.,* Coq [84]). Ivy [67, 68] provides an interactive tool to help users produce inductive invariants that can be used to prove the protocol's safety properties with an SMT solver. Recent works [55, 69, 91, 92] have extended Ivy's approach and automated the process of inferring inductive invariants.TLA+ [10, 62, 94] allows users to model check distributed protocol specification to find safety violations. Each of these strategies offers varying levels of automation and imposes different requirements on how protocols are specified. While these systems can prove that a protocol is correct (i.e. it maintains desired safety properties), they cannot prevent implementation bugs.

Use refinement proofs to prove implementations correct. This approach tries to derive the correctness of DPI implementations from verified protocols using refinement proofs. IronFleet [34] takes as input safety properties (referred to as a high-level specification), a protocol specification together with an implementation, and prove using Dafny [49] that (a) the protocol specification satisfies the specified safety properties, and (b) the implementation refines the protocol and thus also meets the safety properties. Recently, pretend synchrony [86] has shown how to reduce the proof burden for IronFleet by restricting the communication primitives used by the program. Concurrently, Verdi [88, 89] and Diesel [81] implement refinement proof using Coq's Ocaml extraction capabilities. All of these frameworks produce provably correct DPIs, however, to ensure that refinement proof generation and checking is feasible, they need to limit how DPI code is written, what libraries are used, and how the code is optimized [51].

Furthermore, these approaches make assumptions about the runtime environment, including assumptions about system call semantics and the network. Prior work [29] has shown that these assumptions are sometimes wrong, thus provably correct DPIs can still violate safety. Therefore, RPRC systems are useful even when using refinement proofs to produce provably correct implementations.

Use model checking and fuzzing to test existing implementations. Nearly all deployed DPIs use unit and integration tests to catch bugs. However, as with any large software system, developer provided tests cannot provide sufficient coverage. Prior work has developed tools for automatically generating tests. These tools can be classified into ones that use fuzzing or randomized testing [6, 43, 66], and ones that use model checking [3, 4, 6, 41, 42, 48, 60, 87, 90]. Many of these approaches [3, 43, 48, 66] are explicitly designed to be used with existing DPIs. Recent work from Majumdar and Niksic [58] has argued that randomized testing approaches are effective in finding DPI bugs. However, as is common with testing approaches, these tools cannot guarantee that all bugs are found. RPRC complements testing, allowing developers and administrators to discover bugs that occur when DPIs are deployed, but were not found during testing. However, note that as is the case with any runtime verification tool, bugs discovered using RPRC in production can also be found by a fuzzer that runs for long enough and explores enough of the implementation's code paths.

Runtime verification to find bugs in DPIs. Runtime verification approaches, *e.g.,* Dinv [33], D3S [50], Pip [77], Aragog [93], Oathkeeper [53] and Hydra [76], check program properties at runtime. These approaches are designed to check global properties, *e.g.,* agreement or state consistency, which are often expressed as predicates over the state of all (or some subset) of DPI processes. Consequently, these tools check program properties by first collecting a consistent snapshot of the relevant DPI state [13] and then evaluating a predicate on this state (see Franclanza et al's survey [31] for details). The use of DPI state snapshots allows these tools to check richer properties without concerns about decidability or scaling, *e.g.,* Aragog [93] checks performance and probabilistic staleness properties. However, the need to collect consistent state snapshots

adds coordination and communication overheads, and makes verification in the presence of DPI process failures challenging. Recent work has focused on reducing these overheads by minimizing the amount of process state collected [53, 76, 93], using fork-join parallelism to distribute predicate checking [33, 50, 76, 77, 93]. Other work has used multivalued logics [9, 14] to mitigate the effect of failures on runtime verification.

Our approach: Runtime protocol refinement checking (RPRC). RPRC seeks to combine mechanisms from both refinement proofs and runtime verification. Similar to refinement proofs, RPRC aims to ensure that each DPI process correctly implements a protocol, whose safety has verified using other approaches. However, unlike traditional refinement proofs which do so statically, RPRC's refinement checking occur at runtime to compare each DPI process' behavior to that of its protocol specification. Thus, RPRC avoids the feasibility concerns that lead tools like Verdi, Dafny and Verus to impose constraints on how DPIs are implemented. Additionally, runtime refinement checking does not require strong assumptions about system call semantics that are required by existing refinement tools. Unlike runtime verification, RPRC checks that DPI implementation refines a distributed protocol rather than checking that a safety property holds. Refinement can be checked locally without cross-node communication and coordination, and without imposing any limits on fault tolerance. By contrast, checking properties requires gathering that state at all processes, which necessitates coordination and is unavailable under failures.

2.1 Other Related Work

The tools discussed above focus on detecting safety bugs in DPIs. Below we discuss tools that look beyond safety to other issues including performance bugs, non-fail-stop failures and how to fix bugs once they are found. We discuss these below:

Distributed tracing tools. Distributed tracing [7, 20, 30, 57, 70, 82] is the most widely deployed approach to finding bugs in deployed DPIs. These tools generate logs that trace requests through the system, and several tools utilize these trace logs [8, 17, 40, 45, 46, 56, 61] to debug performance problems and failed user requests. These tools are valuable for debugging bugs, but cannot detect them.

Checking behavior under failures. Several tools and engineering practices, including chaos engineering [79], lineage driven fault injection [3–5, 59], crash consistency checking [2], and analysis tools for partial and correlated failures [37, 52, 96] have been developed to improve DPI behavior when recovering from crashes. We assume a fail-stop model, and do not currently handle these failures.

Performance and configuration bugs. Recent work has also developed tools and approaches to identifying performance bugs including gray failures [37], metastable failures [36], and bugs due to misconfiguration [97].

Record-replay based debuggers. Bugs, once found, need to be further diagnosed for debugging. Prior work has proposed several approaches for debugging DPIs [1, 8, 52, 80]. As we discussed previously, these include record-replay [8, 78, 80] based debuggers which, similar to RPRC, also need to consider multiple interleavings when reproducing bugs.

3 Ellsberg Design

We now describe Ellsberg, a RPRC system that we have implemented. We first state our assumptions about DPIs and the deployment environment (§3.1) and describe a ticket-lock service that we use as a running example in this section (§3.2). Then, we discuss the protocol specification a user must provide to Ellsberg (§3.3), and our RPRC algorithm (§3.4).

Overview. Ellsberg (Figure 1) performs runtime refinement checks on whether a deployed DPI correctly implements a protocol by comparing each DPI process's behavior against a user-provided protocol specification (§3.3). To do so, we require administrators to co-locate an Ellsberg instances with each DPI process, and to configure the deployment so that the Ellsberg instance has access to a trace of all messages sent and received by its co-located DPI process. At a high-level, the Ellsberg instance uses the following RPRC algorithm to check its co-located DPI process: it checks refinement by using the incoming messages in the trace to simulate potential protocol executions (using a protocol specification) and decides refinement check has failed if an invalid or out-of-order going message appears in the trace. It notifies administrators when the refinement check fails. Because Ellsberg must account for internal concurrency within a DPI, when simulating the protocol it maintains multiple simulation states, and uses breadth first search to consider multiple event interleavings (or schedules). Ellsberg uses outgoing messages in the trace to prune the set of simulation states that must be maintained, and the event interleavings considered.

3.1 Assumptions and Guarantees

Ellsberg assumes that the DPI and protocol work under the asynchronous (or partially synchronous) model and fail-stop failures. We do not consider byzantine failures.

When checking refinement, Ellsberg instances assume that the user-provided protocol specification is correct. We provide a testing tool (§4), that administrators can use before deploying Ellsberg to check the specification's correctness using the protocol's TLA+ specification.

We assume that the Ellsberg instance and its co-located DPI processes share fate, i.e. if an Ellsberg instance fails, its co-located DPI process also fails. We also require that the trace faithfully records all messages sent and received by its co-located DPI process, and is incrementally updated, *i.e.,* messages are added as the DPI process sends or receives them. Messages in the trace need to be annotated with the connection on which they were sent or received. We impose some ordering requirements on the trace. Specifically, we require that messages received over the same connection appear in order in the trace, and that outgoing messages follow program order, *i.e.,* they appear in the trace in the order in which they are sent, and that any incoming messages processed by the

```
1  struct State {
2      highest: int,
3      current: int,
4      held: bool
5  }
6
7  fn assign(state: State) {
8      let ticket = state.highest;
9      state.highest = state.highest + 1;
10     respond(Assigned(ticket))
11 }
12
13 fn acquire(state: State, ticket: int) {
14     if state.current ==  ticket{
15         state.held = true;
16         respond(Acquired(ticket))
17     }
18 }
19 fn release(state: State) {
20     let ticket = state.current;
21     state.current = state.current + 1;
22     state.held = false;
23     respond(Released(ticket))
24 }
```

Listing 1: *Example ticket-lock server.*

DPI before producing an outgoing message m appear before m in the trace. Our prototype uses an IPC channel, that connects each Ellsberg instance to its colocated process, to collect the trace (§5). Other approaches, *e.g.,* one where a network proxy mirrors messages to the Ellsberg instance, can also be used instead. Beyond the trace, Ellsberg has no access to DPI state: it cannot read the DPI process's memory, nor does it know the order in which received messages are processed.

Guarantees. When our assumptions are met, Ellsberg guarantees that it will generate an alert shortly after a DPI processes sends a message that is inconsistent (either because of its contents, or the order in which it was sent) with the specification, *i.e.,* shortly after a refinement violation is observed. Consequently, Ellsberg does not raise false-alarms because alerts are only generated when a violation is observed. However, similar to trace validation [15, 35], Ellsberg cannot prove that an implementation is correct because (a) it cannot detect refinement violations that do not result in the DPI sending out an inconsistent message; and (b) it is not guaranteed to have observed all possible DPI behaviors.

3.2 Running Example: Ticket Lock Service

We use a simple, non-fault tolerant, ticket lock-service as an illustrative example in this section. The service, shown in Listing 1, runs on a single server and maintains two integers: *highest* tracking the largest ticket the service has previously granted, *current* tracking what client should go next, and *held* which tracks whether a client holds the lock. The service implements three RPC calls:

1. `assign` (line 7), which assigns the client a ticket, increments *highest* so that clients get unique tickets, and responds with the assigned ticket number.
2. `acquire` (line 13), which takes as input a ticket number (*ticket*, previously acquired using `assign`) and checks if it is the client's turn to acquire the lock ($current == ticket$). If it is the client's turn, the service sets *held* to true and responds with an *Acquired* message.
3. `release` (line 19), which releases the lock by incrementing *current*, setting *held* to false, and responds with a *Released* message.

For ease of exposition, we assume that clients using this service are correct, and that a client does not call `release` unless it holds the lock. A correctly implemented version of this protocol guarantees mutual exclusion, ensuring that no-more than one client holds the lock at a time. We use this simple protocol to illustrate how to specify a protocol in Ellsberg, but we use real DPIs (Etcd, Zookeeper and Redis Raft) for the evaluation (see Appendix C for specifications).

3.3 Definitions and Specification

We model a distributed protocol as a collection of communicating processes, each of which is specified by an I/O automaton [27, 54]. More concretely, Ellsberg requires users to specify the distributed protocol as a state machine (executed by each process), whose execution is driven by a sequence of *events* that are *applied* to it. There are two types of events: the delivery of a message, and timeouts. When an event is applied, a process can update its state and send 0 or more messages.

The terms **pending events**, **reachable states** and **inducing states** are defined as follows:

Pending Events: A pending event is one that can be applied to a process, and consists of previously-received messages that the have not yet been processed, and timeouts. Timeouts in a DPI process are not recorded in the trace, and our model assumes that a timeout is always pending. We use the term *schedule* to refer to a sequence of events.

Reachable state: Given a process p in state s, we say that state s' is reachable if and only if there exists a schedule of events (some of which might not yet be received) that when applied to s result in state s'.

Inducing states: Given a message m, we say that state s is m-inducing (we drop the prefix $m-$ when the message is clear from the context) if and only if there exists state s' and event e, such that applying e to a process in state s' results in the process *sending* the message m and then transitioning to state s. In the ticket-lock example (Listing 1), the m-inducing state for an `Acquired` message for ticket 2 is any state s, where $s.current = 2$. Observe that in general, a message m does not have a unique inducing state, and some messages might have an unbounded number of inducing states: in the previous example, any state s for which $s.current = 2$ is m-inducing, regardless of $s.highest$'s value.

3.3.1 Specification

Ellsberg requires users to provide two inputs: a specification for the distributed protocol the DPI purportedly implements and mapping functions that allows Ellsberg to map network messages sent or received by the DPI into messages that appear in the specification. In the remainder of this section, we only refer to messages that appear in the protocol specification. In Listing 2, we use the ticket-lock service's (§3.2) specification to illustrate the parts of a Ellsberg specification.

A Ellsberg protocol specification consists of:

```
1  struct ProtState {
2      highest: int,
3      current: int,
4      held: bool,
5  }
6
7  fn equal(s: ProtState, s': ProtState) -> bool {
8      return s.highest == s'.highest
9        && s.current == s'.current
10       && s.held == s'.held
11 }
12
13 fn infer_inducing(m: Message) -> ProtState {
14     return match m {
15         Acquired(tkt) =>
16             ProtState{highest: None,
17               held: true, current: tkt},
18         // ...
19     }
20 }
21
22 fn apply(s: ProtState, e: Event) -> ProtState {
23   match e {
24     case Message(Acquire(tkt)) => {
25         if s.current ==  tkt{
26             return ProtState{highers
                    : s.highest, current:tkt, held:true}
27         } else {
28             return s
29         }
30     }, // ...
31   }
32 }
33
34 fn reachable(s: ProtState,
35              pending: Set[Set[Message]], e: Event,
36              p: ProtState) -> bool {
37    if state(s).current > p.current {
38     return false
39     } // ...
40   }
41 }
42
43 fn apply_asap?(s: ProtState, m: Message) -> bool {
44     return m.type == Acquire && m.tkt < s.current
45 }
46
47 fn lookahead_type(m: Message) -> Message_type {
48     if Type(m) == Acquired {
49         return Assigned
50     }
51     // ...
52 }
```

Listing 2: *User-provided protocol specification for the ticket-lock server*

(i) The definition for a *protocol state structure*, `ProtState` (line 1), that Ellsberg uses to track the current simulation's protocol state, and a function to create the simulation's initial protocol state. For notational convenience, all elements of the `ProtState` are nullable and we use this to encode sets of states.

(ii) A transition function, `apply` (line 22), that takes as input a protocol state s, a collection of sets of pending events and an event e, and returns the protocol state produced by applying e to s. We guarantee that all events passed to the transition function are pending for s. For notational convenience, we use $apply(s,\Sigma)$ to represent the output of applying the sequence of events in the schedule Σ to s.

(iii) A function, `equal`, to check equality between two protocol states s and s'. Two states are considered equal if the distributed protocol exhibits the same behavior for both. In other words, we assume that $equal(s,s') = true$ implies that for any schedule Σ, applying the schedule to both states results in final states that are equal and produces the same sequence of outgoing messages. In the ticket-lock example (line 7) the function compares *current*, *highest* and *held*.

(iv) An inference function, `infer_inducing`, that given an *outgoing* message m returns a `ProtState` of all m-inducing states. This function populates only those values that can be inferred from m, leaving the others unknown. Line 13 shows this function for our running example: we need to consider each type of outgoing message sent by the service when writing it.

(v) A `reachable` function that takes protocols state s, the set of pending messages, and a target partial protocol state S, and returns true if there exists s' such that $s' \in S$ and s' is reachable from $apply(s,e)$. We assume that this function over-approximates reachability, *i.e.,* it might return true even if there exists no reachable s' such that $s' \in S$, but never incorrectly returns false. For brevity, we only show a portion of the reachable function for the running example, which returns false if the state's *current* value is larger the target state (line 34).

(vi) A function, `apply_asap?`, that we use to reduce the simulation's memory requirements and runtime by reducing the number of schedules that need to be considered (§3.4.2). This function takes a protocol state s and an event e, and returns true if and only if we can safely apply the event immediately, *i.e.,* we do not need to consider schedules that reorder e with respect to other events (including ones that occur in the future). We define `apply_asap?`(s,e) to be correct if it meets the following two requirements:

  (a) **Event e can be reordered.** For any schedule Σ where $e \in \Sigma$ and message m, if $apply(s,\Sigma)$ is m-inducing, then so is $apply(apply(s,e),\Sigma - e)$.

  (b) **Event e does not block outgoing messages.** For any schedule Σ where $e \notin \Sigma$ and message m, if $apply(s,\Sigma)$ is m-inducing, then $apply(apply(s,e),\Sigma)$ is also m-inducing.

  These requirements ensure that applying e to protocol state s does not change the set of reachable m-inducing states, and Ellsberg can avoid exploring schedules that reorder e. An acquire message for a ticket smaller than the server's current ticket meets these requirements in our example (line 43).

(vii) An optional function `lookahead_type` that we use to reduce the number of m-inducing states found by the `infer_inducing` function, thus reducing simulation time. This function takes as input a message m and either returns `None` (indicating there is no such type) or a message type. As we explain later (§3.4.2), this function is used in an optimization to improve Ellsberg's efficiency, but its semantics do not affect correctness. Line 47 shows this function for the lock service: when

processing an outgoing acquire message Ellsberg looks ahead to find the next assigned message. This is because we cannot infer the value of the `highest` field from an acquire message, but can from an assign message, and considering both reduces the number of m-inducing states,and thus schedules that Ellsberg must explore.

In §4, we describe how a user can derive Ellsberg specifications from existing TLA+ specifications used to prove protocols correct, and test the derived specification. However, note that deriving a Ellsberg specification from a TLA+ specification is simpler than deriving an implementation: unlike implementations, Ellsberg specifications do not need to interact with communication libraries, consider failure handling, or implement application logic. Furthermore, Ellsberg specifications are written assuming sequential execution, and operators do not need to protect against data races or other concerns common to concurrent code. Consequently, it is easier to derive a correct Ellsberg specification than an implementation from a TLA+ specification.

3.4 The Ellsberg Algorithm

We now detail the Ellsberg algorithm. Concurrency and incrementally checking DPI correctness (so Ellsberg can report bugs soon after they are observed) were the two main challenges we addressed when developing this algorithm.

Concurrency is challenging because the protocol's behavior depends on the order in which events are applied, but Ellsberg does not know the order in which the messages and timeouts were processed by its associated DPI process. Similar to other work, we resolve this by considering multiple schedules consisting of different interleavings of incoming messages in the trace and timeouts.

Incremental checking makes constructing multiple schedules challenging because the DPI process might process a received message m, which appears in the trace, after message m' that has not yet been received, and thus does not appear in the trace. We resolve this challenge using the assumed the trace ordering property that guarantees that any received messages processed by the DPI process before it produces an outgoing message m must appear before m in the trace, and that outgoing messages appear in program order. Thus, when checking an outgoing message m, Ellsberg only considers schedules that contain incoming messages appearing before m in the trace. For notational convenience, we refer to the trace before m as the m-prefix. Furthermore, if the trace contains a sequence of outgoing messages $m_0, m_1, \ldots, m_n$, the simulation needs to only consider schedules which use incoming messages in the m_0-prefix before producing outgoing message m_0, messages in the m_1-prefix before producing outgoing message m_1, etc.

Ellsberg uses this observation to implement an incremental checking algorithm (Listing 3): Each Ellsberg instance maintains a set of simulation states S, which we define as a protocol state with a set of collections of pending message (line 2). For notational convenience, we use s_{sim}

```
1
2  struct SimState {
3      state: State,
4      pending: Set[Set[Messages]]
5  }
6
7  // The instance's current simulation state.
8  S: Set[SimState]
9
10 fn prune_asap(s: SimState) -> SimState {
11     for e in pending(s) {
12         if apply_asap?(state(s), e) {
13             return prune_asap(apply(s, e))
14         }
15     }
16     return s
17 }
18
19 // Process incoming message m in the trace.
20 fn process_incoming(m: message) {
21     for s in S {
22         // Check if m should be applied immediately.
23         if apply_asap?(state(s), m) {
24             S.replace(s, prune_asap(apply(s, m)))
25         } else {
26             s.add_pending_message(m)
27         }
28     }
29 }
30
31 // Process outgoing message m in the trace.
32 fn process_outgoing(m: message) {
33     // Get m-inducing states.
34     let target = infer_inducing(m)
35     // Check if we need to lookahead.
36     let m_lookahead = if lookahead_type(m) {
37         infer_inducing(
38             find_next_of_type(lookahead_type(m)))
39     } else {
40         None
41     }
42     // Updated simulation state.
43     let S' = new Set[SimState]
44     for s in S {
45         // Find reachable m-inducing states from s.
46         S_s = find_reachable(s,
47                   target, m_lookahead)
48         S' = S'.union(S_s)
49     }
50     if S'.is_empty() {
51         // No reachable m-inducing state indicates
52         // divergence b/w spec and implementation.
53         raise Error
54     } else {
55         S = S'
56     }
57 }
```

Listing 3: *Algorithm for checking a single outgoing message.*

to refer to simulation states, and $state(s_{sim})$ to reference the underlying protocol state. Initially S contains a single element: a simulation state with the initial protocol state and an empty pending message set. The algorithm iterates through the trace, and adds incoming messages (with one exception discussed in §3.4.2) to the pending message set of all simulation states $s_{sim} \in S$ (line 20). It processes an outgoing message m by finding all m-inducing simulation states that can be reached from any $s_{sim} \in S$ using s_{sim}'s pending messages and zero-or-more timeouts (line 46, §3.4.1). The algorithm notifies an error (line 53) if no m-inducing simulation states are reachable, otherwise it updates S to be the set of reachable m-inducing simulation states (line 55).

For example, if the ticket-lock service sends a message m indicating that the client with ticket 2 has acquired

```
1
2  fn find_reachable(s: SimState,
3         target: ProtState,
4         ahead: Option[ProtState]) -> Set[SimState] {
5      // The queue of SimState's to explore.
6      let to_explore = new Queue[SimState]
7      // Previously explored SimState's
8      let explored = new Set[SimState]
9      // The set of reachable m-inducing SimStates.
10     let reachable_inducing = new Set[SimState]
11     to_explore.insert_tail(s)
12     while !to_explore.is_empty() {
13         s' = to_explore.remove_head()
14         explored.add(s')
15         // Is s' m-inducing?
16         if state(s') in t {
17             reachable_inducing.add(s')
18             continue
19         }
20         for e in pending(s') {
21             // Is target reachable from apply(s', e)
22             if reachable(state(s'), pending(s'), e,
                    target) &&
23                (ahead.is_none() ||
24                 reachable(state(s'), pending(s'), e,
                        ahead)) {
25                 s'' = prune_asap(apply(s', e))
26             }
27             // Equivalent to enqueued state?
28             if to_explore.contains_state(s'') {
29                 // Add pending messages
                        in s'' to existing state.
30                 merge_pending(
31                    to_explore.get_state(s''), s'')
32             } else if !explored.contains_state(s'')
                    {
33                 // Add s'' to the exploration queue.
34                 to_explore.insert_tail(s'')
35             } else {
36                 // Add s'' to the exploration queue
37                 // if pending events differ from
38                 // previously explored.
39                 if !pending(explored.get_state(s''))
40                     .contains(pending(s'')) {
41                     to_explore.insert_tail(s'')
42                 }
43             }
44         }
45     }
46     return reachable_inducing
47 }
```

Listing 4: *Ellsberg's breadth-first search algorithm to find reachable m-inducing simulation states (passed in as argument* `target`*) starting from simulation state* `s`.

the lock ($m = Acquired(2)$) message, and S contains a single simulation s_{sim} for which $state(s_{sim}).held = true$ and $state(s_{sim}).current = 1$, then Ellsberg would throw an error if $pending(s_{sim})$ did not contain a release message.

Observe that because the trace is in program order, and the algorithm processes the trace iteratively, Ellsberg only considers incoming messages (and zero-or-more timeouts) in the trace's m-prefix when processing outgoing message m Furthermore, since outgoing messages are processed iteratively in order, the algorithm checks both the order and contents of outgoing messages sent by the DPI process.

3.4.1 Finding reachable states

The algorithm described above needs to find m-inducing simulation states reachable from the current simulation state s_{sim}. To do so, it first uses the `infer_inducing` function to compute *target* (Listing 3 line 34), which is the partial protocol state derived from outgoing message m. The algorithm then calls `find_reachable` with s_{sim} and *target* as arguments to find the subset of simulation states that are both consistent with the partial state *target* and reachable from the current simulation state s_{sim}. To make our state exploration efficient, we must design `find_reachable` to work efficiently by returning the smallest set of simulation state. In particular we require that if $s,s' \in find_reachable(s_{sim},t)$ then $equal(s,s') = false$. We had to solve two challenges when designing the `find_reachable` algorithm to meet this requirement:

Challenge 1: Many schedules can lead to the same m-inducing state. The schedule used to reach a simulation state s_{sim} dictates its pending message set. But there exist cases where `find_reachable` can reach two (or more) simulation states s_{sim} and s'_{sim} with the same underlying protocol state (*i.e.,* $equal(state(s_{sim}),state(s'_{sim})) = true$) but different pending message sets $pending(s_{sim}) \neq pending(s'_{sim})$. Which of these simulation states is returned can affect correctness. In this case, our handling depends on why multiple schedules reach the same semantically equivalent state:

a. There might exist cases where a protocol state s can be reached through two schedules Σ and Σ', and Σ is a subsequence of Σ' . This often happens because applying some message m has no effect on the protocol state s. For example, consider the ticket-lock server (Listing 1) with simulations state s_{sim} such that $state(s_{sim}).current = 1$ and $pending(s_{sim})$ contains an acquire message m_a for ticket 2 ($m_a = acquire(2)$). Applying m_a to s_{sim} does not change its protocol state because the client cannot acquire the lock, and $equal(state(apply(s_{sim},m_a)),state(s_{sim})) = true$. But, the pending set of $apply(s_{sim},m_a)$ does not contain m_a and is a subset of s_{sim}'s pending set.
   However, including the simulation state with a smaller pending state in `find_reachable`'s return can lead to false alarms: consider the case where s_{sim}'s pending set is $\{m_a,m_r\}$ where $m_r = release()$, and we are searching for an $Acquired(2)$-inducing state. It is clear that an inducing state is reachable from s_{sim} using the schedule $\Sigma = [m_r,m_a]$, but is not reachable from $apply(s_{sim},m_a)$, whose pending set does not include m_a.
   Therefore, in this case `find_reachable` should add the simulation state with the *largest pending set*[1] to the set of returned state. We ensure that this is the case by having `find_reachable` use *breadth-first search* (Lines 12–45) to find reachable target states. Breadth first search ensures that shorter schedules, and thus simulation states with larger pending message sets, are explored before simulation states with smaller pending message sets.

b. Semantically equivalent states might also be reached through two schedules Σ and Σ' neither of which is a subsequence of the other. We resolve this by having simulation states in Ellsberg track a set of pending message sets, allowing us to use a single simulation state to track

[1] Σ is a subsequence of Σ', and thus the pending set of the simulation state reached from Σ must be a superset of the other.

the pending message sets in this case (Lines 31 and 40).

Challenge 2: Terminating the search. Our algorithm searches through schedules that consist of pending incoming messages and zero-or-more timeout. These schedules can have unbounded length, because timeouts are always enabled. This poses a challenge, since `find_reachable` might explore unnecessarily long schedules and might not terminate. We address this problem in two ways: (a) We avoid redundant explorations by tracking simulation states that have already been explored by `find_reachable` (line 32). During breadth-first search `find_reachable` checks if a simulation state s_{sim}'s protocol state ($state(s_{sim})$) is the same as that of a previously explored simulation state (line 40, the `contains_state` function finds simulation states with equal protocol states): if not, it enqueues that simulation state for exploration, and otherwise terminates exploration for that simulation state. (b) Before scheduling exploration for simulation state $apply(s_{sim},e)$, we use the `reachable` function in the specification to first check if a target m-inducing state can be reached from s_{sim} (Line 22). We prune exploration from $apply(s_{sim},e)$ if the `reachable` function returns false.

3.4.2 Optimizing State Exploration

We use two performance optimizations:

Avoiding redundant exploration. The `find_reachable` algorithm explores different schedules which reorder incoming messages and zero-or-more timeout events in its search process. However, if the current simulation state s and a pending message m meet the `apply_asap?` requirements (§3.3) then when m is applied does not affect the search.

Therefore, we use the `apply_asap?` function to improve exploration efficiency in two places: (a) When processing an incoming message m from the trace (Listing 3), Ellsberg checks whether it can be applied immediately to a simulation state $s_{sim} \in S$, and if so it uses the recursive function `prune_asap` (Line 10) to replace s_{sim} with the result of applying $apply(s_{sim},m)$ and all other messages that can be applied immediately (Line 24); and (b) in the `find_reachable` (Listing 4) algorithm when adding a new simulation state s_{sim} to the set of states that need to be explored (Line 25) we again use `prune_asap`. Note, that while this optimization is similar in principle to partial-order reduction [28] (POR), our technique is designed for the incremental setting.

In Appendix A we describe how we can mechanically check that `apply_asap?` is correct, and thus the use of this approach does not come at the cost of correctness.

Looking ahead to the next outgoing message. The number of m-inducing states found by `find_reachable` is determined by the outgoing message m being considered: an outgoing message m that reveals little about the DPI's protocol state, *e.g.,* client response messages, may allow for a large set of reachable m-inducing states. Consequently, when processing m, `find_reachable` might return a large set of simulation states that the Ellsberg instance would use when it next processes an outgoing message. However, the time

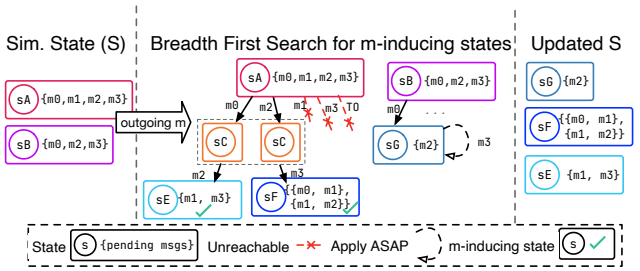

Figure 2: *An overview of how a Ellsberg processes outgoing message m using BFS to find all m-inducing states reachable from the current simulation state.*

taken to process an outgoing message depends on the size of the simulation set S because it determines the number of `find_reachable` calls made (Listing 3 line 44). Smaller simulation sets are thus preferable. Ellsberg implements an optimization that can reduce the set of states returned by `find_reachable` in some cases. Specifically, the optimization "looks ahead" to the next message m_T of type T that occurs after m in the trace and passes to `find_reachable` an optional argument (`ahead`) containing the m_T-inducing state, allowing `find_reachable` to prune any simulation states $s_{sim} \in S$ from which an m_T-inducing state is not reachable (Listing 4 line 24).

We use the `lookahead_type` function in the user-provided specification (§3.3, Listing 2) to decide when to use this optimization. As a reminder, the `lookahead_type` takes as input the outgoing message m that Ellsberg is processed, and either returns `None` (indicating lookahead should not be used) or a message type T. If the function returns a type T, Ellsberg scans the trace, starting at m to find the next outgoing message m_T of type T (Listing 3 line 38) and passes the m_T-inducing state to `find_reachable`. The `find_reachable` function then only returns simulation states that are both m-inducing and m_T-inducing, a smaller set than the set of all m-inducing sets. Note that our use of `lookahead_type` ensures that its output has no impact on correctness: if the function returns type T, then any simulation state s_{sim} pruned by `find_reachable` would have been pruned by a future call to `find_reachable` when considering the next outgoing message of type T.

3.5 Algorithm Summary and Generality

In summary, each Ellsberg instance works as follows: it maintains a set of simulation states S and iterates through the trace. An incoming message m in the trace is processed (Listing 3 Line 20) by iterating through S, and checking for each simulation state $s_{sim} \in S$ if the message should be immediately applied: if so, s_{sim} is replaced by $apply(s_{sim},m)$, if not m is added to s's pending set. An outgoing message m (Figure 2) in the trace triggers a check to determine if the DPI is buggy (Listing 3 Line 32), which involves iterating through the simulation states $s_{sim} \in S$ and using the `find_reachable` (Listing 4) algorithm to determine if an m-inducing state is reachable from s_{sim}. Ellsberg reports a bug if no m-inducing states are reachable from any simulation state $s_{sim} \in S$, otherwise S is replaced by the union of all reachable m-inducing simulation states.

When does Ellsberg detect a bug? Ellsberg? Ellsberg only has visibility into what messages have been sent or

System	Ellsberg LOC	Baseline	Baseline LOC
ETCD	952	CCF Raft [35]	1503
RedisRaft	894	CCF Raft	1503
Zookeeper	989	ZooKeeper TLA+ [38]	1615

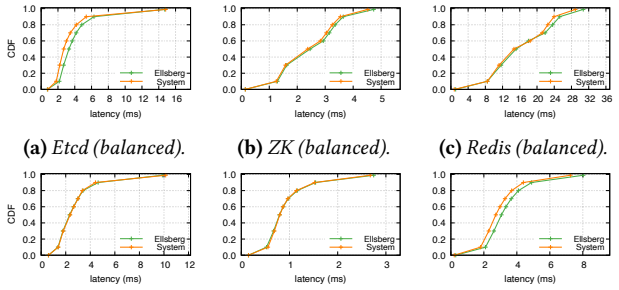
Table 1: *Lines of code in Ellsberg specification when compared to those used by existing tools. For baselines, we use the Raft specification from Microsoft CCF [35] Etcd and RedisRaft, and a recent implementation derived TLA+ specification [38] for ZooKeeper.*

received by DPI thus far, and hence, at any point in time, it can only detect bugs that are apparent from the trace prefix provided to it thus far. Furthermore, even for this prefix, our approach checks if there exists any schedule (*i.e.,* a total order) of incoming messages that when applied to the specified distributed protocol produces the sequence of output messages observed in the trace prefix. So, as we noted earlier (§3.1) Ellsberg can only detect a bug once it observes an output message that is inconsistent with the specification.

Generality & Applicability. Our algorithm assumes that the protocols being checked can be specified as a collection of processes, each of which is an I/O automaton. Concretely, this assumption means that events (received messages or timeouts) must be applied atomically, and a messages behavior cannot be influenced by a message being applied concurrently. This condition holds for many but not all distributed protocols, *e.g.,* it does not hold for a distributed concurrency control protocol where multiple transactions can be executed simultaneously and have their results validated after the fact.

An additional protocol assumption is required to make incremental checking feasible: protocols must include one or more messages that (perhaps together) allow Ellsberg to infer the entire state of a DPI process. Absent such messages, Ellsberg must maintain an ever increasing set of partial states and consider a growing number of schedules when checking outgoing messages, making the use of Ellsberg infeasible in practice. These messages exist for most protocols, including the RSM protocols we use in our evaluation. However, we have encountered one case where this assumption does not hold: databases that use multi-version concurrency control, and whose messages do not include information about what version a transaction read from or updated. In this case applying Ellsberg requires us to consider all possible orderings for concurrent transactions, incurring similar complexity as prior transaction verification approaches [83, 98].

4 Writing Ellsberg Specifications



To use Ellsberg, users or protocol authors need to translate existing specifications, *e.g.,* ones used to verify safety, into Ellsberg specifications. Our evaluation uses specifications derived from TLA+ protocol specifications: for Raft we used the TLA+ specification [63] provided by the Raft authors, while for ZooKeeper we used an implementation derived TLA+ specification [38].

Table 1 shows the length of our specifications ('Ellsberg LOC' column). We use the same Raft specification for Etcd and Redis Raft, the difference in length is because they support different reconfiguration protocols. To put our specifications length into context, we also report the length of specifications used by other tools: for the two Raft DPIs we compare to the Raft specification used by Microsoft CCF (written specifically for use with that tool), and for ZooKeeper we compare to the implementation derived TLA+ specification we used. Note, that the Microsft CCF Raft implementation supports a different (and simpler) reconfiguration protocol than Etcd, but the protocols are comparable. Our specification is comparable in length to these baseline specifications, and indeed a few lines shorter. Appendix C provides additional details about the Ellsberg specifications, including a detailed breakdown of lengths for each part (Appendix C.1).

We adopted the following approach to derive the `ProtState` structure, and the `equal`, `infer_inducing`, and `apply` functions from TLA+:

- **`ProtState`**. The `ProtState` structure contains all per-server variables that appear in the TLA+ specification. We derived it by identifying all variables in the TLA+ specification, filtering out those that are global variables (*e.g.,* `messages` in the Raft specification [63]) or ghost variables (*e.g.,* `voteResponded` in the Raft specification), and adding the remaining variables to the structure.
- **`equal`**. The equal function merely checks that all state variables have the same value, and the language (or runtime) provided equality function suffices.
- **`apply`**. The `apply` function matches over all possible state machine transitions, and updates a provided `ProtState` structure. We derived it by walking through the TLA+ specification to find transitions (*e.g.,* `ClientRequest(i, v)` in Raft) and copying over any state updates that appear in the transition.
- **`inference`**. The `inference` function takes an outgoing message and tries to infer the process' DPI state. To derive this function, we first identify transitions that send messages (*e.g.,* by finding transitions that call `Send` in the Raft specification).Given these transitions, we use three techniques to infer state variables values: (i) If the outgoing message directly uses a state variable, *e.g.,* term, we can infer the state value directly from the message; (ii) If the outgoing message contains a value computed from a state variable, *e.g.,* last log index, we use the inverse computation to infer the state value; and (iii) If the outgoing message is sent only when a particular state variable has a given value, then we can infer the value of the state variable when we observe the message: *e.g.,* we can infer that Raft a node sending a `RequestVoteRequest` message is a candidate.

We had to write de novo `apply_asap?`, `reachable`, and `lookahead_type` functions. Of these, the `apply_asap?` function can be *mechanically proven correct* (described in Appendix A), and the `lookahead_type` function has no impact on Ellsberg's correctness (§3.4.2).

Testing Ellsberg specifications. We also provide a testing tool, inspired by Mocket [87], to check that the derived Ellsberg specification matches the original TLA+ specification, and does not have translation bugs.

Our testing tool takes as input a TLA+ specification, and generates valid message traces (that is message traces that do not lead to safety violations) using this specification. Message traces are generated from the TLA+ specification as follows: first, the tool uses TLC's [44] bounded model checking functionality to generate a transition graph for a bounded number of steps; next, it performs depth first traversal of the transition graph and keeps track of the sequence of states along each traversed path; finally, it translates the sequence of states into message traces. The last step builds on the observation that TLA+ specifications model messages sends and receives as modifications to a message vector, allowing our tool to translate state sequences into sequences of message sends (or timeouts).

The tool then uses the generated traces to exercise Ellsberg specification, and reports a bug if the Ellsberg specification would have (falsely) notified an error for the trace.

5 Implementation

We implemented Ellsberg in Go, and our current prototype requires protocol specifications to be written in Go and compiled with Ellsberg. We evaluated our prototype using specifications for Raft [64] and ZAB [38], and used Etcd, ZooKeeper and RedisRaft as DPIs.

The Raft specification we use consists of ∼500 lines of code, and the ZooKeeper specification consists of ∼2000 lines of code. We describe how we developed these specifications from existing machine checked specifications in Appendix C. We used the Ellsberg testing tool (§4) to test both specifications. For Raft, our test ran 15 steps of bounded model checking (this was sufficient to cover all protocol states), and validated the specification using 8,750,468 message traces; while for Zookeeper, our test ran 20 steps of bounded model checking (again, sufficient to cover all protocol states) and validated the specification using 1,904,456 message traces.

Overall, the Ellsberg implementation (including both specifications) consists of ∼4500 lines of code. Of this total, the testing tool consists of about 500 lines of Python code, and the rest is Go code for the Ellsberg instance and both specifications. In addition to the protocol specification, users must also provide Ellsberg with DPI specific code to deserialize and map implementation messages to specification messages. The mapping function for Etcd is 356 lines of Go code, for ZooKeeper it is 370 lines of Go code, and for RedisRaft it is 380 lines of Go code.

Our prototype uses an IPC channel to get the trace, and we modified the network APIs for both DPIs to update the trace. Doing so required adding logic (to forward messages) to 11 functions in Etcd, 31 functions in ZooKeeper, and 10 functions in Redis Raft. We were careful to ensure that no additional timing or ordering information was sent over this IPC channel. We used IPC for simplicity, but our implementation can adopt alternate approaches, *e.g.,* having a service proxy [19] copy messages to Ellsberg.

6 Evaluation

We evaluated Ellsberg using three widely-used open source DPIs: Etcd, Zookeeper, and Redis Raft. Our evaluation focused on three questions: (a) Can Ellsberg detect bugs at runtime? (§6.2) (b) Can Ellsberg be deployed in production? (§6.3) (c) How does Ellsberg perform: how long does it take Ellsberg to process a trace, and the impact of our design (§3.4) on performance? (§6.4)

6.1 Setup and Workload

Our evaluation deployed Ellsberg on 3- and 5-node DPI clusters. Each cluster node was a C6525-25G instance in CloudLab [18], with a 16-core 3GHz AMD EPYC 7302P processor, 128 GB of RAM, two 25Gbps NICs, and ran Ubuntu 20.04. We deployed a DPI process and Ellsberg instance on each node, and used `taskset` to limit the Ellsberg instance to two cores. Ellsberg instances were configured to process trace messages every second.

We exercised the DPIs using workloads derived from YCSB [16]. We use two benchmarks: a *balanced* workload with 50% reads and 50% writes, and a *read-heavy* workload with 95% reads and 5% writes. For both workloads, keys are drawn uniformly at random from among 1 million possible keys. We used 120 concurrent DPI clients as load generators, we found that this maximized observed throughput for all DPIs. To minimize performance variance, we disabled checkpointing for all DPIs.

In the interest of space, we use *ZK* to refer to Zookeeper and *Redis* to refer to Redis Raft in figure captions in this section.

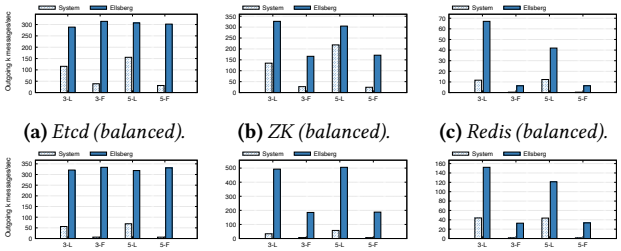
6.2 Can Ellsberg detect bugs?

We evaluated Ellsberg's ability to detect protocol implementation bugs by reproducing previously reported bugs in Etcd, Redis Raft and Zookeeper, and checking whether Ellsberg notified when the bugs occurred. Due to space constraints we provide the bugs and their root causes in Appendix D, but summarize them in Table 2. The bugs we tested on including bugs in the linearizable read protocol implemented by Etcd [25] and Redis Raft [72]; a stale-read

System	Bug	Type
Etcd	741 [25]	Linearizable read
	7331 [24]	Stale read after election
	12133 [22]	Reconfiguration
	7280 [23]	Reconfiguration
Zookeeper	1154 [101]	Data inconsistency
Redis Raft	17 [71]	Reconfiguration
	19 [72]	Linearizable read
	52 [74]	Lost updates
	256 [73]	Reconfiguration
	Unreported	Reconfiguration

Table 2: *Bugs used to evaluate Ellsberg's bug detection capability.*

bug in Etcd [24] because a new leader's commit index might lag behind the previous leader's commit index; a bug in Zookeeper's [101] leader election protocol (leading to data corruption); a bug in Redis Raft's caches that leads to lost updates [73]; and reconfiguration bugs in Etcd [22] and Redis Raft [71]. During testing, we also identified an unreported bug in Redis Raft's reconfiguration protocol implementation.



6.3 Can Ellsberg be used in production?

We demonstrate that deploying Ellsberg in production is feasible by showing that it has low resource requirements, and does not impact DPI performance. In terms of resources: our evaluation uses `taskset` to limits each Ellsberg instance to 2 cores. Furthermore, we found (explained in detail in Appendix E) that across all our evaluations, each Ellsberg instance tracks one simulation state on average (*i.e.*, $|S| = 1$) and has between 0 and 5 pending messages, and thus has minimal memory requirements. Additional, Ellsberg does not use the network by design. We thus conclude that Ellsberg has minimal resource overheads.

In terms of DPI performance impact, Figure 3 shows the performance of the DPIs with ('Ellsberg') and without ('System') a collocated Ellsberg process. We show results for a 5-node Etcd, Zookeeper, and Redis Raft cluster when running a read-heavy and balanced workload. We omit results for 3-node clusters, but they were similar. We observe that collocating Ellsberg increases tail-latencies slightly: the largest increase we observed was for Redis when running the read-heavy workload(Figure 3f) where 99th percentile latency increases by 10.7% (from 7.25ms to 8.03ms). These results show that using Ellsberg has minimal impact on response latency, and thus production deployment is feasible.

6.4 End-to-End Performance

Ellsberg's detection latency is determined by how often it checks the trace, in our evaluation we use a configuration (§6.1) where it checks the trace every second (allowing us to batch checking and reduce overheads). Therefore, we evaluate Ellsberg's performance by measuring its throughput, and report results in Figure 4. We also report the DPI's throughput when it is run without a colocated Ellsberg process: the DPI throughput both serves as a comparison point to evaluate Ellsberg's algorithmic efficiency; and

(a) *Etcd (balanced).* **(b)** *ZK (balanced).* **(c)** *Redis (balanced).*

(d) *Etcd (read-heavy).* **(e)** *ZK (read-heavy).* **(f)** *Redis (read-heavy).*

Figure 4: *Ellsberg's throughput compared to DPI throughput (System) for different workloads and DPIs. In these graphs, 3-L and 3-F respectively refer to the leader and follower in a 3-node cluster, and 5-L and 5-F refer to the leader and follower in a 5-node cluster.*

addresses whether Ellsberg can keep up with the colocated DPI process (if Ellsberg had lower throughput it might not keep up with a loaded DPI). We report results from both 3- and 5-node clusters and both workloads, and measure throughput in outgoing messages per second. The results were collected by measuring throughput in a 10-second interval over 10 experiments. We omit error bars because we observed nearly no variance across experiments.

Our results show that across DPIs and workloads, Ellsberg achieves higher throughput than the DPI: for Etcd Ellsberg has 2.0—51.7× higher throughput, for Zookeeper Ellsberg has 1.4—29.7× higher throughput, and for Redis Raft Ellsberg has 3.1—25.5× higher throughput. In practice, we found that processing a second of trace events took Ellsberg between 30 − 700ms when the co-located DPI node was a leader, 20 − 180ms otherwise. In sum, this means that in our evaluation Ellsberg notifies administrators within 1.7 second of a bug occurring, though this could likely be reduced with a different configuration. Appendix E further evaluates the impact of Ellsberg's optimizations.

7 Conclusion

This paper proposed *runtime protocol refinement checking*, an approach that combines ideas from refinement proofs and runtime verification to notify administrator of protocol bugs in deployed DPIs. Unlike static refinement proofs RPRC can be used with existing unmodified DPIs, and unlike runtime verification RPRC does not require coordination or communication. We also described an algorithm for RPRC, and our implementation of this algorithm Ellsberg, and applied it to three commonly used DPIs: Etcd, ZooKeeper and Raft. We believe that RPRC and Ellsberg provide a practical approach for improving the reliability of deployed DPIs.

Acknowledgment

We thank Wen Zhang, Joe Tassarotti, Mike Walfish and Scott Shenker for discussions that helped shape our approach presentation. We also thank our shepherd Si Liu and the anonymous NSDI reviewers for comments that further improved our presentation. A Proving apply ASAP correct

Protocol specifications in Ellsberg include an `apply_asap?` function (§3.3), whose output we use to avoid redundant exploration (§3.4.2). In this appendix, we look at proving the correctness of this function.

We start by redefining the `apply_asap?` requirements in terms of *dominating states*.

Dominating state: We say a state s dominates state s' (or $s \sqsupseteq s'$) if and only if for any message m, s' being m-inducing implies s is m-inducing.

The `apply_asap?` function takes as input state s and an event e, and returns true if the following conditions are met:

- For all schedules Σ where $e \in \Sigma$, $apply(apply(s,e),\Sigma - e) \sqsupseteq apply(s,\Sigma)$.
- For all schedules Σ where $e \notin \Sigma$, $apply(apply(s,e),\Sigma) \sqsupseteq apply(s,\Sigma)$.

We now turn to describing our approach for proving a supplied `apply_asap?` function meets this requirement.

In our specifications (and indeed in all specifications), an $apply_asap?(s,\ e)$ consists of a set of constraints $C = \{c_0, c_1, ..., c_n\}$ over s and e, and returns true if any constraint c_i holds. For example, in Raft's $apply_asap?$ function one of the constraints deals with append entry responses, and returns true if e is an incoming *AppendEntryResponse* message with term t and the simulation state s's term is larger than t ($s.term > t$).

We prove `apply_asap?` correct by analyzing each constraint $c \in C$. More formally

Theorem 1 *An* `apply_asap?` *function specified as the set of constraints C is correct if and only if for all $c \in C, s \in S, e \in E$, $c(s,e) = true$ implies that the following two properties hold for s,e:*

- *For all schedules Σ where $e \in \Sigma$, $apply(apply(s,e),\Sigma - e) \sqsupseteq apply(s,\Sigma)$.*
- *For all schedules Σ where $e \notin \Sigma$, $apply(apply(s,e),\Sigma) \sqsupseteq apply(s,\Sigma)$.*

Proving these two conditions mechanically is challenging, as it requires reasoning about the set of all schedules Σ. Therefore, we instead prove that if four simpler properties (that can be mechanically checked) hold for any $c \in C$, then c satisfies Theorem 1:

Condition A.1 ***Order Preserving.*** *The protocol should be such that for any event e, states s_1, s_2, if $s_1 \sqsupseteq s_2$, then $apply(s_1,e) \sqsupseteq apply(s_2,e)$.*

Condition A.2 ***Constraints Preserving.*** *For any event e,e', and any state s, if $c(s,e) = true$ then $c(apply(s,e'),e) = true$.*

Condition A.3 ***Expansion.*** *For any event e and any state s that satisfies $C(s,e)$, $apply(s,e) \sqsupseteq s$*

Condition A.4 ***Reorder Safety.*** *For any event e,e', state s that satisfies $C(s,e)$, $apply(apply(s,e),e') \sqsupseteq apply(apply(s,e'),e)$*

Assume c satisfies the four conditions above, we use case splitting to prove that Theorem 1 must hold:

Case 1 $e \notin \Sigma$. Given **Statement 3**, we have $apply(s,\ e) \sqsupseteq s$. Given **Statement 1**, we have $apply(apply(s,e),\Sigma) \sqsupseteq apply(s,\Sigma)$. ■

Case 2 $e \in \Sigma$. Suppose $\Sigma = \Sigma' + e + \Sigma''$ where $\Sigma' = e_1, e_2, ..., e_k$. To simplify the expressions, we denote $apply(s,e)$ by $e(s)$. We first prove that:

Lemma 1

$$e_k \circ ... \circ \underline{e_{i+1}} \circ e \circ e_i \circ ... \circ e_1(s) \sqsupseteq e_k \circ ... \circ \underline{e \circ e_{i+1}} \circ e_i \circ ... \circ e_1(s)$$

Let $s' = e_i \circ ... \circ e_1(s)$, according to **Statement 2**, given that $C(s,e)$ is satisfied, we have that $C(s',e)$ is also satisfied. Then, according to **Statement 4**, we have $e_{i+1}(e(s')) \sqsupseteq e(e_{i+1}(s'))$. Then, given **Statement 1**, we can prove **Lemma 1**.

Therefore, we can further prove this by inductively applying **Lemma 1**:

$$e_k \circ ... \circ e_2 \circ e_1 \circ e(s) \sqsupseteq e \circ e_k \circ ... e_2 \circ e_1(s)$$

Then, let $s_1 = e_k \circ ... \circ e_2 \circ e_1 \circ e(s)$ and $s_2 = e \circ e_k \circ ... e_2 \circ e_1(s)$, given **Statement 1**, we have $\Sigma''(s_1) \sqsupseteq \Sigma''(s_2)$, where $\Sigma''(s_1) = apply(apply(s,e),\Sigma - e), \Sigma''(s_2) = apply(s,\Sigma)$. ■

B Mechanically Checking `apply_asap?`

We used Z3 to check the `apply_asap?` functions in our specification satisfy the four conditions A.2–A.4. To do so, we used the following Z3 specifications:

1) $apply(s,e)$ of each event.
2) $dominates(s_1,s_2)$. It returns whether $s_1 \sqsupseteq s_2$
3) $C(s,\ e)$. It specifies the constraints between e and s. When $C(s,e) = True$, it means we can apply e on s asap.

Among these, we specify $apply(s,\ e)$ using each protocol's TLA+ specification. We show the *dominates* and C specification for Raft below:

```
fn dominates(s1: State, s2: State) {
    //all other states are the same, except
          commit_index, match_index and vote_granted
    //s1's commit_index is not smaller than s2
    //each slot
          of s1's match_index is not smaller than s2
    //if s1'state is candidate, then s1's
          vote_granted is the same as s2. Otherwise,
        s1's vote_granted set is the superset of s2.
    return s1.term == s2.term && ... &&
           s1.commit_index >= s2.commit_index &&
           [for i in range(SERVERS):
            s1.match_index[i]>=s2.match_index[i]] &&
           (s1.state == CANDIDATE ?
                equal(s1.
                     vote_granted, s2.vote_granted) :
                subset(s2.vote_granted
                     , s1.vote_granted))
}
```

```
fn C(s: State, e: Event) {
    //we can apply e asap if this is an event from previous term
    //or it is an AppendEntriesResponse in current state's term
    //or this is a RequestVoteResponse in current state's term, and the state now is not CANDIDATE
    //or this is a AppendEntryRequest in current state's term, but it broadcasts the entires that are a subsequence of the local log.
    //or this is a RequestVoteRequest in current state's term, but server has already voted for someone.
    return e.term < s.term ||
           (e.term == s.term &&
               (e.type == AppendEntriesResponse ||
               e.type == RequestVoteResponse &&
                   s.state != CANDIDATE) ||
               e.type == AppendEntryRequest
                   && s.state == FOLLOWER
                   && subseq(e.entries, s.log) ||
               e.type == RequestVoteRequest
                   && s.votedFor != None)
}
```

The *dominates* and *C* specification for ZAB are below:

```
fn dominates(s1: State, s2: State) {
    //all other states are the same, except last_committed, last_processed, ackid of each log entry, and ack_ld_recv
    //s1's last_committed and last_processed are not smaller than s2
    //each entry's ack set of s2 is the subset of s1
    //if in BROADCAST state, s2's ack leader set is the subset of s2. Otherwise, s2's ack leader set is the same as s1.
    return s1.accepted_epoch
          == s2.accepted_epoch && ... &&
           s1.last_committed >= s2.last_committed &&
           s1.last_processed >= s2.last_processed &&
           [for i in range(ENTRIES):
            subset(s2.Log[i].ack, s1.Log[i].ack)] &&
           (s1.zab_state == BROADCAST?
            subset(s2.ack_ld_recv, s1.ack_ld_recv):
            equal(s1.ack_ld_recv, s2.ack_ld_recv))
}

fn C(s: State, e: Event) {
    //we can apply e asap if this is an ACK
    //or it is an ACKLD in outdated epoch compared with current state's accepted_epoch
    //or ACKLD in current accepted_epoch but current state already has received quorum ACKLD
    return e.Type == ACK ||
           (e.Type == ACKLD &&
                (Epoch(e.Zxid) < s.accepted_epoch
                    || has_quorum(s.ack_ld_recv)))
}
```

C Protocol Specifications

Below, we provide additional information about the protocol specification used in our evaluation, including detailed breakdown of their lengths and additional information about how they were derived.

C.1 Specification Length

Table 3 shows lines of code for each portion of the Ellsberg specifications used in our evaluation. Similar to §4 we also report the length of specification used by Microsoft's CCF project for validating Raft [35] and an implementation derived ZooKeeper specification [38].

Component	Etcd	Redis Raft	ZooKeeper
State	45	47	102
apply	345	312	433
equal	64	64	73
infer_inducing	298	271	236
reachable	37	37	63
apply_asap?	39	39	36
lookahead_type	9	9	6
Other code	115	115	40
Total (Ellsberg)	952	894	989
Baseline	1503	1503	1615

Table 3: *Lines of code in Ellsberg specification when compared to those used by existing tools. For baselines, we use the Raft specification from Microsoft CCF [35] Etcd and RedisRaft, and a recent implementation derived TLA+ specification [38] for ZooKeeper.*

C.2 Raft

We evaluated our approach and Ellsberg using two Raft implementations: Etcd [21], a distributed key-value store that is widely deployed, often as a core component of Kubernetes [39] and other orchestrators; and Redis Raft [32, 75], a module that adds consistent replication to the Redis key-value store. In this section, we describe the specification we used.

Protocol Specification. Our initial approach for producing a specification was to derive one from Ongaro's TLA+ Raft specification [63], since this closely mirrored the protocol described in the Raft paper [64], and we assumed was the distributed protocol implemented in practice. However, we found this was not the case, both implementations we evaluated implement a protocol which makes several changes to the original protocol, and the specification we use includes these changes. The most significant changes from the protocol in the paper affect read-only operations and reconfiguration, and we describe both below.

Read-only operations: Both of the implementations that we evaluated provide linearizable reads, but neither logs read-only operations. Both require the leader to process all read-only requests, and the leader computes the return value using its current state. To ensure linearizability, a node that is processing a read-only request must first assert that it is still the leader, *i.e.*, it needs to check that its term is the same as a quorum's term [95]. Both implementations use the same approach to assert leadership: when a node (that believes it is currently the leader) receives a read-only request, it associates a *request ID* with it and includes this request ID in a heartbeat request (as a reminder, Raft uses empty append entry messages for heartbeats) to other nodes in the cluster. The node then waits until a quorum (majority) of nodes have positively acknowledged the heartbeat message (showing that a quorum agrees on the term, and that the node was the leader when the request

was received), before responding to the read-only request.[2]

Reconfiguration protocol: The other area where both implementations differ is in how they implement cluster reconfiguration: Etcd uses different protocols to handle reconfiguration that adds or removes a single node (the Etcd documentation [26] seems to prefer this protocol) and ones that add or remove multiple nodes (where Etcd largely uses the original joint quorum protocol with minor changes); while Redis Raft only allows the addition or removal of a single node.

Both implementations use a similar (but not identical) single node reconfiguration protocol that avoids the original protocol's use of joint quorums, because in this case quorums are guaranteed to have intersection before and after configuration changes are applied. Therefore, the reconfiguration protocol in this case merely requires that the leader replicate a reconfiguration command to all followers. The two implementation differ on when they apply the reconfiguration command: Redis Raft nodes apply the command as soon as it is added to their log, while Etcd treats reconfiguration commands like any other command and applies them asynchronously after they have been committed. Etcd's approach can pose a safety problem, and recent versions of Etcd change the request vote protocol to ensure that nodes with replicated but unapplied reconfiguration entries do not send request vote messages (and thus do not try to become leaders). This restriction also applies to multi-node reconfiguration in Etcd, and one of the bugs we reproduce and detect with Ellsberg (§6) is due to errors implementing this change.

Beyond differences due to changes in Raft, our specification differs in another crucial way: we model the behavior of messages sent by clients (*e.g.,* `get` and `put`) while Ongaro's specification doesn't.

Our evaluation uses similar protocol specifications for both implementations, and they only differ in when reconfiguration commands take effect.

C.3 Zookeeper Atomic Broadcast

Obtaining a specification for Zookeeper atomic broadcast (ZAB) [38] as implement by ZooKeeper [100] was a bit easier. While the TLA+ specification included in the Junqueira et al's [38] paper no longer reflects the implementation, a recent pre-print [65] has produced an updated TLA+ specification from the implementation, and we used this specification with minor changes.

ZooKeeper is also easier to model, since it does not support linearizable reads, and we did not need to consider modifications for this.

D Bug Descriptions

Below, we describe the bugs used in our evaluation (§6.2), their root-cause and how we detected them.

etcd-741 [25] is a bug that predates Etcd incorporating the linearizable read protocol we described in §C.2. In older versions, an Etcd leader responded to read-only requests with its current value, without asserting that it was the leader, thus violating linearizability. We reproduced this bug by removing the linearizable read logic from Etcd. Ellsberg detected the bug when it observed the leader responding to a client's request before receiving positive heartbeat acknowledgments from a quorum.

etcd-7280 [23] and **etcd-12133** [22] are bugs in Etcd's reconfiguration protocol. As we noted previously (Appendix C.2), Etcd supports two different reconfiguration protocols (a single-node reconfiguration that does not require joint-quorums, and a more general version that uses joint-quorums). Etcd also has two different command types for reconfiguration, one which only allows single node reconfiguration (V1), and one that can be used to trigger both single-node reconfiguration and joint-quorum based reconfiguration (V2). Regardless of command or protocol, reconfiguration takes effect when the command is *applied* by a node. Furthermore, Etcd does not allow a node with an unapplied reconfiguration command in its log to send a request vote message (*i.e.,* to transition to being a candidate).

Both of these bugs are caused by cases where Etcd incorrectly allowed a node with an unapplied reconfiguration command to become a candidate. In the case of etcd-7280 this was caused because Etcd switched to applying reconfiguration requests asynchronously, but assumed that a single reconfiguration request could be in progress at a given time. If more than one reconfiguration request was in progress, then Etcd would allow a node to become candidate after applying the first change, resulting in two leaders being elected simultaneously. Similarly, etcd-12133 was caused by a bug in how Etcd counted the number of pending reconfiguration messages: the bug meant that Etcd did not consider unapplied V2 reconfiguration commands, resulting in a split-brain problem where two leaders are elected for the same term.

In both cases, Etcd's safety invariants say that any inducing states for a request vote message has no unapplied reconfiguration commands. Thus, one might expect that we detect these bugs when a node first sends out a request vote message. However, this is not the case: Ellsberg does not know whether a node has applied a reconfiguration command, since commands are applied asynchronously by a background thread. Instead, when Ellsberg see the request vote message, it merely infers that the reconfiguration command has been applied. However, Ellsberg reports a bug when it later observes that the node has transitioned to being a leader (*e.g.,* by observing outgoing append entry messages) without having received votes from a quorum active in the latest configuration.

etcd-7331 [24] is a bug caused by interaction between Etcd's linearizable read protocol and Raft's leader election protocol that can result in a newly elected leader returning a stale value in response to a read. When an Etcd leader receives a read-only request, it records the current commit index, and checks that

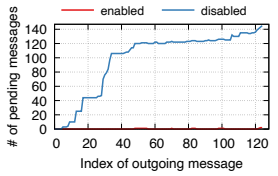
[2] What we have described corresponds to Etcd's `ReadIndex` method. Etcd also implements a lease-based mechanism for linearizable reads, but we neither modeled this mechanism nor use it in our evaluation.

it is still the leader (by sending a heartbeat or append entry message, and waiting for responses from a quorum). However, a newly elected leader's commit index might be smaller than the previous leader's commit index. This is because while Raft's leader election protocol requires that the new leader's log contain all committed entries (and in fact be the most up-to-date log in a quorum), it cannot guarantee that the commit index (which leader's update asynchronously) is up-to-date.

Furthermore, for safety, Raft does not allow a leader to update its commit index until it has replicated an entry in the current term [64, §5.4.2] to a quorum, *i.e.,* it can only update the commit index to point to entries in the current term. Consequently, a read-request handled by a newly-elected leader might return a previous value, violating linearizability.

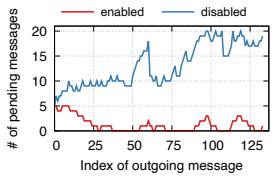
Etcd fixed this protocol bug in its linearizable read protocol by requiring that leaders commit an entry in the current term before initiating a quorum check for a read-only request. Ellsberg uses the same approach to detect this bug: it raises an alarm if it sees the leader is performing a quorum check for a read-only request (which it can detect because heartbeat or append entry messages used for quorum checks include a request ID for the read request) before committing an entry.

Zookeeper-1154 [101] is data inconsistency bug, where after leader election, nodes disagree on the log. In the leader election protocol implemented by ZooKeeper, a node needs to synchronize its log with all other nodes. To do so, the leader collects the largest entry ID (*ZXID*s) from each follower, and compares the follower's latest ZXID to the latest ZXID in its own log. If the follower's latest ZXID differs, then the leader needs to first have the follower truncate its own log (to the last ZXID on which both agree) and then send missing entries to the follower. Similar to other protocols, ZXIDs in ZooKeeper are monotonically increasing. When implementing the leader election protocol, the ZooKeeper developers introduced a bug and assumed that if the ZXID sent by the follower was *smaller* than the latest ZXID in the leader's log, then the follower must contain a subset of the leader's log entries. The leader would then avoid truncating the follower's log, and immediately send new entries. However, this is unsafe since the follower's log might contain an entry that has a lower ZXID but is not present in the leader's log, resulting in an inconsistent log. Our simulation detects this when the leader sends out the DIFF message since the follower's latest ZXID is not contained in the leader's log, and thus no inducing state for the DIFF message can be reached.



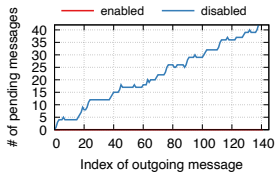
RedisRaft-17 [71] is also a reconfiguration bug: Redis Raft does not allow concurrent reconfiguration requests, and will accept at most one reconfiguration request at a time (rejecting the other). It considers reconfiguration to be complete once the command has been committed to quorum. Due to a bug, it was not checking this correctly. Detecting this bug with Ellsberg was relatively simple: our inference function says that the inducing state for a successful reconfiguration request is one where the reconfiguration command was added to the log. However, our transition function does not allow transitioning into a state with two uncommitted reconfiguration requests, and thus Ellsberg cannot find a reachable inducing state for the second successful reconfiguration response.

RedisRaft-19 [72] is a bug in Redis Raft's linearizable read implementation. Unlike Etcd-741, this bug occurs despite nodes asserting leadership before responding to clients, and is caused by the node being unaware of the current commit index. In Raft, a leader may not know what log entries were committed by the previous leader (in the previous term). Furthermore, Raft requires that leader's only commit entries from previous terms after they have added an entry from the current term to the log [64, §5.4.2]. Therefore, linearizability might be violated if a Raft leader respond to a read-only request before committing an entry in the current term. When writing our protocol specification, we modeled the linearizable read-only protocol by associating a linearization index with each read-only request: a request's linearization index is the log's commit index if the last entry committed in the current term, and is the last log index otherwise. Furthermore, our inference function requires that the *m*-inducing state for a read-only response have committed entries up to the request's linearization index. Therefore, Ellsberg flags a bug in this case, because no valid *m*-inducing states exists for a non-linearizable return value.



RedisRaft Unreported. This previously unreported bug was discovered by Ellsberg when we ran fuzzing loops to find bugs. The bug is due to an additional complication in Redis Raft's reconfiguration protocol: when adding a node, Redis Raft first issues a reconfiguration command to add a *non-voting* node that cannot participate in quorums. After this command has been committed, Redis Raft next issues a second reconfiguration command to switch the non-voting node to a voting node, allowing it to participate in quorums. However, due to a bug, Redis Raft acknowledges the client reconfiguration request once the non-voting reconfiguration command has been successfully replicated. Consequently, Redis Raft reports that reconfiguration is complete before the quorum size has grown, and thus before the cluster can tolerate additional failures. In this case, an ill-timed failure that occurs between the two commands can render the cluster unavailable, despite the administrator believing that this should not occur. Our specification models both steps of the reconfiguration process, and flagged the bug because it observed the leader acknowledging the client's reconfiguration request before the second step had completed.

RedisRaft-256 [73] is a reconfiguration bug related to the unreported bug described above. This bug resulted in leader acknowledging a client reconfiguration command that adds a node before replicating it to a quorum, and can result in situation where the client reconfiguration command is never updated. Ellsberg alerts on this bug when it observes the leader send a client response without having received append entry responses from a quorum, *i.e.,* before it has been committed.



RedisRaft-52 [74] is a bug that leads to data-loss, and is due

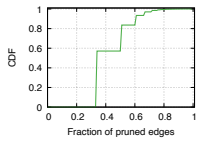
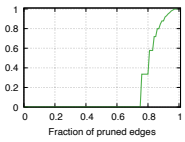
(c) *Redis Raft.*

Figure 6: `apply_asap?` *reduces memory requirements: graphs show number of simulation states* $|S|$ *in a 5-node cluster with* `apply_asap?` *disabled.* ($|S| = 1$ *when* `apply_asap?` *is enabled.)*



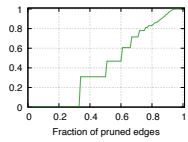
to a performance optimization implemented by Redis Raft where the last few log entries are stored in a cache. When a node appends an entry it adds it to both the cache and the underlying log. When reading an entry, the node first checks the cache, and only refers to the underlying log if it is not in the cache. A bug in Redis Raft meant that it did not update the cache when deleting entries from the log. However, Raft requires to delete log entries in some scenarios, *e.g.,* when a new leader has to overwrite uncommitted entries. This bug can therefore result in an inconsistent state machine replica, which can lead to unexpected node behavior, *e.g.,* rejecting append entry or vote requests that it should have accepted. We reproduced a case where an append entry request was incorrectly rejected due to an old conflicting entry in the cache. The Ellsberg specification detected a divergence when checking the append entry response and raised an alert.

E Effect of Ellsberg's Design Choices



Our evaluation (§6) presented end-to-end performance results for Ellsberg. In this appendix, we evaluate the impact of `apply_asap?` and the `reachable` function on Ellsberg's performance.

E.1 Benefits from `apply_asap?`



Next we evaluate the effect of using `apply_asap?` to avoid redundant exploration. As we discussed in §3.4.2, `apply_asap?` is used when processing incoming messages (Listing 3 line 24) and during breadth first search (Listing 4 line 25) to reduce the number of pending messages, and the size of the simulation state set S. This improves `find_reachable`'s runtime and reduces Ellsberg's memory requirement.

(a) *Etcd.*

(b) *Zookeeper.*

(c) *Redis.*

Figure 7: *CDF of fraction of edges pruned by the* `reachable` *check (Listing 4 line 22). All experiments are run on a 5-node cluster using the mixed workload.*

We evaluate improvements in `find_reachable`'s runtime by comparing the number of pending messages when `apply_asap?` is enabled to when it is disabled. In Figure 5, we show the number of pending messages as a function of the number of outgoing messages processed. We report results from a 5-node cluster when running the balanced workload, the results were similar for other workloads. We observe that when `apply_asap?` is disabled, the number of pending messages grows as Ellsberg processes more of the trace. By contrast, enabling `apply_asap?` limits the number of pending messages: in our workloads we observe between 0 and 5 pending messages.

Using `apply_asap?` also reduces the number of simulation states in S, improving both performance (results in fewer calls to `find_reachable`) and memory requirements. We evaluated this improvement by comparing the size of S as a function of number of output messages processed with `apply_asap?` enabled and disabled. Results from running a balanced workload on a 5-node cluster, when `apply_asap?` is disabled, are shown in Figure 5. When `apply_asap?` is enabled, we found that S contained a single simulation state ($|S|$=1). By contrast, when `apply_asap?` is disabled the number of states can grow large, with an average of ∼444 states for Etcd, ∼478 states for Zookeeper, and ∼43 for Redis Raft.

In sum, these results show the importance of `apply_asap?` for limiting Ellsberg's memory usage and in achieving our performance goals.

E.2 The `reachable` function's impact

Ellsberg uses the specification's `reachable` function to to avoid exploring schedules that cannot lead to m-inducing simulation states (§3.4.1, Listing 4 line 22). As we explained in §3.4.1, we need to use this function to ensure that checking an outgoing message terminates, and we cannot turn it off.

Therefore, we evaluate the effectiveness of reachability checks by drawing a CDF of the fraction of `reachable` calls that return false (and thus prune exploration). In Figure 7, we show results for the three DPIs running on a 5-node cluster evaluated using the balanced workload. As one would expect, the results depend on the protocol and implementation: pruning is most efficient for Zookeeper because it assumes in-order deliver. The in-order delivery assumption ensures that the number of pending messages is bound by the number of nodes and the protocol structure allows the `reachable` function to prune more than 75% of possible paths. While pruning is less effective for Etcd and Redis Raft, we observe that even in

this case, between 40–80% of calls to the `reachable` function return false. These results show that while Ellsberg can work with specification that over-approximate reachability, this approximation can come at a performance cost.

CEGS: Configuration Example Generalizing Synthesizer

Jianmin Liu[1], Li Chen[2], Dan Li[1], Yukai Miao[2]
[1]*Tsinghua University* [2]*Zhongguancun Laboratory*

Abstract

Network configuration synthesis promises to increase the efficiency of network management by reducing human involvement. However, despite significant advances in this field, existing synthesizers still require much human effort in drafting configuration templates or coding in a domain-specific language. We argue that the main reason for this is that a core capability is missing for current synthesizers: identifying and following configuration examples in configuration manuals and generalizing them to arbitrary topologies.

In this work, we fill this capability gap with two recent advancements in artificial intelligence: graph neural networks (GNNs) and large language models (LLMs). We build CEGS, which can automatically identify appropriate configuration examples, follow and generalize them to fit target network scenarios. CEGS features a GNN-based Querier to identify relevant examples from device documentations, a GNN-based Classifier to generalize the example to arbitrary topology, and an efficient LLM-driven synthesis method to quickly and correctly synthesize configurations that comply with the intents. Evaluations of real-world networks and complex intents show that CEGS can automatically synthesize correct configurations for a network of 1094 devices without human involvement. In contrast, the state-of-the-art LLM-based synthesizer are more than 30 times slower than CEGS on average, even when human experts are in the loop.

1 Introduction

Network configuration management plays a central role in network operations (NetOps). Manually managing configurations is costly and susceptible to human errors that can cause severe network downtime [13, 14, 35]. This is especially important for modern large-scale networks with more than tens of thousands of devices. To increase NetOps efficiency and correctness, researchers have made continuous efforts in configuration synthesis [1, 6, 7, 16, 17, 22, 39, 43, 44, 46]. With the descriptions of intents and network topology from network operators as input, configuration synthesis systems are expected to generate correct configurations for network devices to achieve the intents.

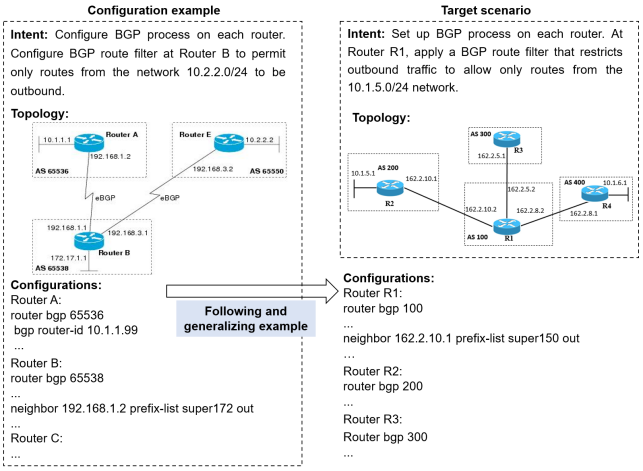


Figure 1: An instance of EFG in configuration synthesis.

Despite considerable advancements in configuration synthesis, existing proposals still require significant human effort. For example, NetComplete [17] requires operators to manually provide configuration templates where some parameters are left symbolic for the synthesizer. Robotron [44] also requires expert effort to construct suitable templates for configuration generation. For Aura [39], operators must learn a new domain-specific language, and code in this language to express their high-level intents.

The main reason for human involvement, we believe, is that a core capability is missing from all existing synthesizers: example following and generalization (EFG). In other words, they cannot identify, follow, and generalize the examples provided by device documentation, and thus must rely on human experts to perform the task. We show an example of EFG in Figure 1, where the configuration example[1] from the Cisco device documentation has a topology with three nodes for an intent, and the target scenario has a topology with four nodes. To make use of an existing synthesizer, such as NetComplete, experts must first look through the device

[1] https://www.cisco.com/c/en/us/td/docs/ios-xml/ios/iproute_bgp/configuration/xe-16/irg-xe-16-book/connecting-to-a-service-provider-using-external-bgp.html

documentation [2] for this example, identify the appropriate configuration snippets, assign the snippets to different devices, and mark symbolic parameters for synthesizers to fill, so that configuration templates can be generated for each device.

EFG is currently a human process, because it requires three sub-capabilities: understanding of topologies in both the example and target scenario, comprehension of natural language description of intents, and code generation of device configuration templates. However, with the recent advances of graph neural networks (GNNs) and large language models (LLMs), we believe that EFG can be automated. This is because 1) GNNs have shown remarkable capability in modeling node characteristics and similarities in many related applications, such as knowledge graph alignment [56,62] and social recommendation [18,55]; and 2) LLMs have demonstrated unprecedented capabilities in comprehending human intents, producing contextually relevant content, and even writing sequential programs in systems such as CoPilot [23] and Jigsaw [28].

Inspired by these achievements, this paper investigates the following research question: *Can we automate EFG for configuration synthesis?* We answer this question affirmatively with the design and implementation of a configuration synthesis system that we call CEGS (Configuration Example Generalizing Synthesizer). This involves solving three main challenges:

C1 Accurately identifying relevant configuration examples from the manual. Given a target network scenario consisting of user intents and target topology, we must find the most relevant configuration examples from the manual. Thus, we need to design a Querier to accurately identify the configuration example that closely aligns with the user intent and target topology from the manual.

C2 Associating the devices in the target topology with those in the example. Establishing accurate associations between devices in the target and example topologies is crucial for EFG. To automate this, we need to design a Classifier to accurately map the nodes in the example to the devices in the target topology, so that the configuration snippets for each node in the example can be assigned to the devices in the target topology.

C3 Accelerating synthesis without compromising correctness. As COSYNTH [36], a pioneering work that applies LLMs to configuration synthesis, indicates, an LLM usually cannot produce the correct configurations for all devices with its first attempt, and it requires multiple iterations (loops) for error correction. Each loop involves call to the LLM inference, and in some scenarios (§4), we show that, without human intervention, COSYNTH is unable to generate the correct results with as many as 300 loops. Since LLM inference is costly, we intend to design an efficient synthesis method that minimizes the number of loops without compromising correctness.

[2] Documentation includes configuration manuals, guides, *etc.*.

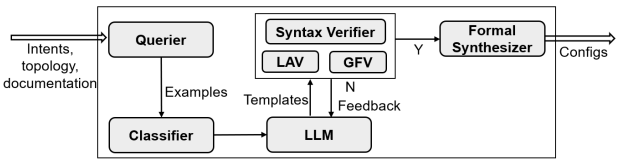

Figure 2: High-level workflow of CEGS.

CEGS comprehensively addresses the above challenges. Taking natural language intents, a target network topology, and the device documentation as input, CEGS attempts to synthesize the correct configuration for network devices in the target topology without human involvement. CEGS utilizes GNN and LLM to achieve EFG automation, and has six core components, namely Querier, Classifier, Syntax Verifier, Local Attribute Verifier (LAV), Global Formal Verifier (GFV), and Formal Synthesizer. The workflow (Figure 2) is as follows: firstly, the Querier identifies the most relevant configuration examples from the device documentation that align closely with the user intents and target topology. Secondly, the Classifier maps the nodes in configuration examples to appropriate devices in the target topology. Thirdly, CEGS leverages an LLM to generate configuration templates for all devices based on configuration examples, leaving the specific parameters of network policies symbolic. Then, CEGS utilizes the Syntax Verifier, LAV, and GFV to verify the templates. Finally, the Formal Synthesizer takes the intents, the topology, and the templates, and attempts to fill the symbolic parameters with values to achieve the intents. In this process, CEGS automatically feeds any errors caught by the Syntax verifier, LAV, GFV, and the synthesizer back to the LLM for error correction.

We enable this workflow with the following contributions:

- We design the Querier to identify relevant examples from the device manual, solving challenge C1. The Querier adopts a two-stage recommendation strategy. The first stage uses an LLM to process the natural language user intent, and then measures the similarity of the user intent to the descriptions of examples. In the second stage, the Querier further incorporates topological similarity information with a GNN, and determines the most appropriate example. In our evaluation with 90 configuration synthesis scenarios, the Querier achieves 100% accuracy in recommending examples.
- We design the Classifier to establish accurate associations between devices in the target and the example topologies, solving challenge C2. Specifically, the Classifier considers both textual and topological similarities to determine the relationships. In our evaluation with 90 configuration synthesis scenarios, CEGS also achieves 100% accuracy in terms of device classification.
- We propose an efficient LLM-driven synthesis method to accelerate synthesis without compromising correctness, solving challenge C3. Compared to prior work, our key innovations are: 1) we guide the LLM configuration generation with appropriate examples from device documen-

tations, instead of relying solely on the "memory" of the LLM; 2) we stipulate the LLM to only generate templates, because they are bad at logical reasoning and analysis [33], thus they struggle to generate specific values to achieve user policy intents; and 3) we instead use Formal Synthesizer to fill in templates, which is significantly faster than calling LLM multiple times with expert in the loop [36].

- We evaluate CEGS using Static, OSPF, and BGP routing intents and a variety of real-world topologies ranging from 20 to 1094 routers. Our results show that CEGS can automatically synthesize correct configurations based on examples, without any human involvement. Compared to state-of-the-art LLM-based synthesis systems COSYNTH, CEGS automatically synthesizes correct configurations for BGP no-transit intents within 2 minutes, while COSYNTH fails to generate correct configurations within one hour. Even with human expert in the loop, COSYNTH is more than 30 times slower than CEGS.

Limitations. This paper introduces the EFG capability to network configuration synthesizers. Enabling EFG does not solve all the challenges in configuration synthesis, and our limitations are as follows. Firstly, we are constrained by the coverage of device documentations: if there is no example of a user's intent, CEGS cannot produce a satisfactory result. When this happens, users of CEGS should ask the vendor for related examples. Secondly, CEGS is also subject to the capability of the Formal Synthesizer. In other words, to guarantee correctness, we can only support intents that are also supported by the Formal Synthesizer we use (NetComplete [17]). We consider the extension of the capabilities of the Formal Synthesizer to be orthogonal to CEGS, and do not claim any contribution in this aspect. Thirdly, the generated configuration is correct only when an LLM can correctly convert a natural language intent to a formal intent. While our evaluation demonstrates 100% accuracy in intent formalization, this result is specific to our evaluation dataset. The generalizability of this accuracy to other datasets or scenarios is not guaranteed and remains an area for further investigation.

2 BACKGROUND AND MOTIVATION

2.1 Current synthesizers require expert effort

Generating and editing configurations of devices based on ever-changing operational intents are daily tasks of NetOps engineers, and configuration synthesizers promise to reduce the load on human operators by generating correct configurations automatically. Recently, many efforts have been made in configuration synthesis [1, 6, 7, 16, 17, 22, 39, 43, 44, 46]. Despite significant advancements, existing synthesizers still require human involvement in the synthesis process.

Existing configuration synthesizers fall into two types: Domain Specific Language (DSL)-based synthesis, and template-based synthesis. Both types require significant expert effort to work. DSL-based synthesizers require experts to express high-level intents using DSLs, such as Datalog (SyNet [16]), RPL (Aura [39]), and regular expressions (Propane [6]). The learning curve and the amount of code needed for large-scale networks are both intimidating for NetOps engineers.

In this paper, we focus on reducing the human efforts for the template-based synthesizers. These systems take a network topology, high-level intents, and configuration templates as input and automatically fill the blanks in the templates. For example, NetComplete [17] autocompletes the configuration templates to correct network-wide configurations. NetComplete uses SMT constraints to model the semantics of network configurations at the level of individual route advertisements and routing policies. Specific configuration values (e.g., BGP policy parameters) are made symbolic, allowing the SMT solver to find a set of values that satisfy the desired policy.

For template-based synthesizers, we observe that the process which requires the most human effort is the process of converting a set of high-level intents into a set of templates for all devices in the topology. For NetOps experts, this process typically involves identifying appropriate configuration examples in the device documentation, assigning the snippets in the examples to devices, and marking symbolic parameters based on intents. We name this process as *example following and generalization* (EFG).

We believe that the automation of EFG can save considerable expert effort. However, automating EFG is challenging, because it requires three sub-capabilities: understanding of topology in both the example and target scenario, comprehension of natural language description of intents, and code generation of device configuration templates. Fortunately, the recent achievements of GNNs and LLMs in AI give us hope in automating these human capabilities. Next, we briefly introduce these two technologies and their prior applications in the area of configuration synthesis.

2.2 LLMs & GNNs for configuration synthesis

GNNs and LLMs have been explored separately in the literature on configuration synthesis, but they have never been combined, to the best of our knowledge.

Graph Neural Networks (GNNs) are tailored to process graph-like data, thus can be useful for topology understanding for EFG. GNNs have been shown to be capable of learning node-level and graph-level representations by aggregating information from neighboring nodes and edges. They are widely applied in various reasoning tasks on graphs [58, 60]. In relation to configuration synthesis, ConfigReco [24] is a configuration recommendation tool that uses GNN. It features a knowledge graph to model network configurations and adopts GNN to recommend configuration templates for manual configuration. However, ConfigReco can only recommend high-likelihood configuration snippets to NetOps engineers, and it cannot generalize the examples to target topologies.

LLMs [3,4,9,47] have demonstrated impressive capabilities in answering questions [41, 42], understanding user intents [34,37,52], comprehending manuals [11,32], generating commands [20, 53, 59], and even composing sequential programs

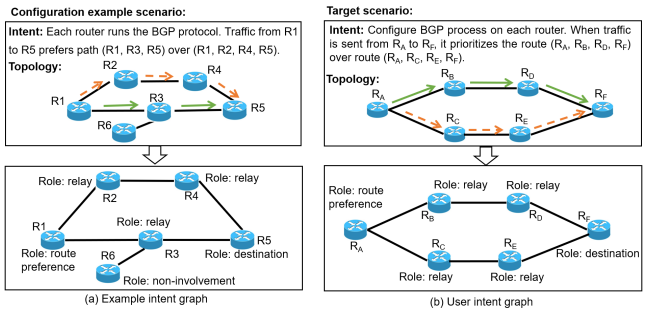

Figure 3: Configuration example and target scenarios, along with the corresponding intent graphs.

in systems like CoPilot [23] and Jigsaw [28]. All of these capabilities show immense potential for automating EFG in configuration synthesis. Using LLMs for configuration synthesis has already been explored in previous work. Rajdeep et al. [36] designed COSYNTH, a configuration synthesis system that uses LLMs to generate network configurations that are aligned with the high-level intents. NETBUDDY [49] [51], a LLM-based synthesis system, leverages LLM to simplify configuration synthesis by splitting configuration generation into multiple fine-grained steps. However, both COSYNTH and NETBUDDY directly employs LLMs to generate concrete configurations based on the specified intents without providing any configuration examples. Thus, COSYNTH and NETBUDDY still require human involvement in the loop to guide the synthesis. For example, as demonstrated in §4.3, without human involvement, COSYNTH and NETBUDDY cannot successfully compile intents into correct network configurations with as many as 300 loops. PreConfig [31] is a pretrained LLM designed for automating network configuration. However, PreConfig only can generate configuration snippets, and it still unable to synthesize network-wide configuration for target network scenarios to achieve specific high-level intents.

2.3 Motivating CEGS's Design Decisions

With the above investigation, we design CEGS which leverages GNN and LLM to automate EFG. To this end, we address the three main challenges. In the following, we list each challenge as **C#** and its related design choice(s) *D#*.

C1. Accurately identifying relevant configuration examples from the device documentation. Given a target network scenario consisting of a network topology and a set of high-level intents, we need to first identify pertinent configuration examples from the device documentation that closely align with the user intent and target topology.

D1. Transforming the recommendation problem into a graph similarity problem. We observe that the most appropriate configuration example should satisfy two criteria simultaneously: 1) the natural language descriptions of the example's intent and the user's intent must be similar; and 2) they share topological similarities. We design a data structure called *intent graph* to take both factors into account. In each intent graph, the nodes represent devices and edges represent links between the devices, thus they correspond directly to network topologies. We embed the high-level intent into the intent graph by adding an attribute called "*Role*" to each node. We use an LLM (GPT-4o) prompted by few-shot examples to process the intent and generate roles for each node (details in §3.1). In this way, we embed the high-level intent into the network topology. Figure 3 illustrates a configuration example scenario and a target scenario, along with the corresponding example intent graph and user intent graph.

With the intent graphs, we transform the problem of finding the most appropriate example to the problem of finding the most similar example intent graph to the user intent graph, which is suitable for GNN algorithms to solve. To accelerate the search, we also propose a two-stage recommendation strategy, and the first stage is to narrow the search space by filtering out irrelevant examples with the help of an LLM (GPT-4o, details in §3.1). The Querier then adopts a GNN algorithm that solves the above graph similarity problem to recommend the most relevant example.

C2. Associating the devices in the target topology with those in the example. To successfully generalize, we must obtain the correspondence between the nodes in the example intent graph and those in the user intent graph. With this correspondence, we can then assign the configuration snippets from the example to the devices in the target topology.

D2. Exact matching of role description of nodes. We observe that, in most cases, nodes can be matched using only the "Role" attribute in the intent graph. Therefore, the Classifier first associates nodes in the user intent graph to nodes in the example intent graph, if their "Role" attribute matches exactly.

D3. GNN-based mapping based on neighborhood similarity. However, in some cases, a node in the user intent graph can be matched with multiple nodes in the example intent graph. To solve this problem, we observe that the configuration of a device is also highly affected by its neighbors. Taking Figure 3 as an example, router $R2$ and $R3$ in the example topology have the same role: acting as a relay, but they have different neighborhood: router $R2$ links a source and a relay, while router $R3$ links a source, a destination, and a router which does not participate in annoucement forwarding. Thus, router $R2$ and $R3$ have different configurations of routing policies affected by their neighborhood topologies. From Figure 3, we observe that router R_B in the target topology has the same role as router $R2$ and $R3$ in the example topology, but router R_B has a neighborhood more similar to that of router R_2 than that of router R_3, so the optimal association of R_B' in the example topology should be R_2.

Therefore, we propose a GNN-based node classification algorithm in the Classifier, because GNNs can learn node-level representations by aggregating the neighborhood information and are well-suited to this problem. If a device is matched to multiple nodes in the example intent graph, the GNN algorithm measures the neighborhood similarity between these nodes and recommends the node in the example intent graph

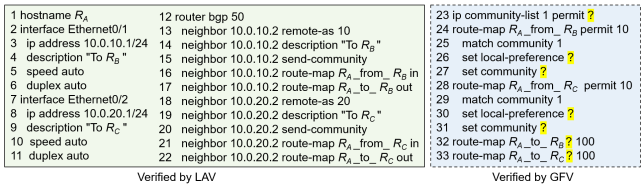

Figure 4: Configuration template for router R_A in Figure 3.

with the highest similarity.

C3. Accelerating synthesis without compromising correctness. Although recent research has demonstrated that LLMs are capable of writing network configurations [36], it is still challenging for LLM to produce concrete network-wide configurations, because it involves logical reasoning, which is not a strong suit for LLMs [36]. As a result, COSYNTH requires many human-in-the-loop iterations to generate the correct configurations. Thus, we seek a new synthesis mechanism to accelerate synthesis and reduce cost (*i.e.*the number of calling LLMs). In the meantime, it is imperative to guarantee the correctness of synthesis results.

D4. Guiding the LLM generation with appropriate examples. LLM can better complete reasoning tasks by introducing a few-shot prompt [12] or combining retrieval-augmented generation (RAG) [21]. Thus, to efficiently guide the LLM in generating the correct configuration, we provide appropriate examples to the LLM as relevant context.

D5. Restricting the LLM to generate only templates. In our configuration generation tasks, determining specific values of network policy parameters for all devices in a network is a highly complex reasoning problem that need to take the entire network into account. To solve this problem, we restrict the LLM to generate only configuration templates, leaving the specific values of network policy parameters as symbols.

D6. Using the Syntax Verifier, LAV, GFV and Formal Synthesizer to guarantee correctness. To guarantee the configuration correctness, we first use the Syntax Verifier to check whether the templates contain invalid syntax. We then utilize the LAV and GFV to jointly verify the semantic correctness of the templates. The LAV performs local verification on individual device templates to check whether the template follows the target topology and user intent descriptions. The GFV conducts global verification across all device templates to verify whether they can collectively achieve the global network policy intent. Any errors checked by the Syntax Verifier, LAV and GFV are fed to LLM for error correction. We finally use the Formal Synthesizer to take the target topology, user intents, and templates for all devices to fill the network policy parameters with concrete values to achieve the user intent.

Take the template (Figure 4) of router R_A in Figure 3 as an example, this template leaves some parameters of BGP import or export policies symbolic, such as *community* value and *preference* value, denoted by a question mark (?). We use the LAV to locally verify the interface configurations and BGP basic configurations from lines 2-22 based on the topology and intent descriptions, and then use GFV to globally verify

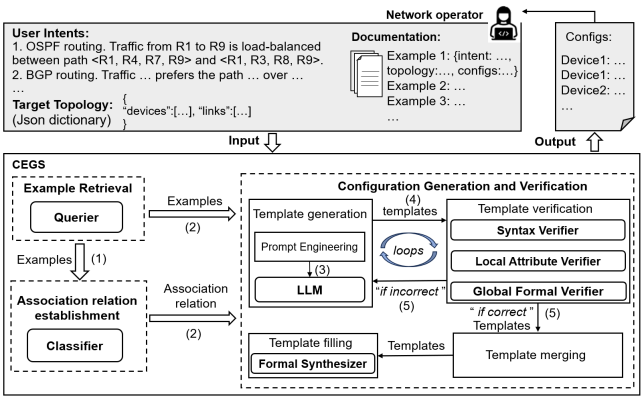

Figure 5: CEGS overview.

the policy configuration templates (lines 23-33) across all devices. Finally, the Formal Synthesizer fills the templates.

3 CEGS DESIGN

Given device documentation and a target network scenario including a target topology T_{tgt} specified in a JSON dictionary and a set of high-level intents $F=\{f^1_{user}, f^2_{user}, \ldots, f^n_{user}\}$ in natural language, CEGS automatically synthesizes network configurations via three phases: retrieval phase, association phase, and generation phase, as shown in Figure 5.

In the retrieval phase, CEGS uses the Querier to retrial relevant configuration examples from device documentation. In the association phase, CEGS utilizes the Classifier to establish accurate associations between devices in the target and example topologies. In the generation phase, given the user intents, target topology, as well as configuration examples and association relations, CEGS aims to generate correct network configuration for all devices in target topology to achieve all user intents. Specifically, we propose an iterative LLM-driven synthesis method to fulfill this task. In each iteration, we first generate configuration templates using an LLM, and validate these templates using the Syntax Veifier, LAV, and GFV. If any errors are checked, they are added to the prompt of the LLM for the next iteration. This phase stops when a set of templates are successfully generated, or when a predefined upper limit (300 in the evaluation) of loops is reached. Finally, we merge templates and fill in them using Formal synthesizer.

3.1 Querier

Given a set of high-level intents F and target topology T_{tgt}, the Querier aims to recommend the most relevant configuration example z_i for each user intent f^i_{user} from the device documentation. To achieve this, we first parse configuration examples from the device documentations. Since the format of device documentations provided by different operators varies, we develop a parsing framework similar to NAssim [11] to convert them into a uniform format. The formats are a uniform container for standardizing the diversity of manual formats. To parse the topology represented in a figure, we utilize GPT-4o to convert the topology figure into the predefined JSON format, followed by manual proofreading of the topology in-

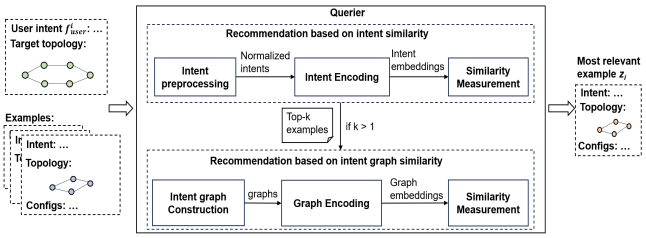

Figure 6: Detailed workflow of Querier.

formation.[3] We use a JSON dictionary to store the parsed configuration examples. Each example consists of a high-level intent in natural language, a network topology specified in JSON dictionary and the configurations of all devices in that topology. We process all the examples using the Querier to obtain the corresponding example intent graphs.

To improve query efficiency and accuracy, we adopt a two-stage recommendation strategy. Figure 6 shows the detailed workflow. For each user intent f^i_{user}, the Querier first adopts text encoding and similarity measurement methods to recommend top-k configuration examples that have the same type of intent as the user intent f^i_{user}, thus filtering out irrelevant examples. The Querier then adopts a GNN algorithm to recommend top-1 example from the top-k examples based on intent graph similarity. The output of the Querier is a set of configuration examples $Z=\{z_1,z_2,..,z_n\}$, where each z_i is the example for each user intent f^i_{user}.

3.1.1 *Recommendation based on intent similarity*

Problem Formulation. The intent is specified in natural language, so recommending configuration examples with the same type of intent can be regarded as a semantic alignment problem. Given a user intent f^i_{user} and example intent f^j_{exp}, this problem is solved by evaluating whether the semantics of intent f^i_{user} and intent f^j_{exp} are consistent.

Intent preprocessing. Due to the flexibility of natural language expression, the same intent can be expressed in various ways. For example, a path-preference intent may be described as "*For traffic from R1 to R4, the route (R1, R3, R4) is preferred over route (R1, R2, R4).*" or "*Traffic from R1 to R4 prioritizing taking (R1, R3, R4) over (R1, R2, R4).*". In addition, there may be some proper nouns in the intent description, such as specific device names and IP address, which do not impact the semantic meaning of the intent. To improve the accuracy of example recommendation, we propose an intent preprocessing approach that normalizes original intents into specific unified expression formats without specific proper nouns. Specifically, we first define a unified expression format for each intent type. We then leverage GPT-4o to convert the original intent into a unified expression format using a few-shot prompt (described in detail in Appendix A.1). For example, for the example intent and user intent described in Figure 3, we use GPT-4o to both convert them into the unified expression format "BGP routing. Traffic from *source* to *destination* prefers *path1* over *path2*". In this unified format, generic terms "*source*" and "*destination*" replace specific device names, and "*path1*" and "*path2*" replace detailed path information. We denote a normalized intent with respect to an original intent f as $norm(f)$.

Intent Encoding. To evaluate the semantic similarity between two intents, Sentence-BERT (SBERT) [40] is the most popular NLP model suitable for this task, as it can efficiently map each sentence to a vector space where semantically similar sentences are close to each other. For each pair of normalized intents of user intent $norm(f^i_{user})$ and example intent $norm(f^j_{exp})$, denoted as $(norm(f^i_{user}),norm(f^j_{exp}))$, we first use the encoder $e(\cdot)$ of SBERT to encode them into a pair of embedding vectors $(e(norm(f^i_{user})),e(norm(f^j_{exp})))$. We then use cosine similarity to measure the similarity between these two embedding vectors, which is calculated by

$$Sim(e(norm(f^i_{user})),e(norm(f^j_{exp})))= \quad (1)$$

$$\frac{e(norm(f^i_{user}))\cdot e(norm(f^j_{exp}))}{\|e(norm(f^i_{user}))\|\times\|e(norm(f^j_{exp}))\|} \quad (2)$$

The cosine similarity calculates the cosine of the angle between two vectors, which is often used to measure the semantic similarity, typically involving text data. If this similarity exceeds a threshold τ (0.9 in the evaluation), we consider intent f^i_{user} and f^j_{exp} to be semantically aligned, i.e., they belong to the same type of intent. Therefore, the configuration example corresponding to intent f^j_{exp} is regarded as a potential reference example c^i_j. We define a set $C^i=\{c^i_1,c^i_2,...,c^i_k\}$ to denote these potential reference examples, where k is the number of these examples. If k=1, we directly consider this example as the most relevant example for the user intent f^i_{user}.

3.1.2 *Recommendation based on intent graph similarity*

The Querier recommends the most relevant example from the top-k examples based on the intent graph similarity.

Problem Formulation. The most relevant example should have the similar intent to the user intent and simultaneously share topological similarity. Thus, we construct an intent graph for a pair of the intent and topology to consider both the two factors at the same. In this way, we transform the problem of recommending the most relevant example into a graph similarity problem.

Intent Graph Construction. Given an intent and a network topology, we first formulate the topology as an undirected graph, where each node v and each edge denote a device and a physical link in this topology, respectively. We then embed the intent into the graph by adding a specific attribute called "Role" to each node based on the intent. We refer to the topology graph embedding the intent as the intent graph g. We use GPT-4o to achieve this more effectively, due to their superior natural language processing capability. We first define a role set for each type intent. The role set should cover all possible roles that a device may play in fulfilling that type of intent. For example, for the path preference intent, as shown

[3] Note: Manual proofreading is required only once for accurate parsing. The parsed examples can be applied to numerous relevant target scenarios.

in Figure 3, we define the role set as *{route preference, relay, non-involvement, destination}*, where *route preference* refers to a device that prefers a neighbor for traffic transmission, such as $R1$ and R_A in Figure 3. *non-involvement* denotes a device that does not participate in traffic transmission, such as $R6$ in Figure 3. We then utilize GPT-4o to extract "Role" r_v for each node v from the intent using few-shot prompt. We describe attribute extraction with GPT-4o in detail in Appendix A.2. Under complex network scenarios, we can use a feature combination to define a role.

Graph Encoding. Give an intent graph g, we first leverage FastText [8], a NLP model, to encode the attribute values of nodes into vectors. FastText is efficient to learn word embedding through learning n-grams at the character level. We construct a corpus including the attribute values of all intent types, and adopt unsupervised learning to train a FastText model on this corpus. For each node $v \in V$, we utilize the trained FastText model to encode its textual attribute r_v into a vector $x_v = e(r_v)$, where $e(\cdot)$ is the encoder.

We then adopt GraphSAGE [25], the most popular GNN algorithm, to calculate the embedding of each node v in the graph g. Before describing how a GraphSAGE model is trained in this work, we show how GraphSAGE is used to perform node embedding. GraphSAGE uses L aggregators (denoted $AGGREGATE_l, \forall l \in \{1,2,...,L\}$) and a set of weight matrices $W^l, \forall l \in \{1,...,L\}$ to generate node embedding through l loops. At each loop l, node v's embedding is calculated by

$$h_v^l \leftarrow \sigma(W^l \cdot CONCAT(h_v^{l-1}, h_{\mathcal{N}(v)}^l)) \quad (3)$$

where, σ is a nonlinear activation function, CONCAT is a concatenation operator. $\mathcal{N}(v)$ is the set of neighbor nodes of the node v. The initial value of node embedding is its feature vector, i.e., $h_v^0 = x_v$. $h_{\mathcal{N}(v)}^l$ is the neighborhood representation of node v at the l-th loop, which is calculated by

$$h_{\mathcal{N}(v)}^l \leftarrow AGGREGATE_l(\{h_u^{l-1}, \forall u \in N(v)\}) \quad (4)$$

where h_u^{l-1} is neighbor node u's embedding at the $l-1$-th loop.

We use a global pooling method to aggregate the embeddings of all nodes in a graph g into a single vector as the representation of the graph through a MeanPool operator. The embedding of a graph g is represented as:

$$E_g = MeanPool(\{h_v, \forall v \in V\}) \quad (5)$$

where h_v denotes the embedding of node v, which is this node embedding obtained from the last loop L.

For each pair of user intent graph g_{user}^i and example intent graph g_{exp}^i, we use euclidean distance to measure the similarity between their graph embedding vectors $E_{g_{user}^i}$ and $E_{g_{exp}^i}$. A similarity score is calculated by

$$Score(E_{g_{user}^i}, E_{g_{exp}^i}) = \frac{1}{d(E_{g_{user}^i} - E_{g_{exp}^i})} \quad (6)$$

where $d(\cdot)$ is the L1 distance, which is often used in graph or node evaluation to capture the absolute differences between corresponding features. For a user intent graph g_{user}^i associated with the user intent f_{user}^i and target topology T_{tgt}, we use the above graph similarity measurement to find the top-1 similar example intent graph, and consider the configuration example associated with the top-1 example intent graph as the most relevant example z_i for the user intent f_{user}^i.

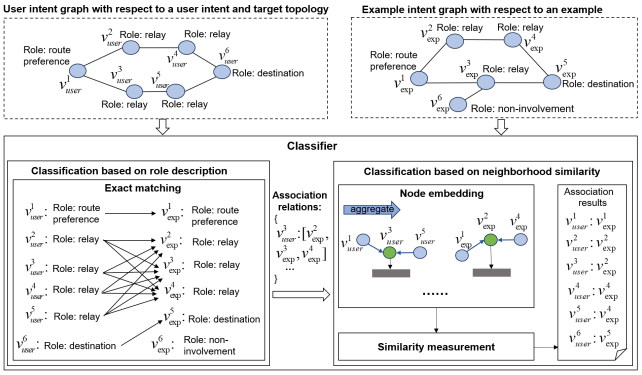

Figure 7: An instance of establishing the association between device in target and example topologies.

3.2 Classifier

For each user intent f_{user}^i and its corresponding configuration example z_i, the Classifier aims to establish the association between devices in target topology T_{tgt} and those in topology T_{exp}^i of the example z_i. The Classifier adopts a two-stage classification strategy to establish accurate association relationships on intent graphs constructed in §3.1.2. The Classifier first establishes the association relation based on the device's roles. If a device in target topology T_{tgt} is associated with multiple devices in example topology T_{exp}^i that have the same roles, the Classifier then adopts GraphSAGE to map this device to a specific one among these multiple devices in example topology T_{exp}^i based on neighborhood similarity. Figure 7 shows an instance of the Classifier establishing the association between devices in the target and example topologies.

Problem Formulation. We formalize this problem as a node classification problem on an intent graph pair of g_{user}^i and g_{exp}^i, where g_{user}^i is the user intent graph with respect to user intent f_{user}^i and target topology T_{tgt}, as well as g_{exp}^i is the example intent graph corresponding to the example z_i of the user intent f_{user}^i. In an intent graph g_{user}^i (or g_{exp}^i), each node v_{user} (or v_{exp}) is characterized by its role $r_{v_{user}}$ (or $r_{v_{exp}}$).

3.2.1 *Classification based on role description*

Given a pair of user intent graph g_{exp}^i and example intent graph g_{user}^i, the Classifier maps the nodes in the example intent graph g_{user}^i to these nodes in the intent graph g_{user}^i based on their roles. For each node v_{exp} in the graph g_{exp}^i, the Classifier sequentially evaluates whether the role $r_{v_{user}}$ of each node v_{user} in the user graph g_{user}^i exactly match those $r_{v_{exp}}$ of node v_{exp}, and if so, establishes an association between node v_{exp} and node v_{user}. In other words, node v_{user} is associated with v_{exp}, if and only if $r_{v_{user}} = r_{v_{exp}}$.

3.2.2 *Classification based on neighborhood similarity*

If a node v_{user} in user intent graph g_{user}^i is associated with multiple nodes in example intent graph g_{exp}^i, the Classifier further

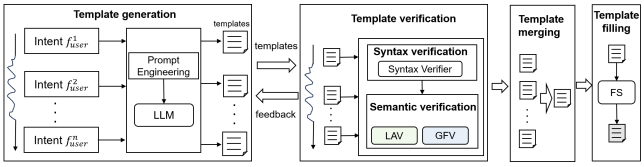

Figure 8: The workflow of LLM-driven synthesis method.

maps this node to a specific one among these multiple nodes. The Classifier first uses FastText to encode the node's textual attribute $r_{v_{user}}$ into a vector $x_{v_{user}}$, as described in §3.1. The Classifier then uses GraphSAGE to calculate the embedding $h_{v_{user}}$ of node v_{user} by aggregating its neighborhood embeddings in the graph g^i_{user}, as described in Equation 3 and 4. Simultaneously, for each node v_{exp} in graph g^i_{exp} that has the same roles with v_{user}, the Classifier uses FastText and GraphSAGE to calculate its embedding $h_{v_{exp}}$. Finally, the Classifier uses the Euclidean distance to measure the similarity between two node embedding vectors. For each node embedding pair of $h_{v_{user}}$ and $h_{v_{exp}}$, a similarity score is calculated by

$$Score(h_{v_{user}}, h_{v_{exp}}) = \frac{1}{d(h_{v_{user}} - h_{v_{exp}})} \tag{7}$$

where, $d(\cdot)$ is the L1 paradigm. The Classifier uses the above similarity measurement to map the node v_{user} to the specific node v_{exp} that has the highest similarity score.

3.2.3 *Training GraphSAGE model*

Given some intent graph pairs and node association relations in these graphs, we can generate a training corpus for training a GraphSAGE model. We construct positive pairs from nodes with associated relationships and negative pairs from nodes that are not associated. We train GraphSAGE model by minimizing the following margin-based ranking loss functions:

$$L = \sum_{(u,v)\in S} \sum_{(u,v')\in S'} [d(h_u, h_v) + \gamma - d(h_u, h_{v'})]_+ \tag{8}$$

where S is the set of positive pairs, S' denotes the set of negative pairs of the node u. h_u, h_v and $h_{v'}$ are the embedding of node u, v and v', which are calculated by GraphSAGE using Equation 3 and 4. γ (set to 3 in the evaluation) is a margin hyperparameter that separates positive and negative pairs.

3.3 An efficient LLM-driven synthesis method

To accelerate synthesis without compromising correctness, we propose an efficient LLM-driven synthesis method. Figure 8 shows the detailed workflow, including four stages. In the template generation, CEGS aims to generate templates with respect to each user intent. To guarantee the configuration correctness, CEGS first verifies template correctness. Once LLM correctly generates templates for all intents, CEGS merges these templates and then employs the Formal synthesizer to fill in the templates so that all intents are achieved.

3.3.1 *Template generation*

In this stage, CEGS leverages an LLM to generate templates for all devices in target topology T_{tgt} with respect to each user intent f^i_{user}. Due to the limited context window of the LLM, it cannot generate templates for all devices under large-scale

```
1 interface Ethernet1/0/0                    9 router ospf 50

Verified by LAV

Figure 9: Configuration template for router R1 with respect to an OSPF routing intent described in Figure 5.

typologies at once. To address this problem, we divide the devices in the topology into multiple subsets and generate the templates of devices in each subset in batches. We verify the templates for all devices collectively, so generating configurations for each batch separately do not compromise the correctness of the final configuration [4]. To speed up synthesis, we parallelize the template generation for devices in each subset, rather than processing them sequentially.

For each user intent f^i_{user}, CEGS first uses LangChain [10] to construct a prompt for each batch. We show an instance of the prompt construction in Figure 14 in Appendix A.4. We then call the LLM multiple times in parallel, feeding each batch's prompt to generate templates for all devices simultaneously. Each template is the configuration where some of network policy parameters (e.g., OSPF cost, route-map import or export parameters) are left symbolic, as illustrated in Figure 4 and Figure 9.

3.3.2 *Template verification*

In this stage, CEGS verifies configuration templates with respect to each user intent. For the templates corresponding to the intent f^i_{user}, CEGS first uses the Syntax Verifier to check the template syntax correctness, and then utilizes the LAV and GFV to jointly verify their semantic correctness.

Syntax verification. To verify template syntax correctness, we develop a Syntax Verifier by extending the Batfish [19] parser to treat symbols defined in the templates as valid syntax. If Syntax Verifier checks any invalid syntax, it reports relevant lines with invalid syntax to LLM for error correction.

Semantic verification. To speed up synthesis, it is crucial to provide localization feedback for LLMs to rapidly correct errors. To achieve this, we develop the LAV and GFV to jointly verify template semantic correctness by performing local verification and global verification. If LAV or GFV check any errors, it provides localized feedback in natural language.

- **LAV** The LLM may produce incorrect templates that do not follow the target topology and user intent descriptions, such as misconfiguring interfaces or incorrectly declaring or missing networks or neighbors. For this, we develop the LAV (that we wrote in Python) to perform local verification on each device template, checking whether it complies with the specified descriptions. Specifically, for each device template, the LAV first parses device attributes such as interface attributes (e.g., interface names, IP addresses), protocol attributes (e.g., AS number, pro-

[4] In our experiments, the size of subset is 40.

cess id) from the topology and intent descriptions. It then checks if the template correctly configures each attribute following these descriptions. If the LAV checks any errors, it provides localized feedback which indicates which configuration lines on which devices may be incorrect.

- **GFV** The LLM may produce templates that do not follow the intended global network policy. For this, we develop the GFV based on the NetComplete to perform global verification on the templates across all devices. The GFV ensures that configurations with interdependencies and cross-device impacts are correct. It reduces this task to a constraint satisfaction problem that it solves with SMT solvers [15]. The GFV uses SMT to encode the templates and uses variables to represent the symbolic in templates. To encode the user intents, the GFV first employs GPT-4o to convert the user intent from natural language to formal specification defined by the NetComplete using a few-shot prompt. We provide an instance how to use GPT-4o to convert natural language intents into formal specifications in Appendix A.3 and discuss the accuracy in section.4.2. The GFV then encodes the formal specification as SMT constraints. The GFV attempts to find a set of values to fill in the policy templates so that the formal specifications are achieved. If the GFV cannot find an appropriate set of values, it provides localized feedback indicating which devices have incorrect network policy configuration templates. Even when the GFV finds feasible values, we do not immediately fill in the templates. Instead, we retain the templates and fill in them collectively during the template filling phase based on all the intents together. [5]

Taking the configuration verification for an BGP routing intent as an example, we illustrate how our LAV and GFV work. Figure 4 shows the configuration template of a device with respect to a BGP routing intent (the user intent shown in Figure 3). We use the LAV to locally verify each device's interface configuration (lines 2-11 in Figure 4) and BGP basic configuration (lines 12-22 in Figure 4) including AS number and neighbor settings. The LAV first extracts the interface description, AS number, and IP addresses of all neighbors from the target topology description. It then checks whether the interface configuration and BGP basic configuration follow these descriptions. Since the routing policy configurations of individual devices affect each other and work together to achieve the intended global routing policy, we use the GFV to globally perform a formal verification on policy configuration templates (lines 23-33 in Figure 4) for all devices.

In some cases, we can complete the template verification using only the LAV, such as for an OSPF routing intent. Figure 9 illustrates a configuration template for a device with respect to an OSPF routing intent. Under the OSPF protocol, achieving a specific global routing policy involves setting an appropriate OSPF cost for each link. The templates represents the OSPF costs as symbols, which are comprehensively filled using the Formal Synthesizer in template filling phase. Thus, we can use the LAV to locally verify each device's template by checking whether the interface configuration (lines 1-8) correctly sets interface attributes following the target topology description and contains the OSPF cost settings (line 4 and line 8). At the same, we use the LAV to locally check whether OSPF basic settings and network statement settings (lines 9-13) comply with the topology description.

[5] While it is theoretically possible for both the formal specification and the template to be incorrectly generated yet still satisfy the SMT constraints, such cases are rare in practice. We plan to address this in future work.

3.3.3 Template merging

Once the LLM correctly generates configuration templates with respect to all intents. We merge the templates of each device with respect to all intents into a whole. In general, the configuration consists of multiple independent configuration segments, each of which implements a specific function. Thus, we merge the templates based on configuration segments. For each device, we merges the configuration segments associated with each specific function across all intents, and then merges the segments corresponding to different functions.

3.3.4 Template filling

Since NetComplete [17] can support configuration synthesis under large-scale realistic networks and cover more type of intents, we select NetComplete as our Formal Synthesizer (FS). We first employ GPT-4o to transform each user intent in natural language into the formal specification defined by NetComplete using a few-shot prompt. We then feed the merged templates for all devices, along with the formal specifications associated with all intents and the target topology to NetComplete to generate concrete values for policy parameters, thereby filling in the templates. The configurations generated by the Formal Synthesizer are correct and can satisfy the specified intents, because the Formal Synthesizer uses SMT-based formal methods to fill templates according to intent constraints, which has been validated in [17].

4 EVALUATION

We implemented CEGS in around 8K lines of Python code. We evaluate CEGS from three aspects: 1) How does CEGS compare to the state-of-the-art LLM-based configuration synthesis system COSYNTH [36] and NETBUDDY [49] [51]? 2) How does CEGS perform in achieving various set of intents across different network scales? 3) How do the core components of CEGS perform?

4.1 Experiment setup

We run all our experiments on a server with 80 core 2.1 GHz processors and 256GB RAM. We evaluate CEGS, COSYNTH, and NETBUDDY in generating Cisco router configurations that comply with the specific routing intents.

Topologies. We sampled 20 real-world ISP PoP-level network topologies from Topology Zoo dataset [29], with scales ranging from 20 to 754 routers. These topologies include 12 commercial networks and 8 educational networks, covering

various areas such as metro, region, country, and continent. Moreover, we constructed a larger topology with 1094 routers by merging three of sampled topologies from the region area.

Intents. We consider six types of prevailing routing intents, covering Static, OSPF, and BGP protocols. For Static protocol, we examine static route intents. For OSPF protocol, we evaluate ECMP and Any-path intents. For BGP protocol, we investigate Simple, Ordered, and No-transit intents. Each intent is defined between a randomly selected source *src* and destination *dst* pair and feasible paths. For a static route or a BGP Simple intent, we randomly select one feasible path p from *src* to *dst*, specifying that traffic from *src* to *dst* must follow the path p. For ECMP, Any-path, or Ordered intents, we first randomly select two available paths p_1 and p_2 from *src* to *dst*. For an ECMP intent, traffic from *src* to *dst* is load-balanced among paths p_1 and p_2. For a Any-path intent, traffic from *src* to *dst* can be forwarded along either path p_1 or p_2. For an Ordered (i.e., path preference) intent, traffic from *src* to *dst* prefers path p_1 over path p_2. We store the source-destination pair and feasible paths for each intent to facilitate configuration validation using Batfish in Sec.4.2. We utilize GPT-4o to generate intent description using few-show examples provided by NetOps experts. We describe these few examples and prompt construction in detail in Appendix.A.5.

Configuration examples corpus. We parsed 300 configuration examples from Cisco documentation and a cloud service provider, covering 40 types of intents, such as BGP routing, OSPF routing, and more. The examples for each type intent cover various networks with different topological features.

LLM selection. In the following experiments, we utilize GPT-4o to generate configurations, owing to its superior capabilities in configuration generation, compared to other models, as shown in Table 9 in Appendix B.2.

GraphSAGE model. We ask NetOps experts to help construct 100 intent graphs. For each pair of matching graphs, we ask the experts to label the associations between corresponding nodes in the two graphs. We then treat the node and its associated counterpart in the other graph as positive node pairs, while pairing the node with other non-associated nodes as negative pairs. These labeled pairs are used to create a training corpus, which is then used to train a GraphSAGE model using the loss function described in equation 8. This model consists of two hidden layers, each with 128 neurons, and is trained with a learning rate of 0.001.

Metrics. We present the synthesis system performance using three metrics: loops, synthesis time, and SMT solving time. We measure intent diversity using a semantic richness metric, defined as the average similarity between pairs of intents of the same type using SBERT embeddings. In our evaluation, the semantic richness across intent types is 0.52.

4.2 Correctness evaluation

Intent Formalization Accuracy. CEGS uses formal methods to verify and fill in templates created by LLM, which depends on accurately converting natural language intents into formal specifications. CEGS handles this with GPT-4o using few-shot prompts. To evaluate GPT-4o's accuracy, we wrote a Python script that converts each intent from our evaluations into the expected formal specification. We then asked GPT-4o to translate these intents and compared its output with the expected results. Our results show that GPT-4o achieved 100% accuracy in converting 1,350 intents from our evaluations.

Table 1: Comparison results between CEGS and COSYNTH. U stands for unsuccessful generation. ✓ (or ×) indicates that the synthesized configurations satisfy (or do not satisfy) the intents as verified by Batfish.

# No-transit intents	3		21		55

Manual loops	**0**	3	**0**	8	**0**	12

Validation. We validate the configurations synthesized by a synthesis system using Batfish. We wrote a Python script to automate this verification process based on the information collected in Section 4.1 about the source-destination pair and feasible paths corresponding to the intent. Specifically, we utilize Batfish "traceroute" to analyze the packet transmission path from a source to a destination specified by the intent. For a Static route intent or Simple intent, we check whether the path matches the expected path. For an Any-path intent, we first check whether the path is either path $p1$ or $p2$ as specified by the intent. We then break a random link on the path $p1$ and a random link on $p2$, and use Batfish "traceroute" to verify whether there is no path for packet transmission. For an Ordered intent, we first check whether the path matches the preferred path specified by the intent. We then randomly break a link on the preferred path, and use Batfish "traceroute" to verify whether the transmission path is changed to the secondary path specified by the intent. For an ECMP intent, we use Batfish "multipathConsistency" to verify whether there are equal paths as specified by the intent for traffic transmission from its source to destination. For a No-transit intent, we first use Batfish's "traceroute" to verify that there is no transmission path between two routers that should not communicate, as specified in the intent. We then use Batfish "traceroute" to verify whether a feasible path exists between two routers that are expected to communicate.

4.3 Comparison to COSYNTH and NETBUDDY

Since COSYNTH and NETBUDDY limit their scopes to different configuration scenarios, we compare them individually. COSYNTH does not have publicly available code, so we reproduced it based on the provided method descriptions in its

paper. We have verified that our reproduction aligns with the experimental results reported in [36]. For NETBUDDY, we use its released source code [50] for evaluation.

COSYNTH focuses on star networks and BGP no-transit intents, so we compare it in this context. In a star network, a central router connects to a CUSTOMER IP, while other routers connect to various ISPs. A no-transit intent specifies that two routers from different ISPs cannot communicate with each other, but can communicate with the CUSTOMER. We evaluate CEGS and COSYNTH on 3 star topologies from a service provider, each with 4, 8, and 12 routers, and containing 3, 21, and 55 no-transit routing intents, respectively. Table 1 presents the performance of CEGS and COSYNTH. We observe that CEGS can synthesize correct configurations that satisfy different set of no-transit intents within 2 minutes without human involvement. However, COSYNTH fails to synthesize correct configuration within 300 loops and requires extra manual loops to correct errors, taking over 3 hours. Despite extra SMT time due to the Formal Synthesizer, CEGS's total synthesis time is much shorter than COSYNTH's. The main reason is that COSYNTH does not fully leverage the EFG capabilities of LLMs. COSYNTH asks LLM to complete configuration synthesis which involves complex logical reasoning based solely on user intents, without providing any examples or leveraging formal methods for logical reasoning. Thus, it requires human experts for correction. As a result, COSYNTH is more than 30 times slower than CEGS, even with expert involvement.

We compare CEGS with NETBUDDY in achieving ECMP (i.e., load-balancing) intents under a topology with 36 routers. To simplify configuration synthesis, NETBUDDY divides configuration synthesis into three subtasks: translating natural language intents into formal specifications, generating high-level configurations (e.g., routing information), and generating network low-level configurations. However, NETBUDDY still fails to produce correct configurations within 3 hours and needs manual intervention, as shown in Table 2. The main reason is that it lacks appropriate configuration examples for LLM reasoning. In contrast, CEGS utilizes the Querier to provide relevant configuration examples, along with formal methods for logical reasoning. CEGS can quickly synthesize correct configurations within 4 minutes without human involvement, over 45 times faster than NETBUDDY.

4.4 Performance under different set of intents and different network scales

In this subsection, we further evaluate the performance of our CEGS for achieving various set of intents under different network scales. First, we evaluate CEGS performance in synthesizing configurations for varying numbers of intents across different network sizes. Table 3 and Table 4 show the results of our CEGS for synthesizing configurations for OSPF intents and BGP intents, respectively. We observe that the synthesis time and SMT time are proportional to the number of intents and the topology size. This is because more times of LLM inference are required for generating configuration templates and more symbolic policy parameters need be calculated by the Formal Synthesizer. The configurations synthesized by CEGS satisfy the corresponding intents, as verified by Batfish. On average, configurations for each device in OSPF intent scenarios consist of about 20 lines, and those in BGP intent scenarios consist of about 35 lines.

Table 3: CEGS performance in synthesizing configurations for various numbers of OSPF intents.

Network size	Intent type	#Intents	Loops	Synthesis time (SMT time)	Verified
20~50	ECMP	2	2	42.4s (4.2s)	✓
		4	2	1m18s (8.1s)	✓

		6	37	24m50s (10m30s)	✓

We then evaluate the performance of CEGS under more complex configuration scenarios, where multiple types of intents must be achieved simultaneously. We construct three scenarios, each involving different combinations of intents across the same or different protocols within a network of 197 routers. In Scenario Scen1, 5 BGP No-Transit and 5 Ordered intents need to be satisfied. Scenarios Scen2 and Scen3 involve different types of intents across different protocols. As shown in Table 5, CEGS can synthesizes configurations that satisfy multiple types of intents simultaneously. Even in the third scenario, including 15 intents across Static, OSPF, and BGP protocols, CEGS can synthesize correct configurations for 197 routers within 11 minutes. Configurations of each

Table 5: CEGS performance in synthesizing configurations for various combinations of multiple types of intents.

Scenarios	Protocols	Intent type	#intents	Loops	Synthesis time (SMT time)	Verified
Scen1	BGP	No-transit Ordered	5 5	13	7m30s (45s)	✓

device in scenario Scen1, Scen2, and Scen3 contain about an average of 40 lines, 23 lines, and 52 lines, respectively.

4.5 Ablation Study

To evaluate the contribution of six core components in CEGS, we conduct ablation experiments on the sampled 20 realistic topologies, each with one BGP Ordered intent. Since the Classifier depends on the Querier, when evaluating the Querier, we both remove Querier and Classifier, and instruct GPT-4o to generate configuration templates without examples. For evaluating other components, we disable the specific component's functionality in CEGS. From Table 6, we observe that CEGS achieves the best performance when all components are employed simultaneously. Without the Querier and Classifier, CEGS fails to synthesize correct configurations within 300 loops, indicating the importance of configuration examples for automating EFG. Compared to not using the Classifier, CEGS can more rapidly synthesizes correct configurations by matching examples to appropriate devices using Classifier. Without a Formal Synthesizer, CEGS requires more loops to synthesize correct configurations, as GPT-4o struggles to correctly specify policy parameters. Without the Syntax Verifier, LAV or GFV, CEGS fails to synthesize correct configurations within 300 loops due to the lack of error feedback. We discuss the performance of Querier's recommendation and Classifier's classification strategies in detail in Appendix B. *We discuss how to generalize CEGS in Appendix D.*

5 RELATED WORK

Intent-based Networking. Intent-based networking [26, 30] is a networking paradigm that automates network optimization to achieve desired goals by defining high-level intents, which has been well-adapted in Software-Defined Networks (SDN) [38, 57, 61]. For example, LUMI [27] allows operators to express intents in natural language, converts them into formal intents and automatically generates configurations. LUMI takes operator feedback to verify the intents are correct.

Configuration Verification. Configuration verification tools [2, 5, 19, 45, 48, 54] aim to check whether the configurations comply with the network policies in control plane using formal methods. For example, Minesweeper [5], FSR [48] and Bagpipe [54] uses SMT solvers for verification.

Configuration Synthesis. Configuration synthesis tools [1, 6, 7, 16, 17, 22, 39, 43, 44, 46] aim at synthesizing network configurations out of high-level intents. These tools can be categorized into two types: DSL-based synthesizers and template-based synthesizers. DSL-based synthesizers require operators to express intents using the customized DSL, after which they compile these intents into correct configurations. Template-based synthesizers require network operators to provide suitable configuration templates, which then automatically fill in the templates. However, these synthesizers still require human involvement (using DSL to express intents or designing appropriate configuration templates) in the synthesis process, because they lack a core capability of EFG.

LLMs and GNNs for configuration synthesis. ConfigReco [24] is a GNN-based configuration recommendation tool, which recommends high likelihood configuration snippets to operators. Researchers have explored the ability of LLM to write network configuration. NETBUDDY [49] [51] uses a multi-stage pipeline to leverage LLMs for configuration synthesis. COSYNTH [36] adopts a verified prompt programming strategy that combines the LLM with verifiers to translate intents into router configurations. However, NETBUDDY and COSYNTH still require expert involvement in the synthesis process, as they do not fully utilize the potential EFG capability of LLM. PreConfig [31], a pretrained model, is designed to automate network configuration. Although it has the potential ability to generate configuration snippets, it cannot generate complete network-wide configurations.

6 CONCLUSIONS

We presented CEGS that leverages LLMs to automate EFG in configuration synthesis. CEGS takes a set of high-level intents in natural language, a network topology and the device documentation as input, and automatically synthesize correct network configurations. Our results show that CEGS can synthesize correct configurations for complex intents on various realistic networks. While this paper focuses on configuration synthesis, we believe that the automation of EFG can be applied to other configuration management tasks.
This work raises no ethical concerns.

Given an intent, please convert it into one of the expression format defined as follows:
Format1: <protocol> routing. Traffic from source to destination prefers path1 over path2.
Format2: <protocol> routing. Traffic from source to destination must follow the path.
Format3: <protocol> routing. Traffic from source to destination is load-balance between path1 and path2.
…

For example:
==========
Intent: Each router runs the BGP protocol. Traffic from from R1 to R4 prioritizing taking (R1, R3, R4) over (R1, R2, R4).
Normalization: BGP routing. Traffic from source to destination prefers path1 over path2.

…
==========

Intent: All routers are configurated with BGP protocol. When traffic is sent from R_A to R_F, it prioritizes the route (R_A, R_B, R_D, R_F) over route (R_A, R_C, R_E, R_F).

Figure 10: Example prompt for normalizing intents.

Given a configuration intent and a network topology, please extract a role attribute for each node in the topology from the intent.

For example:
==========
Intent: Each router runs the BGP protocol . Traffic from R1 to R5 prefers the path (R1, R3, R5) over (R1, R2, R4, R5).
Topology: {"routers": [R1, R2, R3, R4, R5], "links": [{"node1": {"name": "R1"}, "node2": {"name": "R2"}},...]}
Role attributes: {"R1":route preference, "R2": relay, "R3": relay, "R4": relay, "R5": destination, "R6": non-involvement}

Intent: ...
Topology: ...
Role attributes: ...

Intent: ...
Topology: ...
Role attributes: ...
…
==========

Intent: ...
Topology: ...
Role attributes:

Figure 11: Example prompt for extracting attributes for each device in the topology from the intent.

Given a routing requirement type, the source and destination of traffic flows, as well as the possible transmission paths of traffic flows, generate an intent description to express this requirement.

Requirement definition:
Static route or Simple requirement: given a path *p*, this requirement specifies that traffic from a source to a destination must pass the path *p*.
ECMP requirement: given two path *p1* and *p2*, this requirement specifies that traffic from a source to a destination is load-balanced between path *p1* and *p2* .
….

Examples:
==========
The source and destination of traffic flows: R1, R9
Possible transmission paths: (R1, R3, R5, R7, R9), (R1, R4, R8, R9)
Requirement: OSPF ECMP

Intent description: Configure OSPF routing process on each device and implement an OSPF routing policy to load-balance traffic from R1 to R9 across the paths (R1, R3, R5, R7, R9) and (R1, R4, R8, R9).

…
==========

The source and destination of traffic flows: routerA, routerF
Possible transmission paths: (routerA, routerC, routerD, routerF), (routerA, routerB, routerE, routerF)
Requirement: OSPF ECMP

Intent description:

Figure 12: Example prompt for generating intent description.

A Prompt Construction

In this section, we provide detailed examples of prompt construction involved in configuration synthesis with our CEGS.

A.1 Intent preprocessing prompt

Give a user intent, we normalize it using unified expression formats. We utilize GPT-4o to convert it into this format using a few-shot prompt. The prompt includes three parts: the definition of unified expression formats, few examples, and the user intent. Figure 10 illustrates an example of such a prompt.

A.2 Role extraction prompt

Given a pair of an intent and a topology, we leverage GPT-4 to extract a role attribute for each device in the topology from the intent using prompts with few-shot examples to embed the intent to the topology graph. Figure 11 shows a detailed example prompt.

A.3 Intent conversion prompt

CEGS utilizes the formal tool to verify and fill in templates. For this, CEGS first uses GPT-4o to convert the user intent from natural language to formal specification defined by the formal tool using a few-shot prompt. A example prompt is shown in Figure 13.

A.4 Template generation prompt

Figure 14 shows an example of prompt for LLM to generate configuration templates. The prompt includes six parts: background description, configuration example, target scenario, association relation between devices in the target and example topologies, format definition of the configuration template, and instructions. The configuration example consists of a high-level intent, a topology specified in a JSON dictionary and the configurations of all nodes in the topology. The target network scenario includes the user intent f^i_{user} and target topology T_{tgt}. The instruct indicates which devices in the topology the LLM should generate templates for.

A.5 Intent construction prompt

In the evaluation in Sec.4, we generate intent description for each target scenario using GPT-4o. We first ask NetOps experts draft few examples for each type intent. We then utilize GPT-4o to generate intent description using a few-shot prompt, as shown in Figure 12.

B Detailed Experimental Results

In this section, we provide detailed experiment results of ablation study and comparison between different LLMs.

B.1 Ablation study

We conduct detailed ablation studies on the Querier's recommendation strategies and Classifier's classification strategies to further evaluate the performance of Querier and Classifier.

Ablation study of recommendation strategies. Table 7 shows the ablation study results on the recommendation strategies of the Querier. The results convey four important insights. *First*, without adopting intent preprocessing, the Querier achieves 85% accuracy in example recommendations. Owing to inaccurate examples, CEGS is unable to successfully synthesize correct configurations for all networks. This is due to the flexibility of natural language expression, which leads to diverse expressions of the same type intent, posing a challenge for accurate identification. In constract, by adopting an intent standardization preprocessing method, the Querier shows significant improvement in recommending configuration examples with 100% accuracy, enabling our CEGS to successfully synthesize correct configurations for all networks within an average of 28 loops. In addition,

Given that intents in natural language, your task is to transform the intents into the responding formal specifications. There are three types of formal specifications: PathReq(), ECMPPathsReq(), and PathOrderReq().

1. PathReq() is used to represent a specific transmitting path requirement, which is defined as: PathReq(<protocol>, <destination>, <path>, False). It indicates that traffic destined for <destination> transmits following the path <path>.

2. ECMPPathsReq() is used to represent a load-balance requirement, which is defined as: ECMPPathsReq(<protocol>, <destination>, [PathReq(<protocol>, <destination>, <path1>, False), PathReq(<protocol>, <destination>, <path2>, False)], False). It indicates that traffic destined for <destination> is load-balanced along the path <path1> and the path <path2>.

3. PathOrderReq() is used to represent a path-preference requirement, which is defined as: PathOrderReq(<protocol>, <destination>, [PathReq(<protocol>, <destination>, <path1>, False), PathReq(<protocol>, <destination>, <path1>, False)], False). It indicates that traffic destined for <destination> prefers the path <path1> over the path <path2>.

In these formal specifications, <protocol> represents the routing protocol used by the router, with a value range of [Protocols.BGP, Protocols.OSPF, Protocols.Static].

==========

For example:

Intent: BGP routing. The traffic from RouterA to RouterD prefers the path of <RouterA, RouterB, RouterD> over the path of <RouterA, RouterC, RouterD>.

Specification: [PathOrderReq(Protocols.BGP, 'RouterD', [PathReq(Protocols.BGP, 'RouterA', [RouterA, RouterB, RouterD], False), PathReq(Protocols.BGP, 'RouterD', [RouterA, RouterC, RouterD], False)], False)

…

==========

Intent: All routers are configurated with BGP protocol. When traffic is sent from R_A to R_F, it prioritizes the route (R_A, R_B, R_D, R_F) over route (R_A, R_C, R_E, R_F).

Specification:

Figure 13: Example prompt for converting intents into formal specifications.

compared with not using the second-stage recommendation, the Querier uses graph similarity measurement method to recommend the most relevant examples, allowing CEGS to synthesize the correct configuration faster. This is because the graph similarity method can find examples that share similar topological features to the target topology, thus guiding the Classifier better match the example to devices.

Ablation study on classification strategies. Table 8 shows the ablation study results on the classification strategies of the Classifier. We observe that the complete Classifier achieves the best performance. The Classifier achieves 90% accuracy by relaying on exact matching to establish association between devices in the target and example topologies based device's roles. This is because, in some cases, the device configuration is also highly affected by its neighborhood while exact matching cannot measure the neighborhood similarity between devices. By combining exact matching with neighborhood similarity measurement method, the Classifier enhances association establishment accuracy and synthesis speed, allowing CEGS to synthesize correct configurations with an average reduction of 8 loops.

B.2 Comparison of different LLMs in configuration generation

We evaluate the performance of different LLMs for configuration generation, including LLaMA-2-7B, LLaMA-2-13B, Mixtral-8x7B-Instruct, Gemma-1.1-7B-IT, LLama-3-70B-Instruct, and GPT-4o. Table 9 shows the comparison results. We leverage these LLMs to generate configurations under two target scenarios. One scenario consists of a small-scale star network with 5 nodes, and 6 simple no-transit intents. Another scenario consists of a larger network with 22 nodes, and one complex path-preference intent. We observed that the performance of GPT-4o is the best, followed by LLama-3-70B-Instruct. Therefore, in our evaluation, we leverage GPT-4o to generate configuration templates, due to its outstanding configuration generation ability.

Table 7: Ablation study results on the recommendation strategies of the Querier. U stands for unsuccessful generation.

Intent similarity	Intent preprocessing	Intent graph similarity	Accuracy	Loops
✓	×	×	85%	200(U)
✓	✓	×	100%	28
✓	✓	✓	100%	10

Table 8: Ablation study results on the classification strategies of the Classifier.

Exact matching	Neighborhood similarity	Accuracy	Loops
✓	×	90%	18
✓	✓	100%	10

C A case study

We provide a complete case to show our CEGS how to synthesize correct configurations, given a target network scenario. Figure 15 shows a target network scenario consisting two user intents and a target network topology.

C.1 Identifying configuration examples

We utilize the Querier to recommend the most relevant example for each user intent. Take intent f_1 as an example, we elaborate on how we use the Querier to recommend a configuration example. First, we normalize the intent f_1 into an unified expression format of *"BGP routing. Traffic from source to destination prefers path1 over path2"* using GPT-4o

You are an expert in writing network configurations. We provide you with a configuration example. Given a target network scenario including a target topology specified in a JSON dictionary and the target intent, your task is to generate the configuration template for each device in the target topology, following the configuration example, so that the target intent is satisfied.

Configuration example:

Topology T1: {" devices": [" U_A " : {AS: 100}, ...], " links": [{"node1": {"name": "U_A", "interface": "Ethernet2/0/0", "ip address": "10.17.43.1/24"}, "node2": {{"name": "U_B", "interface": "Ethernet2/0/0", "ip address": "10.17.43.2/24}}, ...]}

Intent I1: All routers are configured with the BGP protocol. When traffic originates from router U_A and is destined for U_D, it prioritizes the path (U_A, U_B, U_D) over (U_A, U_C, U_D).

Configurations:

Configuration of U_A : hostname U_A \n interface Ethernet2/0/0\n ip address 10.17.43.1/24 \n …

……

Target network scenario:

Target topology T2: {" devices": [" R_A " : {AS: 10}, ...], " links": [{"node1": {"name": "R_A", "interface": "Ethernet1/0/0", "ip address": "10.25.32.5/24"}, "node2": {{"name": "R_B", "interface": "Ethernet1/0/0", "ip address": "10.25.32.10/24}}, ...]}

Target Intent I2: Each router runs the BGP protocol. Traffic form router R_G to R_D selects the path (R_G, R_F, R_D) as preferred over (R_G, R_E, R_D).

Association relations between routers in the target topology T2 and routers in example topology T1:

$R_A : U_E$, $R_B : U_E$, $R_C : U_F$, $R_D : U_F$, $R_E : U_C$, $R_F : U_B$, $R_G : U_A$

Format requirements for configuration template:

This configuration template considers OSPF cost settings and BGP route-map configuration as templates, while the rest remains as specific configurations. The format of OSPF cost configuration template and BGP route-map configuration template are:

1. OSPF cost configuration template: this template leaves the ospf cost as symbol, represented by [value].

2. BGP route-map policy configuration template:

1) Follow the import route-map name and export route-map name, which are defined as 'RMap_{router}_from_{neighbor}' and 'RMap_{router}_to_{neighbor}', respectively, (where router and neighbor should be replaced with the router's name and its neighbor's name.).

2) The route-map configuration template should leave policy parameters (e.g., local preference value, community value) as symbolic which is represented by [value]. For instance:

```
ip community list 1 [value]
route-map RMap_RouterF_from_RouterM permit 10
 match community 1
 set local-preference [value]
 set community [value] additive
```

3) If the route-map configuration uses the community or prefix, you must first provide the corresponding definition of "ip community list" or "ip prefix-list". The exclamation mark (!) should be used to separate the route-map configuration of different neighbors.

Please directly generate the configurations for routers {R_B, R_F, …} in the target topology T2, referring to the configurations of their association nodes in the example topology T1, so that the target intent I2 is satisfied. Note: You cannot provide any comments in the response, nor provide any comments in the generated configuration.

Figure 14: Example prompt for generating configuration templates.

Table 9: Comparison results of different LLMs for configuration generation. U stands for unsuccessful generation.

Target network scenario	Models					
	LLaMA-2-7B	LLaMA-2-13B	Mixtral-8x7B-Instruct	Gemma-1.1-7B-IT	LLaMA-3-70B-Instruct	GPT-4o
5-node network, 6 no-transit intents	50(U)	50(U)	50(U)	50(U)	5	2
22-node network, 1 path-preference intent	50(U)	50(U)	50(U)	50(U)	30	4

with the few-shot prompt shown in Figure 10. The intent of each configuration example is also normalized into a specific expression format during the configuration example parsing process. For example, the intents of configuration examples shown in 16 and 17, also are normalized as *"BGP routing. Traffic from source to destination prefers path1 over path2"*. These two examples, whose intent semantically match intent f_1 with a similarity score of 1, are considered potential reference examples for intent f_1. We then construct the corresponding user intent graph and two example intent graphs, and using GraphSAGE to calculate the similarity between them. The similarity between the example intent graph of configuration example in Figure 16 and the user intent graph is 0.86, while the similarity between the example intent graph of configuration example in Figure 17 with the user intent graph is 0.75. Thus, we select the configuration example z_1 in Figure 16 as the example associated with intent f_1. Similarly, we recommend the best configuration example for intent f_2. The configuration example in Figure 17 is chosen due to its higher similarity between its example intent graph and the user intent graph corresponding to intent f_2. From Figures 15, 16, and 17, we can observe that when considering intent f_1, the example intent graph corresponding to example z_1 is more similar to the intent graph for f_1, particularly since the nodes R_A, R_B, and R_D in Figure 15 closely match the node attributes and neighborhood relations of nodes V_A, V_B, and V_D in Figure 2. However, only node R_A exhibits high similarity to node U_A in 17. Therefore, the user intent graph for f_1 is closer to the example intent graph of configuration example z_1.

Intents:

Intent f_1: Each router runs the BGP protocol. Traffic form router R_A to R_E selects the path (R_A, R_C, R_E) as preferred over (R_A, R_B, R_D, R_E).

Intent f_2: Each router runs the BGP protocol. Traffic form router R_G to R_D selects the path (R_G, R_F, R_D) as preferred over (R_G, R_E, R_D).

Topology:

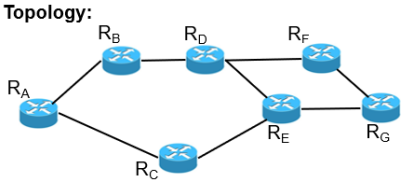

Figure 15: A target network scenario.

Intent: All routers are configured with the BGP protocol. When traffic originates from router V_A and is destined for V_F, it prioritizes the path (V_A, V_B, V_D, V_F) over (V_A, V_C, V_E, V_F).

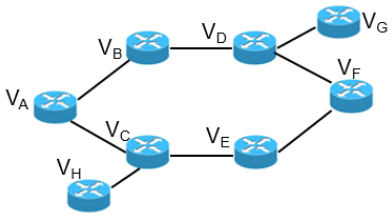

Figure 16: Configuration example z_1 for the user intent f_1.

C.2 Establishing the association between devices in the target and example topologies

For each user intent f_1, we utilize the Classifier to establish the association between the device in the target topology and those in the topology of example z_i corresponding the intent f_i. Figure 18 shows the association results with respect to each example.

C.3 Generating configurations

We first leverages GPT-4o to generate configuration templates for each device in the target topology with respect to each user intent in turn. Figure 14 shows the example prompt for generating configuration templates. Take router R_D in the target topology as an example, Figure 19 and Figure 20 show the configuration template for router R_D with respect to intent f_1 and intent f_2, respectively. We use the Syntax Verifier, LAV, and GFV to verify these templates. We then merge the configuration templates for each device with respect to the two user intents. Figure 21 shows the merged templates for router R_D. Finally, we use the Formal Synthesizer to specify the specific parameters in the templates. Figure 22 shows the full configuration of router R_D.

D Discussion on user guide and generalization for CEGS

In this section, we first provide a user guide detailing how network operators can use our CEGS to synthesize configurations in the real network setting. We then provide a comprehensive guide detailing the steps a network operator needs to follow to generalize CEGS with new intents.

Intent: All routers are configured with the BGP protocol. When traffic originates from router U_A and is destined for U_D, it prioritizes the path (U_A, U_B, U_D) over (U_A, U_C, U_D).

Topology:

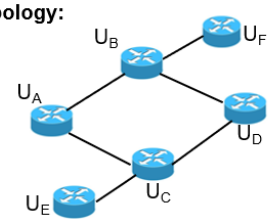

Figure 17: Configuration example z_2 for the user intent f_2.

Association relations between devices in the target topology and those in the topology of the example z_1:

$R_A : V_A$, $R_B : V_B$, $R_C : V_C$, $R_D : V_D$, $R_E : V_F$, $R_F : V_G$, $R_G : V_G$

Association relations between devices in the target topology and those in the topology of the example z_2:

$R_A : U_E$, $R_B : U_E$, $R_C : U_F$, $R_D : U_F$, $R_E : U_C$, $R_F : U_B$, $R_G : U_A$

Figure 18: Association between devices in the target and example topologies.

D.1 A user guide

To utilize CEGS to synthesize configurations for devices in a real network, the network operator needs to prepare the operator intents, network topology in JSON format, and the relevant device documentation. For example, consider a cloud network consisting of three Autonomous Systems (ASes), as shown in Figure 23(b). The operator's network, AS1000, includes four routers: RouterA, RouterB, RouterC, and RouterD. This network is connected to one customer peer AS2000, and two external peers, AS3000 and AS4000. The operator aims to manage traffic flow transmission from the customer peer to two external peers. For this, the operator first needs to draft routing intents in natural language for these traffic flows. Figure 23(a) provides the intent example. The operator then should describe the network topology in JSON format, as illustrated in Figure 23(b). Finally, the operator needs to prepare the device documentation, which should include a configuration guide that contain many configuration examples. At the same time, the operator must ensure that at least one configuration example related to each specified intent is included in the documentation. Figure 23(c) provide a sample documentation example from the cisco[6].

D.2 How to generalize CEGS?

Our CEGS supports static route, OSPF, and BGP configurations across variety of routing intents supported by the Formal Synthesizer (NetComplete). To generalize CEGS to new in-

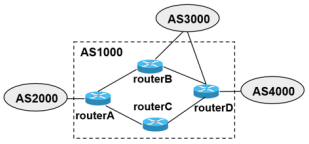
tents for other protocols or network techniques (e.g., VLAN) on specific vendor devices, the user extends CEGS by following six steps:

Configuration example preparation. The user first needs to collect relevant device documentation which contain configuration guide and ensures the configuration guide cover some configuration examples related to the target scenarios.

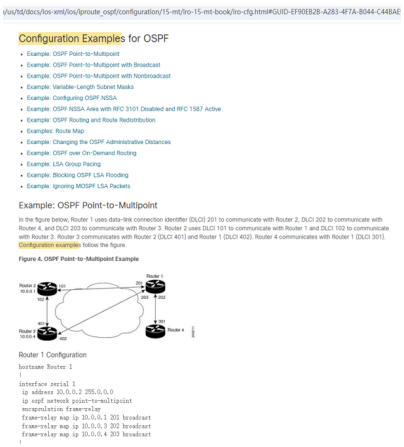
GraphSAGE training. The Querier and Classifier depend on a GraphSAGE model to recommend examples and build association between devices in the target and example topologies. To achieve this, the user needs to train a GraphSAGE model. First, the user should construct a intent graph dataset that contains numerous matching pairs of intent graphs. These intent graphs should cover the relevant target scenarios, including similar intents and topology structures. Each data in the dataset consists of a pair of intent graphs and the labels indicating the associations between nodes in the two graphs. The user then trains the GraphSAGE model on this dataset using the training method described in Sec.3.2.3. The user may need to tune the GraphSAGE model by adjusting hyperparameters such as the number of layers, number of neurons, and learning rate.



Prompt crafting. The user needs to craft the prompt for the LLM to generate configuration templates. The prompt, as shown in Figure 14, consists of six parts: background description, configuration example, target network scenario, association relation between devices in the target and example topologies, format definition of the configuration template, and instructions. The users should tailor the template format definition according to the configuration templates they need to generate. The user can design customized instructions as needed. In addition, the user also needs to craft other prompts, such as those for intent normalization and role extraction, as described in A.

LAV extension. CEGS develops the LAV to locally verify whether each device template complies with the the target topology and user intent descriptions, such as interface configurations and protocol basic configurations. The user can easily

Intent 1: Configure BGP process on each routers to implement the policy: traffic from AS2000 to AS3000 prefers the path <AS2000, routerA, routerB, AS300> over the path < AS2000, routerA, routerC, routerD, AS3000 >.



Intent 2: Configure OSPF process on each routers to implement the policy: traffic from AS2000 to AS400 is load-balanced between the path <AS2000, routerA, routerB, routerD, AS4000> and the path <AS2000, routerA, routerC, routerD, AS3000>.

(*c*) Device documentation

Figure 23: Example input for CEGS.

adapt the LAV for other protocols or network techniques by implementing checks for the protocol-specific basic settings or network technique settings, as well as interface attribute settings when involved.

GFV extension. CEGS develops the GFV to perform global verification on templates across all devices, ensuring that configurations with interdependencies and cross-device impacts are properly validated. For example, BGP route-map policy configurations on different devices influence one another and work together to achieve the intended global routing policy. The user should extend the GFV to globally validate configurations that affect each other across all devices involved in fulfilling the intended network behavior. The GFV provides localized feed about configuration errors for LLM correction. The user can replace the LAV or GFV using other verification tools that can provide localization feedback, indicating which specific configuration on which devices are incorrect.

Formal Synthesizer selection. The user needs to select or develop appropriate Formal Synthesizer that is capable of filling correct parameters in the templates to achieve the intent.

D.3 Why does CEGS need to use formal methods?

In configuration synthesis tasks, it is a significant challenge for LLMs to accurately calculate network policy parameters based on the entire network information. For example, achieving a load-balancing intent under the OSPF protocol requires accurately calculating the cost of each link in the network, which is difficult for LLM reasoning. Therefore, it is essential to use formal method to calculate network policy parameters to guarantee the configuration correctness.

Suppressing BGP Zombies with Route Status Transparency

Abstract

Withdrawal suppression has been a known weakness of BGP for over a decade. It has a significant detrimental impact on both the reliability and security of inter-domain routing on the Internet. This paper presents *Route Status Transparency* (RoST), the first design that efficiently and securely thwarts withdrawal suppression misconfigurations and attacks. RoST allows ASes to efficiently verify whether a route has been withdrawn; it is compatible with BGP as well as with BGP security enhancements. We use simulations on the Internet's AS-level topology to evaluate the benefits from adopting RoST. We use an extensive real-world BGP announcements dataset to show that it is efficient in terms of storage, bandwidth, and computational requirements.

1 Introduction

The Border Gateway Protocol (BGP) determines how packets route between Autonomous Systems (ASes) on the Internet. Despite its crucial role in facilitating Internet communication, BGP is fragile, and when failures occur, they can cause significant disruptions. Some failures are due to benign errors and misconfigurations, while others are attributed to malicious actions [29, 41]. Many of these issues are addressed by the increasing adoption of the Resource Public Key Infrastructure (RPKI) [11, 25, 33], which allows an IP prefix owner to associate it with the ASes allowed to announce the prefix through BGP. Furthermore, the networking community has also devoted tremendous efforts to design and standardize protocols for route authentication (i.e., beyond the origin), most notably, BGPsec [6]. With route validation in place, announcing routes with invalid sources or bogus links becomes less of a problem for global Internet routing.

However, the authentication mechanisms do not solve the problem of *freshness*. That is, how can an AS know whether a BGP announcement has been withdrawn or not since it was announced? This key problem is the root cause of stuck routes, also known as "zombie" routes, where ASes choose to route traffic through withdrawn routes because these ASes are unaware that these routes have been withdrawn [15, 35]. This happens when some AS along the route withdraws an announcement, but a downstream AS does not propagate the withdrawal (intentionally or due to an error). The once valid route keeps appearing "alive" to the following ASes, who may opt to use it and export it further, accidentally misleading other ASes. Since the zombie route *was* legitimate, it continues to pass the route authentication checks even with RPKI and full-fledged BGPsec. Zombie routes can cause disconnections when an AS mistakenly sends traffic to a neighbor who no longer has a valid route to the destination IP address (since that route was withdrawn). Moreover, zombie routes can lead to inefficient routing where an AS would think it uses a better (e.g., cheaper or shorter) route to reach some destination, but a downstream AS will route the traffic differently than expected. In some instances, this misrouting has even led to the creation of routing loops [30]. In many cases, withdrawal suppression is attributed to benign errors rather than deliberate attacks [15], illustrating the fragility of Internet routing.

Currently, the only proposed approach to solve this problem is *key rollover* [39, 42], which requires route validation (i.e., BGPsec) to already be deployed. In key rollover, keys are rotated periodically; as a result, signed routes have a limited validity period and cannot be reused 'forever'. Thus, after a key rollover, the routes signed by the old key cannot be authenticated by the new key. This means that a withdrawal suppression can only be effective until the current keys are rotated. However, key rollover requires a hefty operational effort, since the AS's BGPsec key pair needs to be updated, a new certificate must be issued, and the old one revoked (if the rollover occurs when the previous key is still valid).

In this work, we present *Route Status Transparency (RoST)*, a novel mechanism for mitigating withdrawal suppression. RoST-adopting ASes publish cryptographically-signed information about the routes they export to protect their announcements against withdrawal suppression. Other-RoST adopting ASes download and use this information to verify whether any of the routes they receive were actually

withdrawn. Specifically, RoST uses the transitive attribute capability to identify and monitor routes. Namely, every AS in the path will generate a sequence of route IDs as the announcement is distributed along the path. By combining the transparent route status information with these route IDs, each AS that performs validation based on RoST can check if the announcements match the transparent information, and if not, identify withdrawn routes.

RoST detects and limits the impact of BGP withdrawal suppression to minutes, whether due to intentional attacks or misconfigurations, and adds only a negligible overhead to the BGP protocol. ASes that adopt RoST deploy a local machine (an "agent") that synchronizes with the route status transparency reports and identifies withdrawn routes. The agent machine performs the heavy lifting of validating these reports and then configures the local BGP routers to withdraw invalid routes. In contrast to key rollover, RoST can be adapted with vanilla BGP to mitigate the zombie routes phenomenon, thus circumventing the challenges involved in the deployment of BGPsec and the costs of key rollover. We evaluate RoST in terms of overhead using routing data from multiple vantage points on the Internet and compare it with key rollover.

In summary, this work addresses withdrawal suppression, a fundamental problem in today's Internet routing that will persist even when route authentication mechanisms are fully deployed. We design and evaluate the RoST protocol, the first protocol that efficiently detects and mitigates withdrawal suppression. RoST is compatible with the currently deployed BGP, and we show how it can be deployed without requiring changes to today's routers.

2 Background

Route withdrawals and announcement suppression. A BGP router can withdraw a route either explicitly by sending a withdrawal announcement or implicitly by sending an updated announcement. In Figure 1, we illustrate both explicit and implicit withdrawals. The figure illustrates a scenario in which AS 100 initially chooses AS 666 as its provider, and thus AS 100 sends an announcement with prefix 1.2/16 and AS-path 100 to its provider, AS 666. Then, AS 100 decides to switch its provider to AS 300, so it sends an *explicit* withdrawal announcement to AS 666. In an *implicit* withdrawal, AS 100 sends a new announcement to AS 666 with an artificially inflated AS-path, 100-100-100, known as 'path prepending'. This makes the path from AS 100 to AS 666 three-hop long, making the path from AS 100 to its current provider, AS 300, more favorable (e.g., AS 200 will route to prefix 1.2/16 through AS 300, instead of AS 666). A withdrawal suppression happens when some AS on the route fails to propagate a withdrawal message or an alternative route (explicit/implicit withdrawal, respectively). This can be unintentional due to misconfigurations or software bugs in

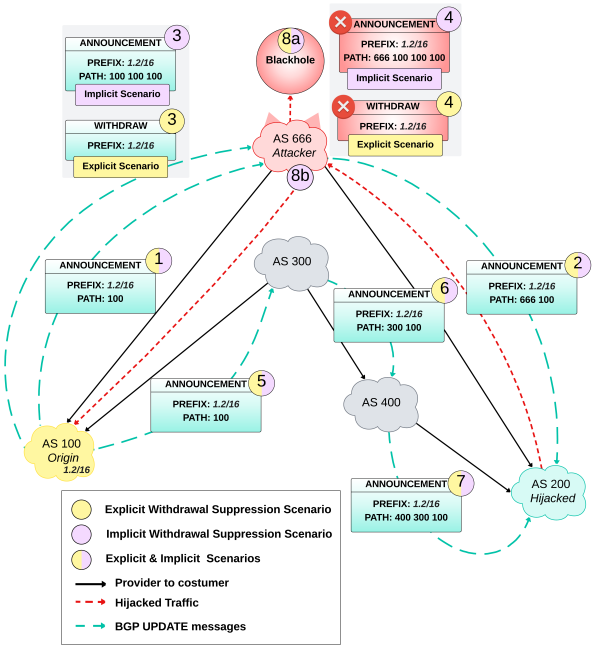

Figure 1: Illustration of explicit and implicit withdrawal suppression attacks. The diagram highlights the sequence of steps involved in each attack and the actions taken by AS 666. Steps unique to explicit withdrawal suppression are marked in yellow with a "b" label, and steps unique to implicit withdrawal suppression are marked in purple with an "a" label. Steps that are common to both scenarios are shown with a combination of yellow and purple.

BGP routers, or intentional, for malicious purposes such as to keep traffic flowing through a route with the attacker's AS (AS 666 in Figure 1).

Stuck or zombie routes. Measurement studies [15, 35] using route beacons confirm that zombie outbreak happens daily, which can cause traffic to follow undesirable and unavailable paths, leading to network congestion, degraded service quality, or even complete loss of connectivity. Specifically, the analysis in [15] reveals that the impact of zombie routes is influenced by the tier of the network where the zombie route was detected, which has significant implications. The authors demonstrate that zombie routes detected within a Tier-1 AS can affect the majority of ASes. A real-world example of this occurred on August 30, 2020, when CenturyLink, which had acquired Level 3 Communications (a Tier-1 AS), experienced a significant incident. According to a report by Cloudflare [36], CenturyLink inadvertently applied a firewall rule that blocked all internal BGP traffic, leading to extensive outages across their network. What made this incident particularly severe was the failure of affected routers to issue BGP withdrawal messages. Without these messages, external networks (including Cloudflare) continued to route

traffic through CenturyLink, unaware of the internal issues. The outage lasted several hours, and many networks were forced to manually reconfigure their systems to reroute traffic away from CenturyLink/Level 3.

3 RoST Design

In this section, we detail the design of RoST. We start with its goals (§3.1) and then present a high-level system overview (§3.2). We then detail how RoST agents maintain routes' status (§3.3), how the routes' status is made transparent (§3.4), how agents track the status of these routes (§3.5) and how routes advertisements are validated (§3.6). A detailed pseudocode for the main RoST operations is presented in Appendix A.

For simplicity, in this section we assume a single trusted repository and refer to it in a singular form ("the repository"). Later, in §7.2, we discuss how to extend it to support multiple repositories and to overcome repository faults. Finally, when we refer to AS-Paths, we write the path from left to right, where the rightmost AS is the origin of the IP prefix.

3.1 Design Goals

RoST aims to detect and mitigate withdrawal suppression in inter-domain routing on the Internet. It does not deal with path manipulation attackers that may alter or spoof route advertisements. Such attackers should be handled by path authentication mechanisms [6, 32]. We design it to achieve the following three desiderata:

- Efficiency, i.e., low computation, communication, and storage overhead.
- Compatibility with BGP and future security enhancement of BGP (e.g., BGPsec [6], BGP-iSec [32]). Namely, it should be possible to deploy RoST without extending or standardizing new routing protocols.
- Compatibility with BGP routers. That is, it should be possible to mitigate withdrawal suppression by having local RoST agent automatically issue commands to the router through existing command line or application interfaces rather than requiring specialized router software or hardware support.

3.2 High-Level Operation

RoST detects withdrawal suppression by providing route status transparency. We outline its operation following Algorithm 1. Each adopting AS deploys a RoST *agent*, which performs three main functions: (1) report the current routes of the AS to a public repository (Algorithm 1, lines 6-7), (2) retrieve the current routes of other ASes from the repository (Algorithm 1, lines 8–13), and (3) validate advertised BGP routes without relying on propagation of withdrawal announcements (Algorithm 1, lines 14–19).

Algorithm 1 High-Level Operations of RoST Agent

```
1:  Input:
2:      AgentAS: AS number for which the agent is responsible
3:      BatchInterval: Time interval for periodic reporting
4:      R: Trusted repository
5:  procedure RoSTAgent(AgentAS, BatchInterval, R)
6:      // 1. Initialize asynchronous tasks
7:      Event 1 - Reports local routes to R every BatchInterval
8:      Event 2 - Subscribe to route updates from R
9:      Event 3 - Listen for BGP update messages from the router
10:     // 2. Handle incoming events
11:     while true do
12:         event ← Wait for the next available event
13:         if event is "Periodic Report Trigger" (Event 1) then
14:             Report local routes to R
15:         else if event is "Route Update from R" (Event 2) then
16:             Validate impacted routes
17:             if a route is invalid then
18:                 Propagate withdraw or alternative route
19:         else if event is "BGP Update Message" (Event 3) then
20:             Validate the new route using repository data
21:             if the route is invalid then
22:                 Propagate withdraw or alternative route
23:             Update route status before forwarding BGP message
```

Using a standalone agent that is separate from BGP routers promotes simpler deployment because it does not require replacing or updating existing BGP routers. Specifically, when the agent detects a route that was withdrawn but the withdrawal was suppressed, the agent instructs the BGP routers of the AS to remove the withdrawn route using the routers' existing API.

To illustrate how RoST detects withdrawal suppression, consider the scenario depicted in Figure 2. AS 4 has two available routes to a prefix that originates at AS 1, either via path 5-3-2-1 or 6-2-1. Assume that AS 4 chose to route through AS 6 as that AS path is shorter. Suppose that at some point, AS 2 decides to stop using AS 6 as a provider, and as a result, AS 2 sends a withdrawal update message to AS 6; however, AS 6 suppresses this withdrawal. This means that AS 4 would continue to route traffic through AS 6 since it is unaware of the withdrawal.

Using RoST, AS 4 *can* detect and mitigate this suppression. That is, once AS 2 issues the withdrawal, its agent updates the repository about the withdrawal. This allows AS 4's agent to learn about the withdrawal from the repository despite AS 6 suppressing it. To authenticate the information recorded at the repository, RoST assumes a standard RPKI deployment. This allows agents to sign the routes' status information they make transparent, and other agents to verify its authenticity. Given the increasing adoption of RPKI, with most unique prefix-

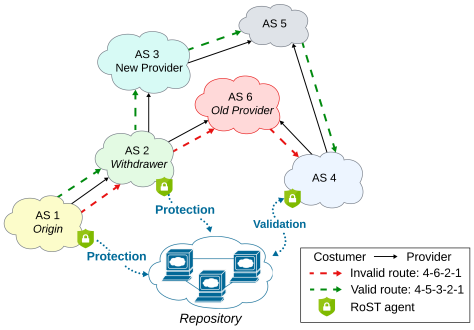

Figure 2: High-level overview of RoST operations. AS1, the origin AS, and AS2, the withdrawer, both perform the protection role by ensuring that their routing information is up-to-date and uploaded to the trusted repository when changes occur. When AS2 switches providers from AS6 to AS3, AS6, the old provider, continues to attract traffic using an outdated route. AS4, a customer of AS6, takes on the validation role by retrieving the updated route status from the trusted repository. This allows AS4 to detect any withdrawal suppression by AS6.

origin pairs already having valid RPKI records (54% [2]), we believe that it will not hinder RoST's adoption.

3.3 Tracking Route Status

An AS's agent maintains the status of the AS's routes using vectors called Route Status Vectors (RSVs). Each RSV represents the route updates to a specific IP prefix and whether or not this route is active. That is, an RSV is in the form of: $(Prefix, RouteID, Status)$.

The agent updates the repository with batches of route updates. These updates are identified using a *RouteID* that consists of two counters, $RouteID = (BatchID, PathID)$. The BatchID counter identifies the batch number where that update occurred, and the PathID counter indexes the specific path update for the RSV's prefix within that batch. This design decision is based on our analysis of real-world route announcements collected by public route collectors (see §4). Our analysis shows that while the average number of path changes per prefix remains under 20 per day, some prefixes can experience more than 1 million route changes per day (see Figure 5a). This can be caused by multiple reasons, such as path prepending, provider change, or path finding [15]. By periodically sending batched updates, RoST minimizes its space requirements: a burst of path changes would be 'absorbed' into one BatchID; PathID would reset (to 0) in the next batch, which avoids the rapid counter increments if RoST were to use a single counter. The PathID would increment within a batch only if the route has changed and still active. If the route is withdrawn, only the status field changes to invalid.

Every RoST agent maintains a set of RSVs per neighboring AS, reflecting the routes that were announced to the specific neighbor. We refer to this set as RSV-Out, and denote the set of RSVs that the agent of AS x maintains for neighboring AS y as RSV-Out$_{(x,y)}$. We refer to the pair (x,y) as the *interface* between AS x and AS y. The RSV-Out$_{(x,y)}$ structure also contains a *BatchCounter*, which is incremented periodically at each batch interval. To illustrate, refer to step ① in Figure 3, where we present how the entries of RSV-Out$_{(100,200)}$ are maintained at the end of batch 54 (i.e., BatchCounter is 54) in five different scenarios:

1. *Prefix 1.1/16, no changes during the current batch*: This prefix has an older BatchID (48) and PathID (1), meaning that the route to this prefix has not changed since batch 48. The status of this route remains active (T).
2. *Prefix 1.2/16, one route change*: The BatchID has been updated from 51 to 54, initialized with a new PathID (1). This reflects that the route to this prefix has been updated once in the current batch and remains active.
3. *Prefix 1.3/16, withdrawn route*: This prefix was previously active (T), but its status has been changed to withdrawn (F), i.e., the route has been withdrawn in the current batch (BatchID 54 and PathID 0).
4. *Prefix 1.4/16, multiple route changes*: Similarly to the case of prefix 1.2/16, but in this instance, there were three different route change announcements within the current batch, as indicated by the PathID of 3.
5. *Prefix 1.5/16, withdrawn route after multiple changes*: This prefix resembles the scenario with prefix 1.4/16, but the route has been withdrawn after two active route announcements (PathID 2) within the current batch, changing its status to withdrawn (F).

3.4 Making Routes' Status Transparent

At the end of each batch interval, the agent updates the repository about the routes that changed during that interval. It generates for every RSV-Out a corresponding delta, ΔRSV-Out, and reports it to the repository. To illustrate, refer to step ② in Figure 3, where ΔRSV-Out$_{(100,200)}$ contains all route status updates that were made to RSV-Out$_{(100,200)}$ during batch 54. Specifically, ΔRSV-Out$_{(100,200)}$ contains all the prefixes in RSV-Out$_{(100,200)}$ except prefix 1.1/16, since it is the only prefix that has not changed during batch 54.

In addition, each ΔRSV-Out contains three other values: (1) the batch counter, (2) a Merkle tree root hash committing to all route updates (the leaves are the entries of the (updated) RSV-Out), and (3) a signature over the batch counter, the interface pair, and the Merkle root, signed by the AS's private key (based on the RPKI deployment assumption). The Merkle tree commitment enables agents from other ASes to fetch an authenticated *subset* of the ΔRSV-Out that only contains updates relevant to the fetching agent, as we explain in §3.5.

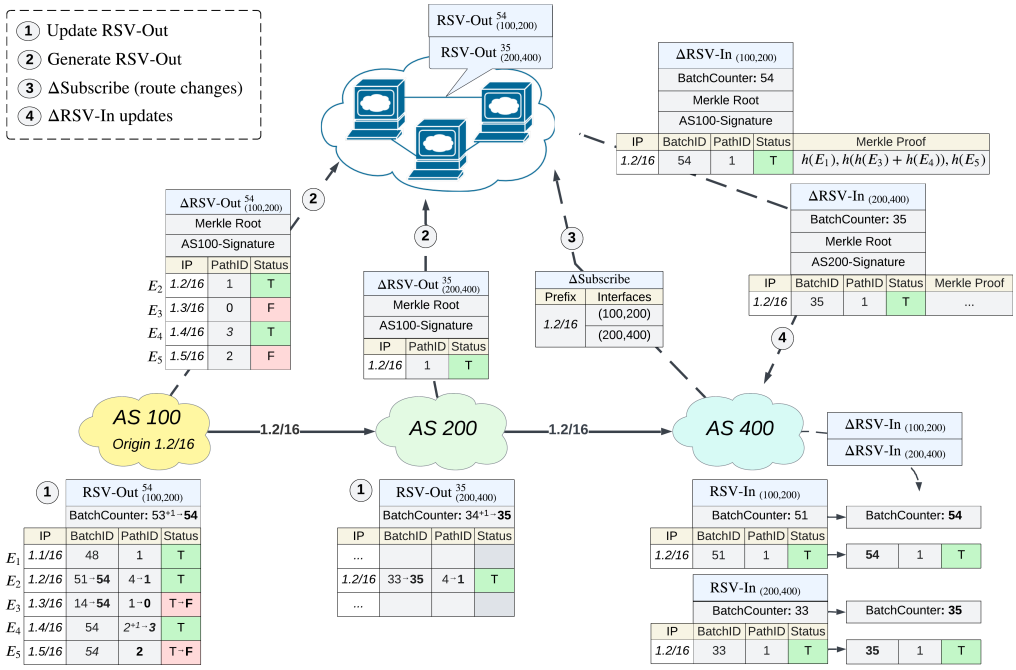

Figure 3: The diagram illustrates the steps involved in RSV processing and distribution between ASes and the trusted repository. AS 100 and AS 200 publish a ΔRSV-Out to the trusted repository, which contains updates for several prefixes. AS 400, which monitors the interfaces (100, 200) and (200, 400), subscribes to 1.2/16 for those interfaces to receive updates. The trusted repository sends ΔRSV-In when there are new updates, which AS 400 then merges with its existing RSV-In data. This ensures that AS 400 has the most current and validated route statuses, protecting the network against the use of outdated or invalid routes.

3.5 Retrieving Route Transparency Data

To learn about route changes, agents receive updates about routes from the repository. However, each agent only cares about some of the RSVs, pertaining to the routes used by their AS's BGP routers. Thus, when a router chooses to use a route to a specific prefix, the agent subscribes to updates about the current RSVs for that prefix from all the ASes on the route's AS-Path. For example, if AS w uses a route with AS-Path $x-y-z$, then the agent of AS w subscribes to RSVs of the routes that z publishes to y, y publishes to x, and x publishes to w, because suppression can occur in each of these hops.

To track these RSVs, the agents store them per interface; we refer to them as RSV-Ins. To illustrate, observe AS 400 in Figure 3, which routes traffic to prefix $1.2/16$ using the AS-Path 400-200-100. As a result, AS 400 tracks the RSVs to this prefix from AS 100 to AS 200 (in RSV-In$_{(100,200)}$) and from AS 200 to AS 400 (in RSV-In$_{(200,400)}$).

To learn about RSVs updates, the agent sends a message called Δ*Subscribe* to the repository, indicating for each prefix which RSVs it is interested in. In response, the repository provides the agent with the latest RSV-Ins according to the subscription; it keeps the agent current using ΔRSV-In messages whenever the relevant RSVs update. For example, in Figure 3, AS 400 notifies the repository that it is interested in the RSV of prefix $1.2/16$ that AS 100 maintains for AS 200 and the RSV of prefix $1.2/16$ that AS 200 maintains for AS 400 (shown in step ③). Before batch number 54, the BatchID of the prefix $1.2/16$ in RSV-In$_{(100,200)}$ at AS 400 was 51. AS 100 and AS 200 changed the route to $1.2/16$ during batch 54 and 35 (respectively), and both ASes sent a ΔRSV-Out reflecting this change (shown as part of step ②). Thus, the repository sends two updates to the agent of AS 400 (based on its subscription): ΔRSV-In$_{(100,200)}$ and ΔRSV-In$_{(200,400)}$, with the updated RSVs (shown as part of step ④).

Using the Δ*Subscribe* request over querying for updates each time allows agents to receive updates sooner without repeatedly polling the repository. It is more efficient since the agent sends Δ*Subscribe* only once after the BGP router selects a new route.

Importantly, the repository attaches proofs to its updates using the information recorded in the latest ΔRSV-Out. The repository attaches the latest batch counter, the Merkle tree root hash and signature from the latest ΔRSV-Out and an inclusion proof for every RSV in the ΔRSV-In (i.e., the neighboring nodes on the tree in the path from the relevant leaf update to the root hash). The repository can compute such proofs since it receives the entire ΔRSV-Out and thus can recreate the entire Merkle tree. The agent, on the other hand, only retrieves a subset of the ΔRSV-Out; it checks the signature to verify the Merkle root and uses these inclusion proofs to verify that the RSVs were indeed issued

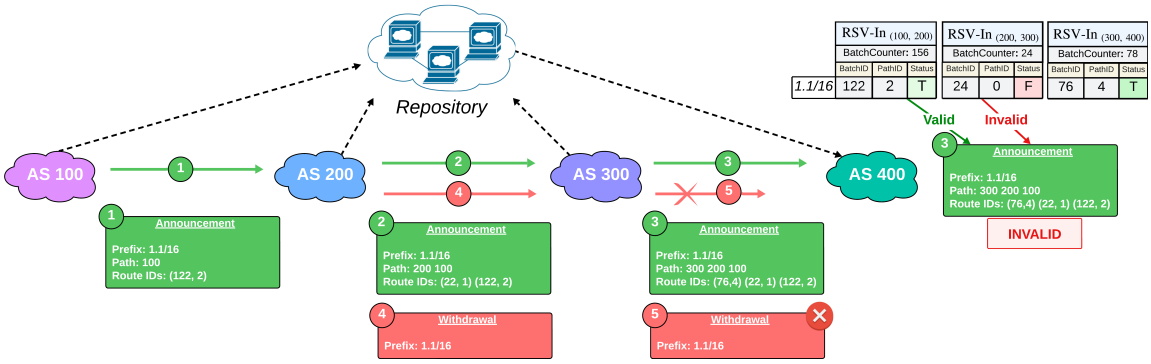

Figure 4: This diagram illustrates Route Status Validation for prefix 1.1/16 across different ASes. AS 100 originates the announcement and propagates it to AS 200, which in turn forwards it to ASes 300, 400. AS 200 later withdraws this prefix, but AS 300 suppresses this withdrawal. The corresponding RSV-In entries for each AS show the status and identifiers for the prefix. AS 400 detects the discrepancy between the announcement and the RSV-In received from AS 200 for the interface with AS 300. It marks the announcement as invalid.

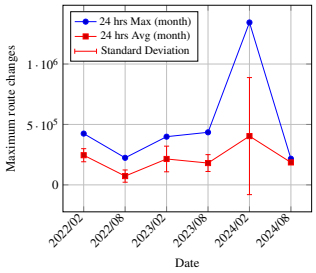
by the claimed AS. After verification, the agent updates the corresponding RSV-In with the updated RSVs. Furthermore, the agent must check if actions need to be taken to withdraw a route that was suppressed; we discuss how an agent can do it by interacting with a standard router interface in §6.

3.6 Route Status Validation

The agent validates routes it receives through BGP against the information recorded in the repository. There are two triggers for running the validation procedure: either when an agent receives a route announced to its AS through BGP or when it receives an update from the repository.

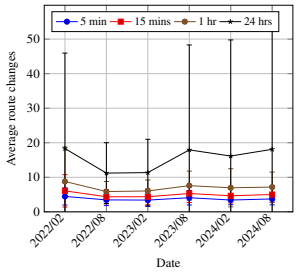
To validate a route for prefix p, the agent must check the route against the relevant RSV-Ins records. To that end, RoST adds a new transitive extended community attribute [5, 26, 40] to BGP announcements. This new attribute contains a sequence of *RouteIDs*, where the BGP routers prepend their (current) *RouteID* to this sequence of *RouteIDs*, before forwarding an announcement. By doing so, agents that receive an announcement can validate whether the announced route is fresh, by comparing the *RouteIDs* in the transitive attribute against the corresponding *RouteIDs* that were retrieved from the repository in the relevant RSV-Ins.

For example, consider an origin AS w that announces to neighboring AS x the AS-Path for prefix p for the first time during batch number n. AS w would add to the announcement the RoST's transitive attribute containing a single *RouteID*, $(n,1)$. Assume that AS x decides to announce this route to its neighbor, AS y, during batch number n', and that AS x has made two other changes to the route to prefix p during batch n'. Thus, AS x would prepend $RouteID = (n',3)$ to the proposed transitive attribute, i.e., the transitive attribute on the announcement sent from AS x to AS y would be: $(n',3),(n,1)$.



To validate the route for the prefix p against its RSV, the agent checks the repository's data about the status of the *RouteIDs* in p's BGP announcement's attributes. If at least one of the interfaces along the AS-Path of the route is not being tracked, the agent subscribes to updates from the repository to make sure it receives the records for all *RouteIDs*. If any of those routes' status is withdrawn, or if there was a later *RouteID* recorded for the same prefix (i.e., with a higher BatchID or the same BatchID but a higher PathID), then it considers that route withdrawn.

In Figure 4, we present route status validation for one route of AS 400, where the prefix is 1.1/16 and the AS-Path is 300-200-100. In the figure, the route withdrawal issued by AS 200 in batch 24 was dropped by AS 300 due to misconfiguration. AS 400 will be able to learn that AS 200 has withdrawn the routes since the status attribute in the RSV entry in RSV-In$_{(200,300)}$ has been set to false.



4 Evaluation Overhead

In this section, we evaluate RoST's overhead in terms of storage, communication, and computation. We use the Internet topology and traces from BGP routers to show that it is feasible to deploy RoST in today's Internet, considering the number of ASes, their announcements, and route update rate.

Methodology. To ensure a comprehensive and realistic evaluation of RoST, we use real-world BGP routing data collected across six distinct months: February and August of 2022, 2023, and 2024. We analyze data from Routing Information Base (RIB) snapshots and BGP update messages provided by RIPE NCC's Routing Information Service (RIPE RIS) [34]. RIPE RIS has multiple vantage points on the Internet that have peering links to multiple ASes and provide the full feed of their BGP traces and RIBs. We utilize RIB snapshots (generated every 8 hours) and traces of BGP

(a) Prefixes with the most daily route changes.

(b) Average over different time intervals.

Figure 5: Comparison of max and average route changes aggregated across the RIPE-RIS vantage points.

	Vantage Point	#Prefixes	RSV-In #Entries
IPv4	AS 51185	991,499	3,578,688
IPv6	AS 44085	220,074	1,078,736

Table 1: AS 51185 and AS 44085 are the RIPE VPs with the maximum number of prefixes connectivity for IPV4 and IPv6 respectively. We show the number of RSV-In entries required for each of them.

updates (batched every 5 minutes) from these vantage points over the data collection month. We collected data from 55 vantage points and processed around 10^{10} BGP updates.

4.1 Storage

Each agent has two storage-related functionalities: (1) storing information in RSV-Out vectors and (2) storing the RSV-In entries from other ASes. The repository stores the full RSV-Out vectors from all ASes.

Storage Overhead					
	Interfaces	**#ASes**	**%**	**RSV-Out**	**RSV-In**
Agent	1-10 (avg 2.14)	68,888	89.11%	22 MiB	65 MiB
	11-50 (avg 22.27)	6,707	8.68%	0.23 GiB	
	51-200 (avg 76.23)	1,607	2.08%	0.80 GiB	
	201-639 (avg 257.95)	108	0.14%	2.7 GiB	
Repository	496,910	118,031	100%	5.1 TiB	3 TiB

Table 2: Storage overhead of RoST with respect to the number of interfaces each AS has. RSV-Out/RSV-In are calculated for the average number of interfaces each group.

4.1.1 Agent Storage

In RSV-Out, every entry for an IPv4 IP prefix requires 89 bits[1] and every IPv6 entry requires 209 bits[2]. Based on RIPE RIS's traces, we observed that the ASes that announced

[1]Prefix: 40 bits, BatchID: 32 bits, PathID: 16 bits and status: 1 bit.
[2]Prefix: 136 bits, BatchID: 32 bits, PathID: 16 bits and status: 1 bit.

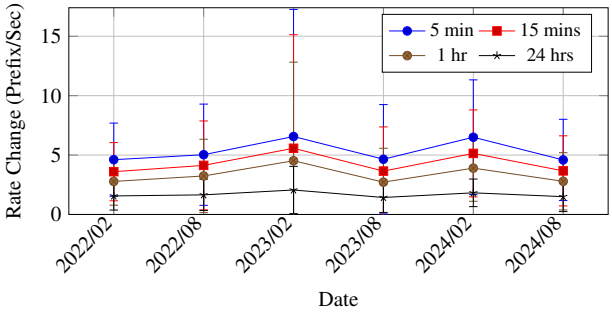


Figure 6: Average route updates per second for different batch sizes (dividing the average $\Delta RSVs$ size by the batch interval length). Across all sample dates, the average rates of changes per prefix were 5.32/s, 4.29/s, 3.33/s, and 1.67/s for the 5min, 15min, 1hr, and 24hrs intervals, respectively.

the maximum number of prefixes have announced 991,499 prefixes for IPv4 and 220,074 prefixes for IPv6, see Table 1. We follow a conservative approach and assume that RIPE RIS's traces do not contain all prefixes, since some prefixes announced to each neighbor might not always be visible to RIPE RIS's vantage points. Hence, we round these numbers to 1M IPv4 prefixes and 250K IPv6 prefixes. Furthermore, we assume a worst-case scenario, in which every RSV-Out has entries for *all* of these prefixes. Thus, by multiplying *entry size* $\times$ *#prefixes*, we estimate that the size of a single RSV-Out is 16.83MiB (10.6MiB for IPv4 plus 6.23 MiB for IPv6).

Each agent creates an RSV-Out for every neighboring AS. Based on the RIPE RIS traces, we found that the average number of interfaces per AS is 6.43 and that 89.11% of the ASes have at most 10 interfaces, see Table 2. Based on the aforementioned size of a single (worst-case scenario) RSV-Out, we get that for the average AS the storage size is 106.76MiB (16.84MiB $\times$ 6.43) and for ASes with 10 interfaces, the storage size is 168.39MiB. For ASes with the maximum number of interfaces observed, i.e., 639 interfaces, the storage size is 10.51GiB.

The agent is also responsible for retrieving and maintaining RSV-In associated with the interfaces of the other ASes appearing in the "best routes" of each of its prefixes. To quantify the expected overhead, we count for each of the 991,499 IPv4 prefixes and 220,074 IPv6 prefixes the number of interfaces based on their AS-paths. We observe that in such a worst-case scenario, any agent would need to process 3,578,688 entries for IPv4 and 1,078,736 entries for IPv6. By multiplying each of them with their corresponding entry size (see RSV-Out entry size for IPv4 and IPv6, 89 and 209 bits respectively, see above), we get 65MiB of storage, which can easily fit in a commodity agent machine's memory; see Table 2 (RSV-In column). Note that this number is identical to all agents because it does not depend on the number of interfaces.

4.1.2 Repository Storage

There are two contributing components to the repository's storage requirement: (1) storing all RSVs from each AS in the network and (2) storing the prefixes that an AS validator is interested in receiving route updates from for each of the interfaces. We aggregate the cost for each AS given the number of interfaces there are on the Internet, and assuming the highest-cost scenario in which every AS announces a route to every prefix announced on the Internet to each of its neighbors. We conclude that the repository would need to store 8.1 TiB, which is feasible even under the demanding assumption above.

4.2 Communication

We quantify the increase in BGP update length due to adding RoST's identifying tags (encoded as transitive BGP attributes) and the bandwidth consumption when ASes exchange ΔRSVs with the repository.

BGP update length overhead. Each BGP announcement in our protocol must include a new transitive attribute, the *RouteIDs*. This attribute slightly increases the size of BGP messages. To quantify this increase, we analyzed the routing table from a RIPE-RIS route collector (rrc00) using the BGPdump tool on August 1st, 2024. The results show that the average AS-path length for IPv4 is 3.86 hops (when excluding AS path prepending). For each hop on the route, RoST encodes its identifier as a 7B attribute (1B for the length and 6B for BatchID and PathID). This 27B increase represents a modest increase compared to the average BGP update length, especially considering that a BGP update message is allowed up to a maximum size of 4096B [37].

Bandwidth overhead. Agents generate ΔRSVs at each batch containing route updates, and agents at other ASes periodically fetch and validate announcements they receive against these vectors. To evaluate RoST's bandwidth overhead, we measure the number of prefixes that experienced route changes at different batch intervals (5 minutes, 15 minutes, 1 hour, and 24 hours). The shorter the batch interval, the faster RoST would be able to react to withdrawal suppression, but the greater the bandwidth overhead. This is because a route update requires a single ΔRSV entry per batch, regardless of the number of updates within that batch and whether it was due to withdrawal or path modification.

We use the route updates observed from RIPE-RIS vantage points through six different months February and August 2022, 2023 and 2024. For each vantage point, we calculate the number of prefixes that experienced route changes within the different batch intervals we consider. Figure 6 illustrates the frequency of route changes; we use this data to calculate the bandwidth cost of sending and receiving updates from the repository.

4.2.1 Agent Communication

Bandwidth overhead for submitting ΔRSVs. Each AS periodically publishes ΔRSV to the repository. As shown in Figure 6, ΔRSV should reflect average changes between 1.67 to 5.32 prefixes per second, depending on the interval length. The bandwidth overhead for a specific agent is also proportional to the number of interfaces its AS has, since any route update requires updating the ΔRSV for each interface. In Table 3 we can see the average bandwidth for each category of ASes and each different batch. Even for ASes in the category with the maximum number of interfaces (201-639), the average bandwidth consumption is very low, at only 122.13 Kbps even when batch interval is 5 minutes.

Bandwidth overhead for fetching ΔRSVs from the repository. A RoST agent synchronizes with the repository to obtain the latest route updates (ΔRSVs). Agents only request updates for active routes within their ASes to minimize bandwidth costs. The average cost per agent is negligible 0.21 Kbps for 5 minute intervals (see Table 3). To derive the repository's cost, we sum across all ASes and get 25.12 Mbps which are more than reasonable costs for a regular server with good Internet connection and negligible compared to the overall response.

The response bandwidth is more significant since it includes a Merkle tree inclusion proof for each updated entry. Each entry contains 89 bits for the RSV regular entry, plus an additional 640B for the Merkle proof, assuming SHA-256 as the hash function, and a tree with depth 20 to support the 1M IP prefixes announced on the Internet. To estimate the number of entries of a response, we refer again to the results in Figure 6, which represent the average number of prefix changes per second.

It is important to note that while these figures represent the prefixes that experienced route changes, the actual number of responses sent by the repository depends on how many interfaces have reported these changes. In the worst-case scenario, all interfaces along the path are impacted and report the changes. As mentioned earlier, on average, non-prepending paths have a length of 3.86 ASes. So the average bandwidth under these assumptions will be around 14KB/s (*route change/sec* $\times$ *path length* $\times$ *entry size*) for 5 minutes of batch interval, which, as explained for the ΔRSV-Out bandwidth, is acceptable for most machines. The overall response cost for the repository, considering a total of 100K ASes across the entire Internet, is between 7.9-12.63 Gbps (see Table 3 for exact results). We expect overhead to be much less than this, however, modern server and network hardware (e.g., Cisco [12]) can support such data transfer rates.

Bandwidth Overhead												
	Interf.	ASes	5min			15min			1hr			
			ΔRSV-Out	ΔRequests	ΔRSV-In	ΔRSV-Out	ΔRequests	ΔRSV-In	ΔRSV-Out	ΔRequests	ΔRSV-In	
Agent	1-10	89.11%	1.01 Kbps	0.21 Kbps	106.97 Kbps	0.82 Kbps	0.17 Kbps	86.26 Kbps	0.63 Kbps	0.13 Kbps	66.96 Kbps	
	11-50	8.68%	10.54 Kbps			8.50 Kbps			6.60 Kbps			
	51-200	2.08%	36.09 Kbps			29.11 Kbps			22.59 Kbps			
	201-639	0.14%	122.13 Kbps			98.49 Kbps			76.45 Kbps			
Repository	496,910	118,031	235.28 Mbps	25.12 Mbps	12.63 Gbps	189.73 Mbps	20.25 Mbps	10.18 Gbps	147.27 Mbps	15.72 Mbps	7.90 Gbps	

Table 3: RoST bandwidth, showing 5-minutes, 15-minutes, and 1-hour intervals.

4.3 Computation

We next analyze the overhead associated with processing ΔRSVs at the agent and the repository. The steps that dominate the computational costs are: agents generating ΔRSV-Outs (§4.3.1), repository handling updates and requests (§4.3.2), and ASes handling ΔRSV-Ins from the repository (§4.3.3).

4.3.1 ASes Uploading Changes to the Repository

Generating a Δ vector involves three main operations:

1. Selecting entries updated in current batch: This can be performed in advance as entries are updated, incurring negligible computational overhead.

2. Calculating the Merkle root: A full RSV contains 1M entries per interface, which results in around 2M hashes per interface.

3. A signature that authenticates the Merkle root with the version and the interface.

The overall average hash rate for agents with the largest number of interfaces sending updates every 5 minutes, results in less than 1M hash/s (859,833-for all numbers, see Table 4; ΔRSV-Out columns). A MacBook Pro with a 3.2 GHz M1 processor can generate *3 million SHA-256 hashes per second* per core (the computation is also parallelizable with multiple cores). Thus, the computational overhead for the root calculation should be reasonable for agent machines. A signature authentication needs to be made for every ΔRSV-Out sent. Assuming the worst-case scenario in which all interfaces were involved in at least one route change at each batch, the number of signatures that need to be made equals the total number of interfaces. Majority of ASes have between 0-10 interfaces (with an average of 2). Assuming that they refresh the repository every 5 minutes, this would result in ≈ 2 signatures every 5 minutes. The same MacBoook used for hash/s benchmarking is capable of performing 100 RSA signatures per second, which would be enough even for AS with higher number of interfaces (639) refreshing every 5 minutes.

4.3.2 Repository Handling Updates and Requests

The repository first validates and stores each agent's updates. Since messages are sent using a TLS session, the validation process is minimal. Updates are stored by the repository which requires targeted reads and writes in the DB. We know from the bandwidth evaluation that if all 118,031 agents are sending updates every 5 minutes, this results in 235Mbps (i.e., 29MBps as noted in Table 3). The majority of common disks can read and write at a speed of 300 - 500 MBps, thus, this adds zero I/O latency. The repository also needs to generate ΔRSV-Ins. In this step, the repository needs to generate an inclusion proof for each of the entries that had a route change. If all agents are being updated every 5 minutes (21 entries will need to be generated per second per agent, *route change/sec* (Figure 6)×*3.86 avg path length*), then a total of ≈2.4M entries per second will need to be processed. Each entry requires a Merkle proof containing ≈20 entry hashes (Figure 6). In total, we get a total of 48M h/s. These costs can be improved by caching hashes of already computed entries, but even without such improvement, the overhead is feasible. (E.g, using 18 cores of CPUs, ≈ 54M h/s, at its full computational power.)

4.3.3 ASes Handling New Updates from the Repository

The repository pushes new entry updates in the form of ΔRSV-Ins to agents, and agents need to process them. The operations that dominate this process are the verification of authenticity and integrity of the data. The agents should first verify the signature (Merkle root+version+interface). On average, as explained above, if the agent gets updated every 5 minutes, then 21 entries are received per second. Assuming the worst case where each entry belongs to a different interface, this requires 22 verifications/s (Mac M1 Pro (1 core) can compute ≈ 25K verifications/s for RSA). The agent also needs to verify all entries (21 for the same scenario) against the set of hashes included in the Merkle proof, which requires ≈20 hashes per entry; this results in 410 h/s, which remains minimal. For detailed numbers for different intervals, see the agents' ΔRSV-In column Table 4.

Computational Overhead								
			5min		15min		1hr	
	Interf.	ASes	ΔRSV-Out	ΔRSV-In	ΔRSV-Out	ΔRSV-In	ΔRSV-Out	ΔRSV-In
Agent	1-10	89.11%	7,133 h/s + 2 sig/5min	410 h/s + 21 vfy/s	2,377 h/s + 2 sig/15min	331 h/s + 17 vfy/s	594 h/s + 2 sig/1hr	257 h/s + 13 vfy/s
	11-50	8.68%	74,233 h/s + 22 sig/5min		24,744 h/s+ 22 sig/15min		6,186 h/s + 22 sig/1hr	
	51-200	2.08%	254,100 h/s + 76 sig/5min		84,700 h/s + 76 sig/15min		21,175 h/s + 76 sig/1hr	
	201-639	0.14%	859,833 h/s + 258 sig/5min		286,611 h/s + 258 sig/15min		71,653 h/s + 258 sig/1hr	
Repository	496,910	118,031	0 h/s + 0 sig/5min	48,475,803 h/s + 0 vfy/s	0 h/s + 0 sig/15min	39,090,450 h/s + 0 vfy/s	0 h/s + 0 sig/1hr	30,342,937 h/s + 0 vfy/s

Table 4: RoST Computational Overhead, showing 5-minute, 15-minute, and 1-hour intervals. MacBook Pro with a 3.2 GHz M1 processor can generate *3 Million SHA-256 h/s, 25K RSA-vfy/s and 100 RSA-sig/s* per core. *Legend: h/s* stands for hashes per second, *sig* for signature, and *vfy* for verification.

4.4 Comparison to Key Rollover

Key Rollover operates in a different fashion than RoST. It relies on BGPsec and rotates its signing key often, making sure zombie routes become invalid. However, this procedure requires refreshing *all* routes an AS advertises since they were all signed by the BGPsec signing key. Thus, if key rollover is ubiquitously adopted, all routes on the Internet would need to be refreshed often . Each provider, for example, that announces routes for all prefixes to its customers, would need to refresh about 1.2M routes per customer, resulting in major computational and communication costs. RoST, in comparison, makes routing status transparent and available to agents in order to detect zombie routes (rather than proactively periodically revoking all routes). Thus, its overhead is much smaller. It only requires 258 signatures (on average) for the ASes with the higher number of interfaces when its agent submits a new RSV-Out (Table 2). Therefore, the agent can refresh its routing data at the repository at a much higher rate than key rollover may be invoked, which results in a shorter withdrawal suppression exposure interval.

5 Benefits Under Partial Adoption

Deploying BGP mechanisms takes effort and usually happens gradually over time. Thus, it is imperative to propose mechanisms that are simple and backward compatible, but also provide benefits even under partial adoption.

RoST is designed with this mindset, providing a direct incentive for adopting ASes. An AS that adopts RoST lets other adopters detect when its own announcements are suppressed, which helps the adopter ensure its routing preferences and business decisions are executed. Though without full adoption, RoST cannot guarantee detection of all withdrawal suppressions, its detection rate increases with the adoption rate.

To illustrate RoST's benefits, consider the scenario depicted in Figure 2, but assume that initially, only AS 4 adopts RoST. First, observe that AS 2 is now incentivized to adopt RoST because it would allow AS 4 to detect that AS 6 continues to attract traffic designated to AS 2 using an outdated route, which AS 2 wants to prevent. Second, once AS 2 adopts

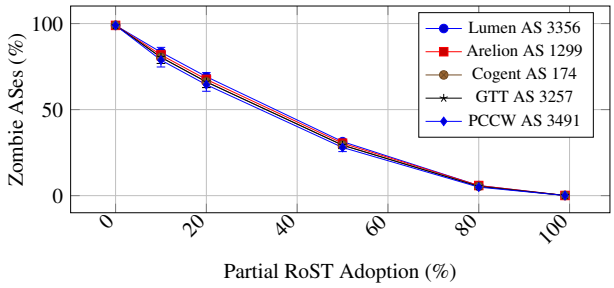

Figure 7: Impact of RoST in partial adoption on all Internet ASes when Tier-1 ASes suppress withdrawals. (Error bars mark standard deviation.)

RoST, AS 4 can detect this withdrawal suppression even though ASes 2 and 4 are the only adopters.

5.1 Evaluation

To evaluate the impact of partial adoption, we used the BGPy simulator [16], which allows simulating routes on the Internet's AS-level topology. We use a snapshot of the Internet topology from January 2025 from CAIDA [9]. We simulated the following scenario: a prefix is announced by a RoST-adopting AS, which then explicitly withdraws that announcement, while some Tier-1 AS suppresses the withdrawal. We then count the number of ASes that kept the withdrawn route active (i.e., use a zombie route). We make this measurement under different RoST-adoption rates across all Internet ASes, and assign different Tier-1 ASes the suppressor role. We use Tier-1s as suppressors in our simulations since they have the most customers, and therefore, intuitively, they should have the highest impact.

Figure 7 illustrate the impact of adopting RoST on other ASes on the Internet. We repeat the simulation for five different Tier 1 ASes as suppressors, where the adopting ASes are selected uniformly at random for each adoption rate and execution. Each data point in the graph is the average of 1,000 executions, each time with a different origin (error bars mark the 95% confidence interval). The graph shows the number of zombie ASes (i.e., ASes choosing the withdrawn route, y-axis)

monotonically decreases with the rate of adopters (x-axis). Moreover, this benefit shows as soon as ASes begin adopting (in contrast to some interdomain routing mechanisms that require near-ubiquitous adoption to provide benefits like BGPsec or key rollover that is built on top of it). Lastly, we notice that the number of non-zombie ASes is greater than the number of adopters, which illustrates the collateral benefit of adopting RoST. Namely, by adopting RoST and filtering zombie routes, the AS may also indirectly protect others since it would not announce the withdrawn route to them.

6 Compatibility with BGP Routers

We now describe how to support RoST on today's routers, without any modification to router software or hardware. Specifically, we describe how the RoST agent of an AS (external to the AS's routers, but with credentials to configure them) can: (1) attach the *RouteIDs* to announcements that the AS exports, and (2) filter withdrawn routes. We illustrate performing these operations on Cisco routers using their standard command interface, but this approach is compatible with devices from other common vendors (e.g., Juniper). Specifically, support for the BGP transitive extended community attribute is widespread [17] and includes the most common routers (such as Cisco [1] and Juniper [22] routers). A library such as Netmiko [8] allows automating interaction with routers for applying these commands. Of course, a complete implementation would need to provide fault tolerance, handling cases where an agent or the repositories fail, e.g., by defaulting to the standard BGP behavior.

6.1 Attaching *RouteIDs*

The agent needs to verify the *RouteIDs* of every BGP announcement, and if valid, the agent adds an additional *RouteID* to the community attribute before the announcements are propagated. To that end, we configure the BGP router to send BGP event logs to the agent:

```
logging host <agent-ip>
```

These logs are parsed by the agent to detect when new BGP routes are announced. To ensure that no routes are automatically advertised until the agent completes the validation and updating of the *RouteIDs*, we configure the router to suppress all routes by default in the outbound direction [14]:

```
# Block all routes from being advertised
ip prefix-list <prefix_list_name> permit 0.0.0.0/0 le 32
route-map <route_map_name> deny
 match ip address prefix-list <prefix_list_name>
neighbor <neighbor_ip> route-map out <route_map_name>
```

The above snippet shows how to suppress all prefixes (0.0.0.0/0 le 32) from being advertised to some specific AS (neighbor_ip). To attach a *RouteID* to an exported route, first we need to allow attaching extended community to advertisements with the neighbor (if not already enabled):

```
# Configure Neighbor to Send Extended Communities
router bgp <agent_AS_number>
    neighbor <neighbor_ip> send-community extended
```

Then, we can use Netmiko to dynamically attach a *RouteID* to an advertisement via the following router command:

```
set extcommunity rt <routeid>
```

6.2 Filtering Withdrawn Routes

The other functionality that RoST requires is to withdraw routes that the agent detects as withdrawn, even though the explicit/implicit withdrawal was suppressed. Thus, the agent needs to instruct the router to remove a specific (withdrawn) route from the Local RIB, which will cause the router to choose a new best route. Cisco supports this with the following command:

```
# Defines a prefix list to allow specific IP prefixes
ip prefix-list REMOVE permit <ip-prefix>
# Remove the routes matching the REMOVE prefix list
clear ip bgp <neighbor-ip> soft in prefix-list REMOVE
```

7 Deployment Considerations

We next discuss privacy and fault tolerance challenges in deploying RoST.

7.1 Privacy

Since RoST is a transparency system, it inventively reveals information about the status of routes ASes advertise. Some ASes might be less willing to share this information, at least for some of their neighbors, although it will help ensure that their announcements don't get suppressed. For example, some ASes might not want to expose (specific) paying customers. However, we argue that RoST's impact on privacy is limited in practice. The information made transparent by RoST is on par with what is available through existing or proposed BGP mechanisms. Moreover, a significant portion of this information is already inferred and made public today, for example, by services like RIPE RIS, which we used as part of our evaluation. Furthermore, many of the relationships between ASes can be deduced (explicitly or implicitly) from other BGP-related protocols. For example, RPKI reveals ASes' prefixes (via ROAs) and customer-provider relations (via resource certificates), and the latter can also be deduced from proposed mechanisms such as Only-To-Customer (OTC) [3] and Autonomous System Provider Authorization (ASPA) [4].

That said, some ASes may still decide to withhold some of their route status information, either by only sharing some of the prefixes they can reach through a neighbor or even

completely the fact that they peer with that neighbor. Luckily, this does not impact RoST beyond protecting the withheld routes. It only means that the withholding ASes deny other ASes the opportunity to detect suppression of those routes.

7.2 Repository Faults

So far, we described RoST with one repository, creating a single point of failure. In practice, however, we envision a deployment with multiple repositories operated by independent entities. This not only improves the scalability and robustness of the system but allows for mitigating the impact of a malicious repository that selectively hides status updates for some routes (note that since the agent updates are signed, the repository cannot generate fake updates). Such a deployment may also piggyback on the existing BGP repositories, such as the RPKI repositories maintained by RIRs, to maintain RoST' information.

A simple approach for running RoST with multiple repositories is to have agents send ΔRSV-Out updates to all repositories. Agents then receive updates from multiple repositories, ensuring that even when some repositories are down (e.g., due to a major outage) or censor the status for specific routes, the agent will retrieve this information from another repository. This approach ensures all (honest) repositories will have their data without the need to synchronize repositories (and it is the sender's interest to make sure their data is stored at the repository, §5).

Facilitating efficient synchronization across the repositories could save the agent communication costs from the previous solution Such synchronization may use Byzantine Fault Tolerance (BFT) protocols to ensure that all repositories hold the same route statuses despite malicious repositories. Further, the repositories can take turns being the leader in the BFT protocol to ensure a malicious repository cannot censor route status updates [10, 23]. Lastly, BFT protocols create a certificate for the data after repositories reach consensus. This allows agents to update from one repository and check the certificate to ensure other repositories have the same updates.

8 Related Work

Significant effort has been devoted to improving the security of interdomain routing [7, 18, 20, 31, 38]. Although not all proposed mechanisms can be used immidiately with currently deployed BGP, the increasing widespread adoption of RPKI [25] is promising since RPKI is a cornerstone for other cryptography-based mechanisms. Specifically, RPKI enables origin validation [11, 19, 24, 27, 33] against prefix hijack attacks, where an attacker advertises a false origin for a prefix to hijack traffic intended for the real origin. BGPsec [28] builds on RPKI to add signatures on route advertisements, providing route authentication that protects against bogus paths advertised with the correct origin. Recently, the IETF published other drafts for mechanisms that aim to increase routing reliability and security. For example, the Only-To-Customer (OTC) [3] transitive BGP path attribute defines a mechanism against route leaks, and the Autonomous System Provider Authorization (ASPA) [4] extends RPKI's origin validation to check ASes beyond the first hop [13].

However, none of the above security mechanisms addresses withdrawal suppression. Approaches that reduce router misconfigurations and software bugs, e.g., through better policy specification, router design, and troubleshooting tools [21, 29], can help reduce the chance of accidental withdrawal suppression, but they require adoption at the suppressing AS rather than the victim. The proposed solution to withdrawal suppression is key rollover [39, 42], which requires route authentication (e.g., via BGPsec). It incurs high operational costs, as well as significant computation and communication overheads from rotating keys often, as discussed earlier in §1. As a result, key rollover cannot operate at short timescales to quickly mitigate withdrawal suppression. In contrast, RoST addresses withdraw suppression by leveraging RPKI to have ASes sign route status data and publish it, requiring no change to RPKI and not relying on a route authentication mechanism. Furthermore, RoST is compatible with BGP and requires no change to BGP routers.

9 Conclusion

In this paper, we presented RoST, an efficient and practical protocol designed to defend against withdrawal suppression. RoST can integrate with current routing hardware by using standard APIs and is thus readily deployable. Further, we showed through simulations that RoST provides benefits even to early adopters. We evaluated RoST's overhead based on real-world routing data and showed RoST incurs reasonable storage, compute, and network costs and can thus mitigate withdrawal suppression at much shorter timescales compared to the key rollover alternative (which also relies on BGPsec).

A RoST Pseudocode

In this section, we detail the operation of a RoST agent in pseudocode, given in Appendix A.

Algorithm 2 RoST Agent

```
1: Input:
2:     AgentAS: AS for which this agent is responsible
3:     BatchInterval: Time interval for batching updates in ΔRSV-Out
4:     R: Repository
5: State:
6:     RSV-Out, RSV-In ← ∅                                  ▷ Tracks outgoing & incoming route status per interface
7:     SubscribedInterfaces ← ∅                             ▷ Tracks subscribed interfaces for each prefix
8:     PrivateKey ← LoadPrivateKey(AgentAS)                 ▷ Private key for signing RSV-Out data
9:     BatchInterval ← Input BatchInterval
10:    RepositoryConnection ← ConnectToRepository(R)        ▷ Manages communication with repository
11:    RouterConnection ← ConnectToRouter(AgentAS)          ▷ Connection to the router of 'AgentAS'
12: procedure RoSTAgent(AgentAS, BatchInterval, R)
13:    // Set up event-driven handlers for router and repository interactions
14:    Register ProcessBGPUpdate(U) as a handler for incoming BGP updates from router   ▷ See Line 18
15:    Register ProcessRSVInUpdates(ΔRSV-In) as a handler for RSV-In updates from repository R   ▷ See Line 24
16:    Schedule periodic tasks every BatchInterval to:
17:        Generate and upload ΔRSV-Out to repository R using GenerateAndUploadRSVOut( )   ▷ See Line 30

18: procedure ProcessBGPUpdate(U)
19:    for each Neighbor AS_y of AgentAS do
20:        if IsEligibleToPropagate(AS_y, U.Prefix) then   ▷ See Line 167
21:            Status ← ValidateRouteStatus(U)   ▷ See Line 34
22:            if Status = Valid or Pending then UpdateAndPropagateBGP(U, AS_y)   ▷ Updates RSV-Out state. See Line 108
23:            else if Status = Invalid then HandleInvalidRoute(U, AS_y)   ▷ See Line 90

24: procedure ProcessRSVInUpdates(ΔRSV-In)
25:    ValidatedPrefixes ← MergeRSVIn(ΔRSV-In)   ▷ Returns validated prefixes. See Line 54
26:    for each Prefix P in ValidatedPrefixes do
27:        for each Neighbor AS_y of AgentAS do
28:            if (RIBOutEntry ← QueryRIBOut(Prefix = P, Neighbor = AS_y)) ≠ ∅ then   ▷ See Line 158
29:                if ValidateRouteStatus(RIBOutEntry) = Invalid then HandleInvalidRoute(RIBOutEntry, AS_y) ▷ See
                   Lines 34 and 90

30: procedure GenerateAndUploadRSVOut
31:    for each interface (AS_x, AS_y) in RSVOut do
32:        if (DeltaInterface ← GenerateDeltaRSV(AS_x, AS_y)) ≠ ∅ then   ▷ See Line 130
33:            UploadRSVOut(DeltaInterface)   ▷ See Line 174

34: procedure ValidateRouteStatus(Route, AS_y)
35:    Extract Prefix, AS-Path, and RouteID sequence (BatchID, PathID) from Route
36:    Status ← Valid   ▷ Initial assumption that the route is valid
37:    MissingInterface ← False   ▷ Flag to check if subscription is needed
38:    for each (AS_prev, AS_current) in AS-Path do
39:        Retrieve RSVInInterface ← RSVIn(AS_prev, AS_current)   ▷ Interface-specific RSV-In
40:        Retrieve RSVInEntry ← RSVInInterface[Prefix]   ▷ Access RSV-In entry by prefix
41:        if (AS_prev, AS_current) ∉ SubscribedInterfaces[(Prefix, AS_y)] then
42:            MissingInterface ← True   ▷ Mark that the subscription needs to be updated
43:        if RSVInEntry does not exist or BatchID > RSVInEntry.BatchID then
44:            Status ← Pending   ▷ Mark status as pending due to missing data
45:        else if BatchID < RSVInEntry.BatchID or PathID ≠ RSVInEntry.PathID or RSVInEntry.Status = Inactive then
46:            return Invalid   ▷ Inconsistent or inactive route
47:    if MissingInterface = True then
48:        // Update the subscription state for this AS_y and Prefix
49:        Replace SubscribedInterfaces[(Prefix, AS_y)] with all interfaces in AS-Path
50:        // Prepare the full subscription set for all AS_y for the Prefix
51:        FullSubscriptionSet ← ⋃_{AS_y} SubscribedInterfaces[(Prefix, AS_y)]
52:        SubscribeToRSVInUpdates(Prefix, FullSubscriptionSet)   ▷ Send a single subscription for the prefix across all AS_y
53:    return Status   ▷ Return Valid or Pending status
```

```
54: procedure MERGERSVIN(ΔRSV-In)
55:     // Step 1: Extract batch-level metadata
56:     Extract BatchCounter, MerkleRoot, Signature, (AS_prev, AS_current) from ΔRSV-In
57:     // Step 2: Retrieve Interface-Specific BatchCounter
58:     RSVInInterface ← RSVIn(AS_prev, AS_current)
59:     if RSVInInterface does not exist then
60:         Initialize RSVIn(AS_prev, AS_current) ← ∅
61:         LocalBatchCounter ← 0                                   ▷ Default value for new interface
62:     else
63:         Retrieve LocalBatchCounter ← BatchCounter stored in RSVIn(AS_prev, AS_current)
64:     // Step 3: Check BatchCounter from ΔRSV-In
65:     if BatchCounter ≤ LocalBatchCounter then
66:         Log: "Stale ΔRSV-In batch from (AS_prev, AS_current) with BatchCounter BatchCounter"
67:         Reject and exit
68:     // Step 4: Verify Batch Signature
69:     Reconstruct SignedData ← HASH(BatchCounter, MerkleRoot, (AS_prev, AS_current))
70:     Retrieve PublicKey ← RPKI[AS_prev]
71:     if not VERIFYSIGNATURE(SignedData, Signature, PublicKey) then
72:         Log: "Invalid signature for ΔRSV-In batch from (AS_prev, AS_current)"
73:         Reject and exit
74:     // Step 5: Process Individual Entries with Merkle Proofs
75:     ValidatedPrefixes ← ∅                                       ▷ Initialize list of validated prefixes
76:     for each entry E in ΔRSV-In do
77:         Extract Prefix, BatchID, PathID, Status, MerkleProof
78:         // Validate Merkle Proof for Entry
79:         if not VERIFYINCLUSIONPROOF(Prefix, BatchID, PathID, Status, MerkleProof, MerkleRoot) then
80:             Log: "Invalid Merkle proof for Prefix from (AS_prev, AS_current)"
81:             Continue                                            ▷ Reject and skip this entry
82:         // Merge Valid Entry into Local RSV-In
83:         RSVIn(AS_prev, AS_current)[Prefix] ← (BatchID, PathID, Status)
84:         Add Prefix to ValidatedPrefixes
85:         Log: "Successfully merged Prefix from (AS_prev, AS_current)"
86:     // Step 6: Update BatchCounter for the Interface
87:     Update RSVIn(AS_prev, AS_current).BatchCounter ← BatchCounter
88:     Log: "Updated BatchCounter to BatchCounter for (AS_prev, AS_current)"
89:     return ValidatedPrefixes                                    ▷ Return the list of validated prefixes

90: procedure HANDLEINVALIDROUTE(Route, AS_y)
91:     Extract Prefix and specific route attributes from Route
92:     // Step 1: Remove the route from the router's RIB for the interface with AS_y
93:     REMOVEROUTEFROMRIB(Prefix, Route, AS_y)                     ▷ Remove route for the interface with AS_y. See Line 161
94:     Log: "Removed invalid route Route for Prefix to AS_y"
95:     // Step 2: Check for alternative routes in the router's RIB for the interface with AS_y
96:     AlternativeRoutes ← QUERYALTERNATIVEROUTES(Prefix, AS_y) ▷ Query remaining routes for the interface with AS_y. See Line 164
97:     if AlternativeRoutes is empty then
98:         // Step 3: Propagate withdrawal using UpdateAndPropagateBGP
99:         WithdrawalUpdate ← Generate withdrawal update message for Prefix
100:        UPDATEANDPROPAGATEBGP(WithdrawalUpdate, AS_y)           ▷ Attach RouteID and propagate withdrawal. See Line 108
101:        Log: "Withdrawal propagated for Prefix to AS_y"
102:    else
103:        // Step 4: Select the best alternative route and announce it using UpdateAndPropagateBGP
104:        BestRoute ← SELECTBESTROUTE(AlternativeRoutes)
105:        AnnouncementUpdate ← Generate announcement update message for BestRoute
106:        UPDATEANDPROPAGATEBGP(AnnouncementUpdate, AS_y)         ▷ Attach RouteID and propagate announcement. See Line 108
107:        Log: "Announced alternative route for Prefix to AS_y"
```

```
procedure UpdateAndPropagateBGP(U, AS_y)
    Extract Prefix, AS-Path, Action (e.g., Announce or Withdraw) from U
    // Step 1: Update RSV-Out for interface with AS_y
    Retrieve RSVOutInterface ← RSVOut(AgentAS, AS_y)
    // New Prefix Entry Handling
    if Prefix ∉ RSVOutInterface then Initialize empty entry for Prefix in RSVOutInterface
    // New Batch Handling for Prefix Entry
    if RSVOutInterface.BatchCounter > RSVOutInterface[Prefix].BatchID then
        Reset RSVOutInterface[Prefix].PathID ← 0
        Update RSVOutInterface[Prefix].BatchID ← RSVOutInterface.BatchCounter
    // Update Existing Entry Based on Action
    if Action = Announce then
        Increment RSVOutInterface[Prefix].PathID
        Update RSVOutInterface[Prefix].Status ← Active
    else if Action = Withdraw then
        Update RSVOutInterface[Prefix].Status ← Inactive
    // Step 2: Attach RouteID to the BGP Update Using API
    RouteID ← (RSVOutInterface[Prefix].BatchID, RSVOutInterface[Prefix].PathID)
    AttachRouteIDToUpdate(U, RouteID)                          ▷ Router API: Attach RouteID
    // Step 3: Forward Updated BGP Message to AS_y Using API
    ForwardUpdate(U, AS_y)                                     ▷ Router API: Forward message to neighbor
    Log: "Forwarded BGP update for Prefix to AS_y with RouteID (BatchID, PathID)"

procedure GenerateDeltaRSV(AS_x, AS_y)
    Retrieve RSVOutInterface ← RSVOut(AS_x, AS_y)
    // Step 1: Identify Delta Entries for the Current Batch
    Initialize DeltaEntries ← ∅
    for each Prefix in RSVOutInterface do
        if RSVOutInterface[Prefix].BatchID = RSVOutInterface.BatchCounter then
            Add RSVOutInterface[Prefix] to DeltaEntries
    // Step 2: Build Merkle Tree for All RSV-Out Entries
    Initialize AllEntries ← All entries in RSVOutInterface
    MerkleLeaves ← Hash(AllEntries)
    // Hash each entry in AllEntries
    MerkleRoot ← BuildMerkleTree(MerkleLeaves)
    // Step 3: Sign the Merkle Root, BatchCounter, and Interface
    ToSign ← Hash(MerkleRoot, RSVOutInterface.BatchCounter, (AS_x, AS_y))
    Signature ← SignWithPrivateKey(ToSign, PrivateKey)
    // Step 4: Increment BatchCounter and Update BatchStartTime
    Increment RSVOutInterface.BatchCounter
    RSVOutInterface.BatchStartTime ← CurrentTime()
    // Step 5: Prepare and Return Delta
    if DeltaEntries ≠ ∅ then
        return {(AS_x, AS_y), RSVOutInterface.BatchCounter − 1, DeltaEntries, MerkleRoot, Signature}
    return ∅
```

Router API Module

The following functions interact directly with the router via the `RouterConnection` state. These functions handle operations such as querying or modifying the router's RIB and propagating updates to neighboring ASes. They are invoked by the `RoSTAgent` to enforce protocol logic.

procedure FORWARDUPDATE(U, AS_y)
    Use *RouterConnection* to send U to AS_y
    Log: "Forwarded BGP update for $U.Prefix$ to AS_y"

procedure ATTACHROUTEIDTOUPDATE(U, *RouteID*)
    Use *RouterConnection* to append *RouteID* to U
    Log: "Attached RouteID ($RouteID.BatchID, RouteID.PathID$) to BGP update for $U.Prefix$"

procedure QUERYRIBOUT($Prefix, AS_y$)
    Query *RouterConnection* for RIB-Out entry matching $Prefix$ for neighbor AS_y
    return Matching entry or $\emptyset$ if not found

procedure REMOVEROUTEFROMRIB($Prefix$, $Route$, AS_y)
    Use *RouterConnection* to remove $Route$ for $Prefix$ on the interface with AS_y
    Log: "Route $Route$ for $Prefix$ removed from the interface with AS_y"

procedure QUERYALTERNATIVEROUTES($Prefix$, AS_y)
    Use *RouterConnection* to query all remaining routes for $Prefix$ on the interface with AS_y
    return List of alternative routes for $Prefix$ on the interface with AS_y or $\emptyset$ if none found

procedure ISELIGIBLETOPROPAGATE($AS_y, Prefix$)
    Query *RouterConnection* for policy decision on propagating $Prefix$ to AS_y
    return True if the policy allows propagation, **False** otherwise

Interaction with the repository The following functions interact directly with the repository via the `RepositoryConnection` state. These functions handle operations such as subscribing to updates and uploading data to the repository. They are invoked by the `RoSTAgent` to implement repository-specific logic.

procedure SUBSCRIBETORSVINUPDATES($Prefix$, $InterfaceSet$)
    Use *RepositoryConnection* to send a subscription request for:
        $Prefix$ and all interfaces in $InterfaceSet$
    Log: "Subscribed to RSV-In updates for $Prefix$ with interfaces $InterfaceSet$"

procedure UPLOADRSVOUT($DeltaInterface$)
    Use *RepositoryConnection* to upload $DeltaInterface$

ValidaTor: Domain Validation over Tor

Jens Frieß[§‡], Haya Schulmann[§†], and Michael Waidner[§‡]

[§]National Research Center for Applied Cybersecurity ATHENE
[‡]Technische Universität Darmstadt [†]Goethe-Universität Frankfurt

Abstract

Domain Validation (DV) is the primary method used by Certificate Authorities (CAs) to confirm administrative control over a domain before issuing digital certificates. Despite its widespread use, DV is vulnerable to various attacks, prompting the adoption of multiple vantage points to enhance security, such as the state of the art DV mechanism supported by Let's Encrypt. However, even distributed static vantage points remain susceptible to targeted attacks. In this paper we introduce ValidaTor, an HTTP-based domain validation system that leverages the Tor network to create a distributed and *unpredictable* set of validators. By utilizing Tor's exit nodes, ValidaTor significantly increases the pool of available validators, providing high path diversity and resilience against strong adversaries.

Our empirical evaluations demonstrate that ValidaTor can achieve the validation throughput of a commercial CA and has the potential to scale to a validation volume comparable to Let's Encrypt, while using minimal dedicated infrastructure and only a small fraction (~0.1%) of Tor's remaining available bandwidth. While unpredictable selection of validators makes ValidaTor fully resistant to targeted attacks on validators, we also show the use of Tor nodes improves path diversity and thereby the resilience of DV to subversion by well-positioned ASes, reducing the number of Autonomous Systems (ASes) capable of issuing fraudulent certificates by up to 27% compared to Let's Encrypt. Lastly, we show that the chance of subversion by malicious, colluding exit nodes is negligible ($\leq 1\%$ even with a quarter of existing exit nodes).

We make the code of ValidaTor as well as the datasets and measurements publicly available for use, reproduction, and future research.[1]

1 Introduction

Digital public key certificates associated with Internet domains are fundamental to Internet security. These certificates include crucial information such as the domain name and the public validation key corresponding to the domain owner's private key, ensuring the authenticity of communicating parties and enabling secure connections. The correct issuance of certificates is critical, as any compromise could allow an adversary to impersonate a legitimate service and intercept sensitive communications.

Certificate Authorities (CAs) use Domain Validation (DV) to verify domain ownership before issuing a certificate. This process typically involves generating a random challenge-response pair, and having the domain owner place the response at the challenged location under the target domain, e.g., in a DNS TXT record or an HTTP-hosted `.txt` file. The CA validates the domain by querying for the challenge and checking that the obtained response matches the challenge. If the CA receives the correct response, the domain owner has successfully demonstrated control over the domain, and the CA issues a signed certificate for the domain with the public key provided by the domain owner.

Although the Public Key Infrastructure (PKI) security relies on the correctness of DV for checking control over domains, the DV procedure itself remains vulnerable. The challenge-response process of DV is conducted over unencrypted and unauthenticated channels and heavily relies on the Domain Name System (DNS) RFC1035 and the Border Gateway Protocol (BGP) RFC4271. Both are largely unprotected and vulnerable to hijacking attacks [1, 2], and adversaries have launched such attacks, e.g., to steal cryptocurrency [3–5].

The attacks and the importance of certificate security triggered research efforts to identify vulnerabilities in the DV procedure and to develop a more secure design. Initially, vanilla DV was performed with a single request to the target domain. However, it was shown that an adversary could manipulate the challenge request of a CA, causing it to be executed against servers that the adversary controls [6]. As a result, the largest CA, Let's Encrypt, developed MultiVA, which uses additional vantage points [7]. During the validation process a number of vantage points independently send a challenge to the target domain. MultiVA became an official market standard with Automated Certificate Management Environment (ACME) in

[1] https://github.com/jenfrie/tova

RFC8555. The use of multiple vantage points aims to increase security despite being conducted over unprotected channels since it is assumed that a realistic adversary cannot control multiple vantage points and it is more difficult to attack them concurrently than a single vantage point.

The MultiVA was also extensively validated in the research community [7, 8]. Simulations have shown that the average resilience of a customer domain against issuance of fraudulent certificates is 88.6% [9], reflecting the percentage of adversarial ASes that cannot intercept communication via same-prefix BGP hiijacks to a sufficient number of vantage points to complete DV successfully. However, the analysis of [9] excluded a number of attack vectors, such as sub-prefix hijacks, as well as attacks against the DNS resolvers. Another important aspect that was not considered in these simulations is the dependency between DNS and the inter-domain routing infrastructures, which further increases the attack surface: DNS cache poisoning can be leveraged to facilitate BGP hijacks [10]. Indeed, [11] exploited a property in the software of many popular DNS resolver implementations to force all the vantage points to query one specific nameserver of the adversary's choice. This reduced the distributed defense to just one weak link, the nameserver. By hijacking the prefix of the nameserver, the adversary could intercept communication with all the vantage points. This shows that fixed vantage points, i.e., always at the same IP address or on the same IP prefix, allow the adversary to launch targeted attack against them in advance, before initiating the domain validation process. Both these issues were exploited in [11] to subvert DV from multiple vantage points, indicating that merely increasing the number of vantage points does not suffice to fully prevent targeted attacks.

A resilience of 88.6% offered by MultiVA [9] against interceptions for a critical building block like PKI is arguably not sufficient. Ideally we should achieve a 100% resilient PKI. Furthermore, 88.6% resilience considers only BGP hijacks, but does not account for other common attack vectors targeting the validators and connected infrastructure, e.g., DNS cache poisoning or infiltration of on-path routers.

The main problem, as pointed out by [11], is that current vantage points are static. In addition to being distributed, the vantage points' selection needs to be *unpredictable*. If the adversary does not know the addresses of the vantage points involved in a given validation, it cannot attack them.

Therefore, to improve security, the validators should be selected at random from the set of vantage points. The pool of vantage points should be large enough that it is infeasible to hijack any significant fraction. With a dedicated deployment, such as that of Let's Encrypt, generating such a large pool is not practical since it would require setting up a significant amount of geographically distributed infrastructure, prohibitively increasing the costs. In fact, scalability and cost are a major inherent limitation of any dedicated infrastructure.

Contributions. Motivated by the limitations in the existing domain validation mechanisms, we aim to design a system that resolves them. We develop a novel approach for distributed domain validation using Tor [12], dubbed ValidaTor. With over 2,200 Tor exit nodes, located across 280 unique BGP origins and 1,221 unique IP addresses, our design substantially increases the scale of the distributed infrastructure available to DV. This is a huge improvement compared to the 7 BGP origins currently used by Let's Encrypt. It allows a randomized selection of a configurable number of validators, effectively preventing BGP hijack attacks for subverting validation. We perform extensive evaluations to demonstrate the security and performance of our proposal based on real-world measurements and simulations. Our contributions:

- Conceptually, we offer a novel use of the Tor network to address practical limitations in DV. Our design and implementation of ValidaTor resolves the scalability of massively distributed DV and enhances its resilience.
- We propose a path overlap metric to capture the diversity of paths taken from validators to target domains through the BGP network, allowing for easy comparison of DV deployments with regard to threats from well-positioned ASes.
- Our experimental evaluations show that ValidaTor decreases average path overlap by ~50% compared to Let's Encrypt's MultiVA, translating to a reduction of 21% with 3 validators (up to 27% with 7 validators) in potential fraudulent certificates from well-positioned ASes. Combined with the resistance to BGP hijacks through unpredictable selection of validators, this significantly hardens DV against subversion.
- We show that with our selection method the chance of an attacker controlling validation with malicious Tor nodes is negligible, amounting to less than 1% even when controlling a quarter of all existing Tor nodes.
- We demonstrate a validation rate of up to 11.9 validations per second with 5 validators and estimate that, even at the scale of the entire Web PKI, Tor's remaining bandwidth would only be taxed by 0.11%. The median duration for a single validation in this case is ~2 seconds, with at least 95% of all validations under 6 seconds. This is comparable with the use of the certbot ACME client.
- We design ValidaTor so that it enables easy adoption and requires no changes to the existing infrastructure of the CAs, which is critical to motivate deployment and avoid misconfiguration. We make our prototype and the collected data available for public use.

Ethical considerations. We ensure that the design of ValidaTor is ethical, does not burden the Tor network and does not interfere with the connections of other Tor clients. As detailed in Section 6.4, the expected network load on Tor from a full switch to ValidaTor by the entire Web, is 635 MBit/s, around 0.1% of the remaining available bandwidth. We also take extensive measures to ensure that our experiments follow the ethical guidelines for network measurements [13, 14].

Organization. We review Related Work in Section 2 and provide an overview of Tor network in Section 4. The design

and implementation of ValidaTor are given in Section 5. We provide experimental evaluations in Section 6 and security analysis against different attack vectors is in Section 7. We conclude our paper in Section 9.

2 Related Work

Security of DV mechanisms in CAs have been extensively studied. We review existing literature related to DV:

Vulnerabilities in DV. Domain validation mechanisms are susceptible to various attacks that can undermine the security of digital certificates. In [15], the authors outline general security considerations for CAs, highlighting potential weaknesses in various validation methods. Compromised or maliciously configured DNS servers can be exploited to redirect validation requests to attacker-controlled servers [16]. Hijacking the DV process is easy against a vanilla DV, where a single validator communicates with a single server in the target domain.

Such attacks can also be extended to MultiVA, where the validation nodes are either fixed, predictable or the set of possible validators is small, allowing the adversary to attack them all in advance. [11] showed that in those cases adversaries can force all the DV nodes to run the validation against a server of the attacker's choice.

These methods allow attackers to pass validation checks and obtain certificates for domains they do not own, posing a serious risk to web security. Furthermore, [17] demonstrated specific attacks on DV mechanisms, including DNS hijacking and email-based validation exploits, which can be used to fraudulently obtain certificates for domains not owned by the attacker. [18] described man-in-the-middle (MitM) attacks and cache poisoning as significant threats to the integrity of domain validation and [6] demonstrated vulnerability of popular CAs to cache poisoning, allowing adversaries to issue fraudulent certificates. These studies underline the necessity for rigorous validation protocols to mitigate the risks of domain spoofing and unauthorized certificate issuance.

Measurements of DV. Empirical evaluations of CA practices have been crucial in assessing the real-world effectiveness of DV and impact of attacks on DV mechanisms. [19] performed a large-scale analysis of HTTPS traffic to assess the security of DV implementations across various CAs. Their findings revealed inconsistencies in how CAs implement and enforce DV protocols, highlighting potential security gaps.

[20] measured the adoption of security enhancements such as DNS Security Extensions (DNSSEC) and found that despite increased awareness, adoption rates remain low. This indicates a persistent vulnerability in the DV ecosystem due to the reliance on insecure DNS infrastructure. Similarly, [21] evaluated the adoption of DNSSEC by CAs, finding that while adoption rates were increasing, significant gaps remained in ensuring consistent and secure validation processes across the board. Additionally, [22] evaluated the security of email-based DV methods, showing that attackers can exploit weak email configurations to intercept validation emails, further emphasizing the need for robust security measures.

Improvements to DV. In response to identified vulnerabilities and attacks, various improvements to DV protocols have been proposed. [23] presented enhanced validation methods leveraging DNSSEC to provide cryptographic guarantees of domain ownership, although its adoption and security still remain a challenge [24]. [25] suggested a multi-factor validation approach that combines DNS-based validation with additional verification steps such as HTTP-based challenges and validation token usage.

Recently, [26] proposed ADDVent: the idea is to inflate the infrastructure available to DV by crowdsourcing web clients over an advertisement network. This approach is expensive due to the involved costs of advertisement network. Another issue is the trust required in the advertisement network - a malicious network can subvert the security of DV.

Despite significant research efforts in the area of DV, the limitations to deployment of distributed DV introduced by the need for dedicated infrastructure has so far not been addressed. Nevertheless, the limited number of vantage points performing validation and their fixed location played a major role in attacks against DV, exposing the PKI to fraudulent certificates. In this work we aim to resolve these limitations by designing ValidaTor: DV based on Tor.

3 Tor vs. Other Proxies

Since ValidaTor leverages the Tor network first and foremost as a massively distributed set of proxies, it is worth discussing alternative solutions that offer the same capabilities for randomized, distributed DV, without some of the constraints incurred by Tor.

Dedicated volunteer networks. RIPE Atlas [27] and NLNOG RING [28] are examples of volunteer-run multi-perspective systems. The former is the RIPE NCC's global Internet connectivity measurement network, consisting of volunteer-hosted probes that can be triggered to ping an arbitrary destination. The latter is a collective of machines exclusively hosted by network operators, made available to participants for testing network connectivity.

In a similar manner, a distributed network of nodes used exclusively for DV could be created. However, whereas in the above use cases there is little incentive for malicious behavior, with DV there is a strong incentive specifically for adversaries to volunteer and control the validation nodes, acting benignly until an opportunity for a high-value certificate presents itself. It is thus risky to allow such a volunteer network to be open to public participation.

A dedicated network would likely only be feasible if **(a)** participation is restricted to CAs (similar to NLNOG's focus on network operators) or **(b)** the network implements sufficient monitoring and maintenance to guard against malicious participants; something Tor already does. In any case, ValidaTor could be readily deployed now and incrementally moved to a dedicated network, when such efforts get off the ground.

Proxy providers. Rather than using Tor circuits, requiring a minimum of two hops to reach a proxy node, we could halve the performance costs[2] by using a simple proxy provider. However, this introduces two problems: **(1)** all proxies are under the control of a single entity, thus requiring trust in a third party. This could potentially be offset by diversifying proxy providers. **(2)** We find that the costs are prohibitive and threaten the economic viability of such a system. Based on a cost comparison of popular providers, Brightdata [29] offers the lowest rate at $0.42/GB. This covers only datacenter IPs, but still provides over 770K IPs across 98 countries. Based on our projected traffic volume of 317 MBit/s for exit nodes (see Section 6.4), this would amount to $4.2M/year.

Public VPN providers. The same considerations apply to VPN providers. These typically offer fewer, but still sufficient and globally distributed, endpoints. ExpressVPN [30], for example, offers 160 endpoints at $100/year, covering 5 devices. Connecting to all 160 endpoints at once to avoid switching overhead would thus result in just $3200/year. While this supposedly covers unlimited bandwidth, with our estimated traffic of ~1.1 TB/hour, this would likely violate terms of service. It is questionable whether this traffic load could be spread among a sufficient number of VPN providers to fall within a reasonable bandwidth use per provider.

Other anonymity networks. Other solutions, like Nym, require cryptocurrency payments to route traffic based on volume. It is also a smaller network than Tor with exit nodes on the order of a few hundred. I2P's focus is on services internal to its overlay network, rather than proxying connections; for DV we require proxies into the clearnet. The selection of outproxies is comparatively limited, on the order of 10 to 100 and not intrinsically mapped out like in Tor.

To conclude, the alternatives to DV over Tor are either limited in their vantage points and capacity, expensive to use, or pose higher engineering hurdles, which hinders their adoption in the real world. As each alternative comes with its own unique implementation challenges, we choose Tor as the most promising candidate to explore in-depth. Tor removes the financial cost as a barrier to the adoption of massively distributed domain validation and allows an easy-to-deploy solution with sufficient capacity.

4 Overview of Tor

Tor (The Onion Router) is a privacy-focused network of volunteer-hosted "relays" designed to enable anonymous, private communication over the Internet by routing users' requests through multiple encrypted hops, preventing traffic analysis and censorship [12]. **Onion proxies (OPs)** are the entrypoint for client software using Tor, responsible for managing circuits and connections to websites. **Onion routers (ORs)** are the relay-components which form the circuits. Each OR decrypts one layer of encryption to determine the next OR to forwards the packets to [31]. The **exit node** is the final node in a circuit, decrypting the user's original packet for its final hop to the destination server. From the server's perspective, the traffic appears to originate from the exit node.

Crucially for ValidaTor, all traffic until the exit node is protected. All unprotected traffic originates at the exit node, including DNS resolution. ValidaTor can therefore leverage a large variety of perspectives (~2.2K) using only a single server. Because the exit node sees the original unencrypted packet, it also presents the most critical threat. Node selection is therefore designed to minimize the risk of malicious, colluding exit nodes (see Section 7.5). Lastly, the list of active ORs is maintained by **directory servers**. These servers provide the necessary information for OPs to build circuits, which is periodically updated and signed to ensure integrity [12].

In this work we leverage the Tor nodes as an overlay to gain two critical benefits: first, we obtain a distributed infrastructure for DV with a large number of potential validator nodes which supports unpredictable selection. Second, the DV communication protocol benefits from security on the network layer making it impossible for any adversary before the exit node to observe the validation requests to the domains.

5 ValidaTor: Design & Implementation

We explain the limitations in existing DV mechanisms, and discuss how we resolve them with our proposal, ValidaTor, which uses Tor as an overlay to validate control over domains. We present the design and the implementation of ValidaTor, and provide motivation for different architectural choices.

5.1 Resolving Limitations in DV

The central problem with DV is that it is, by necessity, unauthenticated and thus vulnerable to manipulation by a Man-in-the-Middle (MitM) adversary. Successive improvements to DV, as laid out in Sections 1 and 2, have therefore focused on increasing the difficulty and resources required to mount a successful attack, and limiting an attacker's degree of influence on the process as a whole.

With vanilla DV, an attacker needs to target only a single server or intercept only a single communication path. With MultiVA this is increased to 3 or 4 servers and previous research has worked towards optimizing the distribution of these vantage points. Nonetheless, there are several ways in which the remaining attack surface can be further reduced and the use of Tor can address all of these by routing DV requests through a random set of exit nodes:

Dynamic validators. A static set of validators is vulnerable to targeted attacks. Adversaries can plan and prepare ahead of time, knowing exactly where their targets are. The same applies for a random but *small* set of validators, which could still be exhaustively targeted. Tor provides access to a large number of endpoints, allowing a vast number of possible combinations to be chosen from for each validation at random. This unpredictability means an attacker needs to be prepared to attack a significant fraction of these endpoints to have a

[2] We would still need to use HTTPS proxies to protect data in transit.

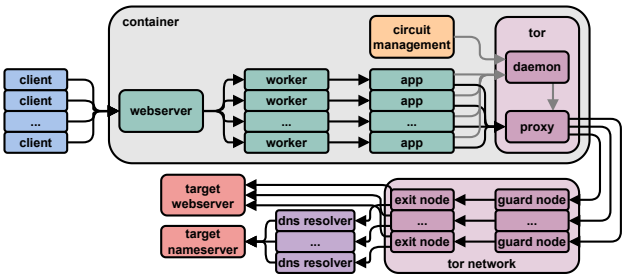

Figure 1: Container design and domain validation request flow.

realistic chance of hijacking DV. The size and distribution of the Tor network makes this prohibitively difficult.

Path diversity. A lack of diversity in the paths from validators to target domains results in more choke points in the network, where an attacker has a larger degree of influence. Whether an adversary is already on-path or uses routing hijacks to gain an on-path position, an attacker's influence in the BGP network is topologically constrained. Thus, reducing the overlap of validation paths reduces the set of remaining potential adversaries. The diverse set of endpoints offered by Tor allows validators to be selected with a significantly higher degree of distribution.

Denial-of-Service. Blocking DV by on-path adversaries can lead to denial-of-service for certificate issuance. As Tor is already set up to circumvent censorship through its distributed nature, Tor-based DV benefits from this as well.

5.2 Design

The core idea behind our design of ValidaTor is to select a random set of Tor exit nodes for each validation to act as validators. The nodes involved in any given validation are selected such that they are highly distributed in the BGP network to limit the degree of path overlap.

Component interactions. To implement a proof-of-concept for the ValidaTor server we construct a containerized environment using Docker, containing the following components: the Tor service, a custom circuit management service, a webserver and Python `Flask` application for handling the validation logic, i.e., triggering requests to target domains and aggregating the results.

As outlined in Figure 1, a validation applicant first sends a validation request to the webserver (see below for further details). A worker process then runs `Flask` application's validation logic, which triggers multiple web requests to the target domain through Tor's SOCKS5 proxy. The application also sends control instructions to the Tor daemon to assign the resulting streams to a random set of circuits, whose exits are ensured to be sufficiently distributed. The circuits are built and managed in parallel by the circuit management service (discussed in detail in Section 5.3), which likewise communicates with the Tor daemon through control instructions. Once streams are assigned to circuits, the Tor proxy forwards each request to its guard node, which then forwards it to the exit node. Each exit node resolves the target domain through its DNS resolver and subsequently queries the challenge resource at the resolved IP address. The responses from the target webserver are then returned via the Tor circuit to the application, which aggregates them and produces the reply that the container's webserver sends back to the client.

Validation. We implement our proof-of-concept ValidaTor as a web service that CAs and other clients can use to validate a domain by specifying the `.txt` resource to be challenged (as used by the ACME standard RFC8555 [32]), the target domain, and the protocol with which to send the request (either HTTP or HTTPS). The service then attempts to retrieve the resource via an initial k exit nodes. If the content of the resource (e.g., in ACME, a 43 character random alphanumeric string) does not match across all k requests, the system attempts to tie-break with additional exit nodes up to a maximum of n. If at least k responses contain the same content, this content is returned, otherwise an error.

This mimics the k-out-of-n validation scheme used by Let's Encrypt, where initially 3 out of 4 validation servers attempt to retrieve a specific `.txt` resource, and only if these do not receive the same result the 4th server is used. Then, if at least 3 out of the 4 results match the expected response, the validation is completed successfully.

5.3 Constructing Circuits

This section details the challenges in managing DV over Tor and how we construct and assign circuits to ensure both randomization and distribution for each validation.

Manual stream assignment. During regular client operation, the Tor service maintains a handful of circuits, constructs new circuits based on demand, i.e., the amount of requests sent through its SOCKS5 proxy, and rebuilds circuits every 10 minutes. A key feature of Tor to protect from profiling is that requests to domains are sent through different circuits. For our purposes such protection does not play a role. It *is*, however, critical that all n requests to the *same* domain are sent through different circuits (specifically, different exit nodes) so that we validate a domain from at least k perspectives.

We therefore configure Tor to allow *us* to choose which circuits to attach which requests (so-called "streams") to. This can be done in Python through Tor's official `stem` library, which provides an interface to send control messages to the Tor daemon. This allows us to ensure that requests for the same domain, i.e., that are part of the same validation, are sent through different circuits.

Choice of exit nodes. In establishing the circuits, we ensure **(a)** sufficient distribution of the exit nodes of the circuits used for a given validation, and **(b)** that exit nodes are chosen uniformly at random. As such, we cannot rely on Tor's relay selection algorithm, which is focused on anonymity and effective load balancing. Multiple requests to the same domain would be routed through the same circuit and there is no guarantee that a new circuit will use an exit node with a different

IP address, let alone an exit node in a different network. Exit nodes are also selected based on available bandwidth, which would reduce the unpredictability of validator selection. We therefore build circuits manually using `stem`. We begin by selecting randomly among all nodes marked with the `EXIT` flag. This flag is assigned to relays that allow their use as an exit node and have been monitored by Tor for some time. We exclude nodes that have been flagged as `BADEXIT`, which is assigned to exit nodes that behave suspiciously (~2.2K out of the ~7K total nodes), but additionally impose the requirement that a selected node's IP address does not share the same /8 prefix with any of the other already selected nodes, thereby ensuring distribution in the BGP network. The prefix length can be adapted to the desired granularity.

Cycling circuits. Constructing a new dedicated circuit for every request produces unnecessary latency and overhead. By default, Tor maintains a handful of open circuits and assigns requests to these based on the target domain. That is, requests to different domains are routed through different circuits. If the current pool of circuits does not accommodate this, new circuits are built on-demand. Circuits are then used for up to 10 minutes, by default, and only cycled after.

Thus, similar to Tor's regular operation, we maintain a set of circuits and periodically rebuild these to avoid too many validations using the same endpoints. However, we maintain a larger set of concurrent circuits than Tor normally would, to increase the unpredictability of the endpoints chosen for a given validation.

A larger pool to select from means a larger number of possible configurations, as given by the binomial function, and thus, greater uncertainty for the selection of any particular configuration. In the opposite extreme, where the number of concurrent circuits is equal to the number of validators, there is exactly one configuration. If this "pool" of circuits is maintained for any significant period of time, an attacker could identify the validators with a single validation request, and use this information to potentially manipulate subsequent validation requests.

Ideally, we would maintain a circuit for every available exit node. However, we observe that upwards of around 70 - 80 open circuits become unstable, as the Tor daemon strongly conflicts with our circuit building application, closing circuits that are not in use, and thus limiting the number of circuits we can keep open concurrently. Through experimentation we find that the largest number of circuits that remain stable is at around 50-60 concurrent circuits. We then rebuild circuits every 3 minutes. This can be configured to match the desired trade-off between network overhead and circuit "freshness".

Validation queries for a given domain can then efficiently be assigned to a random subset of circuits (which, as noted above, are already ensured to be distributed).

2-Hop circuits. Another reason to build circuits manually is that Tor by default builds circuits with 3 hops. We do not require anonymity, hence we can increase performance by building our own circuits and reducing the number of hops. Ideally, our Tor client would connect directly to each exit node. However, exit nodes need to be configured explicitly to allow 1-hop circuits; the default configuration is to refuse these. As this would limit our choice of endpoints from which to validate, we opt for building 2-hop circuits.

Choice of entry nodes. Since anonymity is not of vital concern, we optimize our entry nodes for performance. Conveniently, Tor assigns the `GUARD` flag to nodes that have been active for at least 8 days and have been independently measured to confirm their otherwise self-reported available bandwidth. This indicates that these nodes are particularly suitable as entry nodes.

To maintain a degree of load balancing across the network we randomly select an entry node from among the ~2.5K nodes marked `GUARD` and `FAST`. However, we weigh each node by its advertised bandwidth and IP prefix overlap with our own IP address, in order to favor shorter network paths as well as high-throughput nodes.

5.4 Challenge Methods

While both HTTP and HTTPS requests can be sent through the Tor network, thereby allowing for HTTP-based domain validation, Tor currently supports DNS only partially, i.e., for the resolution of domain names via A and AAAA records and reverse-lookup of IP addresses via PTR records. This allows domains to be resolved by the exit node.

Crucially, DNS TXT records, used for DNS-based domain validation, are currently *not* supported. Our proposed system is thus limited to HTTP-based validation until Tor adds support for DNS TXT records. However, since HTTP-based validation is the default for common ACME implementations, we argue that this is not a severe limitation.

5.5 Easy Adoption

Proposals which require substantial changes to the existing infrastructure take decades to deploy, for instance, DNS Security Extensions with DNSSEC RFC9364. Therefore, to facilitate their adoption, new mechanisms should require minimal changes. Our design follows this principle, requiring only to patch ACME's request for the target resource (e.g., `http://example.com/.well-known/acme-challenge/random`) with a request to ValidaTor (e.g., `https://validator.com/http/example.com/.well-known/acme-challenge/random`). If ValidaTor asserts that the responses match, ACME receives the same file content as from the original request and continues operating unchanged. If ValidaTor finds differing responses, it will return an error, causing ACME to fail the validation.

6 Performance Evaluation

In this section we validate the time required for validation and the throughput with ValidaTor. We then show how to use parallelization to further scale the system. Lastly, we discuss

the implications on bandwidth usage and from blocking of Tor traffic.

6.1 Single Container

For our initial evaluation we run our Docker container on a virtual server with 24 cores, allowing a certain degree of parallel processing of validation requests, using an equivalent 24 workers for the webserver in the container. Once the container is running and the 50 Tor circuits have been built, we trigger validation procedures via HTTPS requests to the webserver in the container. We run 80 querying threads in parallel, each continuously submitting a domain to validate and waiting for the response. We select the top 10k Tranco [33] domains that host a webserver and request the `/robots.txt` document to simulate an ACME query.

This initial evaluation provides a baseline performance benchmark for different numbers of validators. We test three different scenarios: 3-out-of-4 (equivalent to Let's Encrypt), 5-out-of-7, and 7-out-of-9, to provide an intuition as to the impact of the number of validators on performance and security. We note here that we observe no disagreement among the validator results across all of our tests. As such, each validation produces exactly k requests.

We note the resulting hardware requirements derived from `docker stats` for interested readers in the Appendix A.

Validation duration. Figure 2 shows the distribution of the duration of each validation. This refers to the time between the server receiving a validation request from an applicant and receiving the last validator response necessary to produce a verdict. While the spread increases as k increases, a client can still expect their validation request to complete within around 20 seconds, even with $k = 7$.

We compare the duration of certificates issuance to certbot [34]. Certbot is a popular open source ACME client by the Electronic Frontier Foundation (EFF) for automatically requesting certifcates from Let's Encrypt via the ACME protocol. When measuring certbot, we start a manual DV procedure, place the created challenge value on our webserver, start our timer, and then trigger certbot to begin the validation. We stop our timer when certbot exits. We find that for $k = 3$ the median duration is comparable to that observed when using certbot, and can be further improved with parallelization, as shown by the multi-container tests.

Since obtaining a certificate is an occasional process, and tools like certbot can often be used to complete the validation process without the user's interactive involvement, we consider the additional latency incurred by the use of Tor circuits to be negligible for the end user.

Validation throughput. Table 1 shows the validations per second we achieve with our prototype implementation. Increasing k leads to an expected decrease in throughput, as more resources are required for each individual validation. However, ValidaTor can also easily be scaled horizontally to accommodate higher validation throughput. By further optimizing the implementation and parallelizing the deployment, it is thus feasible to scale the system to match even the rate of ~65 certificates Let's Encrypt issued on average per second on peak days in late 2024 [35].

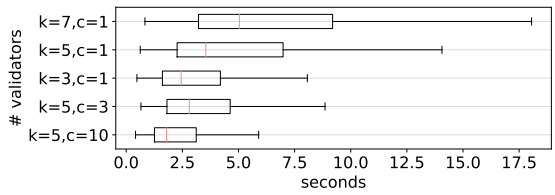

Figure 2: Validation duration with k validators and c containers.

containers	k	validations / s
1	3	2.7
1	5	2.1
1	7	1.6
3	5	6.5
10	5	11.9

Table 1: Validation throughput.

6.2 Scaling

We extend the Tor proxy and circuit management system in ValidaTor to handle multiple validation requests in parallel, assigning each request to a different circuit. As we next show, this parallelization improves the throughput and efficiency of the validation process.

To further scale the throughput of ValidaTor we conduct two additional experiments. For the first we deploy $c = 3$ instances of our container on the same VM, each running 24 workers, building 50 circuits and using $k = 5$ validators per domain. We use 200 client processes to issue the validation requests and load-balance them among the containers.

For the second scaling experiment we increase parallelization even further, deploying $c = 10$ containers, using 20 cores each (on a sufficiently capable server), building 15 circuits each (for the same total of 150 circuits), and also using $k = 5$ validators per domain. We load-balance the same 200 client processes among the containers.

The 3-container deployment achieves the expected, roughly 3x increase over the single-container deployment at 6.5 validations per second. The 10-container deployment does not quite match its expected throughput, but nonetheless increases throughput to 11.9 validations per second.

The increase in performance over the single container is due to parallelization of the Tor daemon (with a separate instance in each container), which mediates the control requests required to manually assign web requests to Tor circuits. This demonstrates encouraging evidence that such a system can be scaled horizontally to production-grade performance through sufficient parallelization.

6.3 Blocking of Tor Traffic

As a well-known anonymity network, Tor may sometimes be discriminated against by networks that seek to prevent anonymous access, potentially limiting its use for DV. We

investigate the significance of this using two validation measurements (2025-02-08), one based on the Tranco top 10K and one sampling 10K domains from Certificate Transparency logs (accessed via certstream), in order to compare potential differences between popular and regular domains, both using a 5-out-of-7 scheme.

We augment our initial implementation to match each exit node and target IP with the request result obtained by that node. If traffic is being blocked we expect to see a `ConnectTimeout` or `ConnectionError`. As shown in Figures 3 and 4, this is the case for around 20% of requests, regardless of the popularity of the domains. CT-sampled domains show no difference to top Tranco domains. In addition, Figure 4 shows that all vantage points tend to agree on the result, i.e. they all either succeed or fail. This strongly suggests that blocking of Tor traffic is done primarily by the domains themselves, rather than transit networks. In the latter case, since the exit nodes are widely distributed, we would expect to see cases where e.g. only one node fails to connect, because its request is routed through a blocking AS, whereas the others are routed differently. This is not the case, however.

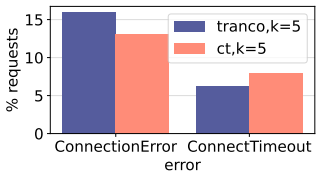

Figure 3: Rates of connection errors.

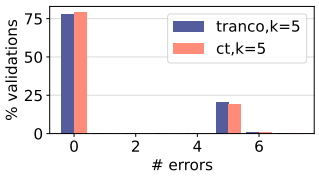

Figure 4: Errors per validation.

We further investigate this by mapping the IP addresses of exit nodes and target servers to their respective AS and simulating the AS paths taken. We then count how often a given AS is on-path for requests that ended in a connection error versus requests that succeeded. If an AS blocks Tor traffic, we would expect to see all requests routed through it to produce connection errors. The impact of such an AS on ValidaTor is significant, if it is implicated in a large number of validation attempts. However, as we see from the data, the impact is not significant. For the CT-based measurement, we see only 10 out of 816 ASes that consistently feature on the paths of failing requests, with only 4 seen in more than 1 validation round and none of them transit ASes. For the Tranco-based measurement it is 35 out of 2531 ASes that consistently produce failures, with each only appearing in 1 validation round and only 8 of them being transit ASes.

These results further solidify the case that blocking of Tor traffic by transit ASes is a rare occurrence without significant impact on the performance of ValidaTor. The key source of validation failures are the destinations of the validation requests. This means it is within the power of domains to allow DV traffic from Tor nodes.

6.4 Bandwidth Impact

In January 2025, the Tor network measured an average 347 GBit/s of consumed bandwidth across all relays (98 GBit/s at exit nodes), a little over a third of the total available advertised bandwidth of 917 GBit/s (less than a third of the 314 GBit/s advertised by exit nodes) [36].

The maximum total traffic produced by our container (as measured by `docker stats`) was 482MB for 10K validations and $k = 7$ (including circuit creation). The average size of the HTTP response bodies observed in our measurements is 528 bytes, whereas an ACME challenge text file is 43 bytes in length. Thus, substituting the proper content for the DV requests, while maintaining the same HTTP headers and Tor circuit building, results in $482MB - 10,000 * 528B + 10,000 * 43B = 477MB$.

As indicated by the steady increase in total traffic and runtime difference between the $k = 3$, $k = 5$ and $k = 7$ conditions (shown in Figure 11), the network load scales linearly with the number of validations and validators. Thus we can fairly reliably extrapolate to the scale of the entire Web PKI. As an estimate of the current certificate volume we track certificate issuances via Certificate Transparency logs (using certstream) for a period of 15 hours, during which we observe an average rate of 104 new certificates per second. Since this accounts only for successfuly validations, we can safely assume at least twice the number of validation attempts. Thus, we can expect:

$$\frac{208}{s} * \frac{477MB}{10,000} * 8 = 79.4MBit/s$$

that is, ~$11.3MBit/s$ per validator. For $k = 5$ and $k = 3$ we get similar rates of $11.7MBit/s$ and $12.7MBit/s$, respectively, matching the expectation that the traffic volume is roughly linear in the number of validators.

In addition to unsuccessful validation attempts, we need to account for chasing of redirects, which is often done during DV, but is not included in our bandwidth data. Redirects are processed by the web client and thus result in two or more distinct requests. Assuming for simplicity an average of 1 redirect per validation, we can expect a rate of $2 * 79.4MBit/s = 158.8MBit/s$. This is a conservative estimate, since we observe redirects on only ~$\frac{1}{3}$ of all domains, with popular Tranco domains using redirects twice as often as the broader Internet, sampled from CT logs.

Our bandwidth measurement also only covers the data flowing in and out of our server. This includes both request and response data, but only for the link between our server and the entry node of our Tor circuit, thus considering only the ingress load at the entry node. This same data is also transmitted between entry and exit node, adding the same load at both the entry node egress and the exit node ingress, as well as between exit node and target server, producing another egress load at the exit node. Thus, the overall load on the Tor network is $4 * 158.8MBit/s = 635.2MBit/s$, with $317.6MBit/s$ hitting the exit node.

Thus, we conclude that even at the current volume of the entire Web PKI and using 7 validators, routing DV traffic through Tor consumes a negligible amount of the network's bandwidth: just 0.11% of Tor's *remaining* total bandwidth and 0.15% of the exit nodes' *remaining* bandwidth. Furthermore, ValidaTor containers could be horizontally scaled to the point where each container has a handful of dedicated Tor exits, avoiding the need for periodic recreation of Tor circuits and thus reducing bandwidth usage.

7 Security Analysis

ValidaTor ensures high path diversity by selecting a random set of exit nodes for each validation request. This randomization makes it difficult for attackers to predict and intercept the validation traffic. We demonstrate experimentally on heuristically derived datasets that path diversity attained with Tor nodes is significantly higher than that obtained with the dedicated infrastructure of Let's Encrypt. Additionally, ValidaTor configures the Tor client to avoid using exit nodes with the same /8 IP prefix, ensuring that the exit nodes are sufficiently distributed across the network. This configuration enhances security by reducing the likelihood that an attacker can control multiple exit nodes in the same circuit.

7.1 Perspective Diversity

Routing domain validation traffic through the Tor network allows us to access many more validation perspectives than a dedicated infrastructure, such as that of Let's Encrypt.

We create a new domain, trigger validation requests for this domain using certbot, and observe the IP addresses logged on our webserver. We repeat this 5 times[3], collecting a total of 11 unique IP addresses. Using Tor's stem library, we obtain all known relays and filter for those marked with the EXIT flag and *not* marked BADEXIT. At the time of our experiments this list contained 2254 nodes with 1221 unique IP addresses.

To consider the diversity in perspectives with regards to BGP routing, we need to map IP addresses to ASes. CAIDA [37] provides a prefix-to-ASN mapping based on BGP origin announcements collected by the RouteViews project. However, as pointed out in [9], this underestimates routing diversity when different prefixes are announced through different paths using the same ASN, as is the case for e.g. AWS datacenters, which host Let's Encrypt validators. Multiple unique origins are thus aggregated under the same ASN. We "de-aggregate" ASNs by considering each prefix as a unique origin, if it is announced through a different path, in line with [9]. This is done based on the most recent available route collector data from RIPE RIS [38] and RouteViews [39].

For the 11 Let's Encrypt IP addresses we obtain 7 unique BGP origins (instead of just 2 when considering aggregated ASNs), whereas for the 1221 Tor exit IP addresses we obtain 280 unique BGP origins (210 with aggregated ASNs).

[3] Certbot allows a maximum of 5 validation attempts in short succession. We see no new BGP origins after the first 3 attempts.

7.2 DNS Perspective Diversity

Tor is implemented such that, when proxying an HTTP request to a given domain through a Tor circuit, the exit node will take care of resolving that domain to an IP address. As pointed out in [9], the DNS resolution path is part of the attack surface for hijacking domain validation. As such, diversifying validators is only useful if the DNS resolvers used by those validators are also diversified. It could be possible that many of the exit nodes use the same few DNS resolvers. While Tor explicitly encourages the use of default resolvers and resolvers within an exit node's network, and discourages the use of public DNS resolvers to avoid centralization, we aim to confirm this by measuring the IP addresses of the resolvers used by exit nodes.

To investigate this we set up a fresh domain with an NS record pointing to a server under our control and log incoming DNS requests on port 53 using `tcpdump`. For Let's Encrypt we again trigger 5 validation requests through certbot, for Tor we send a web request through each of the 2254 exit nodes. In each case this triggers the attempt to resolve our domain using our server, allowing us to track which IP addresses the DNS requests are coming from. By correlating the timeframe of each request as recorded client-side with the timestamps of DNS requests received server-side, we match each Tor exit node IP address with the most likely resolver IP address. Note that, across all certbot measurements, we never actually complete the validation process. Therefore, no certificate is created to be logged in and scraped from Certificate Transparency logs. Thus, our webserver logs are not contaminated by various Internet scans (see for example [40]).

For Let's Encrypt we observe 28 unique resolver IP addresses, corresponding to 9 unique de-aggregated BGP origins. For Tor we matched 1118 unique resolver IP addresses to the 1221 unique exit node IP addresses, corresponding to 174 unique deaggregated BGP origins. While we observed additional IP addresses from another 100 BGP origins, we could not clearly match these to exit nodes and thus use 174 as a lower bound.

7.3 Path Diversity

To test how well diversity of perspectives translates to diversity of BGP paths taken from validators to a target domain we reconstruct the BGP network at the prefix level from route collector data and apply the most recently available CAIDA AS relationships dataset [41]. We map each IP, as observed in our experiments, to its de-aggregated ASN and calculate the paths from each source ASN to the observed destination ASN using the `pybgpsim` library from [42]. We also consider the return paths from destination ASN to source ASN, since these might be different.

Using this method we can recover the transit ASes A for each path and see how many ASes the paths of a given validation have in common. That is, how many ASes can intercept what percentage of validators for how many domains?

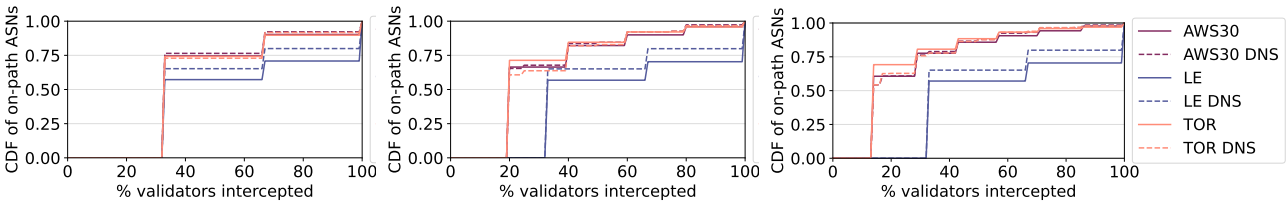

Figure 5: Cumulative distribution of the percentage of validators intercepted by each on-path ASN for each domain ($k = \{3,5,7\}$ from left to right).

In essence, we look at each on-path ASN for each domain validation and determine the percentage of validators that transit through this ASN. We plot the resulting cumulative distribution for each $k \in \{3,5,7\}$ in Figure 5.

For Tor, we use the validator-target pairs as observed in our experiments. For the Let's Encrypt comparison, we simulate the validator-target pairs by truncating to the first 3 pairs (since Let's Encrypt does 3-out-of-4 validation, only using the 4th if the first 3 do not agree) and replacing the first validator with Let's Encrypt's main network (23.178.112.0/24, which is present in every validation attempt triggered with certbot) and the two other validators with a random selection of 2 out of the remaining 6 BGP origins observed in Section 7.1. The same substitution process is also used for the AWS30 comparison, an optimally distributed AWS deployment of 30 locations (discussed in detail in Section 8).

As indicated by Figure 5, using Tor exit nodes as validators significantly decreases the number of ASes in a position to intercept a large fraction of validators for a large number of domains. This is particularly true for ASes that can intercept 100% of validators, and thus forge the overall validation result (reduction of 21%). This number further decreases with additional validators ($k \geq 5$), as the overlap between validation paths decreases (reduction of up to 27%). The comparison with the hypothetical AWS30 deployment shows that such path diversity can also be achieved with a cloud-based deployment, albeit at much greater cost.

7.3.1 Path Overlap Metric

While reducing the number of ASes that can intercept all validators translates directly to fewer threats of fraudulent certificates, it is important to consider the degree of influence of individual ASes on validation more generally. The lower the path overlap between validators, the lower this influence. We therefore propose a metric that summarizes the overall degree of path overlap in a single number, for easier characterization and comparison between deployments.

First, we define the path from a validator i to a domain d as the set of ASes transited both from validator to domain and from domain back to validator, denoted P_{id}. The degree of overlap between the paths can then be calculated as the Jaccard distance between the sets:

$$jaccard(P_{id}, P_{jd}) = \frac{P_{id} \cap P_{jd}}{P_{id} \cup P_{jd}}$$

A value of 0 therefore means the paths of no ASes in common, whereas a value of 1 means both validators transit all the same ASes to reach the target domain. To capture the degree of overlap for a given validation with a group of k validators, we calculate the pairwise Jaccard distance and average over the number of possible pairs:

$$val_overlap(d) = \frac{\sum_{i=1}^{k} \sum_{j=i+1}^{k} jaccard(P_{id}, P_{jd})}{\frac{k(k-1)}{2}}$$

Finally, we average the overlaps across all D validations for a given deployment: $overlap(D) = \sum_{d=1}^{D} val_overlap(d)/D$.

We calculate this metric for ValidaTor $\forall k \in \{3,5,7\}$, as well as the the simulated Let's Encrypt and AWS30 deployments for each of our measurements, and compare the results in Figure 6. We see that the switch to more nodes introduces the most dramatic decrease in average path overlap (~50%), with smaller incremental decreases when using additional validators with the larger Tor pool.

7.4 DNS Path Diversity

To evaluate the diversity of the paths from DNS resolvers to nameservers, we repeat the same evaluation, but with the observed resolver and nameserver IP addresses. Specifically, for ValidaTor, we replace each exit node IP with the matched DNS resolver IP. For the Let's Encrypt comparison we again truncate the validator-target pairs to 3, replace the first exit node IP with the IP of the DNS resolver of the main Let's Encrypt server, and replace the remaining 2 exit node IP addresses with a random selection of 2 IP addresses from the observed DNS resolvers (from different BGP origins).

In both scenarios the target IP of each validator-target pair is replaced with the IP of a random nameserver of the target domain. These IP addresses were previously collected by querying the NS records of each domain and then the A records for each NS result. Due to the randomization we conduct 5 rounds for each deployment and average the resulting path overlap metrics.

The results are also shown (dashed) in Figures 5 and 6. While Let's Encrypt's DNS resolvers show higher path diversity than its validation servers, Tor still offers marked improvements.

7.5 Malicious Exit Nodes

We consider attacks by malicious Tor exit nodes and show how to configure the ValidaTor parameters to substantially decrease the risk of such attacks.

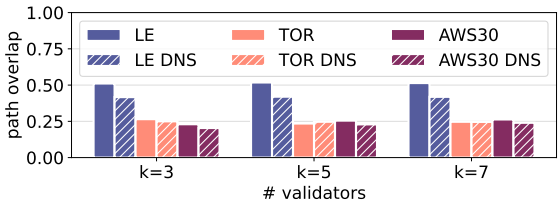

Figure 6: Path overlap for Let's Encrypt, Tor, an optimally distributed AWS deployment of $N = 30$ nodes and respective DNS resolvers.

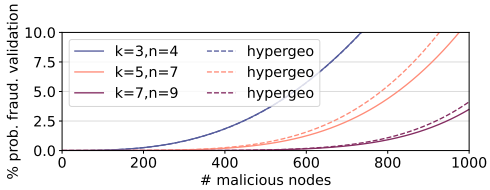

Figure 7: Probability of fraudulent validation using compromised exit nodes.

7.5.1 Probability of Fraudulent Validation

Leveraging Tor exit nodes as vantage points for domain validation introduces the risk of attackers running malicious nodes to intercept and manipulate the validation process. In essence, this is similar to the man-in-the-middle threat posed by BGP hijacks and other routing manipulations. Here, we model the probability of an attacker successfully manipulating validation this way and show that is exceedingly small.

Random selection. Due to the k-out-of-n successful query results required for validation, an attacker would need at least k of his nodes selected for validating the same domain. With a fully random selection, i.e., each node having an equal chance of being selected, the probability of exactly k out of n nodes being malicious is given by the hypergeometric distribution:

$$hg(M,N,n,k) = \frac{\binom{M}{k}\binom{N-M}{n-k}}{\binom{N}{n}}$$

where N denotes the total number of exit nodes in the Tor network (2293 measured at the time of writing) and M denotes the number of nodes under the attacker's control. The probability for *at least* k malicious nodes is thus:

$$p(M,N,n,k) = \sum_{j=k}^{n} hg(M,N,n,j)$$

This is plotted as dashes in Figure 7 for different k and n.

Accounting for prefix-aware selection. However, the node selection process is not fully random, since every time a node is selected, all nodes on the same (configurable) network prefix are excluded as validators for the same validation to ensure distribution. This means an attacker would need to control nodes in at least k different networks to even have the possibility of using them to validate the same domain, significantly raising the attacker's resource requirements.

To simplify the model and give the attacker the highest chance of success, we assume the attacker's M nodes are distributed equally across all networks. Similarly, we assume that each network contains the same total number of nodes. While this is not strictly the case in practice, it allows us to simplify the chance of selecting a malicious node to an average probability of $\frac{M}{N}$, regardless of how many nodes have already been selected. This is because the ratio of malicious to total nodes remains constant if the same number of malicious and legitimate nodes are removed from the pool each round.

Accounting for staged selection. The second difference to a simple k-out-of-n selection is that, for efficiency, the selection is done in stages. That is, we begin with a selection of k validators and only incrementally add additional validators (up to a maximum of n) if agreement has not yet been reached with the validators selected thus far. This means, in order to reach the threshold of k by the n^{th} selection, an attacker would need at least $k-(n-k)$ of his nodes to be selected among the first k. Exactly how many malicious nodes are among the first k then determines how many additional selections are made and need to also be malicious. With the simplifying assumptions above, this selection process results in the following probability, that an attacker can control the outcome of a validation using malicious exit nodes:

$$p(M,N,n,k) = \sum_{j=k-(n-k)}^{k} \binom{k}{j} (\frac{M}{N})^k (1-\frac{M}{N})^{k-j}$$

Figure 7 plots this function for different parameters k and n. While very similar to the hypergeometric distribution, the more accurate modeling of the selection process works slightly to the disadvantage of the attacker for $k > 3$. Overall, we see that, given the current number of $N = 2293$ Tor exit nodes, the attacker's probability of success is very small even when controlling several hundred exit nodes. Note that we assume for the calculation that the attacker controls M of the *existing* N nodes, giving him a stronger advantage than adding M *additional* nodes. Second, we see that the risk can easily and significantly be reduced by simply increasing k. For example, at $M = 700$ the attacker's chance of success can be reduced from ~10% with $k = 3$ to ~2.5% with $k = 5$ and to less than 1% with $k = 7$.

Tor has seen malicious actors adding large numbers of nodes in the past (e.g. ~1000 in 2020 [43]). In this example the attacker would have an 8.7% chance of having all $k = 3$ of their nodes selected to validate their request but only a 0.4% chance of having all $k = 7$ of their nodes selected. A possible mitigation for such attacks could be the temporary increase of k when the Tor network appears to be under attack. For example, at $k = 9$ the attacker's chance of success falls to 0.05%, despite controlling 1000 out of a total of 3293 nodes.

7.5.2 Additional Countermeasures

The threat of colluding exit nodes threatens the security of every other application of Tor. The network is therefore continuously monitored for bad actors by the Tor Project [44], researchers [45] and other volunteers. Implicated nodes are either flagged as `BADEXIT` or removed from the network consensus, aiding the selection against malicious nodes.

Such monitoring could be further extended in the context of our validation system. Across our experiments we very rarely see discrepancies between the results reported by different validators, even when $k >= 7$. Multiple discrepancies involving the same exit IP addresses could therefore easily be detected and flagged, avoiding the use of these exits. Similarly on the the client-side, multiple failed validations in a short period of time could lead to blocklisting of a client's account for that domain, as implemented by Let's Encrypt with certbot. As such, we can effectively prevent an attacker from playing the numbers game and simply attempting many validations until one succeeds.

8 Randomized Distributed DV in the Cloud

Following the comparisons between the Tor network and Let's Encrypt's current MultiVA deployment, it begs the question what a cloud deployment would look like that achieves the same security properties. We begin by fixing the desired maximum probability of a fraudulent validation at a generous 1%. We then consider the following two scenarios: **(a)** using 3-out-of-4 validation as is currently done by Let's Encrypt (more beneficial if traffic is more expensive than additional datacenter nodes) and **(b)** using 7-out-of-9 validation (more beneficial if nodes are more expensive than traffic). We then plot the probability of fraudulent validation, as described in Section 7.5.1, for different numbers of total vantage points N and vantage points hijackable by an attacker x. The results for each scenario are shown in Figure 8.

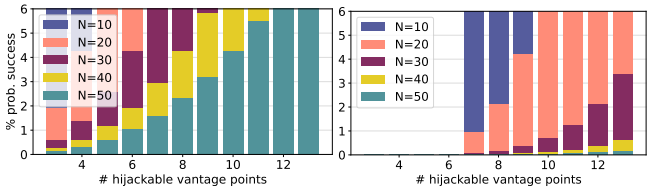

Figure 8: Probability of fraudulent validation by hijacking cloud vantage points, using $k = 3$ (left) and $k = 7$ (right) validators.

For 3-out-of-4 validation, at least $N = 30$ vantage points are required to keep the probability of fraudulent validation under 1%. However, if, for example, the attacker is assumed to be able to hijack up to 6 vantage points, at least $N = 50$ is required. 7-out-of-9 validation naturally remains 100% secure if the attacker cannot hijack at least 7 vantage points. However, even with up to 10 compromised vantage points, the probability of success is still well below 1% at $N = 30$.

To evaluate the path overlap (see Section 7.3.1), for such a deployment, we consult the published IP ranges of AWS EC2 networks and select the 30 vantage points with the least pairwise overlap between network addresses. We then perform the same simulation of AS paths for validation requests as in Section 7.3. For $k = 3$ we see a path overlap of 0.23, comparable to Tor-based validation. For $k = 7$ we see a slightly higher overlap of 0.29 (see Figure 6). It is therefore possible to achieve similar degrees of distribution simply with additional cloud vantage points. However, an increase from 4 to 30 vantage points and the additional traffic of $k = 7$ versus $k = 3$ validators in this scenario would multiply the costs many times. Additionally, a lower risk threshold of under 1% increases the required number of vantage points.

9 Conclusions

Our design of ValidaTor, i.e., DV over Tor, resolves many of the existing limitations of DV and MultiVA. Leveraging Tor as a massively distributed set of vantage points from which to conduct multi-perspective domain validation offers clear advantages over existing systems:

Randomization. Vantage points can be randomly chosen from a large set of available nodes, preventing attackers from knowing in advance which validation nodes to target. This prevents any type of targeted attack, such as prefix BGP hijacks and DNS cache poisoning.

Resilience to interception and malicious Tor exit nodes. Tor exit nodes, as well as the DNS resolvers they use, are more distributed than the vantage points of existing systems. As we show in our experimental evaluations, this results in a significant reduction in the number of ASes that can intercept *all* vantage points used for a validation of a given domain. Such ASes can impersonate validation by intercepting the validation process to obtain fraudulent certificates.

In order to stand a statistically significant chance of fraudulently validating a domain, an attacker needs to control on the order of several hundreds of Tor nodes. Since Tor has a vested interest in avoiding such scenarios to protect from, e.g., traffic correlation attacks, this is unrealistic to persist. Simply increasing the number of validators for a given validation drastically decreases an attacker's chance of success.

DoS resistance. If individual Tor relays, ASes, or routers maliciously drop domain validation traffic, the system can choose new circuits through which to route traffic. Ensuring the same degree of availability with MultiVA requires a much larger deployment.

Lightweight load on Tor network. Since domain validation traffic is lightweight (only querying small text resources, most often via plain HTTP) and circuit management can be implemented without overly frequent rebuilding of circuits, the projected load on the Tor network produced by even a Let's Encrypt-scale volume of validation requests is negligible compared to Tor's available bandwidth.

Open infrastructure. ValidaTor scales with the expansion of the Tor network. The more users operate Tor nodes, the higher the path diversity offered to DV, and the lower load from DV on individual nodes.

Easy adoption. The validation system requires no additional infrastructure to be set up for each vantage point. ValidaTor integrates seamlessly with the CAs and their existing infrastructure, and is easy to adopt into existing DV systems.

A Hardware Requirements

Using `docker stats`, we track the CPU and memory usage of our container over the course of the experiments, in order to give an idea of the hardware required for deployment at scale. As shown in Figures 9 and 10, respectively, the container uses an equivalent of 5 - 8 CPU cores and 800 - 1000MB of memory. There is some dependence on the number of validators used, particularly for CPU usage, but overall the resource usage is fairly stable, both across time and number of validators. This allows fairly accurate extrapolation of the hardware requirements for a large-scale system.

Abstract

Route Origin Validation (ROV) with Route Origin Authorizations (ROAs), built on top of the Resource Public Key Infrastructure (RPKI), serves as the only formally standardized and production-grade defense mechanism against route hijackings in global interdomain routing infrastructures. However, the widespread adoption of RPKI has introduced escalating scalability challenges in validating high volumes of route messages against massive ROA entries.

In this paper, we attribute the performance bottleneck of existing ROV schemes to their underlying validation model, where the route is matched against rules in the form of address blocks. To overcome this bottleneck, we propose the *Authorized Prefix (AP) model* that enables validation at the prefix granularity, and redesign RPKI ROV based on this new model with a hierarchical hashing scheme named h^{2}ROV. Extensive evaluations verify h^{2}ROV's superiority over state-of-the-art approaches in IPv4, with a speedup of 1.7× $\sim$ 9.8× in validation and a reduction of 49.3% $\sim$ 86.6% in memory consumption. System emulations using real-world network topologies further demonstrate h^{2}ROV confines its impact to routing convergence to below 8.5% during update burst events, while reducing ROV-induced delays by 30.4% $\sim$ 64.7% compared to existing solutions.

1 Introduction

1.1 BGP Security and Route Origin Validation

The Border Gateway Protocol (BGP) [1] is a fundamental building block of the Internet, which enables reachability information exchange among autonomous systems (ASes). Despite its critical role in maintaining global connectivity, BGP exhibits inherent vulnerabilities to malicious exploitation, particularly route hijacking attacks that can propagate invalid routing announcements across AS boundaries, causing persistent and large-scale disruptions to the global Internet.

To mitigate these threats, Route Origin Validation (ROV) has emerged as the sole standardized and production-ready security mechanism. Built upon the Resource Public Key Infrastructure (RPKI) [2], ROV utilizes cryptographically signed Route Origin Authorizations (ROAs) to establish a trust anchor for BGP route origination. Network operators implement ROV through router-side verification processes that cross-check advertised BGP routes against RPKI-validated ROAs, thereby identifying and filtering unauthorized origin AS claims.

1.2 Concerns about the Efficiency of ROV

While ROV significantly enhances the security of BGP route origination, its effectiveness remains constrained by incomplete global RPKI adoption. Notably, despite ROAs covering over 50% of BGP route prefixes, only approximately 12% of ASes actively enforce ROV in production networks [3]. This adoption gap persists even among operators with deployed ROAs, highlighting systemic barriers beyond mere infrastructure readiness. A longitudinal study [4] identifies operational efficiency concerns as the primary deterrent to ROV adoption.

ROV introduces two critical operational challenges for routers. First, the validation process imposes per-route computational overhead, requiring real-time verification of ROAs against BGP routes. Second, the sequential validation of bulk routing updates compounds latency, directly impacting BGP convergence—a key performance metric for global routing stability. Our experimental analysis reveals that state-of-the-art ROV implementations increase BGP convergence time by 8.0% $\sim$ 25.6% under update bursts[1], a frequent phenomenon driven by recurring route anomalies (e.g., misconfigurations and hijacks). Worse still, inefficient ROV introduces a new attack vector, enabling adversaries to overwhelm ROV-enforcing routers by amplifying validation overhead [6].

# The first two authors contributed equally to this work. Zedong Ni participated in this study during his master's degree program at the Computer Network Information Center of the Chinese Academy of Sciences.

* Corresponding authors: lybmath@cnic.cn and xie@cnic.cn.

[1]BGPMon [5] shows that route anomalies occur frequently in recent years, which may lead to update bursts.

Another concern arises from ROV's escalating storage demands as RPKI adoption increases. Our empirical analysis demonstrates that contemporary ROV implementations exhibit memory footprints approaching parity with the core Routing Information Base (Table 3, Appendix D.1). This substantial overhead originates from two fundamental requirements: 1) maintaining synchronized replicas of cryptographically validated ROA entries, and 2) supporting specialized lookup structures for accelerated route validation processes. These combined components directly compete with allocation priorities for essential routing functions, creating an operational paradox where network operators face pressure to disable ROV - despite its security benefits - to preserve baseline routing stability.

1.3 Prior Arts and Limitations

Existing research has explored two dominant approaches to optimize ROV performance: hash-based and trie-based validation architectures. Hash-based methods [7] organize ROAs in hash tables, achieving memory efficiency by compressing prefix-to-AS mappings. Nevertheless, this approach increases validation latency, as resolving super/prefix containment requires multiple hash probes. Conversely, trie-based implementations [6–8] improve validation speed by structuring address blocks into hierarchical prefix trees, achieving O(log n) lookup times. However, they introduce higher memory overhead due to trie node proliferation.

Although existing optimizations partially mitigate ROV inefficiencies, our large-scale emulations demonstrate that both trie- and hash-based architectures exhibit critical scalability limitations under projected RPKI adoption trajectories. Specifically, the accelerating coverage of BGP routes by ROAs will substantially increase the proportion of ROV-validated routes. Counterintuitively, validation latency in state-of-the-art systems sharply increases with valid route volume. This divergence leads to an operational dilemma: improved security via RPKI adoption directly degrades real-time route processing capabilities.

1.4 Key Insights and Our Contributions

Regarding the aforementioned challenge in ROV with existing solutions, we conduct a comprehensive investigation to identify the root cause of their performance bottlenecks. Our systematic analysis reveals that the fundamental limitation stems from inherent deficiencies in the conventional validation model [9]. To address this critical issue, we propose a groundbreaking *Authorized Prefix (AP)* validation framework in Section 3, a novel paradigm that establishes two pivotal advancements: (1) superior operational efficiency compared to the traditional model especially when valid route volume is large, and (2) guaranteed equivalence in validation accuracy through formal verification.

Then, in Section 4, we present `h²ROV`, a hierarchical hashing scheme for fast and memory-efficient ROV based on the *AP model*. It employs two hierarchical hash tables to manage authorized prefixes extracted from ROAs with bitmap encoding, enabling ROV at prefix granularity. We further propose two optimizations to improve its validation performance in IPv4 and IPv6 respectively. In addition, we validate `h²ROV`'s practical applicability through a reference implementation integrated with two widely-deployed open-source software routers, `FRRouting`[2] and `BIRD`[3], in Section 5.

At last, in Section 6, we evaluate `h²ROV` using real-world RPKI repositories, BGP routing tables and update traces from operational networks. Compared to state-of-the-art ROV solutions, `h²ROV` reduces memory usage by 49.3% $\sim$ 86.6% and accelerates IPv4 route validation by 1.7 $\sim$ 9.8 times. System emulations using real-world network topologies further demonstrate `h²ROV` mitigates ROV-induced routing convergence delays by up to 64.7%, outperforming conventional validation architectures under routing instability scenarios.

2 Background and Motivation

2.1 Route Origin Authorizations

As defined in RFC 9582 [10], an ROA is a cryptographically signed object, containing an ASN and a sequence of `ipAddrBlocks`. An `ipAddrBlock` encodes a tuple `(IP Prefix, maxLength)`, encompassing all sub-prefixes of `IP Prefix` with prefix lengths up to the specified `maxLength`. We call such a tuple as an *address block (AB)*. The Replying Party (RP) retrieves ROAs from the RPKI repository and validates them locally. Then, all validated ROAs are distributed to routers via the RPKI-to-Router (RTR) protocol [11]. Routers receive these ROAs and extract the key authorization information to guide the ROV process. We define the extracted authorization information as ROV rules. Additionally, to clarify terminology, in this paper, references to ROAs specifically denote an AB paired with its authorized AS, represented by the tuple `(IP Prefix, maxLength, ASN)`, abbreviated as `(pfx, ml, ao)`.

2.2 ROV Model with Address Blocks

Current ROV schemes validate BGP routes using a list of ROV rules, where each ROV rule, extracted from received ROAs, can be represented as a tuple *(pfx, ml, ao)* comprising an *AB* and its authorized AS [9]. We define the *AB model* as the ROV model that uses AB-based ROV rules. Validity states of the *AB model* is defined as follows.

Definition 1 *Let r denote a route, represented as a tuple (rp, ro), where rp is the route prefix and ro is the origin ASN.*

Figure 2: List of ROV rules.

Definition 2 *Let $|p_i|$ denote the prefix length of p_i. $p_i \subseteq p_j$ means p_i is a sub-prefix of p_j.*

Definition 3 ***Validity states:*** *Given a list of ROV rules RL and a route r, the validity state can be valid, invalid, or notFound.* ***Valid*** *means $\exists R \in RL$, R* ***matches*** *r.* ***Invalid*** *means $(\exists R \in RL$, R* ***covers*** *$r) \wedge (\forall R \in RL$, R* ***covers*** *$r \implies$ R does not* ***match*** *r).* ***NotFound*** *means $\forall R \in RL$, R does not* ***cover*** *r.*

Definition 4 ***Cover/Match:*** *Given an ROV rule R and a route r, R* ***covers*** *r means $r.rp \subseteq R.pfx$. R* ***matches*** *r means R* ***covers*** *$r \wedge |r.rp| \leq R.ml \wedge r.ro = R.ao$.*

In the *AB model*, two conditions are defined: *ExistCover (EC)*, which finds an ROV rule that covers route *r*, and *CheckMatch (CM)*, which examines whether the covering ROV rule *R* satisfies $R.ml \geq |r.rp| \wedge R.ao = r.ro$. If the *EC* condition fails, the ROV result is *notFound*. Otherwise, if both *EC* and *CM* conditions are met, the ROV result is *valid*. In this case, the *EC* and *CM* conditions are performed α times, where α ranges from 1 to *n*, with *n* being the number of ROV rules covering *r* in *RL*. If the *EC* condition is satisfied but the *CM* condition is not, the ROV result is *invalid*, and both conditions are performed *n* times. We abstract a decision tree from the *AB model*, namely the *CoverFirst (CF) tree*, as shown in Figure 3.

2.3 Hanging ROA and Bitmap Encoding

Hanging ROA (`h-ROA`) is a bitmap-based encoding scheme for ROAs [12]. It encodes authorized prefixes within ROAs into split sub-trees. In this way, an ROA is transformed into an ASN and a list of encoded sub-trees, each represented as a tuple `(id, bm)`. The `id` uniquely identifies each sub-tree, derived from the root prefix of that sub-tree. The operation of computing `id` can be defined as `ID(p, n)`, which concatenates a set bit ('1') with the first `n` bits of prefix `p` and converts the resulting binary string to a decimal value. The `bm` records authorized prefixes within the sub-tree. Each bit represents a prefix, where '1' indicates authorization and '0' otherwise. Due to its design of encoding authorized prefixes into bitmaps, `h-ROA` supports ROA updates at prefix level.

2.4 Motivation and A Running Example

However, the ROV with *AB model* is inherently limited. We use an example to illustrate the limitations of the *AB model*. There are seven prefixes assigned to three ASes, mapped in Figure 1, generating three ROV rules shown in Figure 2. For

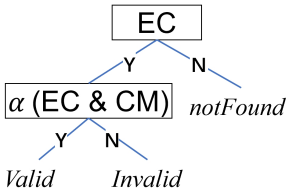

Figure 3: Decision tree of the *AB model*.

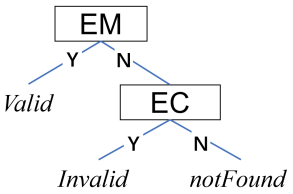

Figure 4: Decision tree of the *AP model*.

a route `(192.0.2.64/32, AS Z)`, the ROV-enforcing router determines its validity state as *valid*. In this example, the router performs three queries, sequentially checking whether each ROV rule covers the route prefix and ultimately identifying a matching ROV rule.

The *AB model*'s performance bottleneck lies in its coarse-grained address block management. The bitmap-based encoding enables fine-grained management of authorized prefixes and provides valuable insights for improving ROV. We propose the *Authorized Prefix (AP) model*, which uses authorized prefixes for route validation and builds on bitmap-based encoding to achieve fine-grained management of ROV rules. Through careful design and optimization, the *AP model* can overcome the performance bottlenecks of the *AB model*.

3 ROV Model with Authorized Prefixes

3.1 Model Definition

Instead of encoding an ROV rule as an *AB* and its authorized AS, the *AP model* maintains ROV rules at prefix granularity. Each ROV rule is encoded as a tuple *(pfx, ao)* comprising a prefix and its authorized AS. Validity states of the *AP model* remain the same as those of the *AB model*, while the definition of Cover/Match differs, as defined below.

Definition 5 ***Cover/Match:*** *Given an ROV rule R and a route r, R* ***covers*** *r means $r.rp \subseteq R.pfx$. R* ***matches*** *r means $r.rp = R.pfx \wedge r.ro = R.ao$.*

In the *AP model*, we define two conditions: *ExistCover (EC)*, which finds an ROV rule that covers route *r*, and *ExistMatch (EM)*, which finds an ROV rule that matches *r*. If the *EM* condition is satisfied, the ROV result is *valid*. Otherwise, the ROV result is *invalid* or *notFound*, depending on whether the *EC* condition is met. Both conditions are executed at most once. We abstract a decision tree from the *AP model*, namely the *MatchFirst (MF) tree*, as shown in Figure 4.

3.2 Cost Analysis of ROV

Cost of the *AB model*. To analyze the validation cost of the *AB model*, we define the execution costs of *EC* and *CM* as X_1 and Y_1, as the complexities of these two conditions obviously differ. Then, the validation costs determining ROV

results are $\alpha X_1 + \alpha Y_1$, $nX_1 + nY_1$, and X_1 for *valid*, *invalid*, and *notFound* routes, respectively. Finally, we formalize the minimal cost of the *AB model* according to the *CF tree* based on the distribution across three validity states (with $\alpha = 1$ and $n = 1$ for minimal cost):

$$\begin{aligned} cost(CF) &= P_1(X_1 + Y_1) + P_2(X_1 + Y_1) + P_3 X_1 \\ &= X_1 + (1 - P_3)Y_1 \end{aligned} \tag{1}$$

where P_1, P_2, and P_3 are the proportions of *valid*, *invalid*, and *notFound* routes, respectively, and their total equals 100%. Clearly, as RPKI deployment increases, the proportion of *notFound* routes decreases correspondingly. Therefore, the validation cost of the *AB model* increases.

Cost of the *AP model*. The costs of executing the *EC* and *EM* conditions are defined as X_2 and Y_2. Thus, the validation costs determining ROV results are Y_2, $X_2 + Y_2$, and $X_2 + Y_2$ for *valid*, *invalid*, and *notFound* routes, respectively. Finally, we formalize the cost of the *AP model* using the *MF tree* based on the distribution across three validity states:

$$\begin{aligned} cost(MF) &= P_1 Y_2 + P_2(X_2 + Y_2) + P_3(X_2 + Y_2) \\ &= (1 - P_1)X_2 + Y_2 \end{aligned} \tag{2}$$

The validation cost of the *AP model* is affected by P_1. As the proportion of *valid* routes increases, the validation cost decreases.

Cost comparison. We compare the validation costs of the two ROV models based on the previous analysis. In both models, the *EC* condition tries to find one or more ROV rules that cover a given route. This can be regarded as the *subset rank problem*, which has a time complexity of $O(\log n)$, where n is the number of ROV rules [13]. Therefore, we assign the same time consumption to X_1 and X_2, denoted as $X_1 \equiv X_2 \equiv x$. The *CM* and *EM* conditions, on the other hand, can be performed in constant time, so we define $Y_1 \equiv Y_2 \equiv y$. Furthermore, it is clear that $x \gg y$. With these assumptions, we can formalize the difference between the minimum cost of $cost(CF)$ (where $n = 1$ and $\alpha = 1$) and the maximum cost $cost(MF)$ as follows:

$$\begin{aligned} \Delta(cost) &= cost_{min}(CF) - cost_{max}(MF) \\ &= X_1 + (1 - P_3)Y_1 - ((1 - P_1)X_2 + Y_2) \\ &= P_1 x - P_3 y \end{aligned} \tag{3}$$

Currently, $P_1 > P_3$, so the difference in cost between the two models is greater than 0, indicating that the maximum cost of the *AP model* is lower than the minimum cost of the *AB model*. Moreover, as RPKI gets more widely deployed, the proportion of *valid* routes (P_1) will increase and that of *notFound* routes (P_3) will decrease. This will further widen the cost difference between the two models.

3.3 Equivalence in Validation Accuracy

This subsection presents the proof that the *AP model* is equivalent to the *AB model* in terms of ROV outcomes.

Definition 6 *Given an ROV rule R (pfx,ml,ao), the set of prefixes contained in R is defined as:* $AP_{set}(R) = \{p \mid p \subseteq R.pfx \wedge |p| \leq R.ml\}$.

Definition 7 *Given a list of ROV rules RL_{AB} under the AB model, the AP model generates its list of ROV rules RL_{AP} as follows:* $RL_{AP} = \{(pfx, ao) \mid pfx \in AP_{set}(R) \wedge ao = R.ao, \forall R \in RL_{AB}\}$

Theorem 1 *Given an ROV rule R (pfx, ml, ao) and a route prefix rp,* $rp \nsubseteq R.pfx \iff \forall p \in AP_{set}(R), rp \nsubseteq p$.

The proof of this theorem is provided in Appendix B.

Theorem 2 *For a given route r (rp, ro), the ROV result under the AB model is identical to that under the AP model.*

By Definition 3, if the ROV result for route *r (rp, ro)* is *notFound* under the *AB model*, then $\forall R \in RL_{AB}, rp \nsubseteq R.pfx$. According to Theorem 1, we can infer that $\forall p \in AP_{set}(R), rp \nsubseteq p$ for all $R \in RL_{AB}$. Combining with Definition 7, $\forall R \in RL_{AP}, rp \nsubseteq R.pfx$, the ROV result for route r under the *AP model* is also *notFound*, and conversely.

If the ROV result for r is *valid* under the *AB model*, then $\exists R \in RL_{AB}, rp \subseteq R.pfx \wedge |rp| \leq R.ml \wedge ro = R.ao$. Let this ROV rule be *MR*. According to Definition 6, $rp \in AP_{set}(MR) \wedge ro = MR.ao$. Since $MR \in RL_{AB}$, by Definition 7, we deduce that $(rp, ro) \in RL_{AP}$. Consequently, $\exists R \in RL_{AP}, R.pfx = rp \wedge R.ao = ro$. Hence, the ROV result under the *AP model* is also *valid*, and conversely.

If the ROV result for r is *invalid* under the *AB model*, it is neither *valid* nor *notFound*. Since the *AB* and *AP models* agree on classifying routes as *valid* or *notFound*, the *AP model* also deem it neither *valid* nor *notFound*. Hence, the result under the *AP model* is *invalid*, and conversely.

In conclusion, given identical ROAs and routes, the validation results produced by the *AB model* and the *AP model* are equivalent.

4 h²ROV: Hierarchical Hashing-Based ROV

In this section, we introduce the basic version of our proposed ROV scheme, h²ROV. Subsequently, we introduce two optimizations specifically tailored for IPv4 and IPv6.

4.1 Maintaining ROV rules with Bitmaps

Instead of refining ROV under the limitations of the *AB model*, we propose a novel ROV scheme, h²ROV, which performs ROV based on the *AP model*. To achieve this, h²ROV employs the basic version of h-ROA for managing ROV rules at the prefix level, which sets the hanging levels as multiples of 5. Figure 5 illustrates how h²ROV maintains the ROV rules at the prefix level and performs ROV based on these finer-granularity

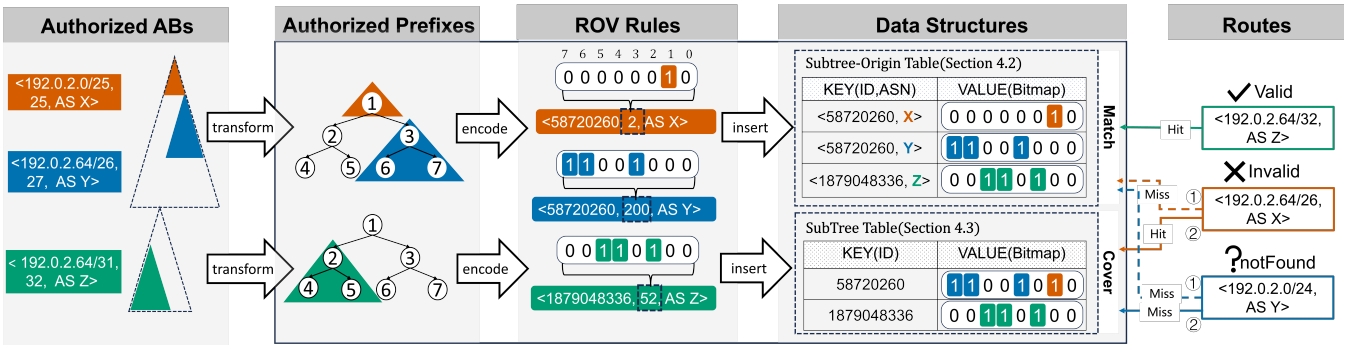

Figure 5: In h²ROV scheme, when the router receives ROAs, it first encodes them into a series of ROV rules and then inserts them into the corresponding data structures.

authorizations. For example, the ROA (192.0.2.64/26, 27, AS Y) (blue square) authorizes three prefixes for AS Y. h²ROV first locates the sub-tree containing these prefixes, rooted at 192.0.2.0/25. The sub-tree's id is calculated as 58720260, derived from the binary string formed by concatenating a set bit ('1') with the first 25 bits of 192.0.2.0. Then, h²ROV encodes the three authorized prefixes into the bitmap 11001000 (only the last 8 bits are shown, as the higher bits are 0). Bits 3, 6, and 7 are set to 1, corresponding to these prefixes. Similarly, ROAs (192.0.2.0/25, 25, AS X) (orange square) and (192.0.2.64/31, 32, AS Z) (green square) are encoded into (58720260, 00000010, AS X) and (1879048336, 00110100, AS Z). In summary, when routers receive ROAs, h²ROV transforms them into ROV rules, which are represented as (id, bm, ASN) tuples.

4.2 Matching the Route

Given a route (rp, ro), h²ROV first calculates the sub-tree's id as ID (rp, |rp|). If a bitmap is found in the SOT for (id, ro), h²ROV calculates the index of rp in the sub-tree as i and checks whether the i-th bit in the bitmap is set to 1. If the bit is set, it indicates that rp is authorized by an ROA for ro, and the route is *valid*. By leveraging the SOT, this matching process achieves a time complexity of O(1).

As shown in Figure 5, the router encodes the fetched ROAs into three ROV rules: (58720260, 00000010, AS X), (58720260, 11001000, AS Y), and (1879048336, 00110100, AS Z). These entries are then inserted into the SOT as ((58720260, AS X), 00000010), ((58720260, AS Y), 11001000), and ((1879048336, AS Z), 00110100). For a received route (192.0.2.64/32, AS Z), h²ROV first calculates the sub-tree's id as 1879048336. It then identifies the index of the route within the sub-tree as 4. Next, h²ROV queries the SOT using the key (1879048336, AS Z) and retrieves the corresponding bitmap 0011**0**0100. Finally, h²ROV determines the route's validity state by checking whether the 4th bit in this bitmap is set to 1. In this case, the bit is set, confirming that the route is *valid*.

4.3 Covering the Route Prefix

For *valid* routes, the SOT enables direct matching. However, for *invalid* or *notFound* routes, where SOT alone cannot confirm status, further validation is needed. We deploy a secondary hash table STT to locate ROV rules covering the route prefix. The STT utilizes sub-tree's id as key and stores a bitmap union of all authorized prefixes within corresponding sub-tree.

When a route (rp, ro) fails SOT matching, h²ROV retrieves the bm in the STT using id=ID(rp, |rp|). If there exists an authorized prefix covering rp marked in the bm, the ROV result is *invalid*. If no covering prefix is marked in the bm or no bm is found for the given id, h²ROV proceeds to query the sub-trees associated with the super-prefixes of rp. This process continues until either an authorized prefix covering rp is found (resulting in *invalid*), or the root of the IP prefix trie is reached without a match (resulting in *notFound*).

As shown in Figure 5, the router inserts the three ROV rules into the STT without their authorized ASes. These entries are (58720260, 00000010), (58720260, 11001000), and (1879048336, 00110100). Since the first two entries share the same id, their bms are merged with a bitwise OR, resulting in an updated entry with the key 58720260 and the value 11001010 (i.e., 11001000 OR 00000010). For route (192.0.2.64/26, AS X), h²ROV calculates the id of the sub-tree as 58720260, and determines its index within the sub-tree as 3. After an SOT query fails, h²ROV proceeds to query the STT using the id as the key. The merged bitmap 1100**1**010 is retrieved, and since the 3rd bit is set to 1, the ROV result for this route is *invalid*. This outcome indicates that the rp is covered but not matched by an ROV rule; otherwise, a matching ROV rule would have been found in the SOT. In contrast, route (192.0.2.0/24, AS Y) receives a *notFound* verdict due to missing matches in both SOT and STT.

4.4 Basic Design of h²ROV

The h²ROV validation process operates through two distinct phases: **matching the route** and **covering the route prefix**.

Algorithm 1: Validate a given route with h²ROV

Input : the Subtree-Origin Table: SOT, the SubTree Table: STT, the Route: (rp,ro)
Output : the ROV result of the given route: res

```
1  res ← NotFound;
2  id, pos ← calculate_ID_AND_POS(rp);
3  if (bm1 = SOT[id + ro] and bm1[pos] == 1) then
4  |   res ← Valid;
5  |   return res;
6  end
7  while id > 0 do
8  |   if bm2 = STT[id] and ExistCover(bm2, pos) then
9  |   |   res ← Invalid;
10 |   |   return res;
11 |   end
12 |   id >>= 5;
13 end
14 return res;
```

First, h²ROV determines whether a route is *valid* by querying the SOT for matching ROV rules (in Section 4.2). If the SOT query fails, h²ROV recursively searches the STT for ROV rules that cover the route prefix to determine whether the route is *invalid* or *notFound* (in Section 4.3).

The pseudo code of h²ROV is shown in Algorithm 1. In the worst case, h²ROV requires one SOT query and $\left\lceil \frac{|rp|}{5} \right\rceil$ STT queries to validate a given route (rp, ro). Therefore, the time complexity of h²ROV for validation is $O(|rp|)$.

4.5 Optimization for IPv4 Route Validation

Obviously, the performance bottleneck of h²ROV arises from repeated lookups in the STT, termed the backtracking issue. This issue occurs as a bitmap only encode authorized prefixes within the sub-tree, leaving coverage by other sub-trees uncertain. To tackle this challenge, we propose optimizations for IPv4 and IPv6 scenarios to reduce backtracking.

In the IPv4 scenario, to expedite the process of checking whether `rp` is covered, we introduce additional bitmap arrays to mark covered sub-tree root prefixes. For root prefixes at hanging levels 5, 10, 15, and 20, we construct bitmap arrays B_i of 2^i bits, respectively. For instance, B_5 has 2^5=32 bits and is initially set to 0. These bitmap arrays are referred to as the **Level Bitmap (LB)**. For each root prefix `p` at these levels, we use the decimal value of first `|p|` bits of `p` as its index in B_i. For example, the index of 8.0.0.0/5 in B_5 is 1(0b00001). When a prefix is authorized, we mark all covered root prefixes at these hanging levels with 1. For a given route `(rp, ro)`, if h²ROV fails to match the route in the SOT, it uses the LB to check if `rp` is covered by other authorized prefixes, thus avoiding multiple STT queries. This optimization enables efficient processing of routes with prefix lengths of 24 or shorter. For routes whose prefix lengths exceed 24, h²ROV requires up to three STT queries and one LB access in the worst case. This is because sub-trees rooted at hanging levels 20, 25, and 30 may contain authorized prefixes covering `rp`, while the LB only records the coverage status up to hanging level 20.

To balance validation speed and memory usage, we refrain from constructing bitmap arrays for hanging levels 25 and 30 for two main factors. First, the vast majority of IPv4 prefixes have lengths of 24 or shorter [14]. Second, constructing bitmap arrays for hanging levels 25 and 30 would demand 32MB and 1GB of memory respectively. By limiting LB construction to hanging levels 5, 10, 15, and 20, h²ROV incurs only an additional 1MB of memory overhead while reducing time complexity of validation to $O(1)$.

4.6 Optimization for IPv6 Route Validation

In the IPv6 scenario, for a route with a prefix length of 128, h²ROV requires 26 ($\left\lceil \frac{128}{5} \right\rceil$) STT queries in the worst case. Despite applying LB, the number of STT queries merely decreases to 22 ($\left\lceil \frac{128-20}{5} \right\rceil$), which is a limited improvement in validation performance. In fact, most IPv6 routes have prefix lengths between 32 and 48 [15]. However, constructing bitmap arrays for hanging levels 30 and 45 is impractical due to the excessive storage requirements. Therefore, a more efficient optimization tailored to IPv6 scenario is necessary.

We introduce **Cover Flag (CF)**, which is the 0th bit of the `bm`, to indicate whether at least one super-prefix covers the sub-tree. The CF enables early termination of STT backtracking by instantly checking coverage upon retrieving `bm`. However, even with the CF effectively reducing the number of STT backtracking queries, 26 queries can still be required in the worst case when intermediate entries are missing from the STT. To further optimize the validation performance, we incorporate a binary search strategy. However, the binary search can only be performed if all intermediate sub-trees along the path from the root of the sub-tree containing rp to the root of the IPv6 address prefix trie exist in the STT. Therefore, before performing binary search, we ensure that all intermediate sub-trees exist in the STT by inserting placeholder entries to fill in the missing ancestor sub-trees. These placeholder entries are initialized with bitmaps set to 0, ensuring structural continuity for binary search.

For binary search on a route `(rp,ro)`, two pointers are initialized: the left pointer (`lft`) to 0 and the right pointer (`rt`) to `|rp|`. The middle pointer (`mid`) is calculated as `(lft+rt)/2`. If the bitmap corresponding to `id = ID(rp, mid)` is absent in the STT, `mid` is recalculated as `(lft+mid)/2`; otherwise, if the corresponding bit in the obtained bitmap for this route is set to 1 or the CF of the obtained bitmap is set to 1, the route is determined to be *invalid* and the search terminates. If neither condition is satisfied, `mid` is updated to `(mid+rt)/2`

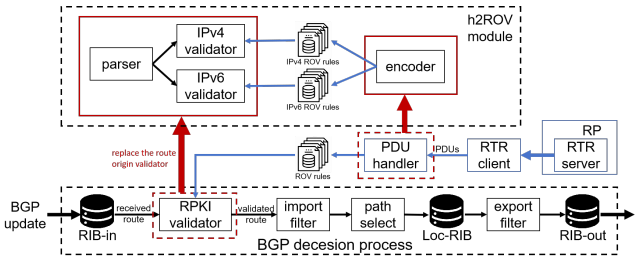

Figure 6: The implementation of the h²ROV scheme in the software router.

and the query to the STT continues. This approach reduces the time complexity from $O(|rp|)$ to $O(log(|rp|))$.

5 Implementation with Software Routers

5.1 System Design

We implemented the h²ROV module in two open-source software routers, FRRouting [16] and BIRD [7]. The module consists of three components: *encoder*, *parser*, and *validator*, whose interactions with the original components of the software router are illustrated in Figure 6. The *encoder* identifies whether ROAs received from the RP are IPv4 or IPv6 by examining the Type field in the RTR Prefix PDU, encodes them into ROV rules, and maintains separate storage for each address family. The *parser* processes BGP updates from neighbors, distinguishing IPv4 and IPv6 routes via the Address Family Identifier field. It extracts essential information for ROV, including the prefix from the Network Layer Reachability Information (NLRI) attribute and the origin AS (the rightmost AS in the AS Path attribute). The *validator* performs origin validation on parsed routes using the encoded ROV rules, applying the appropriate ROV algorithm based on the prefix type (IPv4 or IPv6). Validated routes, along with their ROV results, are forwarded to the *path selection* module.

h²ROV validator. As discussed in Section 6.1, h²ROV excels at validating IPv4 routes but is slightly less efficient for IPv6 routes. This limitation has a negligible impact on overall performance due to two factors. First, IPv4 updates occur $1.8 \sim 3$ times more frequently than IPv6 updates, reducing the proportion of IPv6 validation tasks [17]. Second, expanding RPKI deployment will increase *valid* routes, including those for IPv6, enhancing the validation performance of h²ROV beyond existing ROV schemes. Therefore, we have integrated IPv4 and IPv6 optimizations of h²ROV into our *validator*, ensuring robust performance.

Modifications to the software router. As shown in Figure 6, the software router handles two distinct data flows: the routing message flow (black arrows) and the ROA data flow (blue arrows). The integration of the h²ROV module replaces the original *ROV validator* component within the *RPKI validator* with a *parser* and *validator* for routing messages, and the original *PDU handler* with an *encoder* for received ROAs. This design limits modifications to a minimal scope, ensuring backward compatibility and the integrity of the software router's core functionality.

5.2 h²ROV with Wide ROAs

We define δ as the difference between the maxLength and the prefix length of an ROA. The number of prefixes authorized by an ROA is $2^{(\delta+1)}-1$. With hanging levels as multiples of 5, each sub-tree can encode 31 prefixes. In the best case, an ROA generates $\left(\left\lceil \frac{(2^{(\delta+1)}-1)}{31} \right\rceil\right)$ ROV rules.

Consequently, an ROA with a large δ generates numerous ROV rules. To avoid excessive memory consumption, ROAs with δ exceeding a predefined threshold are classified as *wide ROAs* and stored in the **Wide ROA Trie (WRT)**, a Patricia trie-based structure. The threshold values are chosen to optimize the validation performance and storage overhead in h²ROV (details in Section 6.2.1). WRT allows direct insertion of wide ROAs, bypassing ROV rule encoding. Since the authorized prefixes in wide ROAs are not recorded in the SOT, h²ROV queries the WRT whenever no matching ROV rule is found in the SOT during route matching.

5.3 ROA Update for h²ROV

We introduce the ROA update process for h²ROV in this subsection. For a normal ROA, the first step is to encode it into ROV rules as described in Section 4.1, followed by inserting or deleting these entries in the SOT and STT. For IPv4 ROAs, the LB needs to be updated based on the authorized prefixes contained in the ROAs. For IPv6 ROAs, the process involves checking whether encoded sub-trees from the ROA are covered by existing authorized prefixes and identifying which existing authorized prefixes are covered by the newly encoded sub-trees. Based on these checks, the corresponding CFs should be updated. Wide ROAs are inserted or deleted at the appropriate nodes in the WRT, with their prefixes encoded for insertion or deletion in the STT. Additionally, h²ROV uses a reference count to track bit marking frequency, preventing erroneous deletions when a bit is marked multiple times.

6 Evaluation

In this section, we conduct extensive experiments to evaluate the performance of h²ROV. Each experiment is run 100 times, and the average results are reported [4].

[4] A detailed breakdown of the 100 experimental runs is provided in Appendix D.2.

Table 1: The datasets used for evaluation.

Name	Date/Time Period	Source	Type
ROA_2024	2024/8/25	RIPE NCC	real-trace ROAs
ROA_13Y	2012/1/1∼2024/1/1	RIPE NCC	real-trace ROAs
BGP_RRC00	2024/8/25	RIS RRC00	real-trace BGP updates
BGP_13Y	2012/1/1∼2024/1/1	RIS RRC00	real-trace BGP updates
BGP_20C	2024/8/25	RIS 20 collectors	real-trace BGP updates
BGP_ROV	N/A	N/A	randomly-generated BGP updates
BGP_IP46	2024/8/25	RIS 20 collectors	randomly-selected BGP updates
BGP_SIZE	2024/8/25	RIS 20 collectors	randomly-selected BGP updates

Table 2: The experimental environments.

	NIC	Intel Corporation 82599ES 10-Gigabit

6.1 Methodology

Evaluated schemes. We evaluate our proposed ROV scheme, h²ROV, and all existing ROV schemes mentioned in Section 7 except for *x*BGP. These schemes are represented by their core data structures namely LPFST (RTRLib), HT (BIRD), HT+PT (BIRD), and Patricia (BGP-SRx).

Data sets. We evaluate h²ROV using two types of datasets: ROA and BGP update. ROA datasets, sourced from RIPE NCC [18], include the dataset ROA_13Y, comprising 13 annual sets collected on January 1st from 2012 to 2024 for scalability experiments, and the dataset ROA_2024, collected on August 25, 2024, for other experiments. For BGP update datasets, we use three categories: real-trace, randomly-generated, and randomly-selected updates. Real-trace BGP updates are obtained from RIPE Routing Information Service (RIS) [19] collectors. The dataset BGP_20C comprises BGP updates from 20 RIPE RIS collectors on August 25, 2024. The dataset BGP_13Y contains annual RRC00 BGP updates on January 1st from 2012 to 2024 for scalability experiments. The dataset BGP_RRC00 comprises BGP updates from RRC00 on August 25, 2024. Furthermore, based on the dataset ROA_2024, we generate the dataset BGP_ROV by varying the proportion of randomly generated BGP updates corresponding to each ROV result (*valid*, *invalid*, *notFound*) from 0% to 100% in 10% increments, ensuring the sum of proportions equals 1. This results in 66 sets of BGP updates. The dataset BGP_IP46 consists of 11 sets with varying IPv4/IPv6 ratios, proportionally sampled from BGP_20C. The dataset BGP_SIZE includes 3 sets of BGP updates with sizes of 10K, 100K, and 1M, randomly sampled from BGP_20C. For further details, refer to Table 1 and Appendix E.

Performance metrics. For experimental evaluation, we introduce three key performance metrics to compare ROV schemes. First, validation speed is measured as the average number of routes validated per second, in million validations per second (MVPS). Second, memory consumption is measured in megabytes (MB). Lastly, update performance is measured as the average time taken to update an ROA. For the system implementation, we also introduce three performance metrics to evaluate the impact of ROV schemes. First, the average proportion of delay introduced by ROV in BGP decision process under normal router operation is evaluated. Then, the impact of ROV on BGP update processing speed during an update burst is measured by the average packet processing delay per second. Finally, the impact of ROV deployment on BGP convergence time is measured.

Experimental environment. For system evaluation, a small-scale RPKI and BGP testbed is constructed, with Routinator as the RP and FRRouting and BIRD as ROV-enforcing routers (abbreviated as *validators*). Furthermore, a BGP sender and receiver, both modified from FRRouting, are deployed. The sender replays BGP updates by extracting AS Path and NLRI attributes from archived BGP update files, encapsulating them into BGP updates, and sending them to the *validator* according to their timestamps. The *validator* synchronizes ROAs from the RP, performs ROV on the received BGP updates, and forwards the validated updates to the receiver, which logs the timestamp of each validated update upon arrival. Moreover, we measure BGP convergence time based on our team's self-developed emulation platform [20]. The configuration information of the experimental environment is shown in Table 2.

6.2 Algorithm Performance Evaluation

6.2.1 Configurations of h²ROV

The threshold for δ determines the set of wide ROAs, influencing both validation speed and memory usage in h²ROV. We set the optimal threshold for both original and refined versions of h²ROV via experiments using datasets ROA_2024 and BGP_RRC00, considering both speed and memory costs.

As shown in Figures 7 and 8, the optimal threshold for δ in IPv4 and IPv6 scenarios for the original version of h²ROV is 8 and 5, respectively, and 8 and 7 for the refined version. These thresholds are used in our evaluations.

6.2.2 Performance optimization

Figures 9 and 10 show validation speed and memory cost when performing ROV on BGP updates with the original and refined versions of h²ROV, using datasets ROA_2024 and BGP_RRC00. The refined version achieves an increase in validation speed of 20.1% and 48.6%, respectively, for IPv4 and IPv6 compared to the original version. Correspondingly, memory usage increases by 11.4% for IPv4 and 72% for IPv6 but remains within acceptable limits. Furthermore, we evaluate the validation speed of both versions of h²ROV using BGP_20C. The experimental results in Appendix D.3 demonstrate that

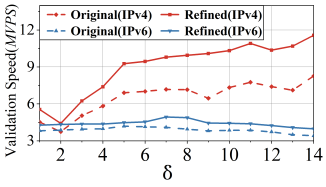

Figure 7: The validation speed with different thresholds for δ.

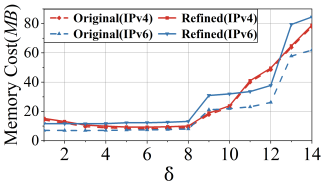

Figure 8: The memory cost with different thresholds for δ.

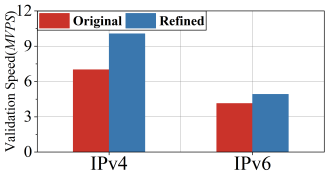

Figure 9: The validation speed of two versions of h²ROV.

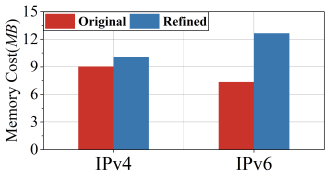

Figure 10: The memory cost of two versions of h²ROV.

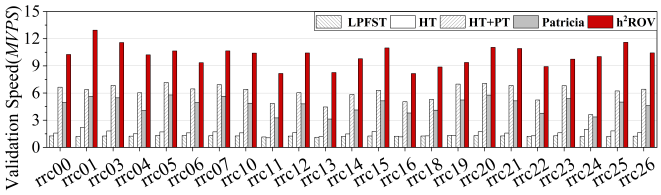

Figure 11: The validation speed of five ROV schemes in IPv4.

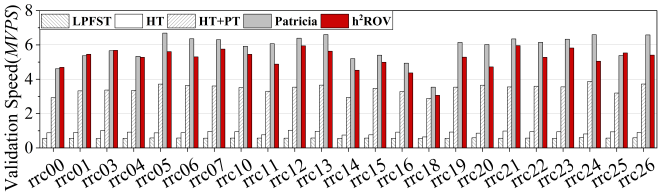

Figure 12: The validation speed of five ROV schemes in IPv6.

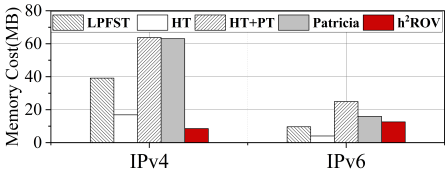

Figure 13: The memory cost.

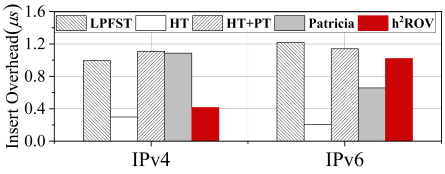

Figure 14: The average insertion time.

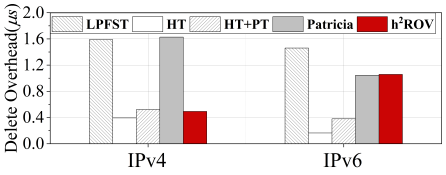

Figure 15: The average deletion time.

the refined version exhibits a clear advantage in validation speed. Therefore, we adopt the refined version for further experiments and system implementation.

6.2.3 Comparison with existing ROV schemes

Validation speed. We evaluate the validation speed of five schemes using datasets `ROA_2024` and `BGP_20C`, as shown in Figures 11 and 12. In the IPv4 scenario, `h²ROV` achieves validation speed of 8.1 to 12.9 MVPS across different BGP collectors. Its validation speed is 6.8× to 9.8×, 4.3× to 6.2×, 1.7× to 2.4×, and 2.2× to 2.9× that of `LPFST`, `HT`, `HT+PT`, and `Patricia`, respectively. These results demonstrate a significant performance advantage of `h²ROV` in the IPv4 scenario. In the IPv6 scenario, `h²ROV` achieves validation speed of 3 to 5.96 MVPS. While it outperforms three ROV schemes—`LPFST`, `HT`, and `HT+PT`—it is slightly slower than `Patricia` across most collectors.

Memory consumption. Figure 13 shows the memory consumption of five ROV schemes. In the IPv4 scenario, `h²ROV` consumes 8.5 MB memory, reducing memory consumption by 78.1%, 49.3%, 86.6%, and 86.4% compared to `LPFST`, `HT`, `HT+PT`, and `Patricia`, respectively. In the IPv6 scenario, `h²ROV` consumes 12.6 MB memory. Although it uses less memory than `HT+PT` and `Patricia`, it requires more memory than `LPFST` and `HT`. Overall, `h²ROV` achieves combined memory consumption of 21.1 MB for IPv4 and IPv6, exceeding `HT` by only 0.2 MB while remaining significantly lower than other evaluated schemes.

Update performance. We evaluate the update performance of five ROV schemes. For insertion evaluation, we use the dataset `ROA_2024`. For deletion evaluation, we randomly select part of the dataset `ROA_2024` for removal. Figures 14 and 15 show that the update performance of `h²ROV` is better than other ROV schemes except for `HT` in the IPv4 scenario. However, in the IPv6 scenario, `h²ROV` outperforms only `LPFST`. Overall, `h²ROV` completes an ROV rule insertion or deletion in under 1μs. Appendix C indicates that the frequency of ROA updates per second is significantly low. Consequently, the ROV update performance does not pose a bottleneck for route validation.

6.3 Scalability of h²ROV

6.3.1 Volume of ROAs

With the ROAs and BGP updates collected from the operational networks every year (datasets `ROA_13Y` and `BGP_13Y`), we measure the validation speed and memory consumption of the five schemes.

As shown in Figure 16, `h²ROV` demonstrates a more stable and upward trend in validation speed for IPv4 BGP updates, whereas the validation speeds of other ROV schemes decline over time, except for `HT`. From the trend demonstrated in Figure 17, we can deduce that the superiority of `h²ROV` over other ROV schemes will become clearer with the increase in the number of ROAs in IPv6 scenario. In terms of memory cost, `h²ROV` clearly outperforms other schemes in IPv4, as shown in Figure 18, and for IPv6 (Figure 19), its memory usage increases but at a slower rate than `Patricia` and `HT+PT`.

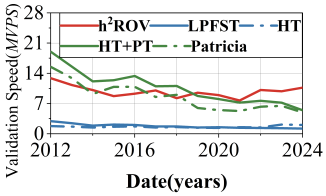

Figure 16: The validation speed at varying times in IPv4.

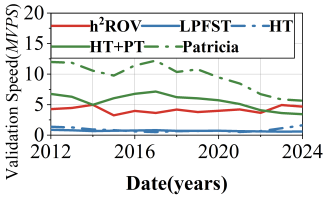

Figure 17: The validation speed at varying times in IPv6.

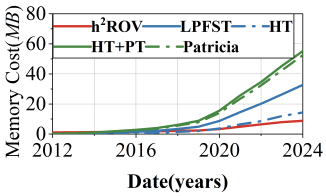

Figure 18: The memory cost at varying times in IPv4.

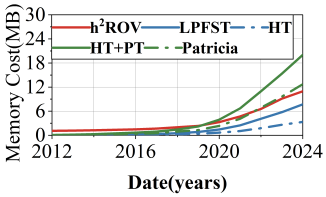

Figure 19: The memory cost at varying times in IPv6.

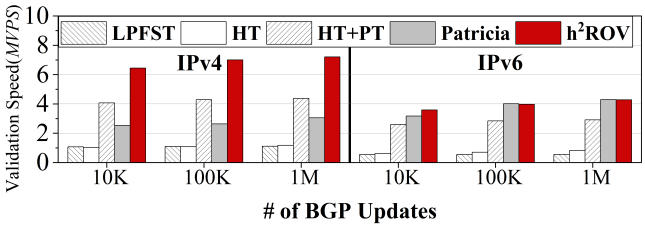

Figure 20: The validation speed with different volume of BGP updates.

6.3.2 Volume of BGP updates

To investigate the impact of BGP update volume on ROV validation speed, we use the datasets `ROA_2024` and `BGP_SIZE`. As depicted in Figure 20, our results demonstrate a consistent pattern across all ROV schemes: validation speed gradually increases with the growing number of BGP updates. This is because extracting more BGP updates increases the cache hit rate due to redundancy in BGP updates, leading to a gradual rise in validation speed.

6.3.3 Distribution of validity states

As RPKI adoption grows, the increasing issuance of ROAs will alter the distribution of route validity states. To measure the impact of these changes on validation speed, we evaluate ROV schemes using the datasets `ROA_2024` and `BGP_ROV`.

The experimental results are shown in Figure 21 and Figure 22. `LPFST`, `HT+PT`, and `Patricia` show a decreasing trend in validation speed compared to the current state (nearly 50% *valid*), as the ratio of *valid* results increases in both IPv4 and IPv6. These ROV schemes achieve the fastest validation when the ratio of *notFound* results is highest. In contrast, `HT` shows an increasing trend in validation speed as the ratio of *valid* results rises. However, it remains slower than `h²ROV` due to the *AB Model*, which prevents `HT` from finding a matching ROA directly. Overall, `h²ROV` outperforms all other ROV schemes when the ratio of *notFound* results is below 40%, a scenario reflecting the future RPKI deployment levels.

6.3.4 Incremental IPv6 deployment

To analyze the impact of the incremental IPv6 deployment, we use datasets `ROA_2024` and `BGP_IP46` to measure the validation performance of five ROV schemes under different proportions of IPv4 and IPv6 BGP updates.

As shown in Figure 23, as the proportion of IPv6 BGP updates increases, a noticeable decline in validation speed is observed for `h²ROV`, `LPFST`, `HT`, and `HT+PT`, while `Patricia` shows an increase in validation speed. The validation speed of `h²ROV` decreases from 6.53 MVPS to 3.99 MVPS as the IPv6 proportion rises from 0% to 100%. However, it still demonstrates significantly better validation performance than `LPFST`, `HT`, and `HT+PT`, except at 100% IPv6 updates, where its speed is just 0.028 MVPS lower than `Patricia`.

6.4 System Performance Evaluation

In the system evaluation, we first measure the average delay introduced by ROV in the *BGP decision process* during normal BGP update reception. We implement five ROV schemes in `FRRouting` and `BIRD` and evaluate them using datasets `ROA_2024` and `BGP_RRC00`. Based on experimental results, `h²ROV` introduces the least average delay to the *BGP decision process* at 19.8%(5.9%) , achieving reduction of 10.4%(13.3%) $\sim$ 56.1%(61.4%) compared to other ROV schemes in `FRRouting` (`BIRD`).

Next, we replicate a real update burst event to evaluate the impact of ROV on average BGP update processing delay during sudden high-volume updates. Using 340K BGP updates from `BGP_RRC00` replayed in a small-scale testbed, Figures 24 and 25 reveal a significant increase in average processing delay during the burst, exacerbated by ROV enforcement. Overall, `h²ROV` exhibits the least impact compared to other ROV schemes. When the average processing delay reached its peak (282nd second), `h²ROV` introduces the smallest average processing delay, reducing it by 48.8%(46.9%) $\sim$ 83.2%(70.9%) compared to other schemes with `FRRouting` (`BIRD`).

Finally, we evaluate the impact of ROV on BGP convergence time in the fully ROV-deployed scenario across real-world and generated topologies, based on our team's self-developed emulation platform [20]. The real-world topologies are constructed using data from the CAIDA's AS relationships [21]. The first real topology includes the top 100 ranked ASes, where ROV deployment is assumed to be more prevalent, following suggestions from studies [3, 22] to prioritize high-ranking or Tier-1 ASes. The second real topology is the South Korean network, chosen for its regional completeness, supported scale in the emulation platform, and the real-world KT network outage incident [23]. We source the top 100 ranked ASes from AS Rank [24] and Korea ASes

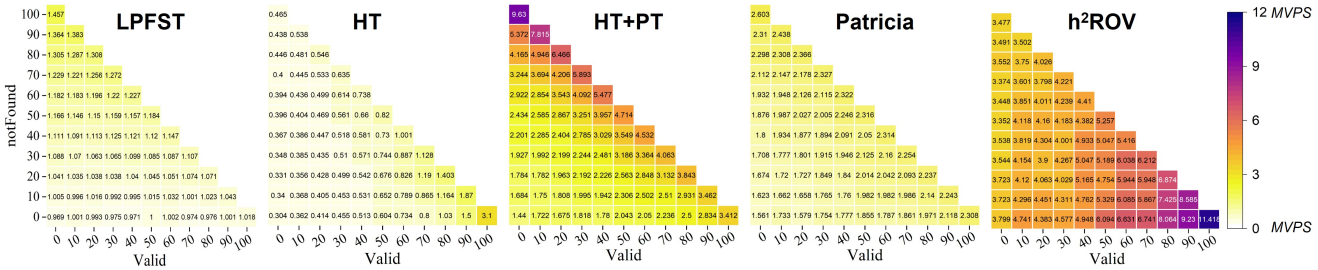

Figure 21: The validation speed of five schemes with different distributions of validity states of routes in IPv4.

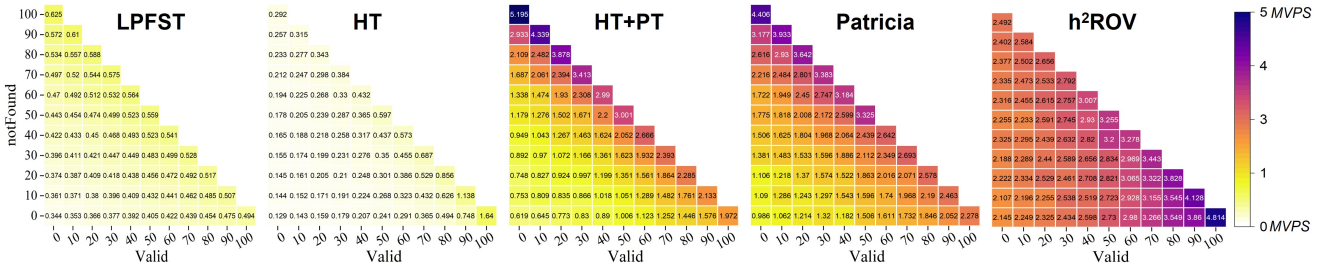

Figure 22: The validation speed of five schemes with different distributions of validity states of routes in IPv6.

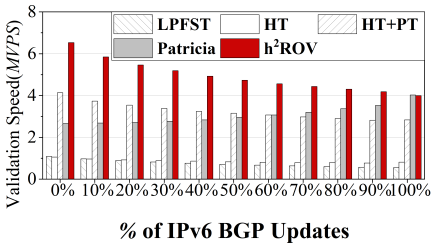

Figure 23: The validation speed with different IPv4/IPv6 updates ratio.

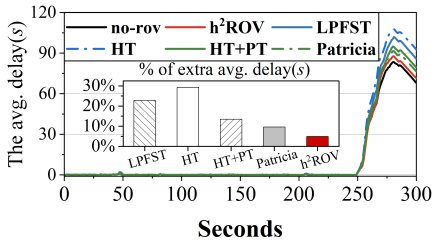

Figure 24: The average processing delay with `FRRouting`.

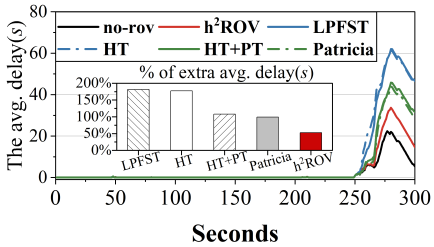

Figure 25: The average processing delay with `BIRD`.

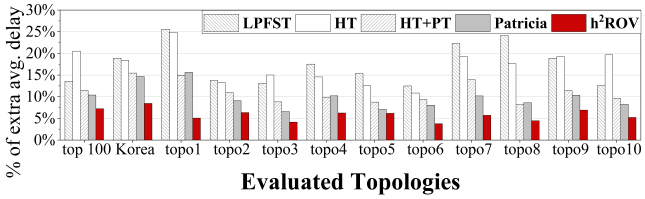

Figure 26: The average proportion of ROV delay in the BGP convergence time.

from Hurricane Electric [25]. Then, we derive sub-graphs containing top 100 ranked ASes and Korea ASes from the complete topology built using CAIDA AS Relationship data on June, 2024 as top 100 topology and Korea topology. The top 100 topology has 100 nodes and 1,916 edges, and the Korea topology has 803 nodes and 1,413 edges. Furthermore, ten AS topologies with statistical parameters aligned with known AS topologies are constructed using the Hyperbolic Graph Generator [26]. Each topology has 1K ASes, an average node degree of 6.4 which is the value observed in the CAIDA AS level topology [21] on June 2024, and a power-law degree distribution with an exponent of 2.1, as in [27, 28]. The AS transit delay is set to 1 ms for all topologies. Once the BGP nodes in the topology are initiated and neighbor relationships are established, BGP updates from the dataset `BGP_RRC00` are injected into the node with the highest connectivity. The BGP convergence time is measured from the start of route reception until all routing tables stabilize without further changes [29]. We evaluate the impact of ROV implementation on convergence time under both normal route updates and update burst scenarios. In the normal scenario, BGP updates were transmitted according to the timestamps in the dataset, whereas in the burst scenario, all updates were transmitted simultaneously. Under normal operating conditions, the convergence time increased only by 1.1% $\sim$ 9.5%. However, during the update burst scenario, ROV-induced routing convergence delays were substantial, reaching up to 8.0% $\sim$ 25.6%. As shown in Figure 26, `h²ROV` increases the convergence time by only 3.8% $\sim$ 8.5%. Specifically, in real-world network topologies, it mitigates ROV-induced routing convergence delays by up to 30.4% $\sim$ 64.7%, while in generated topologies, the mitigation reaches up to 12.5% $\sim$ 81.6%. In summary, `h²ROV` exhibits the minimal impact on convergence time.

7 Related Work

Measurement of ROV enforcement. The quantification of ROV adoption is important to assess its effect in protecting the

inter-domain routing system. Generally, measurement of ROV enforcement can be conducted with uncontrolled BGP data analysis [22] or enhanced passive monitoring [30]. On the other hand, active probing techniques [3, 31] have been used to improve the accuracy. While hybrid approaches [32] and multi-plane analysis [33] achieve better trade-offs between accuracy and efficiency.

Boosting the security benefit of ROV. Partial RPKI deployment limits the security benefit of ROV. It has been demonstrated that Tier-1 ISP adoption [22, 34] and transit provider prioritization [3, 30] maximize effect of ROV in stopping route hijackings. While ROV++ [35] introduces a series of optimizations that can prevent over 90% of subprefix hijackings with a low rate of ROV adoption. Besides, provider-origin validation [4] has been proposed towards asymmetric trust relationships, and RPKIN [36] enables collaborative hijack containment via neighbor notifications.

Advances in ROV implementation. IETF has standardized RPKI ROV [9] for years, its reference implementation using linear search has been outdated. RTRLib [6] employs a Longest Prefix First Search Tree (LPFST) to simplify the validation process at the cost of poor scalability. BIRD [7] introduces a hybrid approach combining prefix trie and hash tables together to improve the comprehensive performance. While BGP-SRx [8] employs a Patricia tree to accelerate the validation, outperforming other solutions.

8 Discussion

8.1 Performance Limitation of h²ROV in IPv6

The basic h²ROV scheme incurs linearly scaling hash probes on the STT relative to route prefix length. In IPv4, our level-bitmap optimization bounds this to a constant three probes, yielding O(1) time complexity. In IPv6, however, the 128-bit address space precludes direct application of level bitmaps. While our binary search approach reduces the complexity to O(log n), it achieves less pronounced speedups than IPv4's constant-time validation. Consequently, h²ROV's performance in IPv6 shows marginal improvements over existing schemes; it is even slightly slower than Patricia in some cases. Our future work will explore heuristic strategies [37] to bridge this performance gap, potentially aligning IPv6 efficiency with IPv4's deterministic guarantees.

8.2 Hardware Implementation Guidelines

Modern hardware routers implement control plane functions—including BGP decision processes and RPKI-based validation—via software stacks [38, 39] running on general-purpose CPUs. Critically, these workflows exhibit structural parity with software router implementations. Consequently, empirical insights we have learned from integrating h²ROV into software routers directly inform its deployment in hardware environments. Two implementation requirements persist across both platforms: (1) augmenting the PDU handler to construct ROV rules with the bitmap encoding, and (2) substituting the legacy route origin validator with h²ROV's validator module that can boost the performance.

8.3 Incremental Deployment of the AP Model

The *AP model* advances the conventional *AB* framework through a redefined validation process with structured encoding format of validation rules. Its deployment occurs in two backward-compatible phases. In the first phase with legacy compatibility, routers operate without RTR protocol modifications, but require h²ROV's validator as well as its encoder. While the encoder introduces marginal overhead, the cost is dwarfed by h²ROV's aggregate performance gains. Crucially, adoption of the *AP model* remains optional per router, allowing autonomous cost-benefit analysis by operators. In the second phase, when RTR PDUs with bitmap-encoded ROV rules become available[5], h²ROV's encoder can be bypassed. Critically, both phases can operate concurrently within a single administrative domain, enabling incremental *AP model* adoption without stranding legacy infrastructure.

9 Conclusion

While ROV remains a critical defense against BGP hijacking, existing AB-model systems struggle to scale with the increasing volume of ROV rules and velocity of BGP updates. Our proposed AP model and its instantiation, h²ROV, address this challenge through prefix-granular validation, reducing IPv4 lookup complexity to O(1) via level-bitmap optimization. However, IPv6's sparse address hierarchy limits these gains, as h²ROV's binary search adaptation achieves only O(log n) complexity. The integration of h²ROV into BIRD and FRRouting demonstrates its compatibility with classic router control planes, providing a practical pathway for hardware router adoption. The source code of the reference implementation of h²ROV is available at https://github.com/FIRLab-CNIC/h-2ROV.

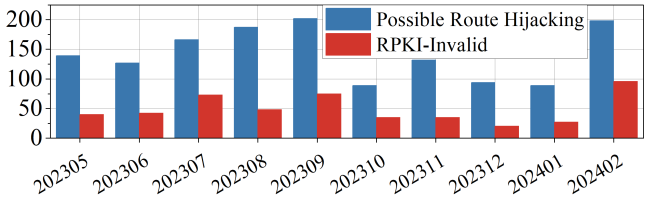

Figure 27: The number of hijacked route prefixes and those protected by ROAs.

A ROA-Protected yet Hijacked Route Prefixes

This appendix provides supplementary results for the measurement described in Section 1.

We measured the number of hijacked prefixes and the number of prefixes for which ROAs were issued. BGPMon [5], a well-known BGP anomaly detection platform[6], reports daily hijacking events. We use reported hijacking events collected from May 1, 2023-February 29, 2024, to measure the number of hijacked prefixes. Then, we identify whether these hijacked route prefixes are protected by RPKI using a set of ROAs archived by RIPE NCC on the same day. As shown in Figure 27, 21% $\sim$ 48% of route prefixes are protected by ROAs but are still hijacked, primarily due to the low ROV adoption rate.

B Theorem Proof

This appendix provides proof of Theorem 1 introduced in Section 3.3.

Definition 8 *Given a prefix p, the first n bits of p are denoted by* $BIT(p,n)$.

Definition 9 $p_i \subseteq p_j$ *if and only if* $BIT(p_i,|p_j|) = BIT(p_j,|p_j|)$ *and* $|p_j| \leq |p_i|$.

Proof. If $rp \nsubseteq R.pfx$, there are two cases according to Definition 9:

[6] It has ceased to offer free service to the public since February 2024.

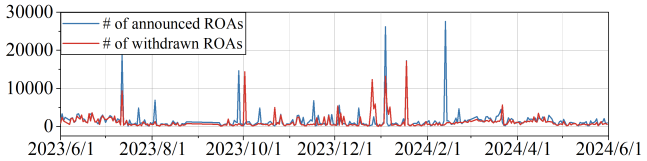

Figure 28: The number of daily announced and withdrawn ROAs.

1. $|R.pfx| > |rp|$, or
2. $BIT(R.pfx, l) \neq BIT(rp, l)$, where $l = |R.pfx|$

For the first case, according to the Definitions 6 and 9, $\forall p \in AP_{set}(R), |p| \geq |R.pfx|$, thus we can get $\forall p \in AP_{set}(R), |p| > |rp|$. Therefore, $\forall p \in AP_{set}(R), rp \nsubseteq p$.

For the second case, according to the Definitions 6 and 9, $\forall p \in AP_{set}(R), BIT(p,l) = BIT(R.pfx,l)$, where $l = |R.pfx|$, thus we can get $\forall p \in AP_{set}(R), BIT(p,l) \neq BIT(rp,l)$. Therefore, $\forall p \in AP_{set}(R), rp \nsubseteq p$.

To sum up, in both cases, rp cannot be a sub-prefix of any authorized prefix in $AP_{set}(R)$. Therefore, we conclude

$$rp \nsubseteq R.pfx \implies \forall p \in AP_{set}(R), rp \nsubseteq p. \tag{4}$$

If $\forall p \in AP_{set}(R), rp \nsubseteq p$, according to Definition 7,we have $R.pfx \in AP_{set}(R)$, then $rp \nsubseteq AB.pfx$. Therefore, we can obtain

$$\forall p \in AP_{set}(R), rp \nsubseteq p \implies rp \nsubseteq R.pfx \tag{5}$$

By combining Eqs. 4 and 5, we prove Theorem 1.

C The Number of Daily Updated ROAs

This appendix provides additional results regarding the number of ROA updates, supplementing the analysis presented in Section 6.2.3 of the main text.

In this section, we measured the number of daily updated ROAs, including both announced ROAs and withdrawn ROAs. We collected the updated ROAs at 30-minute intervals from June 1, 2023 to May 31, 2024 provided by RPKIViews [40]. Then we calculated the number of updated ROAs generated in each interval and sum them up to obtain the total number of updates per day. The result is shown in Figure 28. Obviously, the number of daily updated ROAs is relatively small.

D More Experimental Results

D.1 Memory Usage Compared to RIB

This appendix provides additional results regarding the memory usage of five ROV schemes compared to RIB, supplementing the analysis presented in Section 1.

Table 3: The memory consumption of ROAs of five schemes compared to that of RIB in the current scenarios.

the size of ROAs (MB)			the size of RIB (MB)
	current	future	current
LPFST	48.79	109.40	111.92 (FRRouting) 102.56 (BIRD)
HT	20.97	43.31	
HT+PT	88.70	199.25	
Patricia	78.98	179.00	
h²ROV	21.19	23.25	

To evaluate the additional memory overhead introduced by ROV across five schemes, we conducted a comparative analysis in two scenarios: the current real-world environment and a projected future scenario reflecting increased RPKI adoption. For the current scenario, we used the dataset ROA_2024 to calculate the size of ROV rules. In the future scenario, we assume that all route prefixes will be authorized by ROAs. Therefore, we used BGP updates in dataset BGP_RRC00 as a reference for the issued ROAs. In addition, we use BGP RIB from RRC00 on August 25, 2024 to evaluate the size of RIB. In both scenarios, we evaluated the memory overhead of five schemes used for ROV rule maintenance on two widely-used software routers: FRRouting and BIRD. As shown in Table 3, the memory requirements of existing ROV schemes are significantly lower than those of the RIB in the current environment. However, as RPKI adoption progresses, the memory consumption of these schemes (except for h²ROV) may become comparable to or even significantly exceed that of the RIB. It is noteworthy that h²ROV maintains consistently minimal memory overhead in both current and future scenarios, representing a significant improvement over existing solutions.

D.2 Stability of Results

This section explains why the average of 100 runs was used as the experimental result at the beginning of Section 6.

To evaluate the performance stability of all ROV schemes, both implementations were subjected to 100 independent experimental trials with datasets BGP_RRC00 and ROA_2024, and visualized the results using box plots. As depicted in Figure 29 and Figure 30, the box lengths of all box plots are relatively short, and the median is close to the mean, indicating stable validation speed across trials. Therefore, all experimental results presented in this paper are based on the average of 100 runs.

D.3 Original VS. Refined

This appendix provides additional results for the experiments described in Section 6.2.2.

We compare the validation speeds of the original and refined versions of h²ROV using the BGP_20C dataset. The results, shown in Figures 31 and 32, clearly indicate that the

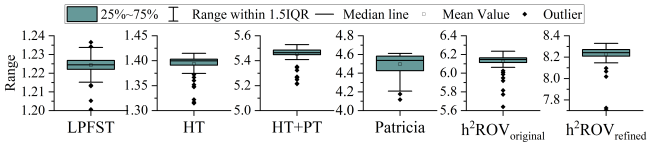

Figure 29: The validation speed (MVPS) distribution across 100 runs in IPv4.

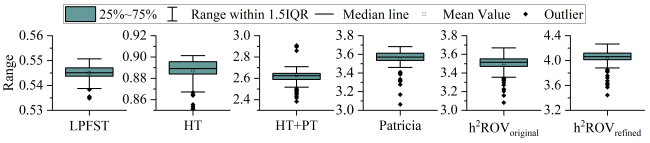

Figure 30: The validation speed (MVPS) distribution across 100 runs in IPv6.

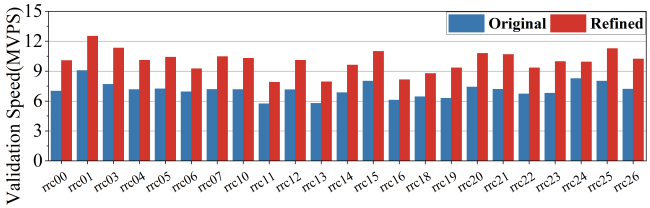

Figure 31: The validation speed of original and refined versions of h²ROV across different sets of BGP updates in IPv4.

refined version consistently outperforms the original version across different collectors.

E More Details about Datasets

This appendix provides further details regarding datasets utilized in the experimental evaluation presented in Section 6.1.

The ROA datasets comprise `ROA_13Y` and `ROA_2024`, both sourced from RIPE NCC. The dataset `ROA_13Y` contains ROAs collected annually on January 1 from 2012 to 2024, while the dataset `ROA_2024` contains ROAs from August 25, 2024. The BGP datasets consist of `BGP_RRC00`, `BGP_13Y`, `BGP_20C`, `BGP_ROV`, `BGP_IP46`, and `BGP_SIZE`. The dataset `BGP_RRC00` contains BGP updates collected by `RRC00` on August 25, 2024. The dataset `BGP_13Y` contains BGP updates provided by `RRC00` on January 1 of each year between 2012 and 2024. The dataset `BGP_20C` contains BGP updates collected from 20 RIPE RIS collectors on August 25, 2024. The dataset `BGP_ROV` is randomly generated based on `ROA_2024`, forming 66 subsets with 10% incremental ROV result proportions, each containing 100K updates. These randomly generated BGP updates are constructed as follows: the origin AS in each BGP update is randomly generated, and the IP prefix is generated by first creating a random 32-bit or 128-bit IP address, then selecting a mask length at random, and finally setting the bits beyond the mask length to 0. The dataset `BGP_IP46` is derived by sampling 400K updates from `BGP_20C` and adjusting the proportion of IPv4 and IPv6 updates in 10% increments, producing 11 subsets. Similarly, The dataset `BGP_SIZE` constructed from `BGP_20C` but varying the number of BGP updates to three predefined sizes: 10K, 100K, and 1,000K. Among these, `BGP_RRC00`, `BGP_13Y`, and `BGP_20C` are based on real-world BGP traces, whereas `BGP_ROV`, `BGP_IP46`, and `BGP_SIZE` are either randomly generated or selected according to predefined rules. Details about `BGP_RRC00`, `BGP_13Y`, and `BGP_20C` are presented in Table 4.

PreAcher: Secure and Practical Password Pre-Authentication by Content Delivery Networks

Shihan Lin[1], Suting Chen[2], Yunming Xiao[3]*, Yanqi Gu[4], Aleksandar Kuzmanovic[2], Xiaowei Yang[1]
[1] *Duke University,* [2] *Northwestern University,* [3] *University of Michigan,* [4] *University of California, Irvine*

Abstract

In today's Internet, websites widely rely on password authentication for user logins. However, the intensive computation required for password authentication exposes web servers to Application-layer DoS (ADoS) attacks that exploit the login interfaces. Existing solutions fail to simultaneously prevent such ADoS attacks, preserve password secrecy, and maintain good usability. In this paper, we present PreAcher, a system architecture that incorporates third-party Content Delivery Networks (CDNs) into the password authentication process and offloads the authentication workload to CDNs without divulging the passwords to them. At the core of PreAcher is a novel three-party authentication protocol that combines Oblivious Pseudorandom Function (OPRF) and Locality-Sensitive Hashing (LSH). This protocol allows CDNs to pre-authenticate users and thus filter out ADoS traffic without compromising password security. Our evaluations demonstrate that PreAcher significantly enhances the resilience of web servers against both ADoS attacks and preserves password security while introducing acceptable overheads. Notably, PreAcher can be deployed immediately by websites alone today, without modifications to client software or CDN infrastructure. We release the source code[1] of PreAcher to facilitate its deployment and future research.

1 Introduction

Websites have been using web authentication to identify users and protect user accounts for decades. Despite alternatives exist [57, 74, 87], websites still heavily rely on password authentication because of its high usability [28, 33]. According to the estimate by prior studies [28, 101] in 2023, more than one-third of websites contain password login interfaces. However, researchers have expressed the concerns about password authentication's security defects, and a long-standing one is Application-layer Denial of Service (ADoS) attacks [2, 41].

ADoS refers to the attacks where attackers aim to deplete a server's resources by sending merely a small number of requests. Differing from Distributed Denial of Service (DDoS) attacks, the traffic volume in ADoS is much less than that in DDoS, so it will not trigger the commonly used DDoS defense [7, 15]. Password authentication is vulnerable to ADoS attacks because it demands intensive computation. Presently, a server stores a password' hash value instead of the cleartext in its database to prevent password cracking in case the database is compromised [14, 31, 36]. Thus, the server computes the hash value of a password and check it against the record in its database. However, a server must use a slow hash function, such as scrypt [81], PBKDF2 [77], or Argon2 [32], for password hashing, in order to slow down brute force guessing when an attacker captures the database. Therefore, this practice makes password authentication compute-intensive. In § 2.1, we present a proof of concept for such ADoS attacks on the Internet, where merely 150 login requests per second can deplete all four modern CPU cores [10] on a server.

In today's Internet, ADoS can occur during credential stuffing [18, 19] incidents. In such cases, attackers use automated bots to repeatedly attempt login with various combinations of usernames and passwords, aiming to impersonate legitimate users. Akamai reports that it detects an average of 280 million suspicious bot logins per day [18]. Such a large number of illegal logins not only poses security concerns on the safety of user accounts, but also imposes a prohibitively high workload on a web server , due to the slow hashing requirement of password authentication.

Presently, there is no effective defense against the ADoS attacks that exploit password authentication. Existing approaches fail to simultaneously achieve the goal of avoiding server overload, preserving good usability, and providing password secrecy. In practice, websites usually adopt rate limit, CAPTCHA, and two-factor authentication (2FA) in login interfaces [25]. However, attackers can bypass rate limits by switching to different usernames and IP addresses and thus keep sending login traffic. As for CAPTCHA and 2FA, they are criticized for their usability by both users and researchers [39, 47, 48, 55, 64, 99]. Although 2FA prevents user account cracking, it does not reduce the workload of failed

*Yunming Xiao is the corresponding author.
[1] https://github.com/SHiftLin/NSDI2025-PreAcher

logins because the server needs to verify the password as the first factor. Currently, some Content Delivery Network (CDN) providers such as Akamai and Cloudflare have deployed bot detection mechanisms to help websites filter out the login traffic generated from bots [18, 25]. However, these bot detection mechanisms use machine learning and behavior analysis to detect bot requests and cannot deterministically avoid false positive or false negative results. Besides, websites have to allow a CDN to inspect their traffic from users, leading to password exposure to the CDN [35, 101].

In addition, a website may delegate password authentication to a third party by using the service of an authentication provider like Auth0 [3] or using the Single Sign-On (SSO) scheme such as OpenID [21] and OAuth [53]. Such delegated authentication releases the burden of user verification on the server. However, it is not suitable for security-sensitive websites such as banks that cannot trust a third party for user authentication. Additionally, delegated authentication introduces a single point of failure where a vulnerability in a single delegate affects millions of user accounts [89], as exemplified by the recent Google OAuth incident [26].

Motivated by the concerns above, we propose a novel web authentication architecture named *PreAcher* to securely offload the password authentication to a third-party CDN without divulging user passwords to the CDN. Our insight is that traditional password authentication were designed between two parties, *i.e.* a client and a server, before CDNs became an essential component in the web ecosystem. Consequently, they were not able to prevent ADoS attacks and password leakage simultaneously. Differently, we design the PreAcher architecture to incorporate a CDN into the password authentication process. At a high level, PreAcher deploys password-agnostic "*pre-authentication*" on a CDN to intercept failed login requests, relieving the server from unnecessary authentication workload. Specifically, when a user sends a login request to a website, the CDN first pre-filters the password without knowing the exact user password. Only when the password is highly likely to be correct, then will the CDN forward the password to the origin server for final authentication. This design enables a CDN to filter out most of the login requests with incorrect passwords, including those malicious ones intended for ADoS/DDoS attacks and account cracking.

To meet our goal of preventing ADoS attacks while protecting password secrecy, we face two main design challenges. The first challenge arises from enabling a CDN to efficiently pre-filter a password without exposing the actual password to it. In this paper, we assume a CDN as a honest-but-curious adversary where it will operate the functionalities and protocols faithfully but may have unintentional bugs exploited by attackers to peek at or guess user passwords through the messages in transmission [49, 75, 76]. To defend against such an adversary, we combine Oblivious Pseudorandom Function (OPRF) [37] and Locality-Sensitive Hashing (LSH) [58] to design a novel three-party authentication protocol involving a client, a CDN, and a server in PreAcher. This protocol not only hides the password in the login requests but also prevents a CDN from guessing the passwords, thereby efficiently safeguarding and verifying user passwords.

The second challenge concerns compatibility issues. The proposed pre-authentication protocol involves new operations of the CDN, the client, and the web server, which inevitably raises the concerns on compatibility. We elaborately design PreAcher's architecture to be compatible with the current web ecosystem. Specifically, we implement PreAcher's CDN operations on the existing serverless computing services [61], such as Akamai EdgeWorkers [1], AWS Lambda [9], and Cloudflare Worker [8]. These services allow web developers to run customized request processing functions on a CDN's edge servers. Besides, we implement all client operations as a JavaScripts library, which are imported into the web pages and seamlessly installed in the browser when a user visits the website. Therefore, a website can immediately deploy PreAcher unilaterally to safeguard its server.

To sum up, this paper makes the following contributions:

1. We design and implement the first secure and practical three-party password authentication architecture that incorporates a client, a CDN, and a server, *PreAcher*. PreAcher not only protects websites from ADoS/DDoS attacks exploiting the login interfaces but also prevents password exposure to third-party CDNs.
2. PreAcher can be immediately deployed in the current web ecosystem by a website unilaterally without any modification of web clients, CDNs, or hardware.
3. We conduct comprehensive analysis and evaluations on PreAcher, and the results show that it enhances the password security and servers' resistance to ADoS attacks. Besides, the security of the proposed authentication protocol in PreAcher is formally proved (Appendix § D). We also show that it introduces acceptable overhead to the throughput and latency of the login process.

Ethical concerns: This work does not raise any ethical concerns. We use our own server as the victim in all experiments, and the network traffic volume we send to the Internet is small ($< 10Mbps$).

2 Background, Threat Model, and Goals

In this section, we first review the ADoS attacks exploiting password login interfaces. We also present a proof-of-concept experiment of initiating such ADoS attacks towards a web server behind a commercial CDN's protection service. Then we introduce the service model of the CDN used in this paper before we present our threat model and assumptions. Finally, we propose the design goals of our solution.

2.1 ADoS Attacks on the Password Login

Password logins are one of the most popular features on websites. To securely verify user passwords, web servers must compute the hash values of passwords [28], as they store only

the salted hash values [14], rather than the plaintext, due to the risk of data breach [24]. Furthermore, the hash function used in password verification must be slow hashing, such as scrypt [81], PBKDF2 [77] and Argon2 [32], so that an attacker who captures a password database still needs a long time to brute-forcedly crack the passwords [14, 31, 36]. Therefore, password hashing is deliberately designed to require intensive computation. As the modern processors become more powerful, password hashing also evolves to remain workload intensive on those processors. For example, PBKDF2's iteration number is recommended to increase from 1000 in 2000 [77] to 10000 in 2017 [51]. Additionally, new algorithms like Argon2 [32] are computationally intensive on both modern CPUs and GPUs. However, such intensive computation also affects the server's throughput in verifying user login requests, leading to not only possible server overload during concurrent user logins but also the vulnerability of ADoS attacks [2, 22, 23].

Different from DDoS attacks where attackers generate volumetric network traffic to the victim server, ADoS usually needs much less traffic to crash the server because of the asymmetric computation between a client and the server, such as the login request processing as mentioned above. An attacker can send a few login requests to consume up all the server's computing resources and block valid users from login.

Proof of concept. We present an experiment to show the feasibility of ADoS attacks on a server behind a commercial CDN through the login interface. We set up a Virtual Machine (VM) of with 4 vCPUs (Intel Xeon E-2288G [10]) and 16 GiB memory on Azure as the web server. We also employ one of the largest commercial CDNs and pay for its DDoS protection, bot detection, and Web Application Firewall (WAF). The CDN applies a rate limit of around 10 req/sec per IP address on the requests. We use a desktop computer in our university as the client. The server hosts a typical password login page, and every login request is enforced to traverse through the CDN to reach the server. Our goal is to use the client as an attacker to deplete the server's CPUs by login requests.

We implement two password hashing algorithms on the server: PBKDF2 [77] and Argon2 [32]. The former is a traditional algorithm standardized in 2000, while the latter is the state-of-the-art one proposed in 2016. We configure the iteration number of PBKDF2 as 10000, which is the default value of OpenSSL [13] and is recommended by NIST [51]. As for Argon2, we use the recommended parameters by OWASP [14]: 19 MiB of memory, 2 iterations, and 1 degree of parallelism. In both cases of server implementation, the client uses Puppeteer [16] to control Chrome to send 150 login requests per second as the attack traffic to the server. This attack lasts for one hour and the requests contain randomly generated login credentials. The client also adopts the distributed proxies of Bright Data [5] to send requests with different source IP addresses.

In both cases of PBKDF2 and Argon2, we observe that the CDN does not intercept any request, and the server's CPU utilization stays around 100% during the one-hour attack. Besides, the server cannot respond to any other user requests. Therefore, we successfully bypass the commercial CDN's protection and launch ADoS attacks on the victim server.

2.2 CDN Service Model

PreAcher leverages third-party CDNs, such as Akamai and Cloudflare, for pre-authentication due to their extensive networks of distributed edge servers around the world. These edge servers provide sufficient computing and network resources to defend against DoS attacks. However, researchers have raised security concerns about CDNs: to enable a third-party CDN to serve the HTTPS connections from clients, websites have to share their TLS private keys to the CDN [35, 68]. This practice allows a third-party CDN to access the private data transferred in HTTPS connections between users and websites [54, 69], such as user passwords [101]. In addition, researchers also showed that attackers can exploit a CDN's configuration error to fetch the transferred private data [49, 75, 76]. Therefore, in PreAcher's design, we aim for not only defending against ADoS attacks but also preventing the password exposure to CDNs.

In this paper, we refer to the web server hosted by a website and hidden behind a CDN as the "*origin server*" or simply "*server*". We use the term "*user*" to denote a website's user rather than a CDN's user. A user accesses a website through a web "*client*" such as a browser. We describe an attacker as being "*inside*" a CDN when it exploits a vulnerability within the CDN to gain internal privileges, or when it is a rogue insider of the CDN provider. For simplicity, we sometimes use "*CDN*" to refer to an attacker inside a CDN. Additionally, an attacker "*outside*" of a CDN refers to any malicious entity except for the CDN itself.

2.3 Threat Model and Trust Assumptions

Attackers inside CDNs. Prior studies [54, 69, 101] describe two threat models of a CDN as below:

1. **Passive attacker**: A CDN will honestly provide the functionalities it promises, but its components such as the log and the storage may contain unintentional bugs like configuration errors. An attacker can exploit these bugs to access to the data, but cannot modify a CDN's behavior. The attacker can eavesdrop on the messages transferred by a CDN but *cannot* tamper with, duplicate, or fabricate any message. For example, the attacker can observe the passwords or attempt to infer the passwords from the transferred messages. This model is also called a "*honest-but-curious*" model.
2. **Active attacker**: A CDN's component such as the control plane contains severe vulnerabilities that an attacker can exploit to not only eavesdrop on transferred messages but also tamper with, duplicate, and fabricate the messages. An active attacker is more powerful than a passive attacker.

In PreAcher, we assume a *passive attacker* inside a CDN due to the following reasons. 1) Researchers have shown that passive attackers could exist in commercial CDNs, such as web cache deception attacks [49, 75, 76], where attackers deceive CDNs to accidentally cache some users' private data and grant public access to the data. 2) Prior studies have proposed methods to ensure the integrity of CDN-hosted content based on a secure DNS channel [46, 69], which prevents a CDN from tampering with the message without being detected. PreAcher can adopt these methods to further defend against an active attacker. We leave the defense against active attackers for future work.

We note that a CDN will not launch DDoS/ADoS attacks on the hosted websites in our study, as the CDN is assumed to be a passive attacker.

Attackers outside CDNs. An attacker outside a CDN can actively manipulate the messages it interacts with. For example, it may gain access to a client's Wi-Fi router and alter, duplicate, or forge the transferred messages. We also consider it has the capability to launch ADoS or DDoS attacks. This may involve sending send a large number of login requests with various combinations of usernames and guessed passwords to the login interface of a website.

Origin servers. Since the origin server is the source of all web content, we trust the server for all users' sensitive data. We do not consider data breaches or web providers' misoperations on the server in this paper.

ADoS-resist registration. We assume the server's registration interface is resistant to ADoS. This assumption is achievable in reality. Firstly, since the registration is a one-time cost, a website can adopt complex CAPTCHA on the registration page without affecting the user experience of future visits. Besides, for those web services that are highly security conscious, the web provider can require a user to register an account offline. For example, a user may need to visit a local branch to open a bank account.

Trusted Computing Base. We trust the implementation of existing cryptographic libraries in the programming languages. We also trust the implementation of the hardware, browsers, and operating systems used by the client and server.

2.4 Design Goals

In this paper, we aim to design and implement a password pre-authentication system on CDNs with the following goals:

1. **Security**: Our system focuses on securing password authentication. It should prevent the ADoS attacks exploiting the login interface, while avoiding password exposure to CDNs or other attackers. Besides, the system should retain the CDN's security benefits such as DDoS protection and WAF. However, we do not aim to prevent ADoS attacks using other channels beyond password authentication, nor do we protect other sensitive data or private communications handled by the current CDNs beyond passwords.
2. **Compatibility**: Our system should be compatible with the current web ecosystem. Its deployment should not involve multiple stakeholders on the Internet. Our design achieves this by enabling websites to deploy the system unilaterally. The system does not require any modification on current browsers, CDN infrastructure, or operating systems. It only requires updating the website's login page and processing.
3. **Efficiency**: Our system should not introduce much overhead to the login procedure from the perspectives of throughput and latency.

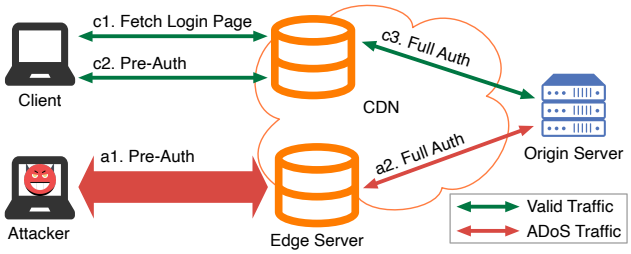

Figure 1: **PreAcher architecture. The width of arrows shows the traffic volume.**

Achieving these three goals simultaneously is non-trivial. We utilize both techniques of authentication protocols and the features of current web development practice and thus finally design and implement PreAcher shown in this paper.

3 Design Rationales

In this section, we first illustrate an overview of PreAcher. Then we discuss the design rationales of PreAcher.

3.1 Overview

The core of PreAcher is an authentication protocol involving three parties: the client, CDN, and the server. It includes a *pre-authentication* stage on the CDN and a *full authentication* stage on the server, which we will elaborate in § 4.

Figure 1 shows an overview of PreAcher. All components of PreAcher run on the application layer of the Internet for compatibility. When a user visits a website and intends to login, the web client (browser) fetches the HTML files of the website's login page from the CDN (`c1`). Since we assume a passive attacker in the CDN (§ 2.3), the CDN cannot modify the login page and thus cannot conduct phishing on user passwords. After the user types in her username and password on the web page, the client communicates with CDN to pre-authenticate the user (`c2`), which may include multiple round trips. Only if the client passes the pre-authentication, the CDN will forward the client's request to the origin server for full authentication (`c3`). If the server also successfully verifies the user's identity, it will return an indication of success to the CDN and the CDN finally notifies the user of a successful login. Otherwise, the client is rejected to login.

When an attacker attempts to compromise some accounts, it can instrument programs to directly send usernames and passwords to the CDN and start the pre-authentication (`a1`), without loading the HTML files into a browser. In most cases,

the pre-authentication will fail, and the CDN immediately rejects the requests without forwarding them to the server. Therefore, if the attacker sends login requests to initiate ADoS on the server, the CDN will filter out most of them to protect the server. Since the CDN conducts a pre-authentication which does not ensure 100% correctness of the credentials, some attack requests may still be forwarded to the server for full authentication (a2). However, the server will reject this portion of requests. Besides, we elaborately design the authentication protocol to ensure that the amount of these requests is small enough and will not lead to ADoS on the server.

3.2 HTTPS Compatibility

PreAcher is compatible with the current web ecosystem, and thus all communications among the client, the CDN, and the origin server use HTTPS connections, including the requests/responses of page loading, pre-authentication, full authentication, *etc.*. We keep current TLS private key-sharing practice between CDNs and websites, so the CDN can still access to the HTTPS payloads. In contrast, an attacker outside of a CDN cannot break HTTPS and view the content, since it does not have the TLS private key.

3.3 Private Communication After Login

PreAcher does not aim to protect general private communication between the client and the server. Instead, PreAcher focuses on preventing the password exposure and ADoS/DDoS attacks caused by current password authentication. A website can adopt the existing proposals, InviCloak [69], to build a secure channel between the client and server with the existence of a CDN and thus transfer the private data securely through the channel. Besides, after a success login, websites usually grant the client authentication cookies to avoid logins for future visits. PreAcher does not provide the protection of these cookies either, but websites can also use InviCloak to protect the authentication cookies.

3.4 Password vs Additional Key

Some design ideas may require a client to hold an additional key—such as a private key—after the registration. We decided not to adopt these designs because they conflict with current user behaviors: users are required to remember or save additional materials beyond the passwords. Although a web client can help a user to store the additional key, a user may change her web client. Thus, PreAcher adopts a design compatible with the current user behavior of memorizing the username and password only, which is arguably the most universal authentication method.

3.5 Preventing Offline Dictionary Attack

In an offline dictionary attack [29, 34, 82], an attacker obtains a dictionary of user passwords, enumerates all password candidates in the dictionary, and verifies the guessed password offline (locally) without communications with the server. Such an attack requires the attacker to find an approach to determine the correctness of the guessed password locally. For example, an attacker may obtain the hash value and the salt of the actual password so that it can compare the hash value of the guessed password with the actual hash value to know the correctness. Therefore, the attacker can enumerate all passwords in the dictionary locally until it finds the correct one, and it will not be detected by the server.

The defense against such an attack becomes particularly challenging when we consider a passive attacker inside a CDN in PreAcher's design. Generally, if a CDN can fully authenticate users to filter out all invalid requests, then the CDN can launch offline dictionary attacks. This is because the passive attacker can observe all transmitted messages and all computational states of the CDN during a legitimate user login. With this information, for each password the attacker guesses, it can simulate the authentication protocol between the client and the CDN to determine the password's correctness. Note that such an attack remains within the bounds of passive attacker behaviors since the simulation relies solely on observed data and is conducted offline.

Furthermore, if we prevent the CDN from obtaining any information about password correctness to thwart such offline dictionary attacks, the CDN will be unable to filter out the failed login requests for the server.

We addresses such a challenge based on two observations:

1. Although offline dictionary attacks are hazardous, *online* password-guessing attacks are considered much less risky since they are detectable and can be easily rate-limited by the origin server.
2. Currently, the state-of-art dictionary generation algorithms generate the passwords based on a user's historical passwords [80,102] or a user's personal information [91]. Thus, the password candidates in a dictionary should be similar to each other to some extent [56].

Therefore, in PreAcher, instead of granting a CDN the capability of determining the password correctness, we propose to only enable the CDN to determine the similarity between the provided password and the actual password. The CDN can still help the server filter out massive failed login requests with erroneous passwords that are not similar to the actual password, and it forwards the login requests with probably correct passwords to the server for further authentication.

Such a design prevents offline dictionary attacks initiated by a CDN because a CDN cannot verify similar passwords offline. By PreAcher's design, for those similar passwords in the dictionary, CDN cannot determine which one is the correct one, and it has to query the server to verify every similar password. Therefore, CDN can only guess the password online with the server.

The design still prevents ADoS attacks. For attackers outside the CDN, if it randomly generates the passwords, the portion of passwords that can pass the CDN's pre-authentication will be very small (see § 5). Moreover, as we analyze in

§ 6, it is difficult for attackers outside the CDN to identify the passwords that can reach the origin server and trigger an ADoS attack. Furthermore, even if they gain access to such passwords, since the password authentication is enforced to be online and shares a pattern of similarity, the attack is detectable by the server.

We describe the algorithm to enable a CDN to determine the similarity of passwords in § 5, which is based on Locality-Sensitive Hashing (LSH).

4 Authentication Protocol

As previously discussed, our protocol consists of two stages: the pre-authentication on the CDN and the full authentication on the server. Although the idea of this two-stage protocol is simple, instantiating such a protocol is non-trivial. In this section, we first present the protocol used in PreAcher, and then we discuss an intuitive but less efficient design.

4.1 PreAcher Protocol

The core idea of our protocol is to combine Oblivious Pseudo-random Function (OPRF) [37] and Locality-Sensitive Hashing (LSH) [58] to enable pre-authentication at a CDN while limiting its knowledge of password correctness.

OPRF is a protocol that allows two parties (Alice and Bob) to obliviously evaluate a PRF function $F(K;X)$, where Alice inputs K and learns nothing, and Bob inputs X and learns $F(K;X)$ without knowing K. In this paper, we use the 2HashDH OPRF proposed in prior work [59]. OPRF is also used by existing Password Authenticated Key Exchange (PAKE) protocols like OPAQUE [60]. Our protocol is inspired by OPAQUE but is different from its design in two aspects:

1. OPAQUE is designed for two-party authentication between the client and server. We extend OPAQUE to three parties.
2. By adding the CDN into the protocol, OPRF itself cannot solve the offline dictionary attacks by the CDN. Our protocol incorporates LSH to defend against the attacks.

Furthermore, the security of this proposed new protocol is also formally proved. We describe the workflow of the protocol in this section, and present the proof in Appendix D.

We first describe the notations used in the protocol below before we elaborate on the protocol details.

- The client obtains the username u and the password p from a user's input. The server generates a new key pair $\langle \mathsf{pk}_s, \mathsf{sk}_s \rangle$ during the deployment of the system. Note that this key pair is different from the TLS key pair.
- For clarity, the symbols with a subscript "$_u$" are related to a specific user u, and the symbols with a superscript "$'$" are related to pre-authentication, *e.g.* a user's key pair used for pre-authentication $\langle \mathsf{pk}'_u, \mathsf{sk}'_u \rangle$.
- The protocol builds upon a Diffie-Hellman cyclic group $G = \langle g \rangle$, where g is the generator, and n is the bit length of the group.
- H_1 is a cryptographic hash function, while H_2 is password hashing. *LSH* denotes a locality-sensitive hashing.

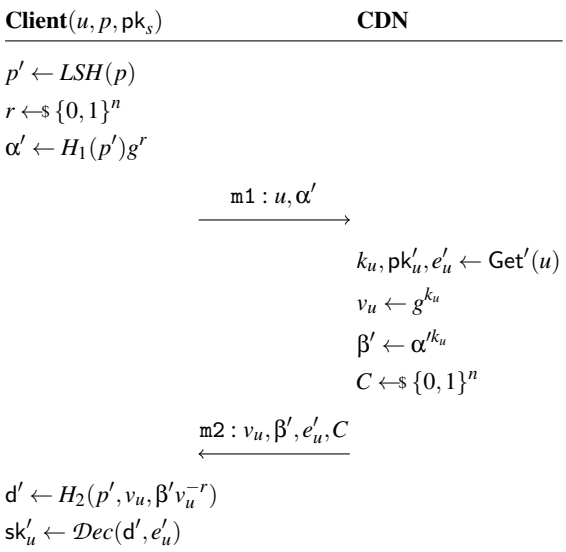

Figure 2: **First round of PreAcher login.**

- The protocol uses a CPA-secure symmetric encryption scheme $(\mathcal{K}g, \mathcal{E}nc, \mathcal{D}ec)$ and a CCA-secure asymmetric encryption scheme $(\mathsf{Kg}, \mathsf{Enc}, \mathsf{Dec})$.
- We use a standard digital signature scheme $(\mathsf{KGen}, \mathsf{Sign}, \mathsf{Vf})$ with existentially unforgeability under chosen-message attack (EU-CMA).
- $\mathsf{Save}(u, \cdot)$ (resp. $\mathsf{Save}'(u, \cdot)$) denotes saving the input into a user-associated record stored by the origin server (resp. CDN), while $\mathsf{Get}(u)$ and $\mathsf{Get}'(u)$ denote the retrieval of the corresponding records associated with a user u.

The protocol is divided into two phases: registration and login. During the registration, we assume trust on first use so the client can communicate directly to the server. The server first generates a random number k_u. Then the client and the server will use OPRF to compute a symmetric key d' through the password and k_u. The client generates a key pair $\langle \mathsf{pk}'_u, \mathsf{sk}'_u \rangle$, and encrypts the sk'_u into an envelope e'_u with the key d'. The server sends $k_u, \mathsf{pk}'_u, e'_u$ to the CDN after the registration, and the CDN will use them to help the server pre-authenticate users and filter out invalid login requests. The client also registers the user with the server by traditional password hashing (without exposing the password to the CDN), which will be used for full authentication on the server during login. Given space constraints, we leave more details of registration in Appendix A. For the rest of this section, we focus on the login protocol.

Initialization. A user inputs u and p to the client. The client obtains pk_s, and the server holds the corresponding sk_s. The server can delivered pk_s to the client with integrity by embedding it in the HTML of the login page as discussed in § 3.1. Besides, the CDN already received corresponding $k_u, \mathsf{pk}'_u, e'_u$ for registered users from the server.

Generating the secret key from the password. Similar to the registration, the client obtains the secret key d' through

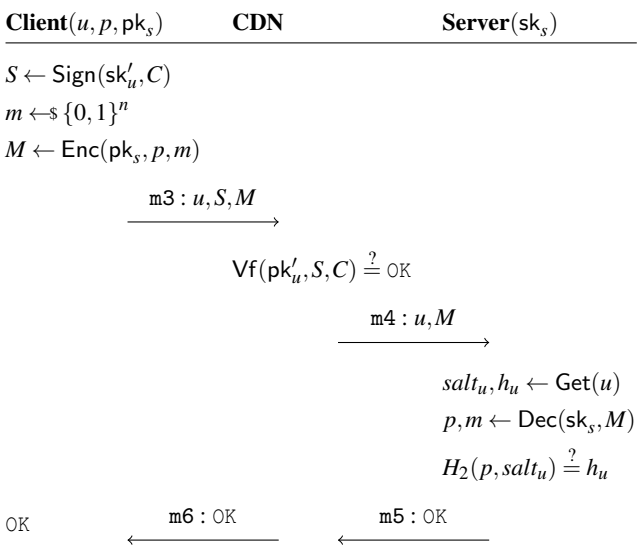

Figure 3: **Second round of PreAcher login.**

the combination of OPRF and LSH, but it communicates with the CDN instead of the server as shown in Figure 2.

Specifically, the client uses LSH to map the password p to a pseudo-password p'. Then it generates a random nonce r and computes α'. After receiving u and α' from the client (m1), the CDN retrieves k_u, pk'_u, and e'_u from the storage according to u. Then it computes v_u and β', and returns them to the client with e'_u and a challenge C (m2). The client computes d' through the same function in the registration.

Retrieving the private key from the envelope. With d', the client can decrypt e'_u to obtain the private key sk'_u which is generated in the registration. This completed the first round of PreAcher login.

Pre-authentication and full authentication. In the second round, the client computes the credentials for pre-authentication and full authentication, respectively. Then it sends them to the CDN and the server together to save the RTTs of the protocol. The procedure is shown in Figure 3.

For pre-authentication, the client signs C with sk'_u and send the signature S to the CDN (m3). Meanwhile, for full authentication, it encrypts p and a nonce m with pk_s and sends the encrypted message M to the CDN without concerns of exposing p (m3). Since the CDN stores pk'_u, it can verify the signature S. The pre-authentication succeeds if and only if the verification succeeds. If the pre-authentication fails, the CDN stops the protocol and sends an error message to the client, which is not shown in the diagram. When the pre-authentication succeeds, the CDN sends u, M to the origin server for full authentication (m4). Note the CDN cannot decrypt M to know p since it does not know sk_s.

When the server receives requests for full authentication, it retrieves $salt_u$ and h_u from records and decrypts M to authenticate the password p by comparing the calculated hash value with h_u. The authentication result is returned to the CDN (m5) and then to the client (m6).

Summary. The protocol uses two different asymmetric key pairs for pre-authentication and full authentication, respectively. For pre-authentication, the client's private key is enclosed in an envelope stored on the CDN with a symmetric encryption key. The encryption key is computed by OPRF from the password in the login. We combine LSH with the OPRF to limit the CDN's capability of guessing passwords. We will discuss how LSH achieves this in § 4.2.

As shown in the protocol, the pre-authentication uses the signature to verify the user, while the full authentication uses the traditional password hashing where the server sees the password and checks against the stored hash value. We expose the password to the server because we trust the server in our threat model (§ 2.3). Besides, we keep such a traditional method in the server to be compatible with the popular authentication implementation in practice. In addition, if we use signature verification and hide passwords from the server, one more RTT will be added to the protocol since a challenge number should be delivered to the client after the pre-authentication. Nevertheless, web operators can easily modify this full authentication approach if they consider the traditional method does not fit their demands.

4.2 Intuitive but Less Efficient Design

In the early stage of our study, we adopted straightforward hashing methods for pre-authentication. Overall, the client hashes p' to obtain $H_1(p')$. The CDN computes password hashing of $H_1(p')$, *i.e.* $H_2(H_1(p'))$, and checks it against with the one in the storage. We call such a double-hash protocol as "*DuoHash*". We illustrate the detail protocol of DuoHash in Appendix C.

However, we found that DuoHash is less efficient in practice, since the protocol runs a slow password hashing on the CDN for pre-authentication. Besides, this slow hashing cannot be replaced by a usual hash function like SHA-256, because such a replacement accelerates the brute-force guessing of p' when an attacker captures the CDN's storage [14,31,36]. For example, using OpenSSL implementation on our testbed, SHA-256 is over 50,000 times faster than PBKDF2. With p', the attacker can simply construct the login requests that pass pre-authentication and thus launch ADoS attacks on the server. Therefore, password hashing is necessary in the double-hash design, leading to a significant performance downgrade of the CDN's edge servers. As a defense of ADoS and DDoS for the origin server, the CDN's operations should be as efficient as possible, so we opt for the OPRF design in this paper. Web developers could adopt DuoHash if they find it suitable for their applicatons, as outlined in our comparison of DuoHash and PreAcher in § 8.

5 Locality-Sensitive Hashing

As presented in § 4.1, we use LSH to map the password p to a pseudo-password p', and use p' in the pre-authentication. The

rationale behind this design is to reduce the CDN's ability to determine password correctness, thereby preventing offline dictionary attacks from the CDN as discussed in 3.5.

The LSH is designed to map a set of similar passwords to the same p' value, and thus, a portion of erroneous passwords can also pass the pre-authentication. Specifically, an attacker inside the CDN may launch offline dictionary attacks by generating a dictionary of password guesses and testing them locally to see which ones pass the pre-authentication. However, by using LSH, the best this attacker can do is to find that a portion (determined by LSH) of passwords are hashed to the correct p', and they are all possibly the actual password. Thus the attacker has to enumerate this portion of passwords and send online requests to the server for full authentication, but the server will reject this login request unless the correct password is guessed. Leveraging LSH, the CDN only knows that a provided password may be similar to the correct one locally. This achieves our purpose of enforcing the CDN to conduct online queries to know the correctness.

For the passwords in a dictionary, we expect to see many of them mapped to the p' of the actual password, so that CDN gains little information through enumerating the passwords in the dictionary. However, to defend against ADoS attacks, we expect to reduce the probability of the passwords in the attack traffic mapped to the actual p' so that the CDN can filter out most failed logins. These two requirements align well with the design of LSH, and we can tune the parameters of LSH to balance the CDN's ability of inference and authentication.

In PreAcher, we use weighted K-mer MinHash [72] as the algorithm of LSH. A string s of length N is first converted to lowercase and then split into $N-K+1$ substrings called "K-mers" by a sliding window of length K. These K-mers form a sequence S, following the order of their positions in s. Formally, let $s[i:j]$ denotes the substring of s from index i to index j. We have

$$S = (s[1:K], s[2:K+1] \ldots s[N-K+1:N]) \quad (1)$$

Then we use weighted MinHash [96] to generate the hash value from S as follows. Since a K-mer (denoted as m) may appear multiple times in S, we use $m^{(w)}$ to denote w-th appearance of m in S. We use w as the weight in weighted MinHash. Then we adopt HMAC [63] with SHA-256 to hash the K-mers in S. Thus, we have a set T consisting of the hashed K-mers.

$$T = \{\mathsf{HMAC}(u, w \parallel m) \mid m^{(w)} \in S\} \quad (2)$$

In Formula 2, we use $\parallel$ to denote concatenation. Finally, we take the minimum element in T as the hash value of LSH.

We emphasize that our LSH design is preimage-resistant. Specifically, an attacker only knows that there exists a cluster of similar p to be mapped onto the same p', but it is difficult to determine the exact p that corresponds to a specific p'. This property originates from our two designs:

1. We use HMAC with SHA-256 to construct the LSH as shown above. As SHA-256 is preimage-resistant, the LSH is also preimage-resistant.
2. We include the username u in HMAC's input. Thus, the mappings from the p to p' vary across different users, further enhancing the resistance to preimage attacks.

We then analyze the collision probability of this LSH. Let c be the alphabet size of a password. Since the K-mer has a length of K and the hash value is generated from K-mers, the size of the hash value space is c^K. Therefore, in the case of ADoS/DDoS initiated by an attacker outside of a CDN, it generates passwords randomly. Then the probability of the collision between a generated password and the actual password is $P_{col} = \frac{1}{c^K}$. This is the fraction of the attack requests that pass the pre-authentication by the CDN. For example, let $K = 4$ and $c = 66$, where c includes 26 case-insensitive letters, 10 digits, and 30 special characters allowed by Linux passwords, then P_{col} is less than 10^{-7}. It means that PreAcher can filter out almost all DoS traffic.

To identify the correct password, an attack inside the CDN could offline determine the password candidates that are mapped to the actual p' and then send these candidates to the server for online verification. In this case, the server will see multiple failed login requests of an account from the CDN. For an account, the server should consider it is under attacks if more than Q times of failed logins happen on the server. The server could temporarily freeze the user account and ask the CDN to inspect the possible insider attackers. However, these frequent failed logins may also come from a valid user's erroneous input. Thus, the server can tune Q to adjust the sensitivity to the attacks. We run an empirical experiment simulating this scenario to show the defense effectiveness of LSH as below.

We collect 5000 distinct users and their passwords from 4iQ dataset [38]. For each user, we collect two passwords, one is regarded as a historical password leaked to a CDN, the other one is regarded as the actual password of the user's account on a website served by the CDN. Suppose the website adopts the CDN for pre-authentication, and the CDN aims at cracking those 5000 user accounts in this website through the collected historical passwords. Suppose the CDN adopts a state-of-the-art dictionary generation algorithm, *pass2path* [80] for password guessing. For each account, it uses this algorithm to generate a dictionary of 10,000 passwords from the historical password. The CDN can locally filter the password candidates that pass pre-authentication and send them to the server for full authentication. When the pre-authentication does not adopt LSH or the website opts for full authentication on the CDN, as long as the dictionary contains the correct password, the CDN will find it locally and crack the account successfully. However, with LSH, only if less than Q password candidates are left after the offline filtering can the CDN ensure itself cracks the account through less than Q online queries without being detected by the server. We compute the success rate of such undetected cracking on 5000 accounts for different values of Q and K in our LSH.

Figure 4 shows the success rate of cracking. Firstly, the

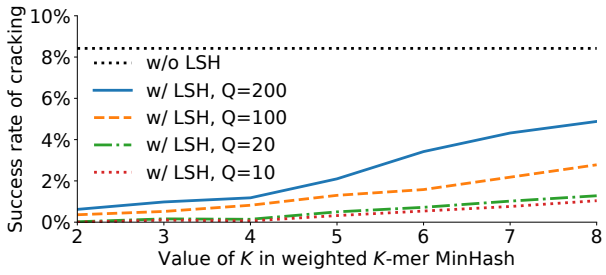

Figure 4: **The CDN's success rate of cracking accounts varying with K and Q in LSH. When LSH is not used (the black line), the success rate does not depend on K or Q.**

black line is about 8.42%, indicating a relatively high chance that the CDN can find out an account's password offline when LSH is not adopted. However, the success rate is dramatically reduced with LSH applied. It is less than 1% When $K \leq 4$ and $Q \leq 100$. The success rate also rises as K and Q increases, because larger K leads to fewer password collisions with p' in LSH, and larger Q allows more trials from the CDN. Nevertheless, a small K also reduces the effectiveness of the ADoS/DDoS defense of the CDN, and a small Q also downgrades the tolerance of the typos from valid users. Therefore, a server adopting PreAcher should select K and Q properly to defend against both DoS attacks and password cracking and reduce the false alarms. According to Figure 4, we set K as 4 and Q as 20 by default in PreAcher, since the cracking rate is less than 0.20% and almost all DoS traffic cannot pass the pre-authentication ($P_{col} < 10^{-7}$). Websites deploying PreAcher can adjust K and Q based on their demands.

We note that the 0.20% cracking rate is not introduced by PreAcher but results from users frequently reusing similar passwords across websites. A website without PreAcher faces the same cracking rate when an attacker outside of the CDN conducts online password guessing. Additionally, without PreAcher, the CDN sees the passwords directly. With OPRF but not LSH in PreAcher, the CDN can guess passwords offline with a success rate of 8.42% (Figure 4). Our LSH design contributes to the reduction from 8.42% to 0.20%.

6 Security Analysis

In this section, we analyze the security properties of PreAcher and explain how our design defends against attacks. We have formal security proof for our protocol, and we provide a proof sketch in Appendix D.

Registration security: As discussed in our threat model 2.3, we consider registration is ADoS-resist. Besides, the server still hides behind the CDN for registration, and the CDN can provide the DDoS defense. Moreover, the password is not exposed to the CDN during the registration according to the protocol shown in Appendix A.

User impersonation: If an attacker tries to impersonate a user without knowing the correct password, it will be rejected by either the CDN or the server. However, there exist cases in which the attacker provides a wrong password but obtains the correct p' because LSH maps the wrong and correct passwords to the same p'. In such cases, the attacker can pass the CDN's pre-authentication because he can compute the correct d' to decrypt e'_u. However, he is guaranteed to fail the authentication on the server since the wrong password cannot pass the password check against the stored hash.

Password invisibility to the CDN: With our protocol, the CDN cannot observe user passwords, as the passwords are neither transferred in plaintext nor decryptable by the CDN during the communication. During the login, the oblivious nature of OPRF allows the client to retrieve the stored private key sk'_u. Then the client and the CDN use $\langle sk'_u, pk'_u \rangle$ for pre-authentication. Moreover, the client encrypts the password with pk_s during full authentication. As a result, both authentication stages ensure the secrecy of the password. We provide two examples of attack attempts in Appendix B to demonstrate how this protocol can defend against a passive attacker inside the CDN.

ADoS/DDoS attacks: PreAcher prevents ADoS/DDoS attacks by filtering out most failed login requests by pre-authentication on the CDN. When an attacker generates brute-force login requests to overload the server, the server is never involved in the pre-authentication while the CDN will intercept the requests accurately.

An attacker may try to find passwords that pass pre-authentication but fail the full authentication to repeatedly involve the server and drain its resources. However, the attacker cannot identify such passwords in PreAcher. Both authentication stages return the same failure message. When a wrong password is guessed, the attacker cannot tell if the failure is due to pre-authentication or full authentication. Therefore, attackers outside the CDN cannot find passwords accepted by pre-authentication to launch ADoS attacks. While the CDN knows the pre-authentication result, as assumed in § 2.3, a CDN would be improbably involved in ADoS/DDoS attacks.

An attacker may also register an account and use the account's credentials to launch ADoS. The origin server can defend against such attacks by monitoring the login behavior of users. If a user repeatedly logs into her account in a very short time, the website can block the account.

Dictionary attacks: The key idea of PreAcher's defense against dictionary attacks is to force attackers to guess passwords online, and the server enforces a rate limit on the failed login attempts to detect such attacks.

For an attacker outside of the CDN, since it does not know k_u, it can only conduct online guessing for each of its password guesses. The only information the attacker gains is (1) the OPRF output which is indistinguishable from random bits to the attacker due to the pseudorandomness of OPRF and (2) envelops e'_u which the attacker cannot learn anything from due to the semantic security.

PreAcher also prevents offline dictionary attacks from a passive CDN attacker. As discussed in § 3.5, we have to

allow a CDN to guess p' offline to enable it to conduct pre-authentication. However, even with the knowledge of p', the CDN cannot guess p easily online due to our LSH design. As shown in § 5, our design of LSH reduces the cracking rate from 8.42% to less than 0.20%, even when a CDN uses a user's historical password and a state-of-the-art password generation algorithm to make 20 guesses for a single account.

Credential stuffing: Credential stuffing is a type of dictionary attacks where the attacker collects the existing dataset (dictionary) to guess the password. Since PreAcher defends against dictionary attacks, it also mitigates credential stuffing. In addition, PreAcher provides the benefit of reducing the origin server's workload in credential stuffing since most incorrect credentials are filtered out by the CDN.

Replay attacks: For the attacker outside of the CDN, it cannot replay any message of a valid user, as all communications in PreAcher are inside HTTPS. Moreover, the CDN cannot replay messages either, since it is assumed as a passive attacker (§ 2.3). Furthermore, the server can also record the recent messages of M (Figure 3) to prevent the CDN from replaying them, which is adopted by prior work [69].

Side-channel attacks: An attacker outside of the CDN may attempt to identify the passwords passing the pre-authentication by a side channel so that it can launch ADoS attacks with these passwords.

For example, an attacker may exploit response times by sending login requests with different passwords, as failed pre-authentication attempts are rejected by the CDN and replied faster than the successful ones. However, PreAcher can mitigate such a timing side channel by delaying failed responses, masking the pre-authentication results. Such a delay should approximate to the latency between the CDN's edge server and the origin server. Moreover, valid users remain unaffected, since this delay is not applied to successful logins.

In additional, an attacker could send many login requests with a specific password and infer the the server's workload through the website's page load time. A significant increase in the page load time indicates this password pass the the pre-authentication. PreAcher can generally prevent this side-channel attack as well as others aiming at differentiating pre-authentication results because

1. The values of p' used for pre-authentication spread in a large space ($> 10^7$, see § 5), requiring many trials to guess a correct p'. Moreover, each trial takes considerable cost as it involves one or more online requests.
2. The LSH mappings are different across users, and the server freezes an account after Q failed full authentication attempts. Thus, an attacker is limited to Q requests per p' inferred through the side channel, and it must repeat the trails of guessing p' across numerous users to gather enough p' to carry out a meaningful ADoS attack.

Finally, researchers have discovered other side channels that may compromise user data, such as through CPU cache [107], keystroke video [104], improper app isolation [105]. These attacks pose threats not only to PreAcher but also to many other systems. Addressing these attacks is beyond the scope of this paper and requires broader efforts extending beyond websites and CDNs.

7 Implementation

We provide a prototype implementation of PreAcher to facilitate the deployment and future research.

We implement the client operations in the protocol as a JavaScript library so that web developers can easily apply PreAcher by importing the library into their login web pages. The implementation does not require any modification or extension of existing browsers. Therefore, the websites can be seamlessly upgraded without cooperation from users.

We implement the server in C++ with Sogou Workflow framework [17], which is an efficient C++ server engine used in the industry to serve billions of requests per day. Web developers can adapt our server implementation into their web servers, or they can simply run our implementation as a separate process and redirect the received login requests to the process by setting up a reverse proxy [62, 83].

As for CDN operations, we implement them as a JavaScript code snippet running on a CDN's serverless computing service. Currently, CDN providers offer serverless computing to allow websites to run customized code at their edge server to process requests, such as Akamai EdgeWorkers [1], AWS Lambda [9], and Cloudflare Workers [8]. Therefore, our implementation runs seamlessly without requiring changes to the CDN infrastructure, despite introducing new operations on CDN edge servers. Web developers can deploy our JavaScript code snippet directly to the CDN to enable pre-authentication, as all the mentioned CDNs support JavaScript.

For cryptography operations, we adopt the existing libraries Web Crypto API [94] and libsodium [11] in JavaScript implementation and OpenSSL [12] in C++ implementation.

Overall, we elaborately design and implement PreAcher so that it is compatible with the current web ecosystem and can be immediately deployed by websites. Furthermore, PreAcher supports incremental deployment across websites since each website can unilaterally manage its deployment progress.

8 Evaluation

In this section, we evaluate PreAcher's efficacy in defending against ADoS attacks and the overhead introduced to throughput and latency on both the testbed and the Internet.

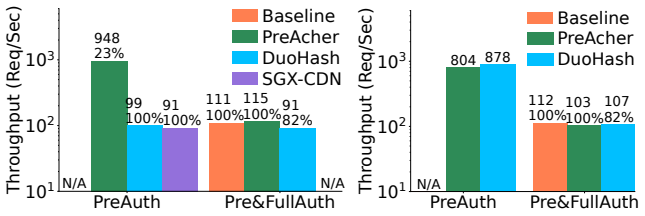
8.1 Experiment Setup

We set up a testbed on Azure using three VMs as a client, a CDN, and an origin server. Each VM has 4 vCPUs and 8 GiB of RAM and runs Ubuntu. As for Internet experiments, we deploy PreAcher on a commercial CDN, *i.e.* Cloudflare [6] and evaluate it using Azure VMs as the client and the server.

Besides PreAcher, we implement three strawman methods for comparison. The first one models the current password au-

thentication practice in a CDN-enabled website. The CDN's edge servers forward login requests to the origin server for authentication. Although this method directly exposes passwords to the CDN, it is simple and widespread [101]. We call this method as "*Baseline*" in this section. Another method is "DuaHash" discussed in § 4.2. Theoretically, DuaHash also prevents password exposure and ADoS attacks. Finally, we implement a method based on Intel SGX [40]. Specifically, we adopt Occlum [85] to run a traditional password hashing to authenticate users in SGX. We call this method as "*SGX-CDN*', which theoretically prevents password exposure and ADoS attacks but requires hardware support.

PBKDF2 is used for password hashing as shown in § 2.1.



8.2 ADoS Defense

Method	Testbed		Internet	
	w/o ADoS	w/ ADoS	w/o ADoS	w/ ADoS
Baseline	100	0	99	0
PreAcher	100	97	100	100
DuoHash	91	0	98	97
SGX-CDN	90	1	N/A	N/A

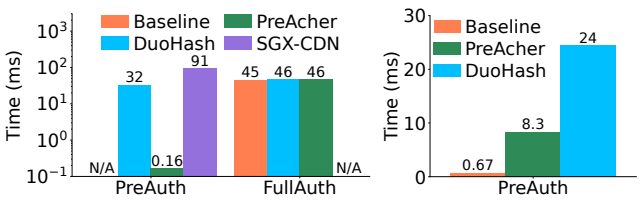
Table 1: **The successful logins per second for four methods with and without ADoS attackers. Since Cloudflare does not deploy SGX, we cannot measure the SGX-CDN on Cloudflare.**

We simulate ADoS attacks on the server and compare the efficacy of four proposed methods on the testbed and the Internet. We set up two processes on the client VM to act as valid users and an attacker, respectively. The user process sends login requests at the speed of 100 req/sec to simulate the case where 100 valid users intend to login to the website per second. All requests contain correct usernames and passwords. As for the attacker process, it sends login requests at the speed of 400 req/sec to simulate the case where an attacker initiates ADoS traffic to crash the server. These requests contain erroneous credentials since the attacker does not know the correct one. We run the experiments in two settings on both the testbed and the Internet. In the first setting, only the user process sends requests, representing a normal network condition without attacks (`w/o ADoS`). The second setting contains both the user process and the attacker process, representing a network condition under the ADoS attacks (`w/ ADoS`).

Table 1 shows the throughput (the number of successful logins per second) of each method. On the testbed without attack traffic, the server can respond to the user process timely with any of the methods deployed. However, during ADoS attacks, only PreAcher can maintain high throughput, *i.e.* 97 req/s, while the other methods fail to serve nearly all valid requests. For the baseline, it does not conduct the pre-authentication on the CDN and all attack requests will be forwarded to the server for processing. As for DuoHash and SGX-CDN, the pre-authentication overloads the CDN VM due to the intensive computation for password hashing, and thus the CDN cannot forward the valid requests to the server.

(a) Testbed (b) Internet

Figure 5: **Throughput of pre-authentication (`PreAuth`) and the whole system (`Pre&FullAuth`) for four methods. "N/A" indicates the absence of corresponding operations. Numbers above bars represent the values of throughput and CPU utilization. Some CPU utilizations are missing because Cloudflare does not provide the information.**



For the experiments on the Internet, the methods also serve user requests normally when there are no attacks. The throughput of DuoHash is improved because Cloudflare has plentiful CPU resources for password hashing. Due to the same reason, DuoHash can serve valid users with 97 req/s even under attacks. PreAcher also prevents ADoS attacks when it is deployed on Cloudflare, and it consumes less CPU than PreAcher as we will presented in § 8.4.

8.3 Throughput

We separate the experiments in this section into two groups: one measures the throughput of failed logins rejected by the CDN, and the other one measures the throughput of successful logins accepted by the server. The former represents the pre-authentication's throughput on the CDN, and we indicate this group as "`PreAuth`". The latter represents the whole system's throughput including both authentications on the CDN and the server, indicated by `Pre&FullAuth`. Specifically, we use `wrk` [20] at the client to send login requests to the CDN by 64 parallel connections (`wrk -c64`).

Figure 5a and Figure 5b show the throughput of the two groups for the four methods on the testbed and the Internet, respectively. Firstly, the baseline does not use the CDN for pre-authentication, and SGX-CDN does not run authentication on the server (it totally relies on the CDN for authentication), so we put "N/A" in the corresponding positions of bars. Figure 5a shows that PreAcher achieves a much higher throughput (948 req/s) than DuoHash (99 req/s) and SGX-CDN (91 req/s) in the `PreAuth` group. Moreover, it takes PreAcher only 23% of CPU to handle these requests, while DuoHash and SGX-CDN use up all CPU resources (100%). These results demonstrate the high efficiency of PreAcher's pre-authentication, which explains the effectiveness of its ADoS protection in § 8.2. The pre-authentication throughput of DuoHash and SGX-CDN is due to the slow password hashing, and SGX-CDN also introduces the overhead of SGX. As for the `Pre&FullAuth` group, all methods' throughput is around 100, because they all use password hashing on the server.

For the Internet experiments shown in Figure 5b,

(a) Testbed (b) Internet

Figure 6: **Median CPU time of pre-authentication (`PreAuth`) and full authentication (`FullAuth`) for four methods. "N/A" indicates the absence of corresponding operations. We omit `FullAuth` results on the Internet since they match those on the testbed due to the identical operations and server machine. The numbers above bars indicate the time values.**

PreAcher's `PreAuth` throughput reduces. We find that this reduction originates from the 2-RTT design of PreAcher and `wrk`. Specifically, the 2-RTT design increases the latency, and in `wrk`, each connection waits for a request to complete before sending the next one. As a result, a higher latency leads to a lower throughput when all 64 connections are saturated. In contrast, DuoHash's `PreAuth` throughput improves because the computation is no longer a bottleneck on Cloudflare.

8.4 CPU Time

We measure the CPU Time of the pre-authentication and full authentication operations. Figure 6 shows the median CPU time measured on the testbed and the Internet.

In Figure 6a, both DuoHash and SGX-CDN take much over 100× more CPU time than PreAcher for pre-authentication on the CDN VM, because they both use password hashing while PreAcher does not. Such a difference in CPU times explains the results of ADoS defense and throughput on the testbed in § 8.2 and § 8.3. As for full authentication on the server VM, PreAcher and DuoHash are comparable with the baseline since they all use the same password hashing algorithm.

For the Internet experiments, full authentication results should remain consistent with Figure 6a as we run identical operations on the same server. Therefore, we focus on pre-authentication's CPU time, which is provided by Cloudflare's statistics. As shown in Figure 6b, PreAcher's CPU time enormously increases to 8.3 ms, compared to 0.16 ms on the testbed. This increment arises from the implementation difference: PreAcher adopts C++ for pre-authentication on the testbed but use JavaScript on Cloudflare, as C++ is not supported in its serverless computing. The performance gap reflects the efficiency difference between these two languages.

However, DuoHash's CPU time does not increase on Cloudflare even though it also uses JavaScript. The reason stems from the cryptographic library. For DuoHash, we implement password hashing with Web Crypto API [94], which actually executes native code with little performance downgrade. Since this API does not support the primitive elliptic curve operations required by PreAcher, we adopt a pure JavaScript library libsodium [11] for it, downgrading the performance.

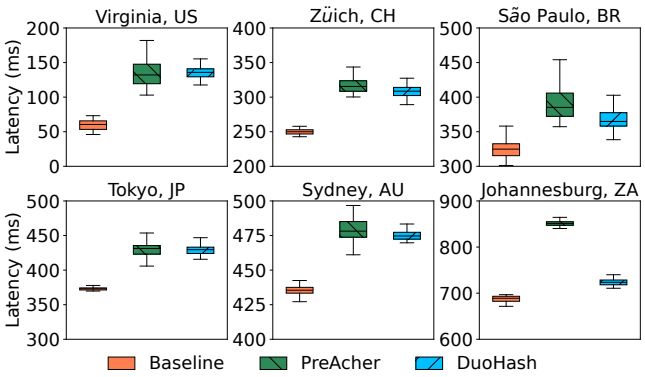


Figure 7: **The latency of a successful login for the clients in six regions around the world.**

Nevertheless, DuoHash still consumes 3× the CPU time of PreAcher on Cloudflare due to password hashing, which will be charged more to websites. Overall, DuoHash is a simple solution, but PreAcher achieves better CPU efficiency. We leave the choice between them for web developers.

8.5 Latency

We measure the end-to-end latency of a successful login for each method. To show a realistic latency, we set up six geographically distributed VMs as clients in six Azure regions covering all continents except Antarctica, including Virginia (US), Zürich (Switzerland), São Paulo (Brazil), Tokyo (Japan), Sydney (Australia), and Johannesburg (South Africa). We set up the origin server in Virginia (US). In each region, we send 100 valid login requests to Cloudflare edge servers. The edge servers will run deployed pre-authentication and request the origin server for full authentication. We define the latency as the time from starting the request to receiving the login success indication.

As shown in Figure 7, in all regions, PreAcher and DuoHash has a higher latency than the baseline. The latency overhead of PreAcher comes from its 2-RTT design in the protocol. However, the additional RTT happens between the client and the CDN, and thus it should not introduce much overhead because the clients are usually close to a CDN's edge server. We spot that PreAcher introduces a high latency overhead in Johannesburg, South Africa. This is because Cloudflare redirects the client's request to an edge server far from Johannesburg, leading to about 140 ms inflation. Except for this region, the overhead of PreAcher's median latency ranges from 42 ms to 72 ms in all other regions, compared to the baseline. Besides, DuoHash introduces overheads ranging from 34 ms to 75 ms to the median latency compared to the baseline in all regions, which is close to PreAcher. The latency overheads of PreAcher and DuoHash primarily stem from their computation time and the access delay of Cloudflare's storage. Since the login process is usually a one-time cost for users during web browsing, we consider the overhead of PreAcher and DuoHash to be acceptable.

9 Discussion

ADoS attacks through other interfaces. Although PreAcher avoids the ADoS attacks exploiting the login interface, other interfaces of a website may still be vulnerable. If the exploited interface requires authentication, the website can track and block accounts that initiate attacks. If the interface is open to public, the website can enforce authentication to remove the attack surface. Websites can also adopt the general ADoS defense proposed in prior studies [44, 67, 73, 90].

Password reuse and weak passwords. A user may reuse exactly the same password across websites. PreAcher cannot prevent account cracking caused by password reuse, which is an inherent limitation of password authentication. To mitigate password reuse, websites can adopt existing password reuse prevention [92] and detection [84] methods, which are compatible with PreAcher.

Similarly, a user may use a common or weak password, and an attacker inside a CDN could collect these passwords and enumerate them offline to guess the user's password. Nevertheless, PreAcher still resists such attacks. Since those common or weak passwords also share similarities, the LSH in PreAcher will mitigate the attacks as discussed in § 5. Additionally, a website can prevent users from using these common or weak passwords during registration.

Alternative solution. An alternative solution to achieve ADoS mitigation and password protection simultaneously is to simply use Trusted Execution Environment (TEE), such as Intel SGX [40]. We evaluate this solution in § 8. However, as TEE requires both hardware and software upgrades and is not enabled by CDNs yet, it is difficult to deploy such a solution. In contrast, PreAcher does not require upgrading of CDNs and can be deployed by websites unilaterally.

10 Related Work

DoS protection. In the past decades, researchers have explored plenty of DDoS defense mechanisms by using the network capabilities [70, 103, 106], the cloud defense [50, 71, 108], the routing polices [86], and the new Internet architecture [97]. In practice, websites widely adopt the DDoS protection offered by a CDN provider or a cloud provider [4, 7, 15]. We do not innovate DDoS protection in PreAcher, but we retain the DDoS protection of CDNs in PreAcher.

Protecting ADoS is more difficult than DDoS because the requests are application-specific and the request amount is usually too small to be detected [2]. Prior studies have proposed ADoS defense mechanisms. However, their solutions focus on the ADoS caused by either regular expressions [66] or specific programming languages [43, 73]. Researchers also propose to detect and filter out ADoS traffic by profiling requests' resource usage and learning the pattern of attack traffic [44, 67, 90], which are less effective to login requests due to the consistent payload pattern of a username and a password. In this paper, we show that ADoS attacks exploiting password login are feasible, even for a server hidden behind a CDN (§ 2.1), and our design of PreAcher mitigates such attacks.

User privacy leakage to CDNs and countermeasures. Researchers have spotted the user privacy leakage to third-party CDNs caused by TLS private key sharing for years [35, 68]. A line of research has proposed countermeasures, including certificate delegation [68], Keyless SSL [88], TLS modifications [30, 65, 79], TEE-based CDNs [27, 54, 78, 95], differential privacy [100], homormophic encryption [98], and a new encryption channel for web [69].

Although these proposals are useful for protecting users' sensitive data against an attacker inside a CDN, none of them mitigates ADoS attacks. PreAcher is related but has different goals. It is not meant to protect all private communication between the client and the server. Instead, it focuses on preventing password leakage and addressing ADoS vulnerability caused by current password authentication.

Password authentication. A series of literature has discussed the security of the password authentication, including the password exposure on CDNs [101], password guessing techniques [80, 102], password storage mechanisms [14, 31], new efficient protocols of password authentication [45, 52, 60], the password reuse practice [42, 93] and its defense [84, 92], etc. PreAcher's authentication protocol is inspired by the advance of Password Authenticated Key Exchange (PAKE) protocol [60], which enables authenticated key exchange between a client and a server without cleartext password checking on the server. However, existing PAKE protocols cannot be directly applied to our system, because the origin server must engage directly with the user in each PAKE session which makes DoS attack unavoidable. Thus, we design a novel three-party authentication protocol in PreAcher to securely offload password authentication to a CDN.

To sum up, PreAcher is the first solution that simultaneously prevents ADoS/DDoS attacks, preserves password secrecy, and provides good usability.

11 Conclusion

This paper introduces PreAcher, a comprehensive solution designed to combat the ADoS/DDoS attacks exploiting password authentication and preserve password secrecy. PreAcher incorporates a three-party authentication protocol that allows CDNs to perform password pre-authentication without accessing the actual passwords. We extensively analyze PreAcher's security features and evaluate its performance. Websites can deploy PreAcher independently and immediately, without requiring any modifications to clients or CDNs.

A PreAcher Registration Protocol

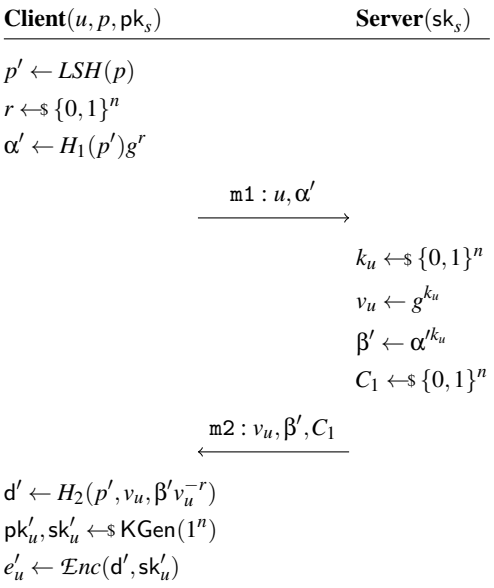

Figure 8: **First round of PreAcher registration.**

In the registration, the client communicates to the server through a CDN. The CDN simply forwards the messages and is not involved in the protocol. As we discuss in § 2.3, the registration can be considered as ADoS-resist in reality, but the CDN can observe the message content. At the end of the registration, the server will send some registration information without exposing user passwords to the CDN so that the CDN can use such information for pre-authentication. The registration protocol works as follows:

Initialization. A user inputs the username u and password p to the client. As discussed in 3.1, the client obtains the server's public key pk_s from the HTML of the login page, and the server keeps the corresponding private key sk_s.

Generating a symmetric key from the password. The client and server compute a symmetric key d' together through OPRF. This step combines the OPRF with LSH as shown in Figure 8.

Specifically, the client uses LSH to map p to p'. Then it generates a random nonce r and computes α' used by OPRF. The client sends u and α' to the server for registration (`m1`). The server generates a user-specific k_u and computes v_u, β' from α' and k_u. The server also generates a one-time random challenge C_1 to verify the client's identity in the next round of communication. Then v_u, β', and C_1 is returned to the client (`m2`). Thus, the client computes a secret symmetric key d' through H_2 and d' is hidden from the server. Note that it can be proved that d' is independent from the choice of r.

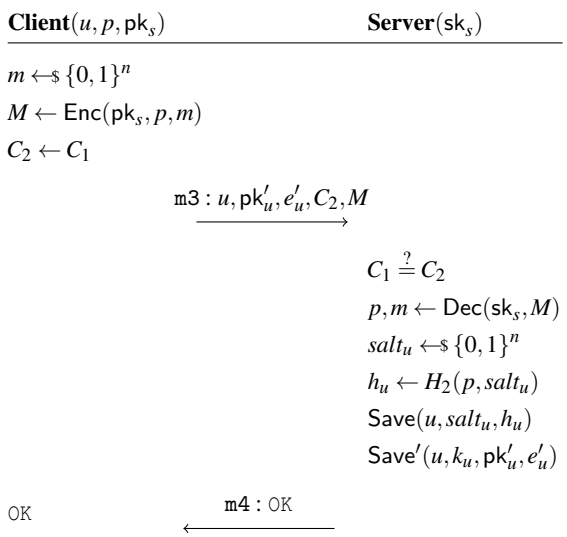

Figure 9: **Second round of PreAcher registration.**

Enclosing a new private key with the symmetric key. The client generates a new key pair $\langle \mathsf{sk}'_u, \mathsf{pk}'_u \rangle$ for the user. Then sk'_u is enclosed into an envelope e'_u by encryption with d'. This new key pair and e'_u will be used for pre-authentication by the CDN in the login.

Registing with the server for full authentication. Finally, the client and the origin server register the user through the traditional password hashing for compatibility with existing authentication in websites. Note that since we trust the origin server (§ 2.3), we can expose the password to the server. Nevertheless, the password sent to the server is encrypted by the server's public key to avoid exposure to the CDN.

As shown in Figure 9, the client uses pk_s to encapsulate p with a random nonce m. The client copies received C_1 as C_2 and sends it back to the server with pk'_u, e'_u, and M (m3). The server first needs to check C_2 against C_1 to identify the client as the one who initiated the registration in the previous round. The server obtains p by decrypting M with its own sk_s. Then it computes the corresponding salted hash value h_u from p. The server saves $salt_u$ and h_u in a user-specific record for future full authentication. Besides, the server saves $k_u, \mathsf{pk}'_u, e_u, e'_u$ and sends them to the CDN for the future pre-authentication ($\mathsf{Save}'(u, k_u, \mathsf{pk}'_u, e'_u)$). Then the server returns the indication of a successful registration (m4) to the client.

B Attack Attempts and Defense

PreAcher can defend against a passive attacker inside the CDN. To make this tangible, we provide two examples of attack attempts to demonstrate the effectiveness of PreAcher's defense.

For instance, an attacker inside the CDN can observe M in $m4$ (Figure 3) during a valid user login. The attacker may attempt to guess the password offline by computing a M value with each guessed password and validating it against the observed M. PreAcher defends against this attack because M is generated by the client using not only the password but also a random nonce m, forcing the attacker to guess m from a vast space in order to obtain a M value that matches the observed one.

Moreover, an attacker may replay the collected M from a valid login and send this M to the server for full authentication. However, the server can prevent such replay attacks by recording the recently received M and thus reject duplicate ones, which is already adopted by prior work [69].

C DuoHash Protocol

We use the same notations described in § 4.1. Figure 10a illustrates the protocol of registration by following steps:

1. The user inputs the username u and password p. Then the client encrypts the password with the server's public key pk_s and sends the username u and encrypted messages M to the server.
2. The origin server decrypts M with its private key sk_s to obtain the password. The server stores a salted hash value h_u for future authentication. Besides, the server calculates another hash value h'_u, which will be used by the CDN for pre-authentication. To avoid offline dictionary attacks by the CDN, the server first uses LSH to map the p to a value p'. Finally, the server uses two layers of hashing H_2 and H_1 to map p' into h'_u, and it is an indication of successful registration to the client.

After the registration, the server sends h'_u and $salt'_u$ to the CDN (not shown in the figure). The CDN stores h'_u and $salt'_u$ for future pre-authentication in the login phase.

The protocol in Figure 10b shows the login phase by following steps:

1. Similar to the registration, the client has u and p and creates the encrypted password M with pk_s. In addition, the client uses LSH to generate p' and the corresponding first-layer hash value h'_1, which is sent to the CDN with u and M.
2. The CDN retrieves $salt'_u$ and h'_u from the user-specific record according to username u. It then conducts the authentication by checking whether $H_2(h', salt'_u)$ is equal to h'_u. If they are equal, the CDN considers the password pre-authentication succeeds and then sends u and M to the origin server for further authentication. If the pre-authentication fails, the CDN directly returns an indication of failed login to the client (not shown in the figure), and thus filters out most failed login requests for the origin server.
3. When the server receives an authentication request from the CDN, it decrypts M with the private key to extract the password p. The server authenticates the user by comparing h_u with the computed $H_2(p, salt_u)$. The server returns the final authentication results to the CDN.
4. The CDN directly forwards back the authentication result to the client.

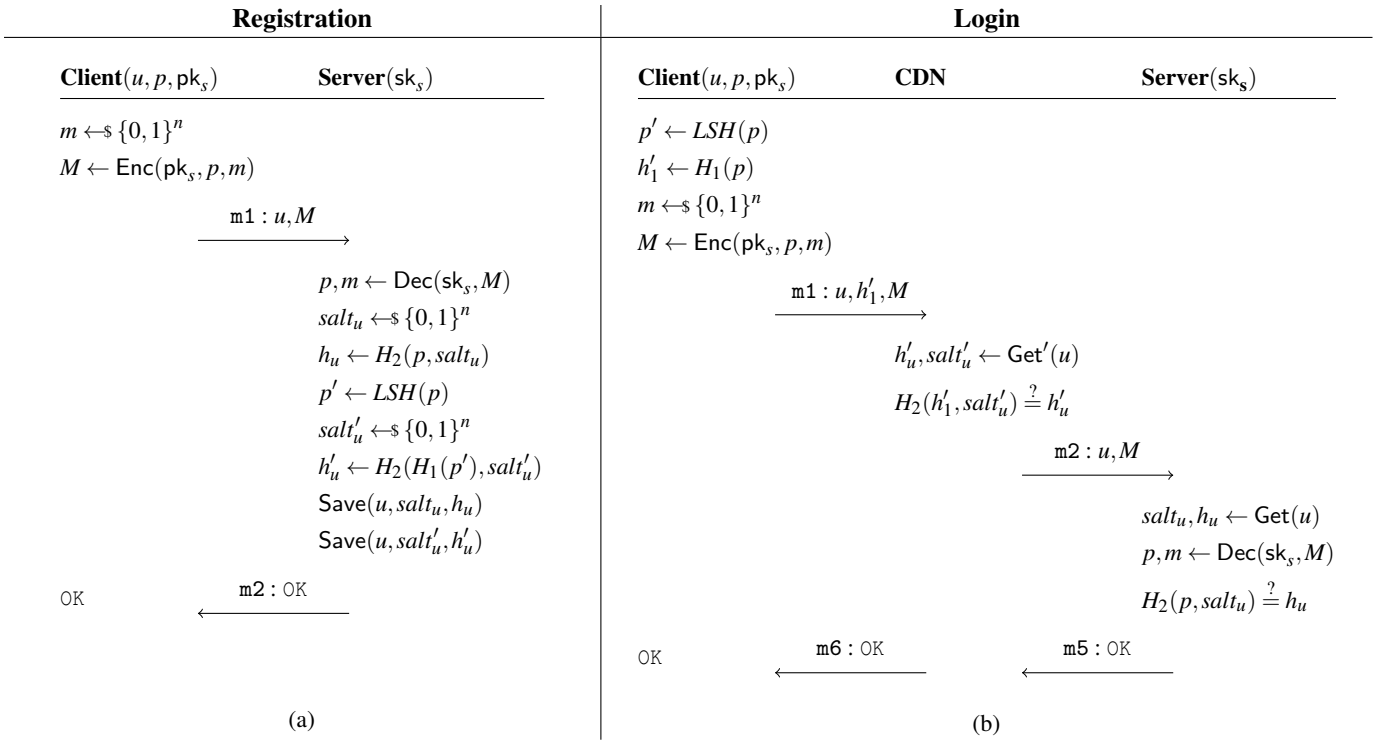

Figure 10: **DuoHash Protocol**

D Security Proof Sketch

In this section, we present a proof sketch to show the security of our protocol. The security requirements are discussed in Section 6. For clarity, we show the complete flow of PreAcher authentication protocol in Figure 11. We use the following probability $\varepsilon_{\mathsf{oprf.random}}$, $\varepsilon_{\mathsf{CPA}}$, $\varepsilon_{\mathsf{CCA}}$, $\varepsilon_{\mathsf{EU-CMA}}$ to denote adversarial advantage of winning the pseudorandomness game of OPRF, the CPA security game, CCA security game, unforgeability game of signature scheme, respectively, which are all negligible in terms of security parameter n.

Theorem 1. *PreAcher is secure against an external attacker, assuming a secure OPRF, a CPA-secure encryption Enc, a CCA-secure encryption* Enc*, and an EU-CMA-secure signature.*

Proof. First, we consider a passive external attacker, and if this attacker provides a wrong password and obtains a p' to authenticate with CDN, there can be two cases:

(1) p' is incorrect. In this case, the attacker gets a random d'^* which is independent from the correct d'. The adversarial advantage of distinguishing this d'^* from d' can be reduced to the adversarial advantage of winning the pseudorandomness game of OPRF[2] and thus is bounded by $\varepsilon_{\mathsf{oprf.random}}$. And since the attacker doesn't know the correct d', the adversarial advantage of distinguishing sk'_u is bounded by the adversarial advantage of winning the semantic security game of the encryption scheme, i.e. $\varepsilon_{\mathsf{CPA}}$. Without knowing the correct sk'_u, the probability of the attacker issuing/forging a valid signature can be reduced to the probability of the attacker winning the unforgeability game of the signature scheme, which is bounded by $\varepsilon_{\mathsf{EU-CMA}}$.

(2) p' is actually correct. This happens because the password guess is close to the correct one and thus gets mapped into the correct p' by LSH with probability $\varepsilon_{\mathsf{LSH}}$. Since p' is correct, the attacker can successfully authenticate with CDN. However, to authenticate with the origin server, the attacker needs to construct a valid adversarial ciphertext M^* from the honest M. This case can be reduced to the CCA security game and thus bounded by ε_{CCA}.

To summarize, the probability of an external adversary breaking the security of PreAcher is negligible. □

Theorem 2. *PreAcher is secure against a passive CDN attacker, assuming a secure OPRF, and a CCA-secure encryption* Enc*.*

Proof. Second, we consider the case of a malicious CDN. Here we no longer consider adversarial authentication to CDN and mainly focus on authentication to the origin server.

Because this malicious CDN holds OPRF key k_u, it can attempt to launch an offline dictionary attack by running OPRF locally multiple times and computing a dictionary D of d's corresponding to its password guesses, and try to decrypt

[2]Our protocol implements a secure OPRF assuming H_2 is a secure hash function, as proved by OPAQUE [60]

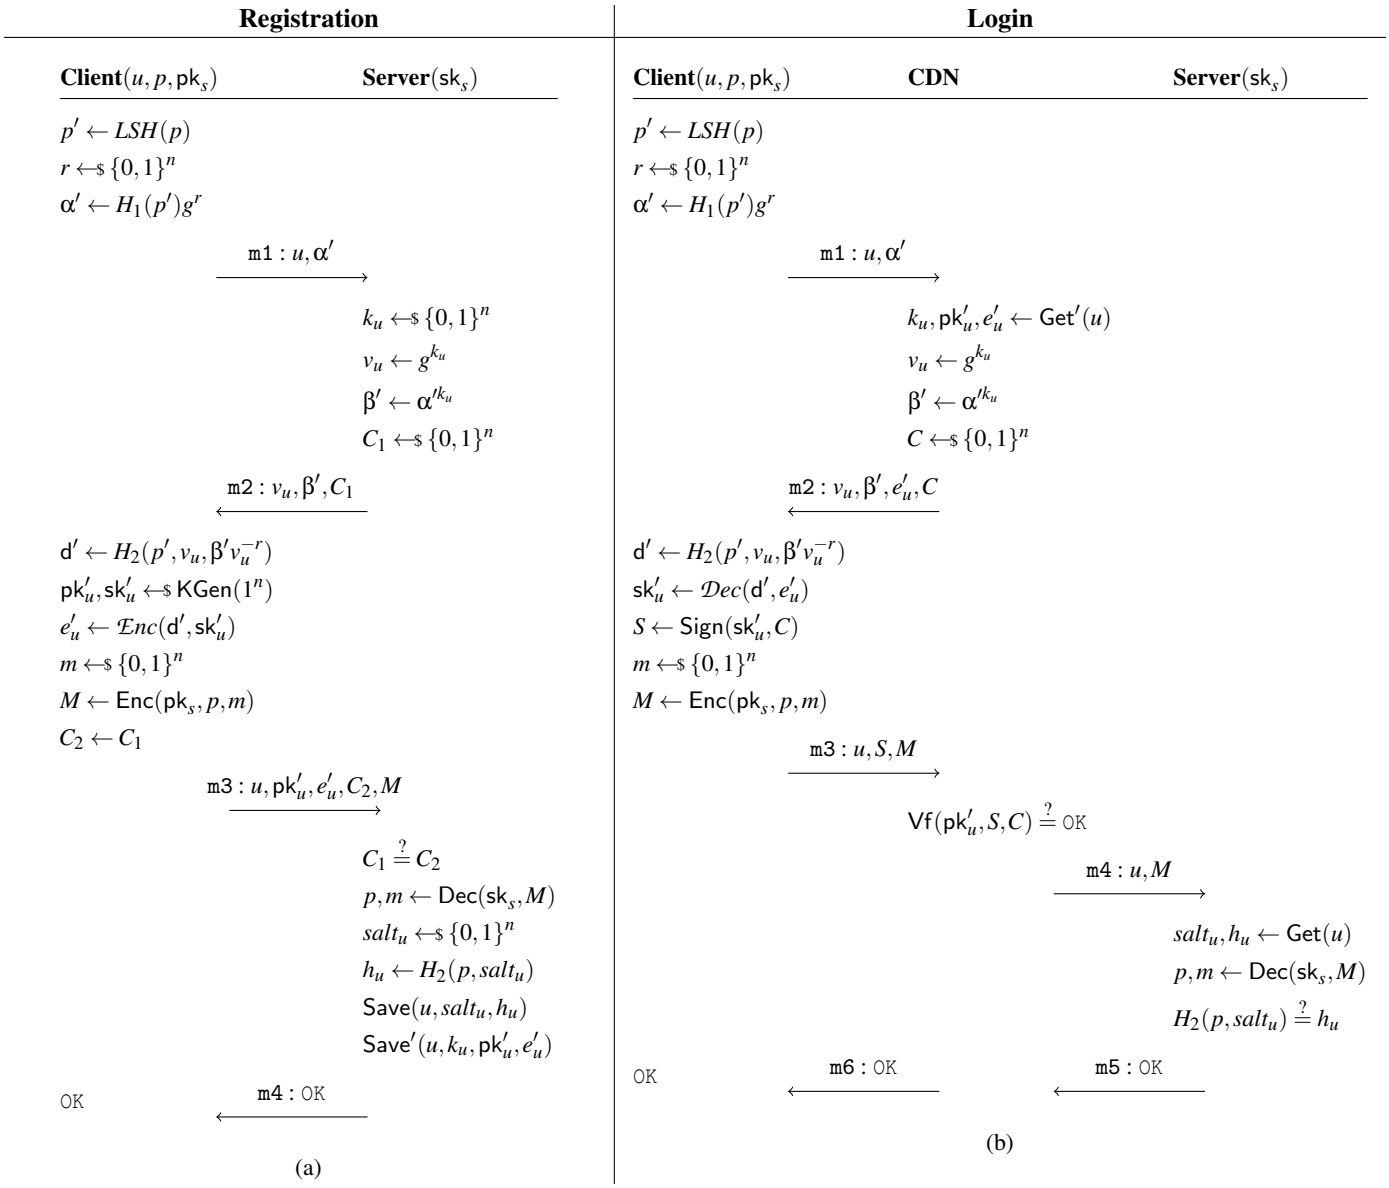

Figure 11: **PreAcher Protocol**

e_u with these d's. However, by the decryption randomness of $\mathcal{D}ec$, any wrong decryption key can only decrypt e_u to a random bitstring, which in the attacker's view is indistinguishable from the correct sk'_u, and the attacker cannot tell from this decryption result whether it uses the correct password or not. The probability of successfully launching such an offline dictionary attack is thus bounded by $\frac{1}{|2^n|} \cdot \frac{1}{|D|}$.

To summarize, the probability of a passive CDN adversary breaking the security of PreAcher is negligible. □

ClubHeap: A High-Speed and Scalable Priority Queue for Programmable Packet Scheduling

Abstract

While PIFO is a powerful priority queue abstraction to support programmable packet scheduling in network devices, the efficient implementation of PIFO faces multiple challenges in performance and scalability. The existing solutions all fall short of certain requirements. In this paper, we propose ClubHeap to address the problem. On the one hand, we develop a novel hardware-friendly heap data structure to support faster PIFO queue operations that can schedule a flow in every clock cycle, reaching the theoretical lower bound; on the other hand, the optimized hardware architecture reduces the circuit complexity and thus enables a higher clock frequency. The end result is the best scheduling performance in its class. Combined with its inherently better scalability and flexibility, ClubHeap is an ideal solution to be built in programmable switches and SmartNICs to support various scheduling algorithms. We build an FPGA-based hardware prototype and conduct a thorough evaluation by comparing ClubHeap with the other state-of-the-art solutions. ClubHeap also allows graceful trade-offs between throughput and resource consumption through parameter adjustments, making it adaptable on different target devices.

1 Introduction

In a network switch, packet scheduling, which determines the packet delivery order and time, is an essential function in Traffic Manager (TM). To satisfy the diverse application requirements, a number of packet scheduling algorithms have been proposed [6,7,15,21,22,25,31,35,45,63,65], e.g., Weighted Fair Queueing (WFQ) [15], Hierarchical Packet Fair Queueing (HPFQ) [6], Least Slack Time First (LSTF) [31], etc. Fine-grained priority scheduling [3,34,46] based on specific fields, e.g., Shortest Remaining Processing Time (SRPT) [46], is also widely used.

As the programmable network devices play a more important role in Software-Defined Networking (SDN), the programmable schedulers in those devices can support different scheduling algorithms on generic hardware. A popular queue abstraction, Push-In First-Out (PIFO) [51], has been accepted as a foundation to realize a wide range of algorithms. A PIFO is a Priority Queue (PQ) which allows elements to be pushed to an arbitrary location, but can only pop elements from the head. A series of PIFO blocks with mesh interconnections can be configured into a tree to support multi-level hierarchical scheduling. Each PIFO block contains a physical PQ which can be partitioned into multiple logical PQs (named logical PIFOs) at the same level of the tree. In a PIFO block, a flow is inserted in a queue location based on its *rank* [51], the calculated scheduling order or time (e.g., the remaining flow size in SRPT [46]), and popped when it reaches the queue head.

A PIFO queue needs to support two primitives: *push* and *pop*. In a PIFO-based scheduler, a popped flow is immediately pushed back into the queue if it still has unscheduled packets [51], forming a *pop-push* pair. We introduce a *replace* primitive to represent the pair. During scheduling, all operations for a flow are *replace* except for the first *push* and the last *pop*. Therefore, we can use Cycles-Per-Replace (CPR) as a metric to evaluate the throughput performance under the same clock frequency. In pipelinable implementations, we consider the delay between two consecutive *replace* operations as the equivalent CPR because the operations may overlap.

Reducing CPR is an effective means to increase throughput, because the clock frequency is limited in silicon chips. The original PIFO implementation [51] uses shift registers (referred to as SR-PIFO henceforth), in which both *push* and *pop* operations require 2 cycles to complete (i.e., CPR$=4$). Some PIFO queue implementations support parallel *push* and *pop* operations [5,8,26,28,62], enhancing native *replace* support. For example, RPU-BMW [62] allows a *push* every 2 cycles, a *pop* every 3 cycles, but a *replace* every 3 cycles (CPR$=3$) due to its pipeline design. Nevertheless, thus far no scalable PIFO implementation can achieve CPR$=1$ which is the lower limit of a PIFO-based packet scheduler.

In this paper, we propose a novel data structure called

ClubHeap (short for Clustered Binary Heap)[1] to support PIFO queue implementation, and a high-speed and scalable programmable scheduler solution based on it. Our major contributions are summarized as follows.

1. We design ClubHeap, a new PQ data structure supporting the PIFO abstraction. ClubHeap leverages the scalability of the heap-based data structures, and overcomes the challenge of inter-operational data dependencies troubling the other heap-based data structures [8, 26, 28, 62]. ClubHeap is the first heap-based design which supports a fully pipelined implementation with the theoretical lower bound of CPR= 1.

2. To validate the design, we synthesize ClubHeap with a 45nm ASIC toolchain [17, 23, 55] by Design Compiler [53] and implement it on a Xilinx Alveo U280 Data Center Accelerator Card [60]. The prototype supports up to 2^{17} elements in up to 2^8 logical PIFOs, with each element having a priority precision of 32 bits. The prototype achieves a throughput of approximately 200Mpps on FPGA, ensuring 100Gbps line-rate processing in the worst case. We show ClubHeap is the only solution which is scalable in terms of elements, priority levels, and logical PIFOs at the same time.

The rest of the paper is organized as follows. In Sec. 2, we discuss the gap between the requirements of a programmable packet scheduler and the existing hardware implementations using priority queues. In Sec. 3 we introduce the ClubHeap data structure. We present its hardware design in Sec. 4 and its implementation in Sec. 5. A detailed evaluation including comparisons with existing implementations is presented in Sec. 6. We summarize the related works in Sec. 7 and conclude the paper in Sec. 8.

2 Background

2.1 Requirements for PIFO Implementations

The PIFO abstraction can be applied to both programmable switches [10, 50] and SmartNICs [33, 52]. Recent research shows that the priority queues in these two scenarios share the similar requirements as follows [4].

Throughput. Due to the rapid growth of port speed and count on network devices, a single scheduler instance cannot schedule all packets at line rate. For example, a 64x400GE NVIDIA Spectrum SN5400 switch [41] supports up to 33.3 billion packets per second, exceeding any known scheduler capabilities. Therefore, a mesh of PIFO queues is needed for high aggregated scheduling throughput. Fewer queues are needed if each PIFO queue has higher throughput. SmartNICs have a lower peak packet rate than switches, allowing the use of a single PIFO queue. Some recent PIFO queue implementations (e.g., BBQ [4]) can meet the demands of FPGA-based SmartNICs operating for 100GE (148.8Mpps). However, increasing NIC throughput also puts more pressure on the packet scheduler.

Scalability. Scalability is measured in two dimensions: the number of priority levels (P) and the number of elements (N) allowed in the priority queue. In a PIFO queue, the rank of a flow might be a timestamp (e.g., in LSTF [31] or EDF [34]), which often requires high precision. A large P also extends the time span for data retention in the scheduler under non-work-conserving algorithms [21, 29, 57, 67]. On the other hand, today's multi-tenant networks may require the scheduler to handle hundreds of thousands of flows [18, 19, 43], which pose significant scalability challenges for N.

Logical Partitioning. Logical Partitioning (LP) refers to partitioning a physical PIFO block into multiple logical PIFOs. In hierarchical scheduling algorithms, queues at the same level of the scheduling tree can be considered as different logical PIFOs within the same PIFO block. The same applies to the packet queues for different output ports.With LP, a k-port switch requires only $2k$ physical PIFOs, compared to k^2+k PIFOs without LP [4], resulting in a 32.5x reduction for k=64. The significant difference in resource consumption makes LP crucial for the implementation of PIFO-based schedulers.

2.2 Existing Implementations

The requirement for high-performance PQs to support packet scheduling precedes the PIFO abstraction. Numerous PQ implementations exist, but none satisfies all three requirements in Sec. 2.1. We brief three typical implementations below, which can all be used in a PIFO-based scheduler and programmed using Domino [37, 50, 51].

Implementations based on linear data structures. Implementations based on shift registers [9, 13, 42, 51, 54] (e.g., SR-PIFO [51]) and systolic arrays [5, 30, 38] (e.g., OPQ and APQ [5]) fall into this category. For an operation, a shift register performs all comparisons within one cycle, whereas a systolic array breaks it down into multiple sub-operations, and propagates them linearly through the entire data structure in a systolic manner, thereby simplifying the combinational logic for each cycle and improving the clock frequency. APQ, with the highest throughput among them, organizes elements into groups, and leverages the Single-Instruction-Multiple-Data (SIMD) technique to achieve CPR= 1. However, these implementations need $O(N)$ comparators to compare the elements[2] in the PQ in parallel, resulting in significant hardware overhead, and a decrease in clock frequency as N increases. Therefore, these implementations cannot meet the scalability requirements for N. For example, SR-PIFO requires approximately 900K LUTs on an FPGA (∼70% on Xilinx Alveo

U280 [60]) when $N = 4,096$, and can only operate at a frequency of 40MHz [62]. With CPR= 4, this translates to a throughput of only 10Mpps.

Implementations based on buckets. These implementations assign a bucket to each priority level and group flows with the same priority into the same bucket. BBQ [4] introduces Hierarchical Find-First Set (HFFS) [44, 58] to manage buckets and store elements in SRAMs, achieving scalability with respect to N. However, dedicated hardware for each priority level limits scalability for P. For example, BBQ provides 2^{15} buckets in total [4]. Considering that a PIFO block supports 256 logical PQs (a typical number in [51]), each logical PQ can only support P=2^{15}/256=128, which is unacceptable for many algorithms [6, 22, 31].

Implementations based on heaps. A heap is a tree in which the rank of each node is not greater than that of its child nodes. The operation on a heap-based structure resembles a systolic array but positions sub-operations at distinct tree levels. This design requires only $O(\log N)$ comparators, each with $O(\log\log P)$ latency. P-Heap [8] is the first to exploit the heap structure, achieving scalability for both P and N. BMW-Tree [62] introduces an insertion-balanced multi-way heap with better pipeline support to reduce CPR from 6 to 3. However, both P-Heap and BMW-Tree do not support logical partitioning. Pipelined Heap [28] implements a complete binary heap which can support logical partitioning. However, the global bus required to connect all tree levels becomes a bottleneck in the pipeline, limiting the frequency and making it less scalable with respect to N.

Another challenge for heap-based implementations comes from the inter-operational data dependency problem (detailed in Sec. 2.3), which prevents a fully pipelined implementation with CPR= 1. H-PQ [26] is a hybrid structure of systolic array and a series of heaps, which attempts to eliminate this impact by distributing operations across different heaps. Unfortunately, real traffic may access the same heap continuously, causing the performance instability of the packet scheduler. ClubHeap solves the inter-operational data dependency problem through a novel data structure design.

The characteristics of the aforementioned implementations are summarized in Table 1. We use CPR as the performance indicator for simplicity[3][4]. In summary, implementations based on linear data structures have poor scalability for N, while implementations based on buckets have poor scalability for P. ClubHeap, as a heap-based implementation, achieves a high performance with CPR= 1, presents good scalability for both N and P, and possesses the logical partitioning capability.

2.3 Inter-Operational Data Dependency

Pipelining the queue operation is critical for the scheduling throughput. However, the inter-operational data dependency is a hurdle that prevents the heap-based PIFOs from applying the pipeline technique efficiently. Its solution is the key factor for a high-performance implementation of ClubHeap.

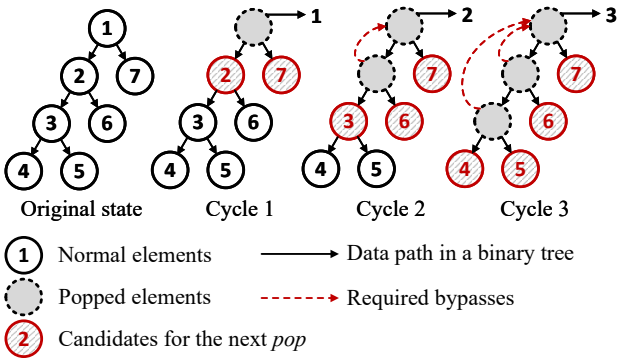

Figure 1: The inter-operational data dependency on a traditional binary heap.

Since it is impossible to predict the rank of the subsequent elements pushed into the PIFO when pushing a current element, the distribution of elements in the heap can be unbalanced. As shown in Fig. 1, in a binary heap, the distribution of the smallest ranked elements may form a dependency chain: 1 is the parent of 2, 2 is the parent of 3, and so on.

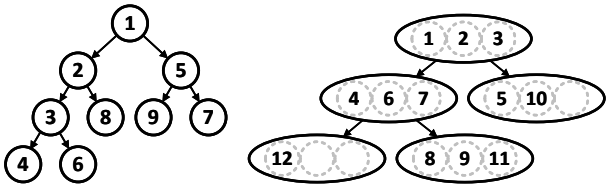
Consider consecutive *pop* operations under this circumstance. In Cycle 1, the element 1 at Level 1 (i.e., the root node) is popped, leaving a temporarily empty root, which means both elements stored in its child nodes can be the new minimum element in the heap. Therefore, a comparison must be made between the element 2 and the element 7 at Level 2. In Cycle 2, the second *pop* arrives, which needs to pop the element 2, the smaller one between 2 and 7. However,

[3] Besides CPR, the scheduling throughput is also affected by clock frequency, which may vary for different implementations and different scale specifications (i.e., P and N).

[4] P-Heap claims CPR=2 [8], but it allocates three dependent operations (read, compare, and write) in one cycle. For a fair comparison, we convert one P-Heap cycle to three physical clock cycles as suggested in [28].

the newly arriving instruction just reaches the root node and cannot operate on the element 2 which is still located at Level 2. In order to allow the element 2 to be popped immediately, a bypass from Level 2 to Level 1 (as depicted in the dashed line in Fig. 1) is required. After the element 2 is popped, its two children at Level 3 become the new candidates as well as the element 7. The comparison to elect the next minimum must be made among the three candidates. Similarly, the next *pop* operation arriving in Cycle 3 requires another bypass from Level 3 to Level 1 and increases the number of candidates to four. If the heap has L levels, $L-1$ bypasses are needed from the other levels to Level 1, and a comparison between L candidates needs to be made after $L-1$ consecutive *pop* operations.

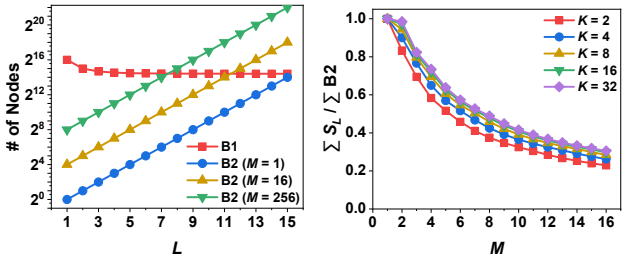
In the case of $L = 16$ (i.e., supporting $N = 2^{16} - 1$) and $P = 2^{16}$, the operation to compare 16 16-bit element values and select the minimum one requires a complex combinational circuit, which can severely affect the achievable clock frequency. The wire delay introduced by the bypasses from Level 2, 3, ..., L to Level 1 worsens the problem. In other words, to guarantee a certain performance level, the heap depth is constrained, resulting in poor scalability for N. Because of this, the existing heap-based priority queue implementations [8, 28, 62] are difficult to reconcile with performance and scalability simultaneously.



3 ClubHeap

In a traditional heap [8, 28, 62], an operation proceeds along the path from the root to a certain node in the tree structure, resembling a systolic array. Inspired by the SIMD technique where APQ [5] achieves CPR= 1, we organize elements into *clusters* (different from *groups* in APQ, elements in a cluster are rank ordered), so that consecutive operations may only access different elements within a cluster, thereby eliminating the inter-operational data dependency problem.

3.1 Definition and Corollaries



As shown in Fig. 2(a), a traditional binary heap (used in P-Heap [8] and Pipelined Heap [28]) stores a PQ element in each node of the binary tree. Denote the rank of the element on node x as $E(x)$, and consider the rank of an empty node as $+\infty$. Then for any child y of any node x, it holds that $E(x) \le E(y)$.

The key difference between ClubHeap and a traditional binary heap is that each binary tree node in ClubHeap holds more than one element which forms a *cluster*. Each node can store up to K sorted elements. A node that contains K elements is called *full*. For a *non-full* node containing T ($T < K$) elements, the $K-T$ free slots are considered to have the $+\infty$ rank value. We denote the rank array of node x as $E(x)$. For nodes x and y, if $\max(E(x)) \le \min(E(y))$, i.e., the rank of any element in node x is less than or equal to any element in node y, we denote that $E(x) \le E(y)$.

(a) Traditional binary heap. (b) ClubHeap (K = 3).

Figure 2: Comparison of a traditional binary heap and a ClubHeap.

(a) **B1** vs **B2**. (b) S_L vs **B2**.

Figure 3: Comparison of **B1** given by Corollary 2 and **B2** given by the binary tree structure.

Definition. A binary tree is a ClubHeap if and only if: for any child y of a node x, it holds that $E(x) \le E(y)$.

Corollary 1. The definition leads to a corollary: for any child node y of a node x in a ClubHeap, if x is not full, then y must be empty. This is because, for a non-full x, $\max(E(x)) = +\infty$; according to the ClubHeap definition, $\max(E(x)) \le \min(E(y))$, so $\min(E(y)) = +\infty$, meaning that all items in $E(y)$ have the value of $+\infty$ and thus y must be empty.

The corollary implies that the elements in a ClubHeap are always compactly located in the nodes of the upper levels, and the minimum ranked elements must be located at the root node. The corollary below quantitatively describes the concentration of elements in the upper levels of ClubHeap.

Corollary 2. For a ClubHeap containing N elements, the number of non-empty nodes at the L-th level is no more than $\frac{N}{K\left(1-\frac{1}{2^{L-1}}\right)+1}$. The reason is as follows. Assume there are N_L non-empty nodes at the L-th level, so there are at least N_L elements at this level. Meanwhile, due to Corollary 1, there are at least $\frac{1}{2^i} \cdot N_L$ full nodes at the $(L-i)$-th level (i=1,2,...,L-1). Therefore, these nodes contain at least $K \cdot \left(1-\frac{1}{2^{L-1}}\right) \cdot N_L$ elements. Summarizing the two parts of elements, we have $N \ge N_L + K \cdot \left(1-\frac{1}{2^{L-1}}\right) \cdot N_L$, and thus $N_L \le \frac{N}{K\left(1-\frac{1}{2^{L-1}}\right)+1}$.

The concentration of elements is a key factor for ClubHeap to support LP. Consider a ClubHeap forest consisting of M logical PIFOs, with a total of N elements. According to Corol-

lary 2, the total number of nodes at the L-th level across all M logical PIFOs has an upper bound $\frac{N}{K\left(1-\frac{1}{2^{L-1}}\right)+1}$ (**B1**), which may be tighter than the upper bound given by M independent binary trees, i.e., $M \times 2^{L-1}$ (**B2**). Fig. 3(a) presents a comparison of **B1** and **B2** when $K = 2$ and $N = 2^{16} - 2$ (i.e., $L = 15$). It can be observed that **B1** effectively controls the number of nodes at deeper levels.

The memory space required by ClubHeap at the L-th level can be set as $S_L = \min(\mathbf{B1}, \mathbf{B2})$. Fig. 3(b) shows the ratio of the space required by ClubHeap to the space of M physical PIFOs, namely $\sum S_L / \sum \mathbf{B2}$, for different values of K and $N = 2^{16} - K$ (i.e., $L = 16 - \log K$). When $M = 16$, $\sum S_L$ is only 22.9%∼30.5% of $\sum \mathbf{B2}$, indicating the memory efficiency of **B1**. A smaller K leads to a smaller ratio. In summary, **B1** ensures that the memory required by ClubHeap to store nodes does not increase linearly with M, providing better support for LP than BBQ [4].

3.2 Operations

The *push* and *pop* operations on ClubHeap are similar to those on the other heap-based PIFO queues [8, 62]. For the *push* operation, if the root node r is not full, the element is inserted in it directly. Otherwise, the maximum ranked element in r (also including the newly inserted element) is removed and inserted into a child node in the next level. The recursive process continues until the element is settled. For the *pop* operation, the minimum ranked element in the root node r is popped, and then the minimum ranked element among the two children (if non-empty) is raised to fill the node r. The process is recursive at the deeper levels until no more elements are available to promote.

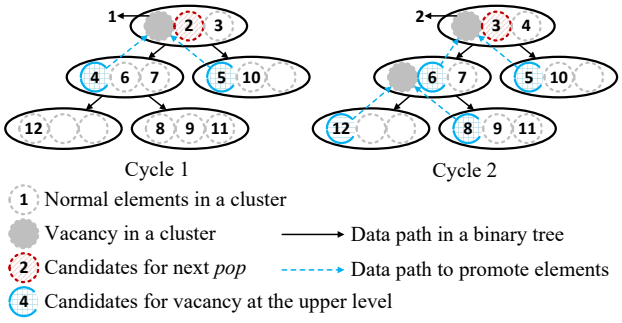


Figure 4: The consecutive *pop* operations on a ClubHeap with no inter-operational data dependency problem.

ClubHeap solves the inter-operational data dependency problem by decomposing the recursion into a sequence of sub-operations without data dependencies. As shown in Fig. 4, we perform consecutive *pop* operations on the ClubHeap in Fig. 2(b). In Cycle 1, element 1 is popped, leaving a vacancy in the root node. Elements 4 and 5 on Level 2 are candidates for promotion. According to ClubHeap's definition, the rank of the promoted element is not less than the remaining elements, so the *pop* operation in Cycle 2 does not depend on the promoted element. In Cycle 2, the element 2 is popped, the element 4 is promoted to Level 1, and elements 12 and 8 on Level 3 compete for the vacancy left on Level 2. Recursively, ClubHeap ensures that each node stores at least $K-1$ smallest ranked elements in its subtree. As long as $K \geq 2$, it can eliminate inter-operational data dependencies between sub-operations on different levels, and ensure that only data paths between adjacent levels are used, thereby reducing pipeline complexity and wire latency.

4 Architectural Design

In the architectural design of ClubHeap, our goal is to achieve CPR= 1 and high clock frequency. We design a pipeline to support CPR= 1, and employ a series of techniques to strive for simplifying the combinational logic circuit in each clock cycle in order to enhance the clock frequency.

In this section, we first present the pipeline architecture in Sec. 4.1 and the technique for efficient cluster storage in Sec. 4.2. We then discuss how the three primitives, i.e., *push*, *pop*, and *replace*, fit into the design in Sec. 4.3. Finally, we discuss the dynamic memory allocation optimization to support the flexible logical partitioning in Sec. 4.4.

4.1 Pipeline Overview

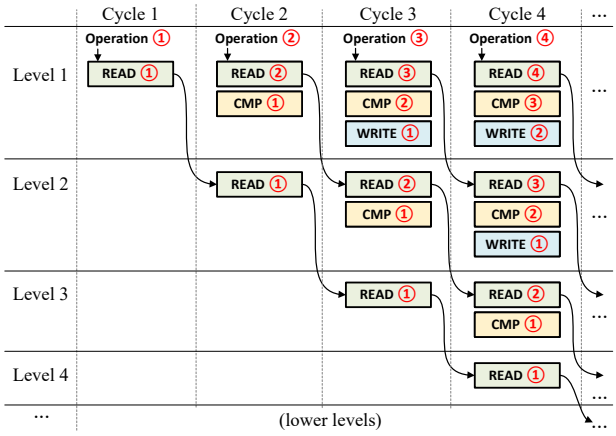

Figure 5: Overview of the ClubHeap pipeline.

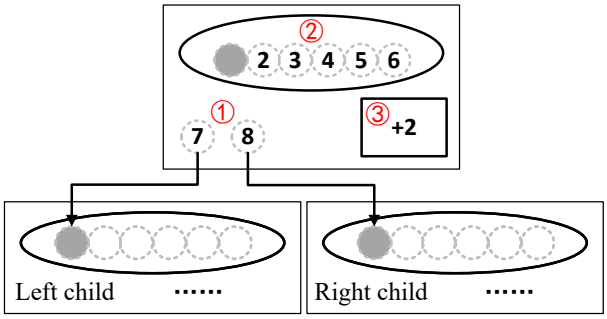
In ClubHeap, each primitive, *push*, *pop*, or *replace*, undergoes three stages at each level of the heap: READ, CMP (short for Compare), and WRITE. These stages are executed in different clock cycles to boost clock frequency. Fig. 5 shows the pipeline design of ClubHeap, where four arbitrary primitive operations ①∼④ enters the pipeline sequentially from Cycle 1 to Cycle 4.

When a signal for an operation arrives at a level, it goes through the three stages in sequence. For example, ① arrives at Level 1 in Cycle 1, so its READ stage is performed in Cycle 1, reading the cluster at the root node. In Cycle 2, ① proceeds to the CMP stage at Level 1, comparing the elements within the read cluster. If ① carries an element (*push* or *replace*), it also compares it with the elements in the cluster. In Cycle 3, ① enters the WRITE stage at Level 1, writing the updated cluster back to Level 1 based on CMP results.

For consecutive operations, different stages of different operations overlap. For instance, at Level 1, the CMP stage of ① and the READ stage of ② are performed in the same cycle (Cycle 2), and the WRITE stage of ①, the CMP stage of ②, and the READ stage of ③ are performed in the same cycle (Cycle 3). Each level can handle up to three parallel operations at different stages. Since no two operations can be in the same stage at the same level, each level only requires one hardware module for each stage, eliminating the concern of resource contention.

When a signal for an operation arrives at a level, it continues to propagate downward until it reaches the bottom level. For example, if ① arrives at Level 1 in Cycle 1, it will propagate to Level 2 in Cycle 2 and Level 3 in Cycle 3, and so on. Although in Cycle 3, ① is not yet aware of the comparison results of the CMP stage at Level 2, the heap structure guarantees that the node operated on at Level 3 must be one of the two child nodes of the node operated on at Level 2. Therefore, while the CMP stage is being performed at Level 2, the READ stage can be initiated at Level 3 simultaneously, reading the two child nodes of the current node.



An operation may complete its task at an intermediate level. For example, when ClubHeap is empty, if ① is a *push* primitive, it only needs to insert the element it carries into the root node at Level 1. After this, the operation becomes a no-op (equivalent to pushing a $+\infty$), continuing to propagate downward and perform READ, CMP, and WRITE stages at each level without any real effect.

4.2 Node Data Structure

As explained in Sec. 4.1, because the CMP stage on the previous level has not yet produced the result when the operation enters the READ stage at the current level, both child nodes of the node being processed at the previous level need to be read simultaneously. This implies that the sibling nodes are better to be stored together to enable a single memory access to acquire both nodes. In addition, as shown in Fig. 6, the storage of the clusters adheres to three characteristics.

(1) The minimum ranked element in a cluster for a non-root node is stored in its parent node.

To illustrate the necessity, we assume that all the elements of a cluster are only stored on its corresponding node. According to Corollary 1 in Sec. 3.1, when a *pop* operation is performed on a node x, if x is full and its two child nodes, y and z, are not empty, we must choose the smaller value between $\min(E(y))$ and $\min(E(z))$ and promote the corresponding element to x to fill the vacancy left by the *pop* operation.

① The minimum ranked element in left and right child
② Elements in the cluster (except the minimum ranked)
③ The difference field

Figure 6: The node data structure in ClubHeap.

Assume x is at Level 1, and y and z are at Level 2. Since both elements with $\min(E(y))$ and $\min(E(z))$ are at Level 2, their comparison results can only be obtained after the CMP stage of Level 2 is completed. However, at the moment, the WRITE stage of Level 1 needs to determine the new $E(x)$ based on the comparison result and write it to memory. The data dependency prohibits the pipeline described in Sec. 4.1 from working properly. To fix the problem, it is necessary to store on node x the two elements with the ranks of $\min E(y)$ and $\min E(z)$ in y and z's clusters, so their comparison can be done during the CMP stage of Level 1.

(2) The elements in the cluster at each node are rank ordered.

If the cluster elements are unordered, comparators are needed to determine the minimum ranked element, which is resource consuming and requires complex combinational logic that can affect the achievable clock frequency. With the ordered elements in a cluster, the CMP stage only needs to compare the carried element of the operation with the first element in the cluster to determine the new minimum ranked element.

(3) At each non-leaf node, a field is used to indicate the difference in the number of elements between the two subtrees.

The `difference` field is used by the *push* operation in ClubHeap to achieve insertion-balance of the element distribution, which ensures free location can be found for the new elements before the heap memory is exhausted. Incoming elements are always inserted into the subtree with fewer elements. In case of a tie, the left subtree is chosen. Some existing heap-based implementations [8, 62] use two `counters` to record the number of elements in both subtrees. However, a field only recording the difference is sufficient to achieve the same effect by saving $\log N - 1$ bits per node.

4.3 ClubHeap Processor

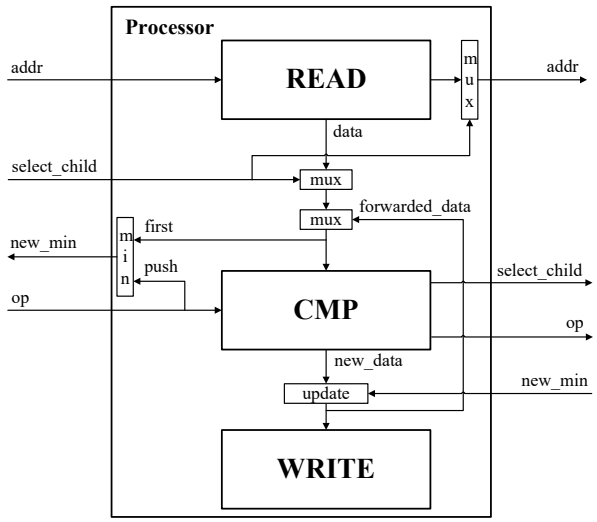


Figure 7: The structure of a processor in ClubHeap.

Each level of ClubHeap has an operation processor and the associated memory. As described in Sec. 4.1, a processor may simultaneously handle the WRITE stage of ①, the CMP stage of ②, and the READ stage of ③. Therefore, a processor in ClubHeap can be divided into three modules with each handling the task for one stage, as shown in Fig. 7. The arrows in the vertical direction represent the data path between the three modules in a single processor. A processor also exchanges data with the upper-level processor and the lower-level processor via the signals in the horizontal direction.

Overall, the READ module reads out a list of rank ordered elements, the CMP module performs parallel comparisons to find the position for writing (*push* or *replace*) or simply removes the first element (*pop*), and the WRITE module writes the result back. The two cycles for the CMP and WRITE stages are similar to the two cycles required for writing into a shift register [51]. Next, we describe the operation of the three modules in detail.

The READ module has only one input signal from the previous level: `addr`, which represents the address line for the nodes to read. As mentioned in Sec. 4.2, sibling nodes are stored together, so the READ module can read a pair of sibling nodes with a single address, and output the data via the `data` signal. Each node contains the data as shown in Fig. 6. Simultaneously, the READ module also obtains the addresses of the respective child nodes of this pair of sibling nodes. The method of storing these addresses is discussed in Sec. 4.4.

The CMP module is the core for executing *push*, *pop*, and *replace* primitives. Firstly, the data from sibling nodes acquired by the READ module passes through a data selector, which selects a branch based on the `select_child` signal generated during the CMP stage of the previous level. Assume the selected node is x. The address of x's child nodes is passed to the READ module of the next level via the `addr` signal, while x's data is sent to the CMP module for comparison. The CMP module determines the current operation type, *push*, *pop*, or *replace*, based on the `op` input signal. It outputs processed node data on the `new_data` signal for writing, and generates a new `op` signal to guide the CMP module at the next level to execute the operation. The `new_data` signal is forwarded as `forwarded_data` when processing the same node in consecutive cycles.

For the *push* operation, we assume the element to be pushed is e. If x is not full, e is directly inserted into the cluster as `new_data` and a new `op` signal, $push(+\infty)$, is generated, which is essentially a no-op. If x is full, e is inserted into the cluster if $rank(e) < \max(E(x))$. In this case, the original element with the $\max(E(x))$ rank value becomes the new e to be pushed to the next level. Otherwise, if $rank(e) \geq \max(E(x))$, the cluster on x is unchanged, and e is to be pushed to the next level. The `difference` field determines the child node for the next level insertion. If $rank(e)$ is less than the minimum rank value of the selected child node (note that the corresponding element e' is stored in node x), e replaces e', and e' is passed to the next level via the output `op` signal; otherwise, the *push* operation with the element e is passed to the next level.

For the *pop* operation, when the CMP module receives the operation from the signal `op`, because the element with $\min(E(x))$ is stored at the previous level, the *pop* operation on the cluster is actually done a cycle earlier. Therefore, the CMP module only needs to select a new minimum to fill the vacancy caused by popping the minimum ranked element, and pass it through `new_min`. Since the elements in a cluster are stored in order, the minimum ranked element can be determined without comparison, i.e., it must be the first element stored at x, or the second smallest ranked element in the cluster of x. Besides, the CMP module compares $\min(E(y))$ and $\min(E(z))$ stored at x, selects the smaller ranked element to be appended to the cluster of x, and passes the *pop* operation via `op` to the corresponding child node at the next level.

For the *replace* operation, since the minimum ranked element is stored at the previous level, the *pop* operation on x is actually performed a cycle earlier in the CMP stage at the previous level, and in the current stage, only two actions are needed: (1) select the new minimum ranked element to fill the vacancy via `new_min`; (2) push a new element e to the cluster, and e can also be selected as `new_min` if its rank value is smaller than that of any other element stored in the node. If $rank(e) < \min(\min(E(y)), \min(E(z)))$, e is directly inserted into the cluster of x, and the new minimum ranked element of x is popped out and returned to the upper level via the `new_min` signal. Otherwise, if $rank(e) \geq \min(\min(E(y)), \min(E(z)))$, the smaller ranked element with the rank value $\min(E(y))$ or $\min(E(z))$ fills the vacancy in the cluster of x, and the $replace(e)$ operation is passed via the `op` signal to the corresponding child node at the next level.

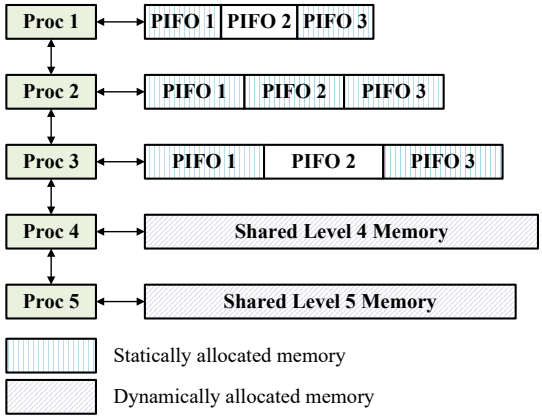

Figure 8: The ClubHeap pipeline structure.

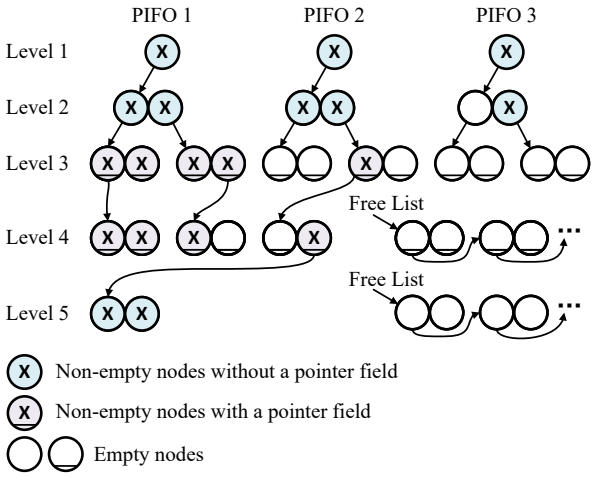

Figure 9: The logical structure of a ClubHeap partitioned into three logical PIFOs.

Finally, the `new_data` output signal from the CMP module is updated by the `new_min` output signal from the data selector in front of the CMP module at the next level, which represents the new minimum ranked element selected by the next level and should be stored at the current level as described in Sec. 4.2. The updated node data is sent to the WRITE module and written to the memory.

4.4 ClubHeap Memory Organization

ClubHeap maintains the memory alongside a processor at each level. The memory is used to support the logical PIFO queues. Since the minimum ranked element of each cluster is actually stored at the upper level, ClubHeap guarantees that the data required in a CMP stage is available at the same level, and thus data dependencies between levels are alleviated. Each processor only accesses the memory at the same level. As shown in Fig. 8, a processor only reads data from memory during the READ stage and writes it back during the WRITE stage, so a dual-port SRAM is sufficient to meet the needs.

Furthermore, as shown in Fig. 8, ClubHeap supports two different forms of memory allocation methods. The static allocation method, similar to P-Heap [8] and BMW-Tree [62], allows for direct child-node address calculation from the current node's address, without the need for storing the child-node's address in memory. Thus, one pointer per node can be saved. However, the drawback is that such allocation implies a complete binary tree, meaning the L-th level of each logical queue requires storage space for 2^{L-1} nodes. With M logical queues provisioned, the memory size required at deeper levels can be prohibitively large.

The discussion in Sec. 3.1 illustrates that the actual storage space required by ClubHeap at the L-th level, S_L, may be significantly less than $\mathbf{B2} = M \times 2^{L-1}$. It is worthwhile to trade a pointer field by reducing **B2** to **B1**. Therefore, as shown in Fig. 8, we employ static memory allocation in shallow levels where **B2**<**B1** and dynamic memory allocation in deep levels where **B1**<**B2** to achieve an optimal space management strategy for different values of M.

As shown in Fig. 9, to achieve dynamic memory allocation for the L-th level, we need to enable the pointer fields of this level and the upper level. During initialization, the pointers at the $(L-1)$-th level are set to *null*, and the pointers at the L-th level are linked into a unidirectional linked list called *free list*. For each pair of sibling nodes in the free list, the left child's pointer field points to the next node, while the right child's pointer is null. If a node is not in the free list, its pointer field either points to its child nodes at the next level if it has non-empty children, or is set to null otherwise. Leaf nodes at the bottom level do not need the pointer field. The `head` address of the free list is maintained by the READ module.

We take dynamic memory allocation at $L = 4$ as an example. The pointer field read from Level 3 is passed as `addr` to Level 4. If `addr` is null (the initial value), the READ module replaces `addr` with `head`, updates `head` with the pointer field of the read node, and resets this pointer field to null. If, at the beginning of the CMP stage at Level 4, it is found that the current node is about to become empty[5] and its sibling node is already empty, a signal is sent to Level 3 to reset the corresponding pointer field to null. Subsequently, during the WRITE stage at Level 4, the pointer field of this empty node is updated to `head`, and the new `head` becomes the address of this empty node. In short, the free list is a stack composed of free nodes, which pops nodes when allocating space and pushes nodes when recycling space. If allocating and recycling occur in the same cycle, the recycled space can be immediately allocated to the new pair of nodes.

[5]The criterion for determining that a node is about to become empty is (1) *push*(+∞) on an empty node, or (2) *pop* on a node with no more than one element. This circuit is only concerned with the valid bits of the elements. The signal to update the pointer field is passed along with `new_min` to the WRITE module of the upper level.

5 Implementation

We implement ClubHeap using 919 lines of Chisel [14] code, and evaluate it on a Xilinx Alveo U280 Data Center Accelerator Card [60] with an FPGA containing 1,303k LUTs, 2,607k Flip-flops (FF), 2,016 Block RAMs (BRAM), and 960 UltraRAMs. The implementation is parameterized, allowing users to specify the parameter K, the maximum number of elements (N), priority levels (P) and logical PIFOs that a ClubHeap can be partitioned into (M). We also implement the existing state-of-the-art PIFO queues BMW-Tree [62] and BBQ [4] on the same FPGA for comparison.

We also analyze the ASIC implementations for some typical specifications with Design Compiler [53] on an open-source 45nm toolchain [17, 23, 40, 55] at a frequency of 800MHz[6]. The reported area is listed in Table 2.

Design	K	N	P	M	Area (mm^2)
BBQ	N/A	2^{17}	2^{16}	1	27.23
ClubHeap	2	2^{17}	2^{16}	1	4.83
ClubHeap	16	2^{17}	2^{16}	1	6.15
ClubHeap	2	2^{17}	2^{32}	2^8	61.00
ClubHeap	16	2^{17}	2^{32}	2^8	63.60

Table 2: ASIC area comparison.

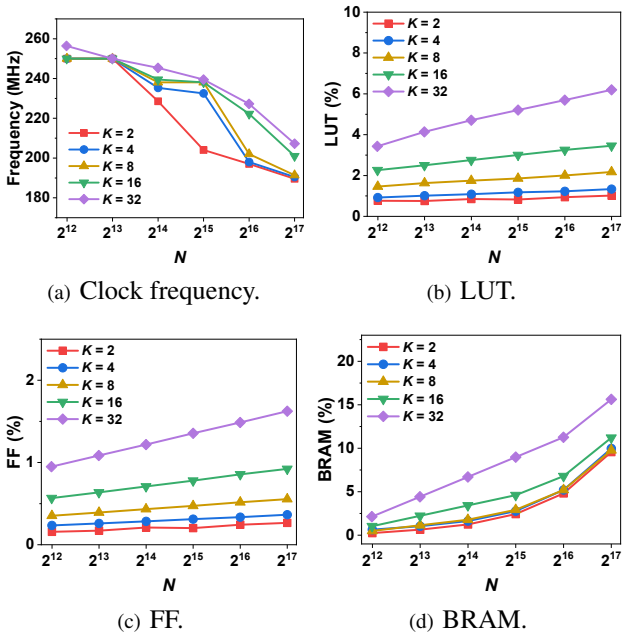

Table 2 indicates ClubHeap consumes only 17.7% (K=2) or 22.6% (K=16) of area used by BBQ for the same specification[7]. BMW-Tree is not listed here because the open-source 4-way implementation can not support N=2^{17}. We conduct a more detailed comparison between ClubHeap, BMW-Tree, and BBQ on FPGA in Sec. 6.

6 Evaluation

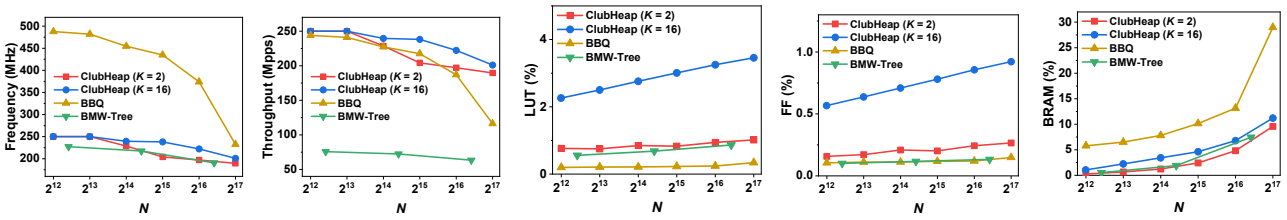
We evaluate ClubHeap through experiments and analysis to show that ClubHeap can meet the demands mentioned in Sec. 2.1, and is the most performant PQ implementation for a PIFO scheduler so far. We first introduce the experimental methodology in Sec. 6.1, then discuss the selection of parameter K in Sec. 6.2, and compare ClubHeap with the state-of-the-art implementations, BMW-Tree and BBQ, in Sec. 6.3. In Sec. 6.4, we show that a clustered multi-way tree is inferior in terms of throughput and resource consumption, which explains why we choose a binary heap rather than a multi-way one.

[6]BBQ claims their *logic* can achieve 3.1GHz in a 7nm process [4, 59], but the bottleneck in large SRAM access is ignored.

[7]Since a ClubHeap with L levels can contain a maximum of $N = K(2^L - 1) = 2^{K+L} - K$ elements, there may be slight variations in N for different values of K. For example, when K=2 and L=15, N=65,534, while for K=4 and L=14, N=65,532. Since these minor differences have almost negligible practical effects, both cases are denoted as $N = 2^{16}$ in our evaluation and considered as the same data point.

(a) Clock frequency. (b) LUT. (c) FF. (d) BRAM.

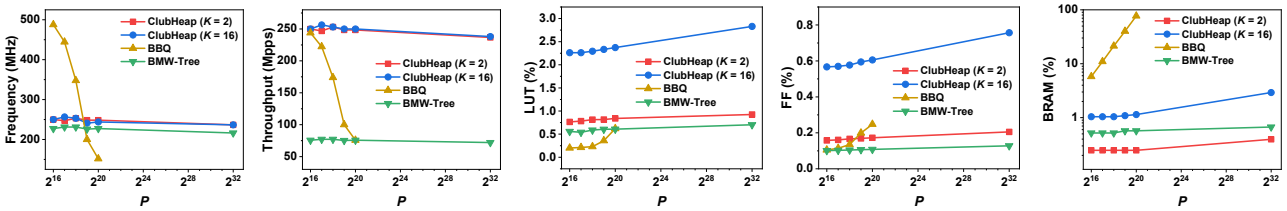
Figure 10: Frequency and resource consumption of ClubHeap with different K.



6.1 Methodology

We evaluate the FPGA implementations of ClubHeap, BMW-Tree, and BBQ for comparison. Clock frequency and resource consumption are reported by Xilinx Vivado, which may differ from existing papers [4, 62] due to different FPGAs. We measure the achievable clock frequency by testing different cycles (step size: 0.025ns) and selecting the minimum allowed. The throughput is obtained via FPGA simulation, as it is independent of traffic characteristics or scheduling algorithms for these structures. For resource consumption, we focus on LUTs, FFs, and BRAMs; UltraRAMs are converted to BRAMs with equivalent storage capacity in results.

Unless otherwise specified, we assume each scheduler element includes a 16-bit rank value (P=2^{16}) and 32-bit metadata (for flow ID, packet ID, etc.), sufficient for most PIFO-based scheduling algorithms [51, 62]. For a fair comparison, we focus on scenarios with one logical PIFO (M=1), as ClubHeap better supports logical partitioning than BMW-Tree and BBQ.



6.2 Effects of Different K Values

We first evaluate the clock frequency and resource consumption of ClubHeap with different K values. As shown in Fig. 10(a), when N=2^{12} and N=2^{13}, clock frequencies are approximately 250MHz regardless of K. As N increases, the clock frequency decreases, and differences in clock frequency begin to emerge for different K. Experiment results indicate that for the same N value, a larger K generally corresponds to a higher clock frequency. At N=2^{17}, the frequency for K=32 is

(a) Clock frequency. (b) Throughput. (c) LUT. (d) FF. (e) BRAM.

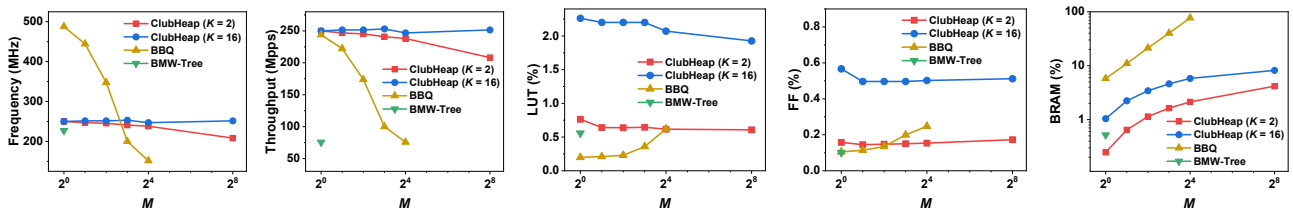
Figure 11: Frequency, throughput and resource consumption for ClubHeap, BBQ and BMW-Tree at different N.

(a) Clock frequency. (b) Throughput. (c) LUT. (d) FF. (e) BRAM.

Figure 12: Frequency, throughput, and resource consumption for ClubHeap, BBQ, and BMW-Tree at different P.

207.25MHz, which is approximately 10% higher than that for K=2 (189.57MHz). This is because a larger K results in fewer levels in ClubHeap, reducing the place and route complexity.

However, a larger K requires more resources on the FPGA, as shown in Fig. 10(b), 10(c), and 10(d). At N=2^{17}, a ClubHeap with K=32 requires relatively 6.2% LUTs and 1.6% FFs, which are approximately 6x those for K=2. Additionally, the growth rate of LUT and FF overhead with increasing N is also higher for a larger K. Comparing N=2^{12} and N=2^{17}, for a 32x increase in N, ClubHeap with K=2 experiences a 33% increase in LUTs and a 68% increase in FFs, while ClubHeap with K=32 experiences an 80% increase in LUTs and a 71% increase in FFs. Overall, ClubHeap's demand for LUTs and FFs is approximately $O(\log N)$, ensuring its good scalability.



For BRAM, although the same number of elements requires the same space, a larger K implies more wasted space and thus requires more BRAMs. Since sibling nodes are stored at the same address, there are only 2^{L-2} addresses for the 2^{L-1} nodes on the L-th level. When L is small, only a small portion of a BRAM block is utilized, leaving the unused space wasted. At N=2^{12}, the number of BRAM blocks required by ClubHeap with K=32 is 8.6x that for K=2. At deeper levels, a BRAM block can be fully utilized, and the number of BRAM blocks is mainly determined by the number of storage bits. A smaller K indicates each node stores fewer elements, leading to more nodes and a greater demand for the difference field and the pointer for dynamic memory allocation. Therefore for a larger N, a smaller K results in more space requirements, reducing the relative savings compared to a larger K. At N=2^{17}, the BRAM consumption for K=32 is only 1.63x that for K=2.

In summary, the analysis indicates that for the same N, ClubHeap with a larger K exhibits a higher clock frequency but also demands more resources. When applying ClubHeap in practice, K can be selected based on the specific requirements as a tradeoff between performance and resource consumption. A proper K value could be 2, 4, 8, or 16.

6.3 Comparison with BMW-Tree and BBQ

We compare ClubHeap with K=2 and K=16 to RPU-BMW, which is the scalable version of BMW-Tree [62], and BBQ [4]. The comparison focuses on three parameters: the number of elements (N), the number of priority levels (P) and the number of logical PIFOs (M).

Evaluation on N. In Fig. 11 we fix P=2^{16} and M=1 to evaluate the scalability of the implementations on N. We observe that for all three PQ implementations, the critical path affecting clock frequency is the combinational logic when N is small, whereas it shifts to SRAM access when N is large, because they all access SRAM in one clock cycle as part of the pipeline design. ClubHeap and BMW-Tree have similar comparator-dominated combinational logic latency; thus, they have similar frequencies. ClubHeap achieves a throughput 3x higher than BMW-Tree with CPR= 3. On the other hand, BBQ's HFFS uses the least combinational logic and has the highest frequency for small N, but the frequency drops rapidly as N increases due to the memory access constraints. As shown in Fig. 11(a), when N=2^{17}, BBQ's clock frequency is comparable to ClubHeap and BMW-Tree, making CPR a more decisive factor for throughput. Fig. 11(b) indicates that ClubHeap's throughput is approximately equal to BBQ for small N, but 63% (K=2) or 72% (K=16) higher when N=2^{17},

(a) Clock frequency. (b) Throughput. (c) LUT. (d) FF. (e) BRAM.

Figure 13: Frequency, throughput, and resource consumption for ClubHeap, BBQ, and BMW-Tree at different M.

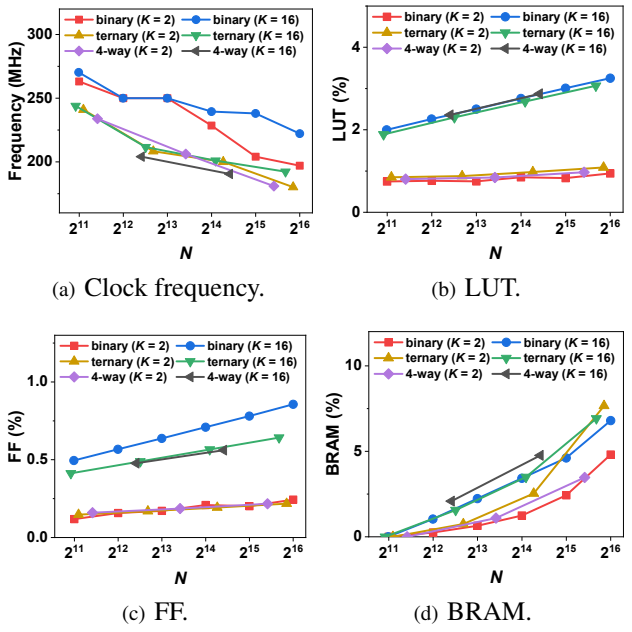
showing better scalability for N than BBQ.

As shown in Fig. 11(c) and 11(d), ClubHeap processors at each level require more LUT and FF resources than BMW-Tree and BBQ. As shown in Fig. 11(e), ClubHeap consumes the similar BRAMs as BMW-Tree, but much fewer than BBQ. At N=2^{17}, ClubHeap consumes 33% (K=2) or 39% (K=16) fewer BRAMs than BBQ. Note that the proportion of LUTs and FFs used by these structures to the total FPGA resources is significantly less than that of BRAMs. Therefore, it is worthwhile for ClubHeap to consume more LUTs and FFs to save BRAMs compared to BBQ.

The 45nm ASIC analysis in Sec. 5 supports the same conclusion. For N=2^{17}, P=2^{16}, and M=1, the clock frequency bottleneck for both ClubHeap and BBQ is SRAM access. BBQ requires larger SRAM which causes higher access latency, while ClubHeap's memory is distributed across levels which has lower access latency. Additionally, ClubHeap consumes less chip area than BBQ. The following evaluations indicate that ClubHeap's advantages become more pronounced as P and M increase. We believe that ClubHeap will remain a better choice at more advanced process nodes.

Evaluation on P. We evaluate the implementations for different P with N=2^{12} and M=1 in Fig. 12 (for BMW-Tree, we select the nearest N=5,460). When the range of ranks is 2x wider, the only changes needed in ClubHeap are an additional bit for the rank field and an additional 1-bit width of the comparators.When P increases from 2^{16} to 2^{20}, the clock frequency of ClubHeap only drops less than 3%. As a heap-based PQ implementation, BMW-Tree exhibits similar scalability for P. However, BBQ needs to expand the number of buckets to support a larger range of P, resulting in poorer scalability. As shown in Fig. 12(a), the large number of buckets poses challenges in routing, causing its clock frequency to drop lower than that of ClubHeap when P=2^{19}. Considering CPR, ClubHeap achieves a throughput 3.28x higher than BBQ when P=2^{20} as shown in Fig. 12(b). BBQ with a larger P fails to be synthesized on our FPGA because of the exhausted BRAMs, while ClubHeap can scale up to P=2^{32} with a cost of only 5.5% frequency reduction.

As shown in Fig. 12(c), 12(d), and 12(e), with the increase of P, BBQ requires more levels or a larger bitmap width for HFFS, resulting in higher consumption of LUTs, FFs, and BRAMs following an $O(M)$ trend. Among them, BRAM consumption grows the fastest, reaching 70x more than ClubHeap (K=2) when P=2^{20}. In contrast, the LUT and FF consumption for ClubHeap grows slowly. When P increases from 2^{16} to 2^{20}, ClubHeap consumes only about 10% additional LUTs and FFs, and the BRAM consumption remains constant when the additional bits do not cause the node size to exceed the width provided by BRAMs at P=2^{16}.



Evaluation on M. Support for logical partitioning is an advantage of ClubHeap over BMW-Tree, so BMW-Tree is represented by only one point (M=1) in Fig. 13. BBQ supports logical partitioning, but it requires evenly dividing buckets among various logical PIFOs. With a constant N and P, M logical PIFOs in BBQ use M times more buckets, which is equivalent to a M times larger P. Fig. 13 shows the frequency, throughput, and resource consumption when a physical queue with N=2^{12} and P=2^{16} is divided into M logical PIFOs. We draw a similar conclusion as for Fig. 12. The frequency of ClubHeap with K=2 decreases by only 16.7% when M scales to 2^8, while at K=16 there is no frequency reduction.

As shown in Fig. 13(c) and 13(d), the LUT and FF consumption decreases when M gets larger, because more memory is synthesized as BRAMs rather than LUTMEMs. It is worth mentioning that the memory space required for ClubHeap has an upper limit independent of M, bounded by **B1**.

In summary, although BBQ achieves a high throughput for small N, it lacks scalability on P and M. BMW-Tree, on the other hand, offers scalability on both N and P, but has lower throughput and does not support logical partitioning.

6.4 Binary Heap vs Multi-way Heap

We compare ClubHeap with clustered ternary and 4-way heaps to explain the rationale for choosing a binary heap rather than a multi-way one. As shown in Fig. 14(a), the frequency of a clustered multi-way heap is always lower than that of ClubHeap. The frequency degradation is because the clustered ternary heap requires more comparisons and selections during the process of selecting `new_min`, resulting in a longer critical path. Meanwhile, as shown in Fig. 14(b), 14(c), and 14(d), the clustered multi-way heap does not reduce the resource consumption as well.

(a) Clock frequency. (b) LUT.

(c) FF. (d) BRAM.

7 Related Works

PIFO [51] is a classical programmable packet scheduling abstraction that can express a wide range of algorithms, but it faces two limitations. (1) PIFO's programmability is achieved through a mesh composed of multiple PQs, but its original implementation , SR-PIFO [51], encounters significant challenges in terms of throughput and scalability. (2) PIFO assumes that the rank of a packet is already calculated when it enters the scheduler and is unchanged thereafter. The assumption makes the abstraction unable to express algorithms with dynamic ranks, e.g. pFabric [3], which introduces a starvation avoidance mechanism to SRPT [46].

Optimization of PIFO. Replacing SR-PIFO with other PQs can help improve the throughput and scalability of PIFO. OPQ and APQ [5] introduce the Single-Instruction-Multiple-Data (SIMD) technique on systolic arrays to enhance throughput, but they lack scalability on the number of elements. Calendar Queues [11], CPI [58], and BBQ [4] implement PQs using buckets, but the number of buckets limits the number of priorities. P-Heap [8], Pipelined Heap [28], H-PQ [26], and BMW-Tree [62, 68] distribute the storage and computation of a PQ across levels using heaps, achieving good scalability. However, the inter-operational data dependency problem discussed in Sec. 2.3 restricts their performance. ClubHeap, proposed in this paper, is the first high-speed and scalable PIFO queue implementation, which can help PIFO overcome the first limitation.

Approximation of PIFO. Another direction to overcome the first limitation is to approximate PIFO by eliminating the need for using a mesh of PQs. UPS [36] employs LSTF as an approximate universal packet scheduling algorithm, enabling programmable packet scheduling with a single PQ. SP-PIFO [1] utilizes a group of FIFOs, clustering flows with similar ranks into the same FIFO to achieve scheduling approximation. FDPA [12], AFQ [47], PCQ [48], PUPD [56], GearBox [20], QCluster [61], and PR-AQM [32] also use multiple FIFOs for approximate scheduling. AIFO [64], on the other hand, only uses a single FIFO, which limits its ability to approximate scheduling order but ensures approximation for whether a packet is admitted or dropped. FAIFO [69] extends AIFO by considering information freshness to better support time-sensitive applications. RIFO [39] improves AIFO's admission control using min-max linear normalization. PACKS [2] is a hybrid structure of SP-PIFO and AIFO, which achieves approximation of PIFO in terms of both scheduling and admission.

Extension of PIFO. New abstractions are proposed to overcome the second limitation. PIEO [49] allows the PQs to pop elements from any location rather than the head only, enabling scheduling with eligibility predicates. PIPO [66] implements an approximated PIEO with multiple PIFO queues for bounded-delay scheduling algorithms. PCSQ [27] extends PIPO to large-scale deterministic networks with long-distance links. CIPO [24] proposes an approximation of PIEO with two-dimensional predicates. DR-PIFO [16] combines a PIFO queue with a group of FIFOs to support dynamic ranks. Eiffel [44] introduces a queue structure based on Circular FFS to provide on-dequeue scheduling. ClubHeap does not support these extended abstractions, but it can be incorporated as a PIFO queue in their implementations.

8 Conclusion

ClubHeap is a novel heap-based PIFO queue implementation. It overcomes the performance and scalability challenges of PIFO's implementations to achieve line-rate scheduling for a large number of flows with a wide range of priority levels. It is beneficial to any programmable schedulers implemented with the PIFO abstraction on switches or SmartNICs based on either FPGA or ASIC.

Abstract. Deficit Round Robin (DRR) is the de facto fair packet scheduler in the Internet due to its superior fairness and scalability. We show that DRR can perform poorly due to its assumptions about packet size distributions and traffic bursts. Concretely, DRR performs best if (1) packet size distributions are known in advance; its optimal performance depends on tuning a parameter based on the largest packet, and (2) all bursts are long and create backlogged queues. We show that neither of these assumptions holds in today's Internet: packet size distributions are varied and dynamic, complicating the tuning of DRR. Plus, Internet traffic consists of many short, latency-sensitive flows, creating small bursts. These flows can experience high latency under DRR as it serves a potentially large number of flows in a round-robin fashion.

To address these shortcomings while retaining the fairness and scalability of DRR, we introduce Self-Clocked Round-Robin Scheduling (SCRR), a parameter-less, low-latency, and scalable packet scheduler that boosts short latency-sensitive flows through careful adjustments to their virtual times without violating their fair share guarantees. We evaluate SCRR using theoretical models and a Linux implementation on a physical testbed. Our results demonstrate that while performing on an equal footing with DRR on achieving flow fairness, SCRR reduces the average CPU overhead by 23% compared to DRR with a small quantum while improving the application latency by 71% compared to DRR with a large quantum.

1 Introduction

The Internet is continuously evolving as a multi-party environment. To meet service performance requirements, enforcing isolation at various levels, from tenants to applications and individual flows is crucial [40, 43, 58, 72, 80, 83]. Packet scheduling offers fine-grained control over network bandwidth at both the edge and core of the network. Despite the abundance of scheduling techniques relying on explicit labeling, such as strict priority queues [28, 77, 89] or time wheels [72, 78], obtaining flow priorities or timestamps from Internet transports is usually not feasible. Instead, Fair Queuing provides fine-grained fairness without flow information, and has been deeply studied from fairness, latency bounds, and computational complexity standpoints [21, 32, 41, 42, 64, 68]. Since Fair Queuing schedulers suffer from non-linear computational complexity that hinders deployment [21, 41, 42], a middle-ground alternative is to use Deficit Round-Robin (DRR) scheduling due to its low overhead and scalability [56, 69, 81, 90]. Indeed, DRR is used everywhere from hardware traffic management pipelines to software middleboxes, host stacks, and network interface cards [6, 7, 12, 14, 15, 82, 83].

Regrettably, Internet traffic has evolved since Deficit Round-Robin was proposed, and its drawbacks are increasingly problematic. Workloads like real-time video conferencing and voice communication, streaming, cloud gaming, and instant messaging are now widespread among more traditional web and file transfer [27, 35, 52, 59, 60, 65, 67, 86, 87]. Such workloads feature diverse properties concerning flow counts, flow arrival rates, flow sizes, packet lengths, packet inter-arrivals, and burstiness [22, 23, 27, 39, 67, 85, 86]. First, concerning burstiness, Internet traffic traces show bursts of packets with diverse lengths and inter-arrivals [1, 4, 20, 22, 29]. Long bursts are prone to creating backlogged queues at the packet scheduler, while, broadly, short bursts from latency-sensitive applications such as web and streaming [61, 74] exhibit periodic on-off arrivals. For example, the median response size for web workloads does not exceed 10 kB, while Variable Bit-Rate (VBR) streaming workloads such as Zoom have a median frame length of 10 kB with large idle gaps between frames [61].

Our experiments with DRR reveal that under a backlogged scheduler, a bursty latency-sensitive flow has to wait for up to a full scheduling round, i.e., until all flows have been serviced at least once, before it can send its traffic. This can be detrimental to the performance of such flows, causing much higher application latency compared to Fair Queueing Schedulers. Even with recent DRR enhancements, such as Sparse Flow Optimization (SFO) [47], which prioritize new incoming flows over backlogged ones to improve responsive-

ness, bursts with more than one packet are prone to being quickly demoted to lower-priority and forced to compete with backlogged flows, thus experiencing long delays.

Secondly, packet lengths are diverse and skewed [1,4,16,20, 22,29] and packet length distribution for wide-area network traffic is difficult to generalize. Many modern applications use small packets to reduce latency and the impact of packet loss [30,79]. Network Interface hardware acceleration [11] may produce very large packets (64 kB). DRR relies on a fixed, user-specified quantum equal to (or larger than) the maximum packet size in the network [81], making it hard to tune. A large quantum can be detrimental to intermediate buffers as it allows large bursts of packets to be sent when servicing each flow [56,69], ultimately increasing response times for latency-sensitive applications. *No packet scheduler today offers low resource utilization, low latency, and adaptability to packet sizes without explicit flow information feedback.*

Our work makes several novel contributions to fair scheduling. First, we show that DRR's drawbacks, i.e., high latency for bursty flows and vulnerability to quantum choice, are measurable at the application level, even on high-speed networks. We further identify the trade-off between latency and CPU utilization to be intrinsic to DRR's design and argue that there's no correct answer to configuring DRR (§2).

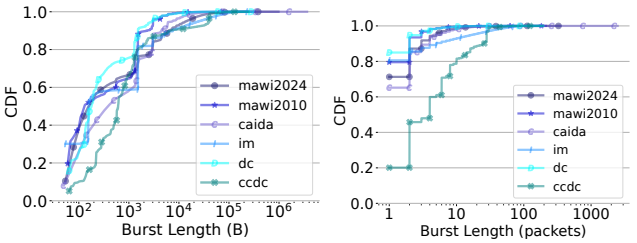
Second, we outline the design of Self-Clocked Round-Robin (SCRR), a novel multi-queue round robin scheduler. SCRR borrows virtual clocking from Fair Queuing [41,42] to eliminate the quantum and enforce fairness, and services sub-queues like DRR in strict sequence for simplicity and scalability. SCRR is parameter-less, light, scalable, and adapts to bursts and packet length variations. We design various SCRR enhancements to efficiently prioritize bursty flows and reduce application latency. When an idle flow becomes active, the scheduler decides its bandwidth allowance via its virtual clock setting. Backed by strong theoretical virtual clocking principles, SCRR can efficiently adjust the virtual clocks for short, bursty flows, allowing them to quickly make progress without violating fairness bounds (§3). Third, we provide rigorous proofs of flow burstiness and fairness for SCRR, guaranteeing that SCRR has the same fairness as DRR with a low maximum burstiness bound (§4).

Fourth, we evaluate SCRR and competing schedulers on a physical testbed under Cubic and BBRv3 using novel experiments. Application-level fairness is tested with thousands of active flows while application latency is measured for request-response flows and VBR traffic. Our results demonstrate that employing SCRR in a software switch reduces CPU utilization by 23% when compared to DRR with 1500B quantum. Our results further reveal that SCRR offers 93×, 71%, and 45% lower response times over tail-drop, DRR with a small quantum, and DRR with a large quantum, respectively. (§5)

SCRR is a step toward more dynamic packet scheduling for multi-party wide-area deployments. It is the first true alternative to DRR, offering the low latency of Start Time Fair Queuing with the low complexity of DRR. Our ultimate goal is for SCRR to replace existing hardware and software packet schedulers because of its plug-and-play deployment, low resource consumption, low latency, and desirable fairness.[1]

2 Packet Scheduling for Modern Internet

Internet workloads incorporate a mix of heavy, throughput-intensive flows, as well as bursty latency-sensitive flows with diverse arrival patterns. Can Deficit Round Robin [81], as the de facto candidate for fair scheduling cope with modern traffic characteristics?



2.1 A brief history of packet scheduling

Historically, Packet-by-packet Generalized Processor Sharing (PGPS) [68] was among the first scheduling paradigms that target fair bandwidth allocation among tenants. Tenants or flows are classified into separate FIFO queues that are then processed by the packet scheduler. Subsequently, numerous Fair Queuing schedulers [32,41,42,45,66,81,90] were introduced with distinct bounds and computational complexities. Classical Fair Queuing algorithms such as Start-Time Fair Queuing (STFQ) [42] have the downside of expensive per-packet sorting operations as they need to constantly track and update the bandwidth allocation for each flow and choose the most eligible sub-queue, i.e., the sub-queue with the least progress. Further, computing requirement scales up with the number of sub-queues.

Deficit Round Robin (DRR) scheduling addresses this shortcoming by allowing constant complexity dequeue operations irrespective of scale [81]. Instead of maintaining a sorted data structure to keep track of flow progress, it visits each sub-queue in a round-robin fashion and allocates a fixed amount of bytes, called *quantum*, to each queue at each round. The part of the quantum that is too small to send the next packet is accumulated as a deficit for the queue. Other variants of DRR, including Weighted Round-Robin (*WRR*) and Modified Deficit Round Robin (*MDRR*) [12] can operate on a limited number of FIFO queues strictly reserved for different flow priorities [6]. These variants have a coarser fairness granularity (per priority group, instead of per-flow) and need to be configured with a deficit value that determines the amount of bytes each priority group transmits on each pass.

Due to its constant computational complexity and low memory footprint, *DRR* is one of the most widely deployed packet schedulers in both software and hardware [6, 7, 12, 14, 15, 81–83]. Even with the emergence of novel queuing abstractions such as *PIFO* [82] and calendar queues [78] that offer advanced traffic classification and shaping, *DRR* endures as a robust and widely used option for flow scheduling, particularly in scenarios where intricate packet

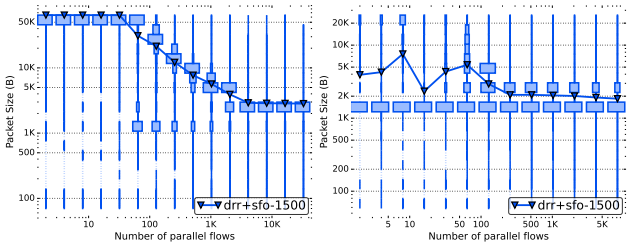
classification is unnecessary [26, 33, 37, 91, 93] and standard TCP support is required.[2]

2.2 Flow burstiness in modern traffic

Burstiness is a well-known phenomenon for Internet traffic due to its multitude of root causes [20, 22, 50, 51, 76, 92]. The emergence of interactive applications such as cloud gaming, video streaming, and video conferencing further underscores a type of traffic that experiences long idle times due to user behavior, network congestion, and variable bit-rate enforcement by the application [20, 44, 61, 75, 87]. Traffic studies further report that many latency-sensitive workloads primarily produce short flows. For example, the median response size for web requests entering Facebook data centers is reported to be less than 10 kilobytes [74], and frames in Zoom video traffic do not exceed 10 kB, with large gaps in between [61].

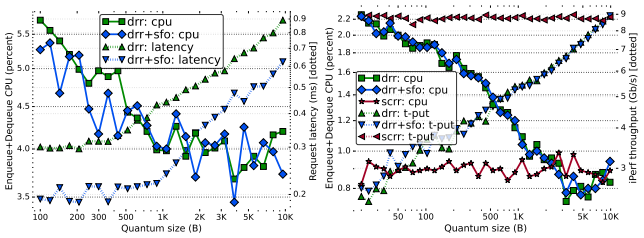
Fig. 1 presents the CDF of burst length distributions for various Internet traces, ranging from backbone internet (*caida*) [4], campus networks (*dc*) [22], and ISP gateways (*mawi*) [29], to instant messaging (*im*) [20] and anonymized traces (*ccdc*) [1] using an Inter-Packet Gap (IPG) threshold of 50 μs (distributions with other IPG thresholds are similar and reported in Appendix C). The diversity in burst sizes suggests that not all Internet flows tend to remain active for a long time as they arrive at a bottleneck. Notably, many flows exhibit small bursts of packets followed by large idle periods. But we also see a number of very large bursts belonging to heavy flows likely to congest the packet scheduler.



DRR has effectively the same theoretical bounds as Fair Queuing schedulers (§2.1): it is fair and has a maximum service deviation of 2× the quantum [81]. The fairness, burstiness and latency guarantees of *DRR* and Fair Queuing schedulers are based on the assumption that all flows arriving at the scheduler are always backlogged [41, 42, 81]. Alas, the above evidence suggests that this is rarely the case for modern Internet traffic! In practice, DRR usually has higher latency for those short bursty flows which are not backlogged at the scheduler, and this is seldom studied. With gaps in arrivals, short flows are prone to get stuck behind backlogged flows in the scheduler. Fig. 2 compares the response times for a request-response workload under two software implementations of *DRR*, the original design presented in [81], and the state-of-the-art implementation of *DRR* which implements *Sparse Flow Optimization (SFO)* [47], a technique that prioritizes interactive traffic (§3.3.1). We compare *DRR* with two different quantum settings: 1500B and 9000B, and with *STFQ* [42]. Two senders generate a total of 16 parallel streams of requests composed of bursts of 150B MSS packets, while the burst length increases on the x axis. Two other senders generate 64 heavy flows each to ensure the scheduler is backlogged. The full experiment setup can be found in §5.5. Latency gaps as large as 4× between *DRR* and *STFQ* suggest that *DRR* degrades the application performance due to poor scheduling decisions regardless of its quantum setting, as consecutive packets in a burst have to wait for full scheduling rounds before they are transmitted. *DRR+SFO* is initially able to bridge this gap by boosting short flows through the scheduler, but as the burst size increases, consecutive packets of the burst do not benefit from prioritization and have to wait.

2.3 The amplifying impact of packet sizes

Packet lengths are diverse in today's networks. Recent studies report a wide variety of packet length distributions observed in the network [4, 20, 22, 71, 92]. Fig. 3 presents the packet size distribution for a few Internet traces. According to these studies, heavier workloads such as instant messaging (*im*) tend to transmit MTU-sized packets while mixed workloads such as *mawi* send a wider range of packet sizes with a considerable number of short packets in the mix. The available backbone traffic packet traces [4] further highlight that packet length distribution constantly alternates in short periods (e.g., between bursts of 550B, 1500B, and 60B segments). Many modern interactive applications use small packets to reduce latency and to minimize the impact of packet loss, while some even adapt their packet sizes based on performance feedback [30, 79]. The quantum for DRR needs to be set based on the packet size [81], which makes it even harder for operators to tune their fixed quantum scheduler since these variations in packet lengths are not only workload-dependent but also volatile in the short term.



Hardware offloads and large packet buffers make it difficult to configure quanta. Software network stacks rely on

[2] We later compare the performance of state-of-the-art implementations of *PIFO*, such as AIFO [89] and *SP-PIFO* [17], with *DRR* in §5. Our results suggest that *AIFO* suffers from severe throughput loss at large RTTs, while *SP-PIFO* causes heavy packet re-ordering.

(a) *TSO on TX machine* (b) *LRO on RX machine*

offloading support in the network interface (NIC) to keep up with their increasing bandwidth [25]. On the transmit side, *Transmit Segmentation Offload* (TSO) breaks large Socket Buffers (SKBs) into MTU-sized packets in the NIC [11]. On the receiving side, *Large Receive Offload* (LRO) aggregates small segments into larger frames [11]. In Linux, by default, the SKB size can run as high as 64 kB and with proposals to greatly increase this maximum [34]. The reduction in SKB rate provided by TSO and LRO improves software performance by reducing the overhead of context switches, cache misses, and metadata handling. However, TSO and LRO force any software packet scheduler to deal with a wide and unpredictable range of packet sizes.

For packet schedulers deployed as part of virtual switches in the datacenter or cloud, the packet size distribution will be dictated by *TSO*. Fig. 4a presents the packet size distribution of experiment §5.3, in the form of parallel histograms (wider bins indicate higher occurrence and the straight horizontal line presents the average packet size over the number of parallel flows) as received by the packet scheduler for different numbers of concurrent *Iperf* flows generated on that server. With more flows, TSO tends to generate smaller packets, as each flow has a smaller bandwidth and TSO tries to match the smaller bandwidth delay product.

For packet schedulers that are part of home routers, SD-WAN gateways, access points or middleboxes, the packet size distribution will be dictated by *LRO*. Fig. 4b presents the packet sizes generated by LRO for experiment §5.3. LRO causes less aggregation than TSO, but is also less predictable, likely due to the interplay of LRO with actual packet arrivals at the NIC and NIC interrupt coalescence. TSO and LRO make it harder to set the quantum optimally, and a quantum greater than the largest packet size, 64 kB, is much too large in most cases.

Mis-configuration with Jumbo Ethernet. Many network devices may not be optimally configured, or are configured conservatively. Most end hosts are configured for standard Ethernet, in case a network device does not support Jumbo packets. If a network device enables support for Jumbo Ethernet [57], e.g., in case some end-hosts need it, then DRR on this device would use a 9 kB quantum when the MTU is effectively 1500 B.

2.4 DRR quantum configuration trade-offs

DRR's quantum is usually set to the maximum packet size in the network (MTU) [81]. Such configuration impacts application performance and resource utilization. With a large quantum, *DRR* produces large bursts of packets that belong to a single flow and a latency-sensitive flow has to wait longer to be allocated its share, increasing the application latency (Fig. 2). Conversely, with a quantum smaller than MTU, DRR may need to spend a few scheduling rounds accumulating enough deficit to transmit a large packet, such missed visits ultimately result in wasted compute resources.[3] Fig. 5a presents the results of an experiment with the *DRR* scheduler mixing latency-sensitive 500B requests traffic (a two packet burst) with heavy background traffic using 1500B packets as an attempt to mimic the mixed and diverse nature of Internet bursts arriving at a bottleneck (the experiment is fully described in §5.5). Increasing the quantum to 10 kB increases the latency of the small requests experienced at the application level (by 140% compared to the best-case latency for *DRR+SFO*). Reducing the quantum to 100B raises the CPU utilization of the scheduler to nearly 7% of the system (around 75% increase), in this case 93% of its scheduling visits are missed due to insufficient deficit.

CPU utilization is a good proxy for the overall resource requirements of the packet scheduler. Some software implementations of packet schedulers in Internet gateways result in reduced network throughput due to their high CPU usage [2, 3]. Fig. 5b shows an incast of heavy flows sharing a bottleneck link serviced by *DRR* as we increase the CPU utilization by reducing the quantum. We use *perf* [9] to measure the CPU consumption of the scheduler's qdisc module. At higher quanta, the lower per-packet processing time is balanced by the increasing packet rate, and CPU usage is constant. A small 20B quantum makes *DRR* the bottleneck and reduces aggregate throughput to 3 Gb/s, which is a third of the capacity. During packet processing many parts of the Linux network stack must be exercised (§D.4). The CPU usage for *DRR* is less than 2.5%, however this increases CPU contention, cache misses and overall pressure on the rest of the networking stack, causing this slowdown.

[3] Some hardware implementations of *DRR* use negative deficits, however after sending a large packet, missed visits will be needed to recover the deficit and avoid unfairness. The only way to eliminate missed visits is either to accept unfairness or to restrict the quantum to be greater than MTU.

3 Self Clocked Round Robin

An ideal packet scheduler should adapt to workload dynamics, such as varying packet sizes and burstiness, both at the flow and packet level, without the need for explicit user input. Conversely, DRR requires quantum configuration based on packet lengths and flow types. In addition, a widespread deployment requires scalability, resource efficiency, and tight bounds on both performance and fairness, which cannot be satisfied altogether by Fair Queuing schedulers. In this section, we introduce *Self-Clocked Round-Robin Scheduling (SCRR)* to address those needs. We design SCRR with the following goals in mind:

- Per-flow or per-class QoS scheduling.
- Fair bandwidth allocation.
- Low scheduling latency for bursty flows.
- Low resource consumption at high loads.
- Scalability to large number of sub-queues.
- Compatibility to any transport, including TCP.
- Parameter-less and agnostic to flow information.
- Plug and play replacement for DRR and Fair Queuing.

To envision SCRR, we find that virtual clocking proves to be a great asset in realizing dynamic scheduling paradigms that adapt to workload changes. Unlike conventional deficit round-robin that sends a predetermined burst on each sub-queue visit, SCRR aims to track virtual times for sub-queues and transmit as much as a flow sub-queue's virtual time allows in order to achieve fair scheduling without relying on any flow information. In order to eliminate the expensive ordered list maintenance as in classical fair scheduling [41, 42], SCRR visits each flow sub-queue in a round-robin fashion. SCRR can be used in both low-load and high-load environments as a parameter-less improvement over DRR. (§3.1)

SCRR is flexible and is augmented by various customizations and enhancements. SCRR can optionally use weight for the sub-queues (§3.1) [32]. It can use the *virtual finish time*, like SCFQ [41], or *virtual start time*, like STFQ [42]. *No Packet Metadata* (§3.2) eliminates the need to tag packets with their virtual time while enqueued, reducing resource requirements. The combination of *Sparse Flow Optimization* (§3.3.1), *Initial Advance* (§3.3.2), and *No Empty* (§3.3.3) use the properties of virtual time to decrease the latency of bursty flows beyond the state of the art, without violating the fairness and burstiness guarantees of SCRR. With these enhancements, when both heavy and short flows are present at the scheduler, bursty flows will not have to wait for multiple scheduling rounds to make progress and enjoy lower scheduling latency.

3.1 Virtual Clocking Semantics

We start by laying out the formal foundations of the SCRR scheduler. All mathematical notations used are summarized in Table 1. The SCRR scheduler maintains a *global virtual clock*, which is updated to the maximum virtual time of dequeued packets at the end of each round. Each sub-queue features a head virtual time which is determined by the virtual time of the packet at the head of the queue. Depending on the head virtual time, sub-queues can be either *lagging* or *leading* compared to the global virtual clock. During each sub-queue visit, the scheduler allows a lagging sub-queue to catch up with the global virtual scheduling time, while a leading sub-queue advances the global virtual clock. During a period that is longer than a scheduling round, sub-queues may change their state from *lagging* to *leading* and vice versa.

Definition 1. A *scheduling round* is the period of time when all active sub-queues have been visited once, and only once. A sub-queue is active when it contains outstanding packets.

Definition 2. A sub-queue is *lagging* (catching up) as long as its head virtual time is smaller than the global virtual clock.

Definition 3. A sub-queue is *leading* as long as its head virtual time is larger or equal to the global virtual.

During each round, the scheduler visits sub-queues in round-robin and forwards all packets that have a virtual time that is older than the global virtual clock. If a sub-queue does not feature a lagging packet, the head packet is transmitted, and the scheduler moves to the next sub-queue. This ensures that no processing cycle is wasted when visiting each sub-queue, while still ensuring that fairness can be achieved via virtual clocking. SCRR effectively implements round-robin scheduling with byte-level fairness granularity and an adaptive quantum equal to the largest serviced packet in a round.

Enqueue Process. Since SCRR is a multi-queue scheduler, the arrived packets undergo a classifier to determine their target sub-queues. In implementations that target per-flow fairness, each flow is stochastically assigned to a separate sub-queue using a flow classifier (e.g., *fq* in Linux). If the sub-queue is backlogged, the virtual time of the tail packet plus its size is used as the virtual time for the new packet. However, if the sub-queue had been idle, the current global clock is used as the packet virtual time. This is to ensure that an idle sub-queue does not receive a large (and consequently, unfair) scheduling share due to inactivity for a long period.

Formally, at scheduling round k, the virtual time of packet p_f^j, i.e., the j'th packet of sub-queue f, is defined as:

$$S(p_i^j) = max\{F(p_i^{j-1}), c(k)\} \quad (1)$$

where $F(p_i^j)$ is the virtual finish time of the previous packet and $c(k)$ denotes the current virtual time of the scheduler. The virtual finish time for packet p_i^j is defined as:

$$F(p_i^j) = S(p_i^j) + \frac{l(p_f^j)}{r_f} \quad (2)$$

Table 1: *Description of mathematical notations.*

Notation	Description
p_f^j	Packet j of flow f
$l(p_f^j)$	Length of packet p_f^j
$c(k)$	Global virtual clock at scheduling round k
$v(p_f^j)$	Virtual time of packet (p_f^j)
r_f	Rate (weight) of flow f
N	Number of packets in the scheduler
Q	Vector of active sub-queues in the scheduler
n	Number of active sub-queues in the scheduler
M	Maximum length among all packets

where $l(p_f^j)$ denotes the length of the packet and r_f is the weight of the sub-queue f. Algorithm 1 in Appendix A presents the enqueue procedure.

Dequeue Process. The majority of virtual timekeeping processes take place during the packet dequeue. SCRR starts with the first non-empty sub-queue and schedules one packet. The scheduler then loops through that sub-queue and transmits packets as long as the virtual time of the head packet is older than the global virtual clock. This approach accomplishes two key objectives. First, it guarantees the transmission of at least one packet from each sub-queue, preventing missed schedule opportunities that lead to wasted compute cycles. Second, it helps the lagging sub-queues to catch up with the leading sub-queues by sending multiple packets. Upon moving to the next sub-queue, the scheduler records the start time of the last dequeued packet and cycles through the remaining active sub-queues. When a scheduling round is finished, SCRR updates the global virtual clock to the maximum packet virtual time that was transmitted during that round. Therefore, an update of the global clock only occurs once during each round to ensure the correct operation of the scheduler. The dequeue procedure is outlined in Algorithm 2 in Appendix A.

The self-clocking semantics in SCRR uses Start-Time Fair Queuing (STFQ) [42] as its basis. Alternatively, as a design choice, it is possible to schedule packets using their virtual finish times as in [41]. In §4, we perform all the correctness proofs for the *start time* version, and in Appendix B.1, we do the same for the *finish-time* version. The two self-clocking paradigms offer identical fairness and burstiness bounds for SCRR and differ slightly in the state-keeping required for the scheduler's implementation. It is also worth noting that all virtual time calculations in SCRR support sub-queue weights to implement QoS, i.e., the packet's length is divided by the weight of its corresponding sub-queue.

3.2 Eliminating per-packet metadata

Both SCFQ [41] and STFQ [42] need to store the virtual time of the packet while the packet is enqueued. Since this is usually done in the packet metadata, it has the downsides of added complexity and increased memory operations. **No Packet Metadata** (NPM) is an enhancement to the SCRR algorithm that computes packet metadata after dequeuing the packet, and therefore eliminates the need to store the virtual time of the packet as metadata.

When dequeuing a packet, the first issue is to know if the sub-queue was idle or backlogged when the packet was enqueued (§3.1). With **NPM**, the scheduler saves the global virtual clock of the previous round. If the virtual time of the last dequeued packet in the sub-queue is greater than previous virtual clock, then that sub-queue was scheduled in the previous or current round, and was backlogged. When a sub-queue is backlogged, the start time of any queued packet can be derived from the finish time of its predecessor in the sub-queue. Consequently, the sub-queue must store the finish time of the last dequeued packet, instead of the finish time of the last enqueued packet. When a sub-queue was idle, NPM always sets to virtual time of the packet to the current global clock. When the sub-queue was idle, the packet virtual time is supposed to be the value of the global virtual clock at the time the packet was enqueued (Equation 1). The insight is that in SCRR, precise virtual timing does not really matter as long as the packet is included in the proper scheduling round and its virtual time does not change the computation of the next global clock. Further, in many cases the sub-queue was added to the schedule in the current round, so the packet virtual time would have been the current global clock anyway.

NPM computes the virtual time of dequeued packets based on the scheduler's previous global time and the previous packet's finish time in the same sub-queue. This simple heuristic makes SCRR as memory efficient as DRR while making the enqueue process a breeze by removing four memory operations during insertion. The theoretical proofs obtained for SCRR also apply to SCRR with NPM, using either the finish time of packets or their start times.

3.3 Flow Latency Enhancements for SCRR

Packets of *backlogged flows* need to wait for all prior packets of the sub-queue to be dequeued, so their queuing delay is the sub-queue's length times the duration of each scheduling round. The latency of such packets is dominated by the queuing delay, therefore their exact position in the scheduling round has little impact on their latency. Further, backlogged flows are usually associated with throughput-intensive applications whose performance is dictated by the fairness of the scheduler. For backlogged flows, round robin schedulers, such as DRR and SCRR, are in practice as good as Fair Queuing schedulers, such as SCFQ and STFQ.

Non-backlogged flows, also called *sparse flows*, don't accumulate packets in the sub-queue, therefore, their packets are immediately eligible to be dequeued. The position of those packets in the scheduling round makes a big difference to their latency. Further, interactive and latency-sensitive

applications are major origins of sparse flows, or flows that alternate between sparse and lightly backlogged. Our aim is to make the latency of SCRR for sparse flows as good as the Fair Queuing schedulers.

Our enhancements for SCRR reduce the latency of *sparse flows*, and as a result make the latency of backlogged flows slightly worse than DRR. As pointed above, backlogged flows are almost never sensitive to such minor differences in latency. This design choice aims to improve the latency of flows that care the most about it. This enables to balance the scheduling performance for various types of flows without explicit flow information.[4] The above enhancements involve various trade-offs between resource usage, latency, and fairness. Hence, it is at the discretion of the network operators to decide which combination of SCRR features to use. We empirically evaluate the direct impact of each of these enhancements on application performance in Appendix D.2.

3.3.1 Sparse Flow Optimization

Sparse Flow Optimization (SFO) is a technique developed for DRR that reduces the latency of bursty flows by prioritizing sparse flows [47]. **SFO** was trivially added to SCRR. In **SFO**, sub-queues that were previously inactive (i.e. sparse) are no longer added at the back of the schedule, but instead in the *new list* of sub-queues that always take precedence over the *old list* of sub-queues (that were already part of the schedule, i.e. backlogged). To prevent sparse sub-queues from starving backlogged sub-queues, newly empty sub-queues are kept in the schedule and are only potentially removed from it during the next scheduling round [19].

3.3.2 Initial Advance for new sub-queues

The trivial version of SFO in *SCRR* does not benefit the bursty flows as well as SFO for *DRR*. With *DRR*, if multiple packets have accumulated prior to a sub-queue being scheduled via SFO, those packets can be sent in the current scheduling round, up to a quantum. With basic SCRR, when a sub-queue has been idle, the virtual time of the first packet is set to the current virtual clock (same as *SCFQ/STFQ*). When the sub-queue is scheduled with SFO, the first packet can be sent, but any subsequent packet has a virtual time in the future and needs to wait for the next scheduling round.

Initial advance fixes this issue by allowing SFO to send multiple packets in the first schedule of a previously inactive sub-queue. It simply sets the virtual time of the first packet based on the previous virtual time instead of the current virtual time (Fig. 6c). The virtual time of subsequent packets is based on the virtual time of the first packet, packet size, and the sub-queue weight, therefore setting a virtual time closer

[4]The Completely Fair Scheduler is a relevant case study. While the original process scheduler design heavily depended upon the use of nice values for latency-sensitive processes, the scheduler was gradually improved to automatically favor interactive applications [24].

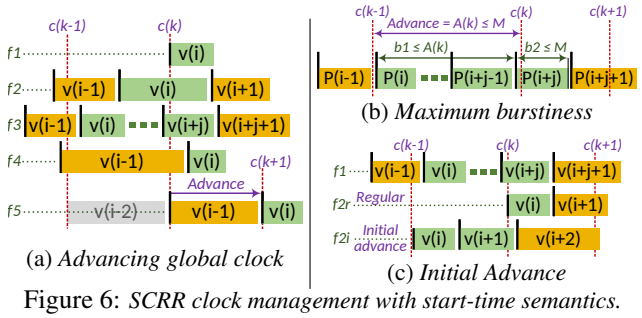

Figure 6: *SCRR clock management with start-time semantics.*

to the previous virtual clock enables potentially more subsequent packets to have a virtual time lower than the current virtual time, and consequently to send more packets in current schedule.

Initial advance will not violate the scheduler's fairness and burstiness properties. The current scheduling round processes packets from sub-queues with virtual times later than the previous virtual clock $c(k-1)$ (Fig. 6a). Therefore, setting the virtual time of the first packet to any value later than the previous virtual clock is still compatible with SCRR. To further prevent unfairness and avoid starvation, SCRR makes sure that the virtual time of a sub-queue used to tag packets can only go forward, not backward. **Initial advance** can be further tuned. To reduce the average flow burstiness, we set the virtual time of the head packet to the previous virtual clock plus the packet's size times the sub-queue weight: if all packets in the sub-queue are the same size, the burst of packets from the sub-queue scheduled by SFO is equal to the advance, instead of the advance plus an additional packet (Fig. 6b).

3.3.3 Getting rid of empty visits with No Empty

SFO in DRR keeps newly empty flows in the schedule for at least one round to prevent unfairness and starvation [19]. This means that the next time that sub-queue is scheduled, if it is still empty, the scheduler needs to remove it from the schedule and pick another sub-queue. This is problematic in software as such empty visits create extraneous cache misses. This is also problematic in hardware with fixed-delay processing pipelines, it makes the amount of work to schedule one packet unpredictable, as many successive empty sub-queues may need to be processed.

No Empty improves SFO and eliminates these empty visits by leveraging the virtual clocking semantics. With **No Empty**, idle sub-queues are never kept in the schedule. To prevent starvation, when a previously inactive sub-queue needs to be inserted into the schedule, its virtual time is checked against the current clock. If a sub-queue has transmitted more than its fair share of packets in the current schedule, its virtual time will have advanced beyond the global virtual clock. If a sub-queue has a virtual time greater than the global virtual clock, it is denied the use of SFO, and is instead added to the back of the *old list* of sub-queues, similar to the original DRR.

Otherwise, it can use SFO and is added at the back of the *new list* of sub-queues.

No Empty is especially attractive to hardware implementations as it makes the processing of SCRR with SFO completely deterministic, without loops and recursions. It also combines with **Initial advance** to benefit bursty flows. In many cases, the packets of the burst do not arrive at the same time. With the original SFO, only the packets already accumulated prior to SFO scheduling are sent in the current schedule, if a packet arrives later, the sub-queue is at the back of the schedule and the packet has to wait a full scheduling round. With **No Empty**, when this later packet arrives, the sub-queue is inactive, and can be inserted in the current scheduling round another time, as long as the virtual time of the packet is older than the current virtual clock.

4 Theoretical Analysis

In this section, we explore the theoretical properties of the scheduler and provide upper bounds for the throughput, fairness, and burstiness.

4.1 Analysis of Backlogged SCRR

Initially, we show that the movement of the global clock under SCRR is tightly bounded during each scheduling round. Next, using this insight, we establish the fairness index of the backlogged scheduler and argue that SCRR enjoys the same fairness index as DRR in the long run. Finally, we argue that the per-flow burst sizes are strictly bounded by two maximum-sized packets, similar to DRR.

Definition 4 (**Single Clock Update per Round**)**.** For the smallest time interval $[t_1, t_2]$ that includes a full round-robin scheduling round, i.e., a period when all active flows are visited at least once, SCRR global clock is updated only once according to the scheduled packet with the highest virtual time value.

Definition 5 (**SCRR Global Clock Updates**)**.** All global clock updates in SCRR occur at the end of a scheduling round, the global clock only advances forward, and the clock update marks the start of a new scheduling round.

Theorem 1 (**The Global Clock Advance Upper Bound**)**.** At each scheduling round, the global clock advancement in SCRR, $A(k)$, is bounded by the maximum packet length.

Proof. Suppose that for the SCRR scheduler with backlogged sub-queues, the global clock is set to $c(k)$ at the beginning of a scheduling round. Since SCRR guarantees the dequeue of a packet upon a visit, packet p_f^i is dequeued for flow f. The packet's virtual time (start time) is $v(p_f^i)$. The following cases can be observed (Fig. 6a):

(1) $v(p_f^i) \leq c(k)$:
The dequeued packet has a virtual time earlier than the global clock (flows *f1*, *f2*, *f3*). In this case, the flow is lagging behind the global clock and the dequeued packet will not move the global clock forward according to Definition 5. The flow will have a chance to dequeue consecutive packets as long as the above condition holds, without an impact on the global clock.

(2) $v(p_f^{i-1}) \leq c(k) < v(p_f^i)$:
The dequeued packet has a virtual time later than the global clock, therefore, this packet can move the global clock to $v(p_f^i)$ (flows *f4*, *f5*). The flow can only send a single packet, since dequeuing any packet with a virtual time after the clock will force the scheduler to switch to a new sub-queue (see §3.1). The value of $v(p_f^i) - v(p_f^{i-1})$ is the size of packet p_f^{i-1}, and is therefore always smaller than the maximum packet size. Let M denote the maximum possible packet size in the scheduler, i.e., $M = max_{f \in Q}(l_f^{max})$. In this condition, the updated virtual clock has the following bound:

$$v(p_f^i) \leq v(p_f^{i-1}) + M \leq c(k) + M$$

$$c(k+1) = max_{f \in Q}(v(p_f^i)) \leq c(k) + M.$$

No other conditions are possible, Theorem 1 follows. □

Theorem 2 (**Maximum Burstiness of SCRR**)**.** At each scheduling round, the aggregate size of a set of packets dequeued from one sub-queue is at most $(r_{\max} + 1)M$, where $r_{\max} = \max_{f \in Q} r_f$.

Proof. We denote the burst size for flow f at round k as $Burst_f^k$. If the flow has become active during the scheduling round, or if the virtual clock of the dequeued packet is later than the global clock, it is only allowed to send a single packet, according to Theorem 1.

If the virtual clock of the dequeued packet is earlier than the global clock, the flow is lagging and all packets with virtual time earlier than the global clock can be dequeued. Given that the virtual time of these packets is later than the global clock of the previous round–otherwise they would have been dequeued during the previous scheduling round–, the set of packets dequeued is constrained by:

$$c(k-1) < v(p_f^i) \leq v(p_f^{i+j}) \leq c(k)$$

The virtual time difference between the first and last packet is bounded by the clock advance, which is bounded by the maximum packet size, M:

$$v(p_f^{i+j}) - v(p_f^i) \leq c(k) - c(k-1) \leq M \tag{3}$$

In a flow, the virtual clock increase of successive packets corresponds to the size of those packets. The virtual clock is based on packet start times (see Fig. 6b for a demonstration), so the clock increase is based on the previous packet. Since $v(p_f^i) - v(p_f^{i-1}) = l(p_f^{i-1})$ and by (3),

$$v(p_f^{i+j}) - v(p_f^i) = \sum_{n=i}^{i+j-1} l(p_f^n)$$

$$Burst_f^k = \sum_{n=i}^{i+j-1} r_{\max} \cdot l(p_f^n) + l(p_f^{i+j}) \leq (r_{\max}+1)M \quad \square$$

4.2 Throughput and Fairness in SCRR

In this section, we derive theoretical bounds for SCRR.

Theorem 3 (Fairness Index for SCRR). The fairness index of SCRR, FairnessIndex_f, is 1 for any flow, f.

Proof. Suppose each flow in our system is continuously backlogged and each packet is tagged with their start-time at enqueue. Let $A(k) = c(k+1) - c(k)$, $n = |Q|$, $M = \max_{f \in Q}\left(l_f^{\max}\right)$, and $R = \sum_{f \in Q} r_f$.

By Theorem 1, $A(k) \leq M$ for each round k. If a packet has a virtual time before or equal to $c(k)$, our algorithm will send it by the end of round k. Thus, the total amount of bytes sent by flow f by the end of round k, $\text{Sent}_{f,k}$, is bounded by

$$r_f \sum_{j=1}^{k} A(j) - M \leq r_f \sum_{j=1}^{k-1} A(j) \leq \text{Sent}_{f,k} \leq r_f \sum_{j=1}^{k} A(j) + M.$$

Similarly, summing over all flows provides bounds for Sent_k, the total amount of data sent overall by round k.

$$\sum_{f \in Q}\left(r_f \sum_{j=1}^{k} A(j) - M\right) \leq \text{Sent}_k \leq \sum_{f \in Q}\left(r_f \sum_{j=1}^{k} A(j) + M\right)$$

Then combining these inequalities gives us

$$\frac{r_f \sum_{j=1}^{k} A(j) - M}{R \sum_{j=1}^{k} A(j) + n \cdot M} \leq \frac{\text{Sent}_{f,k}}{\text{Sent}_k} \leq \frac{r_f \sum_{j=1}^{k} A(j) + M}{R \sum_{j=1}^{k} A(j) - n \cdot M}.$$

As the number of rounds approaches infinity, the fairness quotient converges to r_f/R by the squeeze theorem, and thus our fairness index is

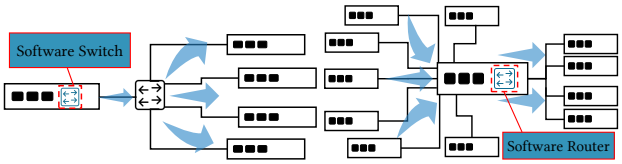
$$\text{FairnessIndex}_f = \frac{FQ_f}{\frac{r_f}{\sum_{g \in Q} r_g}} = \frac{FQ_f}{\frac{r_f}{R}} = 1. \quad \square$$

5 Testbed Evaluations

We present a scalable way to evaluate SCRR by developing a novel approach to testing packet schedulers. We use a physical testbed with synthesized traffic and perform measurements at the application level. For simplicity, we only evaluate flow scheduling, i.e., all scheduling entities (flows) have the same weight. We believe that our findings apply to QoS scheduling, where flows have different weights. Our experiments yield the following findings:

- In the presence of NIC acceleration functions, SCRR reduces the CPU utilization of the packet scheduling operations by up to 46% and 23% compared to STFQ and DRR (with 1500B quantum), respectively (§5.3).
- SCRR achieves equivalent Jain fairness to all fair scheduling schemes when facing up to 20k active flows (§5.4). E.g., SCRR maintains a Jain index of > 0.97 when scheduling up to 20k active flows.
- SCRR offers 87×, 50%, and 18% lower latency for a request-response workload, compared to tail-drop, DRR-1500 with Sparse Flow Optimization, and STFQ, respectively (§5.5).
- SCRR offers 15× and 40% lower frame latency compared to *tail-drop* and *DRR+SFO-1500*, respectively, when scheduling synthetic VBR traffic (§5.5).

A more comprehensive set of results on performance of PIFO approximations (D.1), SCRR's individual components (D.2), application performance under TCP BBRv3 congestion control (D.3), CPU utilization and throughput (D.4), flow fairness (D.5) and application performance under TCP Cubic (D.6) can be found in Appendix D.



5.1 Scheduler Implementations

We implement various queuing disciplines and schedulers in Linux *tc* subsystem as a set of 'qdisc' modules for Linux version 5.10. These software implementations in the *tc* subsystem enable us to use the schedulers on a real system and employ them as part of a sender software switch, a software router, or combined with other qdiscs. Our implementations are compatible with all accelerations of the Linux TCP/IP stack, such as segmentation offloading and interrupt coalescing. Our implementations are intentionally single-threaded to remove the interference from the NIC driver's weighted round-robin scheduler among parallel packet rings [7, 84]. The evaluated systems are as follows:

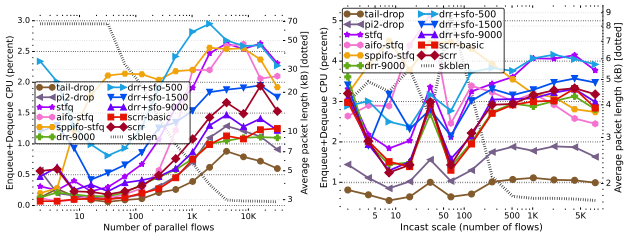
Tail-drop uses the standard byte-FIFO from the Linux kernel (*bfifo*) on a single queue with the default capacity of 18 MB (15 ms of traffic) for a 10 Gbps setup. **PI2** is our own optimized version of the PI2 reference implementation [31]. As a representative of modern Active Queue Management (AQM) [73], PI2 uses a single queue and its target delay is 15 ms (the recommended default).

DRR+SFO is the Deficit Round Robin implementation from the *sch_fq* module [33]. We stripped all extraneous features from this scheduler and kept only the classifier and the scheduler. The simpler code and smaller sub-queue structure help dramatically reduce CPU usage. The classifier is based on a small hash table, and each hash bucket contains an RB-tree [10] holding the sub-queues. This implementation improves the original DRR algorithm [81] with *Sparse Flow Optimization* [47], which prioritizes newly active sub-queues to reduce the response times of latency-sensitive flows. We also include **DRR** in our results to represent the original DRR algorithm without Sparse Flow Optimization. This is the implementation widely found on hardware targets. The suffix of DRR+SFO and DRR indicates its quantum.

SCRR is our implementation of SCRR. This scheduler

(a) *Edge Switching* (b) *Software Routing*

Figure 7: *Topologies in the physical testbed.*



reuses the structure and classifier of the DRR scheduler, along with its sub-queue management and instrumentation. **SCRR** includes four enhancements: *No Packet Metadata* (§3.2), *Sparse Flow Optimization* (§3.3.1) *Initial Advance* (§3.3.2), and *No Empty* (§3.3.3). **SCRR-basic** refers to the SCRR algorithm without these enhancements.

STFQ is our implementation of STFQ [42]. We reuse the structure and classifier of the DRR and SCRR modules. The sub-queue pointers are stored in a sorted RB-tree [10], ordered by the virtual time of the head packets. Using an RB-tree for implementing STFQ proved to be the most efficient way to manage a dynamic sorted list– inspired by CFS [5].

AIFO and **SP-PIFO** are two approximations of Push-In First-Out queuing abstractions that use STFQ prioritization [17, 82, 89]. We implement AIFO using a single FIFO queue with default parameters set as 64 for the sampling and 10% for the burst headroom. SP-PIFO uses 8-level priority FIFOs with no restrictions on their size. We include both techniques in our results and refer the readers to Appendix D.1 for further analysis of these schemes,

5.2 Experiment Setup

We use the two topologies as depicted in Fig. 7. The edge switching topology (Fig. 7a) represents packet switching on a sender host machine, for example in a virtual switch deployed on a server in a datacenter or in the cloud. One server acts as the traffic generator and the schedulers are configured on that server to forward the traffic. This mimics a small-scale outcast traffic pattern setting. The software routing topology (Fig. 7b) is used by default and represents in-network scheduling where one software gateway routes traffic between the senders and receivers, this represents deployment on home routers, SD-WAN gateways, access points or middleboxes. The schedulers are configured on the middle server to forward the traffic between seven receiving network interfaces and one transmitting interface being the bottleneck. This topology enables us to emulate incast traffic patterns. These topologies are implemented in a testbed consisting of ten Linux servers connected via X710 10 Gbps NICs to Aruba 5406R switches. The scheduling server machine in the edge topology features 2x Intel Xeon E5-2643 CPUs totaling 24 logical cores (3.4 GHz). The scheduling server for the routing topology leverages 2x Intel Xeon E5-2680 CPUs totaling 28 cores (2.4 GHz). A subset of our experiments is done in a 25 Gbps topology consisting of four servers in

(a) *TSO* (b) *LRO*

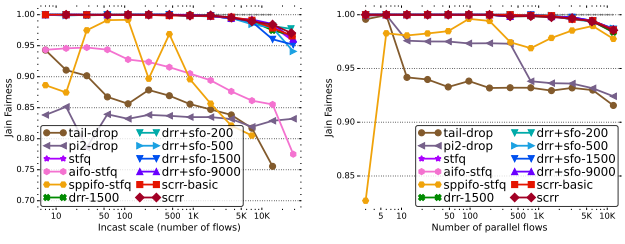


Figure 8: *Impact of increasing Incast scales on CPU utilization in the presence of NIC offloading functions.*

the edge-switching topology, connected via Intel E810 NICs and a Tofino 2 switch. By default, each experiment runs for 1 minute. The workload traffic is generated using versions 2.1.9 and 2.1.10 of *iperf* [8]. The default TCP congestion control is Cubic (refer to §D.3 for BBRv3 results). The default MSS is 1456 bytes and LRO/GRO are disabled unless specified otherwise. In some experiments, Byte Queue Limits are lowered [48], to shrink the NIC transmit queue and to reduce transmit batching, which can decrease application latency. Finally, CPU utilization is measured using Linux *perf* framework [9] by summing the usage of the enqueue and dequeue functions of each scheduler.

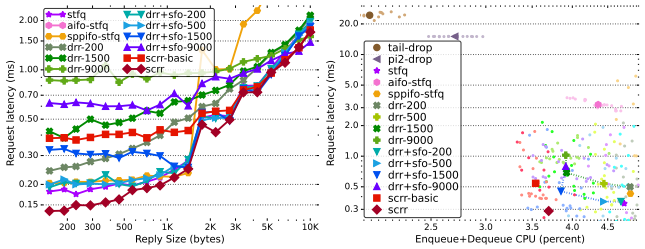
5.3 NIC Accelerations - TSO & LRO

We start by investigating the interaction between hardware offloading functions and the schedulers. Fig. 8a shows the impact of TCP Segmentation Offloading (TSO) on software packet schedulers as we increase the number of TCP flows in the edge switching topology (Fig. 7a). With a larger number of flows, the individual bandwidth share decreases and the average TSO packet size (dotted line) decreases from 64 kB to 1500B (full packet size distribution is in Fig. 4a), causing an increase in CPU usage in all schedulers. Decreasing the quantum of *DRR* increases CPU cycles wasted in missed visits (§2.4). The CPU utilization of *SP-PIFO* and *AIFO* is atypical and described in §D.1.1. We also observe that *SCRR-basic* scheduling automatically lowers CPU usage by adapting to the packet sizes, yielding a similar CPU overhead as *DRR-9000*. This experiment is a worst case for *SCRR*, in our other experiments it often has equal or lower CPU usage than *DRR+SFO-9000* (§5.5). Nevertheless, with 2048 flows, *SCRR* reduces the CPU utilization compared to *STFQ* and *DRR-1500* by 46% and 23%, respectively.

Fig. 8b presents the LRO packet sizes (dotted) received on the router in topology 7b, where each of the two sender machines produces half of the workload flows. The impact of LRO is a lot less predictable than TSO, and less packet aggregation is done (full packet size distribution is in Fig. 4b). *DRR* with smaller quanta cannot adapt to the dynamics of the traffic, causing CPU wastage while *SCRR* offers lower CPU overhead amongst schedulers with flow classification at high scales. Our previous results in Fig. 5b indicate that for

(a) *TCP flows and MSS bias* (b) *UDP flows and rate bias*

Figure 9: *Jain fairness index with different bias settings.*



every 1% increase in the overall CPU utilization of the qdisc up to 17% reduction in throughput can be expected. In other experiments, we disable the offloading functions to prevent the schedulers from dealing with unwanted large segments.

5.4 Application Fairness

The crucial property of a packet scheduler is enforcing fairness and QoS. To better scale the experiments, we configured all sub-queues with identical weights and configured biases between flows to showcase how the scheduler overcome the bias and achieves fairness under backlogged flows.

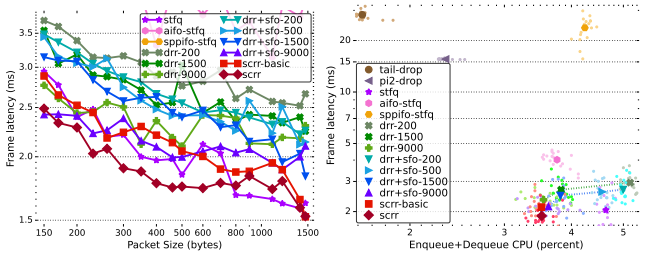


Fig. 9a uses maximum segment sizes (MSS) as the bias between TCP flows, each of the seven senders is using an MSS set to 2500, 3000, 3500, 5000, 6000, 8500, and 8956 bytes, respectively. This forces the schedulers to send more packets from flows that feature smaller packets and can verify the proper byte-level accounting of the schedulers. On each sender, the number of TCP connections varies from 1 to 4096, for a maximum of 28,672 flows. The Jain Index [49] based on the throughput of every flow shows that all Fair Queuing and Round-Robin schedulers, including *SCRR*, offer superior fairness as they enforce byte-level fairness for every flow. Since TCP congestion control is not designed to provide byte-level fairness, *tail-drop* and *PI2* show poor fairness. *AIFO* and *SP-PIFO* also show poor fairness due to their limited number of sub-queues. At a very high number of TCP flows (28k), the fairness of all schedulers is impacted by hash collisions in the classifier, a well-known caveat of using hashing in flow classifiers. Most QoS classifiers have well-defined QoS classes that do not use hashing and would not suffer from this issue. With 28k flows, some flows experience reduced performance or stalls, especially with the *tail-drop* queue.

We repeat the above experiments using UDP and flow rates as the bias in a 25 Gbps setup consisting of one sending machine and three receivers. Each connection pair is configured to offer 16.6, 12.5, and 8.3 Gbps, respectively, all bottlenecked by the sender's 25 Gbps egress bandwidth. According to Fig. 9b, a similar trend can be observed for all evaluated schedulers. The only difference is *AIFO*, which is able to throttle faster flows in order to control the queue utilization. A more comprehensive set of results on fairness using UDP and different bias settings can be found in Appendix D.5.

(a) *Frame size vs latency* (b) *CPU util. vs latency*

Figure 11: *Impact of packet scheduling on VBR frame latency.*

5.5 Bursty Flow Performance

Request-response workloads. Modern networks are filled with small request-response flows [22, 62, 71]. This improved BufferBloat experiment [38] showcases how our schedulers can help those small requests when they are mixed with long-lived heavy flows. Here, two of the receiver machines generate 8 latency-sensitive flows each, the flows are a sequences of short back-to-back request-response with a request of 50B and varying response lengths. The replies are usually a short burst: the TCP ack and one or more packets for the reply. Another two senders generate 32 parallel background long-lived TCP flows each, to force the scheduler to be congested (uncongested schedulers just act as FIFOs).

Fig. 10a presents the latency of a selected subset of the schedulers. As the response size increases, they are split across more TCP segments, requiring more scheduling rounds to be forwarded, and we see a corresponding increase in latency. *SP-PIFO* has poor latency and fairness beyond one MSS, this is detailed in §D.1.3. *DRR+SFO* variants with smaller quanta are able to produce lower response times as smaller response packets experience lower queuing delays, similar to *STFQ*. *SCRR* with its latency enhancements offers superior performance compared to all other alternatives because when a sub-queue is added to the schedule, it can send multiple packets in the round instead of a single packet.

Fig. 10b averages CPU overhead and average latency over all reply sizes of fig. 10a. *Tail-drop* and *PI2* use a single queue that is quickly filled by background TCP flows, imposing a full queuing delay to the request packets. *AIFO* keeps its single queue short (§D.1.2), which only slightly helps its latency at the cost of increased CPU utilization. *SP-PIFO*'s CPU utilization is amongst the highest, and higher than *STFQ*

(§D.1.1). The performance trade-offs of *DRR* is detailed in Fig. 5a. In this experiment, 500B looks to be a sweet spot for quanta setting. Other configurations may lead to different sweet spots (see §D.6). Both *SCRR* and *SCRR-basic* adapt to packet sizes and are therefore able to offer smaller latency than the optimally configured *DRR+SFO-1500*. Specifically, *SCRR* is able to achieve lower CPU utilization than all *DRR* counterparts while improving the application latency by 87×, 1.5×, and 1.18×, compared to *tail-drop*, *DRR+SFO-1500*, and *STFQ*, respectively. A more comprehensive performance study of SCRR components can be found in Appendix D.2.

Streaming workloads. Streaming workloads are nowadays popular [55]. They commonly use *Variable Bit Rate (VBR)* encoding and reduce their packet sizes to mitigate the impact of packet losses [30, 79]. Those short bursts of small packets will alternate between sparse and backlogged, demanding low latency and high throughput performance from the scheduler. We use the *isochronous* capability in *Iperf* to emulate 64 concurrent VBR UDP flows on two servers, each targeting 1.5 Mbps and 30 Frames Per Second (FPS), which represents a typical 720p Zoom video communication bitrate. The VBR flows are competing in 7b topology with 128 long-running heavy TCP flows from two servers. Fig. 11 presents the one-way latency of each frame for different schedulers. Reducing packet size decreases performance as the header and processing overheads of small packets hurts their throughput. For *DRR*, the increased CPU utilization of short quantum hurts the throughput of the burst. *STFQ* manages low latency despite its high CPU utilization. Much like the request-response workload, the majority of VBR frames are bursty, therefore, *SCRR* which is carefully designed for bursty flow performance offers superior latency compared to all alternatives. Concretely, *SCRR* offers 15×, 1.4×, and 1.08× lower frame latency compared to *tail-drop*, *DRR+SFO-1500*, and *STFQ*, respectively. Our experiments with BBRv3 congestion control in Appendix D.3 further confirm that while congestion control has no impact on the performance of short bursty flows, *SCRR* can provide lower latency and resource utilization compared to the state-of-the-art schedulers.

6 Related Work

Starting from Nagle's [64] practical fair queuing, packet scheduling has been the focus of numerous works.

The Origin of Self-Clocking. Packet-based Generalized Processor Sharing (*PGPS*) scheduling [68] studies latency and burstiness bounds with virtual clocking and leaky bucket admission control. Self-Clocked Fair Queuing (*SCFQ*) [41] tags packets with a virtual clock, indicating their *virtual finish time* (expected end of transmission). To determine eligible queues for transmission, the scheduler maintains a sorted list based on virtual times of head packets. Upon enqueue, each packet's virtual time is calculated as the queue's current virtual time, augmented by the packet's length, proportional to the queue's assigned weight assigned. After transmission, the scheduler updates its virtual time to the transmitted packet's time.

Start-Time Fair Queuing (*STFQ*) [42] is a similar fair queuing paradigm, using virtual clocking but tags packets with their virtual start time (expected start of transmission). This virtual time equals the finish time of the tail packet if the queue is backlogged or the scheduler's global virtual time if idle. *STFQ* improves *SCFQ*'s average scheduling delays by 53% [42], but its O($log(n)$) computational complexity limits its practicality. Several works explore *STFQ*'s implementation [45, 53, 88] or attempt to approximate it in programmable hardware [17, 63, 89]. However, scalability challenges remain [45, 82], and existing approximations fail to ensure flow fairness and ideal sparse flow performance. Fair queuing schedulers have strong performance, and may outperform SCRR for some workloads or configurations. Finally, *DRR* variants [56, 69, 81] offer flow-level fairness, but using a user-specified quantum makes it difficult to argue their performance trade-offs.

Programmable and priority packet scheduling. [78] implements a programmable queuing abstraction for complex scheduling and queue management paradigms such as *Weighted Fair Queuing*. Similarly, *PIFO* [82] enables packet-level prioritization at a limited scale in hardware. As shown in Appendix D.1, existing programmable scheduling implementations suffer from under-utilization and heavy packet reordering. *AFQ* [77] similarly approximates fair queuing paradigms in programmable hardware. *Karuna* [28] presents packet scheduling for deadline flows. *SCRR* focuses on standard TCP/IP networks while allowing for future extensions.

7 Conclusions

Dating back to almost three decades ago, deficit round-robin is still one of today's widely used fair queueing paradigms. This paper identifies the diversity in packet sizes and burstiness as two critical characteristics of modern Internet traffic that make DRR's performance unpredictable and sub-optimal. We then revisit classical fair queueing and introduce the *Self-Clocked Round Robin Scheduler (SCRR)* with strong fairness bounds. We augment SCRR with enhancements that target bursty, latency-sensitive flows over the Internet. Our physical testbed evaluations, carefully crafted to probe the performance of the packet scheduler, reveal that *SCRR* offers lower resource consumption and superior latency performance compared to widely deployed scheduling and policing mechanisms.

Acknowledgments

We thank our shepherd John Sonchack and all the anonymous reviewers for their constructive feedback. We thank Hewlett Packard Labs for hosting the first two authors as interns during this work. The work is partially supported by NSF CNS NeTS grant 2313164.

A Self-Clocked Round-Robin Scheduling

This section expands on the design of the Self-Clocked Round-Robin (SCRR) packet scheduler. Both *SCRR-basic* and *SCRR* with its enhancements are presented.

Algorithm 1 SCRR-basic Enqueue

```
function ENQUEUE(pkt)
    cur_queue ← classify(pkt)
    if cur_queue is inactive then
        sub_queues.tail ← cur_queue
        rounds ← rounds + 1
    end if
    pkt.virtual ← max(virtual_clock, cur_queue.clock)
    cur_queue.clock ← pkt.virt_tag + pkt.length
    cur_queue.enqueue(pkt)
end function
```

Algorithm 2 SCRR-basic Dequeue

```
Require: NP ≥ 0                                   ▷ Packet Count
function DEQUEUE                                  ▷ Packet Retrieval
    if NP == 0 then return NULL
    end if
    cur_queue ← sub_queues.head
    pkt ← cur_queue.dequeue()
    NP ← NP − 1
                                                  ▷ Global Clock Advance
    if NP == 0 then
        virtual_dequeue ← pkt.virtual + pkt.length
        virtual_clock ← virtual_dequeue
    else if pkt.virtual > virtual_dequeue then
        virtual_dequeue ← pkt.virtual
    end if
                                                  ▷ Sub-Queue Round Robin
    virtual_next ← pkt.virtual_time + pkt.length
    if virtual_next > virtual_clock or cur_queue is empty
then
        if rounds ≤ 0 then
            virtual_clock ← virtual_dequeue
            rounds ← all_queues.length
        end if
        rounds ← rounds − 1
        sub_queues.head ← cur_queue.next
        if cur_queue is not empty then
            sub_queues.tail ← cur_queue
        end if
    end if
     return pkt
end function
```

A.1 Pseudo code of SCRR-basic

SCRR-basic is the simplest of all the variants of SCRR. The pseudo-code for the **enqueue process** of SCRR-basic is shown in Algorithm 1. This is the process that is run when a new packet arrives at the scheduler. First, the arrived packet passes through the classifier to obtain its sub-queue handle, i.e. the sub-queue where it will be enqueued. When doing per-flow classification, the 5-tuple from the packet header is used to select a sub-queue (source IP, destination IP, protocol, source transport port and destination transport port). Other QoS classifiers can also be used with SCRR. The current sub-queue may be active (already in the schedule) or inactive (empty). In the case the sub-queue is inactive, it is added at the end of the schedule, the schedule is a simple linked list of sub-queues. Tagging a packet with its virtual time is implementation dependent and usually done in the metadata associated with the packet. The packet virtual time is computed here exactly like *STFQ* [42], i.e., the most recent of the global clock and the finish time of the previous packet added to the sub-queue. The virtual time of the sub-queue is updated with the finish time of the new packet by adding its length in bytes. In the weighted version of SCRR, the packet length would be multiplied by the sub-queue weight. Ultimately, the packet is added to the SKB list of the corresponding sub-queue.

The pseudo-code for the **dequeue process** of SCRR-basic is shown in Algorithm 2. This is the process that is run when a packet needs to be sent over the outgoing link. First, a packet is extracted from the current sub-queue. Then, the global clock advance is computed. While conceptually similar to *STFQ* [42], SCRR makes sure that the clock can only go forward. Then, to advance the global clock, the scheduler maintains a temporary *virtual_dequeue* clock that tracks the largest virtual time of packets dequeued during the scheduling round. After finishing a scheduling round, the global clock is set to *virtual_dequeue*. The next part is where SCRR distinguishes itself from *STFQ*. SCRR uses the virtual time of the next packet in the sub-queue to decide if it stays on that sub-queue or round robin to the next sub-queue. If the virtual time is in the future (greater than current clock), or if the sub-queue is empty, then the scheduler moves on to the next sub-queue (that will be used next time the function is called). If a number of scheduling rounds equal to the number of sub-queues has elapsed, the virtual clock is updated with *virtual_dequeue* (the largest of the packet virtual times dequeued during that scheduling round). If the sub-queue is not empty, it is put at the back of the schedule, so that its packets can be sent at the next scheduling round.

The dequeue process must properly keep track of scheduling rounds. The enqueue process may add a previously inactive sub-queue to the current scheduling round. Tracking the scheduling round is needed to ensure that the global clock is only updated between rounds. If the global clock were to be

Algorithm 3 SCRR Enqueue (with enhancements)

```
function ENQUEUE(pkt)
    cur_queue ← classify(pkt)
    if cur_queue is inactive then
                                                ▷ No Empty
        if cur_queue.clock <= virtual_clock or nq == 0
then                                  ▷ Sparse Flow Optimization
            new_queues.tail ← cur_queue
            rounds ← rounds + 1
        else
            old_queues.tail ← cur_queue
        end if
    end if
    cur_queue.enqueue(pkt)
end function
```

updated after each packet transmission, the later sub-queues might fall further behind the global clock, leading to large unwanted packet bursts.

The algorithm describes SCRR-basic using the *start-time* of the packet like STFQ [42]. SCRR can also be implemented using the *finish-time* of the packet, similar to SCFQ [41]. We chose the *start-time* because it enables us to make SCRR's implementation simpler by computing the virtual time of the next packet without any information about that packet.

A.2 Pseudo code of SCRR with enhancements

SCRR, for brevity, refers to the variant of SCRR scheduler that includes all the enhancements, *No Packet Metadata*, *Sparse Flow Optimization*, *Initial Advance* and *No Empty*. In this section, we will only highlight the differences from SCRR-basic in §A.1.

The pseudo-code for the **enqueue process** of SCRR is shown in Algorithm 3. SCRR uses the *No Packet Metadata* enhancement, therefore the packet virtual time is not computed in the enqueue process, but in the dequeue process. Consequently, the packet is not tagged with its virtual time. In case the sub-queue has been inactive, SCRR uses the *No Empty* enhancement to decide how to schedule that sub-queue. If the finish time of the last packet on this sub-queue is in the past (earlier than the current clock), then the new packet can be fit into the schedule. In this case, it is eligible to use *Sparse Flow Optimization* and the inactive sub-queue is added to the list of sub-queue for priority scheduling. Otherwise, it is added at the end of the schedule.

The pseudo-code for the **dequeue process** of SCRR-basic is shown in Algorithm 4. SCRR uses *Sparse Flow Optimization*, therefore it first looks for a sub-queue in the list of previously inactive sub-queues, and only if that list is empty, it looks in the regular schedule. With *No Packet Metadata*, packet virtual time can be computed in dequeue. If the virtual finish of the last packet on the sub-queue is older than the virtual clock of the previous scheduling round, then that sub-queue was inactive. If the queue was inactive, and *Initial*

Algorithm 4 SCRR Dequeue (with enhancements)

```
Require: NP ≥ 0                                  ▷ Packet Count
Require: nq ≥ 0                    ▷ Active Sub-queue Count

```

Advance is enabled, the packet virtual time is based on the virtual clock of the previous scheduling round, this enables the sub-queue to potentially send a few packets in the current scheduling round before its clock advances beyond the global clock. Otherwise, it uses the current virtual clock, and the sub-queue can only send one packet in the current schedule. If the sub-queue has been active, the packet virtual time is based on the virtual time of the previous packet in that sub-queue, like in *SCRR-basic* and *STFQ*. After that, the sub-queue's clock is advanced based on the packet length and optionally the sub-queue's weight. The rest of the dequeuing process is identical to *SCRR-basic*, except the need to keep track of the global clock of the previous scheduling round.

B Extended Theoretical Analysis

This section expands the theoretical properties of the scheduler, extending our findings in §4. We present the analysis of SCRR using finish-time semantics.

B.1 Analysis of Backlogged SCRR Using Finish-time Semantics

Section 4.1 studies the SCRR scheduler using start time, similar to STFQ [42]. SCRR can also use finish time, similar to SCFQ [41]. Using the finish time in SCRR does not change the way the schedule behaves and similar proofs can be obtained for SCRR's fairness.

In Theorem 1, the packet virtual time is $v(p_f^i)$ and is equal to its finish-time (Fig. 12). In case (2), The value of $v(p_f^i) - v(p_f^{i-1})$ is the size of packet p_f^i (instead of packet p_f^{i-1}), this packet is still smaller than the maximum packet size, therefore the bound for case (2) is:
$v(p_f^i) \leq v(p_f^{i-1}) + M \leq c(k) + M$.
$c(k+1) = max_{f \in Q}(v(p_f^i)) \leq c(k) + M$.

The bound for case (2) is unchanged, and the other case is unchanged, therefore Theorem 1 also applies when using finish time.

In Theorem 2, equation 3 remains unchanged. Since the virtual clock is based on packet's finish time (Fig. 13), the increase in the global clock occurs based on the current packet (instead of the previous packet) :

$$v(p_f^{i+j}) - v(p_f^i) = \sum_{n=i+1}^{i+j} l(p_f^n)$$

$$Burst_f^k = \sum_{n=i}^{i+j} l(p_f^n) = l(p_f^i) + \sum_{n=i+1}^{i+j} l(p_f^n)$$

$$Burst_f^k \leq M + M$$

Throughput Bounds and Fairness. The proof of fairness with the finish time is identical to the proof using start-time (§4.2). The only difference is that we define $A(k) = c(k) - c(k-1)$ (instead of $A(k) = c(k+1) - c(k)$). The rest of the proof is unchanged, and as the number of rounds approaches infinity, the fairness quotient converges to $\frac{1}{n}$ and the fairness index converges to 1.

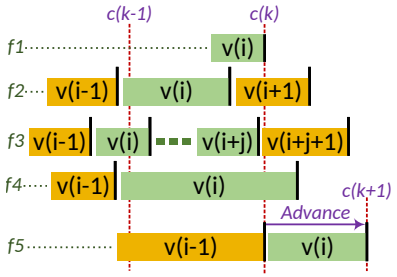

Figure 12: *Advancing the global clock in SCRR with finish-time semantics.*

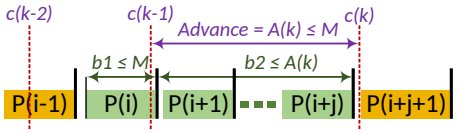

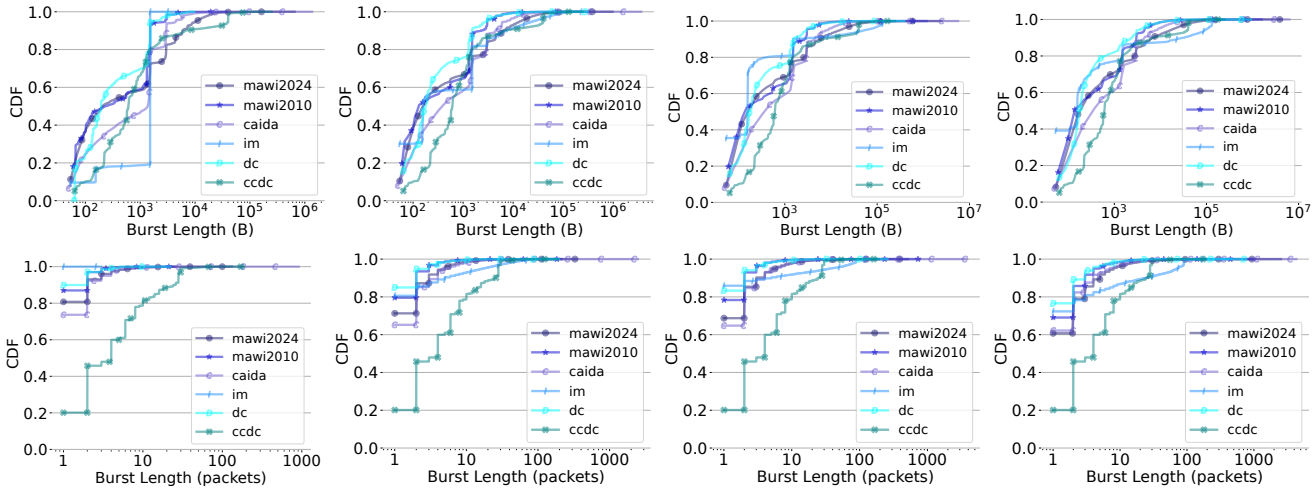

Figure 13: *Burstiness of SCRR with finish-time semantics.*

C Burstiness in Internet Traces

A burst is a train of packets with inter-packet gaps smaller than a threshold [51]. Using this definition, we plot the CDF of burst lengths for six representative Internet traces [1, 4, 20, 22, 29] in Fig. 14. Regardless of the threshold, a diverse range of burst lengths can be observed which suggests that Internet workloads feature both heavily backlogged and short flows arriving at the bottlenecks. In fact. the similarity among burst size distributions with different Inter-Packet Gap (IPG) thresholds suggest that our analysis of Internet bursts in §2 is independent of the chosen threshold. Additionally, the above figures highlight the presence of back-to-back packets with very small gaps, forming up a burst, and large inactivity gaps between bursts. This can be partly attributed to factors such as user behavior, especially for workloads like video streaming. We explore the performance of packet scheduling under VBR workloads in §5.5 and more thoroughly in Appendices D.3 and D.6.

D Extended Testbed Evaluation

This section presents an extended version of the testbed evaluation in §5, putting together our results of scheduling in the presence of NIC offloading, fairness experiments, and application latency experiments, *SCRR*'s component analysis, and a closer look at the performance of existing *PIFO* implementations.

(a) *IPG < 10µs* (b) *IPG < 50µs* (c) *IPG < 100µs* (d) *IPG < 500µs*

Figure 14: *Burst length distribution for Internet traces using various IPG thresholds.*

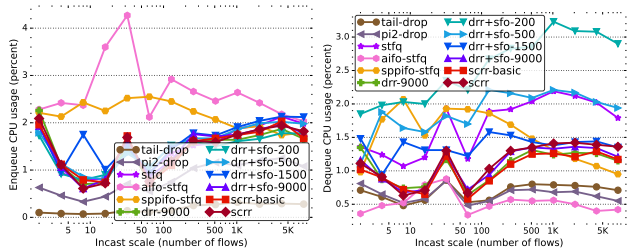
D.1 Performance of *PIFO* Approximations

Push-In First-Out abstraction [82] presents an interesting breakthrough in realizing priority packet scheduling, paving the way for maintaining priority lists in hardware that can realize schemes such as *STFQ* [42] and *pfabric* [18]. To overcome the practical roadblocks of deploying *PIFO*, recent works attempt to approximate *PIFO* using admission control on a single queue [89], and using strict-priority FIFOs [17].

D.1.1 CPU utilization in *AIFO* and *SP-PIFO* is high

The CPU utilization profile of *AIFO* is strikingly different from conventional packet schedulers. Fig. 15 shows the CPU utilization of the enqueue and dequeue functions separately for the experiment shown in Fig. 8a (§5.3). The CPU utilization of *AIFO* dequeue function is lower than even Tail-drop (Fig. 15b), because *AIFO* keeps the queue much shorter than other packet schedulers (§D.1.2) and reduces the overall cache footprint. On the other hand, the CPU utilization in enqueue is very high (Fig. 15a) due to the rank sampling and percentile calculation [89]. Since the rank sampling of *AIFO* can be tuned, we configured *AIFO* to sample the rank every 16 packets and to maintain up to 64 samples. We increased the maximum number of samples from the default [89] to improve *AIFO*'s fairness. In practice, the number of samples is usually much lower than 64, because only the samples still in the queue are considered, and the queue is kept short. Changes to the rank sampling rate and the maximum number of rank samples would obviously impact *AIFO*'s fairness and CPU utilization, however we haven't found a configuration giving better overall performance than *STFQ* in our experiments.

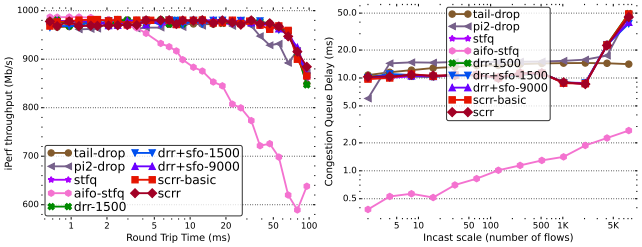
The CPU utilization profile of *SP-PIFO* is more balanced. In enqueue, there is additional overhead in choosing the proper priority sub-queue and keeping track of the rank of each priority sub-queue (Fig. 15a). In dequeue, there is additional overhead in scanning the priority sub-queues (Fig. 15b). For the majority of data points, *SP-PIFO* has higher CPU utilization than *STFQ* with higher application latency (Fig. 21, 22, 23).



D.1.2 *AIFO* causes queue underutilization

AIFO selectively drops packets prior to admitting them in its single queue. For each packet, it computes a rank, and compares this rank to the distribution of ranks for packet already in the queue. If the percentile of the packet is lower than the current queue occupancy, the packet is dropped, otherwise it is admitted. *AIFO* implements *STFQ* by calculating the packet rank from packet virtual times.

In Fig. 16a, a single TCP flow with increasing RTT is run through a bottleneck. The bottleneck is created using Linux TBF rate limiter [54], while the RTT in increased by adding a fixed delay with Linux *NetEm* [46]. Each scheduler is configured for 15 ms queuing delay. The theory of buffer sizing [46] predicts that the 15 ms queue should be large enough for TCP Cubic traffic with RTT up to 35 ms. This is the case for all schedulers, except *AIFO*.



The problem is that when using *STFQ*, the statistical distribution of ranks is highly biased, and the statistical admission control of *AIFO* is no longer appropriate. With a single flow, the virtual time of incoming packets is strictly increasing, as it is always larger than any other packet in the queue, and is therefore always rejected based on its rank. *AIFO* also includes a burst mechanism: when the queue utilization is below 10%, packets are never dropped. As a result, with a single flow, *AIFO* can only use the portion on the queue configured for burst. This underutilization of the queue has direct impact on TCP performance as depicted in Fig 16a.

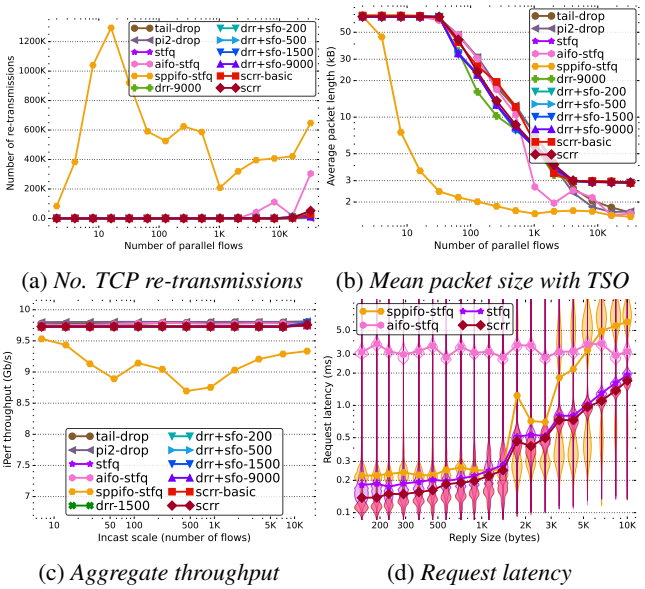
Fig 16b shows that even for very large number of flows

(a) *LRO - Enqueue* (b) *LRO - Dequeue*

Figure 15: *Impact of increasing Incast scales on CPU utilization in the presence of NIC offloading functions.*

(a) *Throughput as RTT increases* (b) *Queue utilization*

Figure 16: *Throughput and queue utilization of AIFO under different schedulers as RTT and flow count increase.*



(10k), the statistics of packet virtual times are still sufficiently biased to show severe queue uderutilization with *AIFO*. The amount of queue underutilization decreases with the number of flows, therefore it is not possible to fully compensate for it.

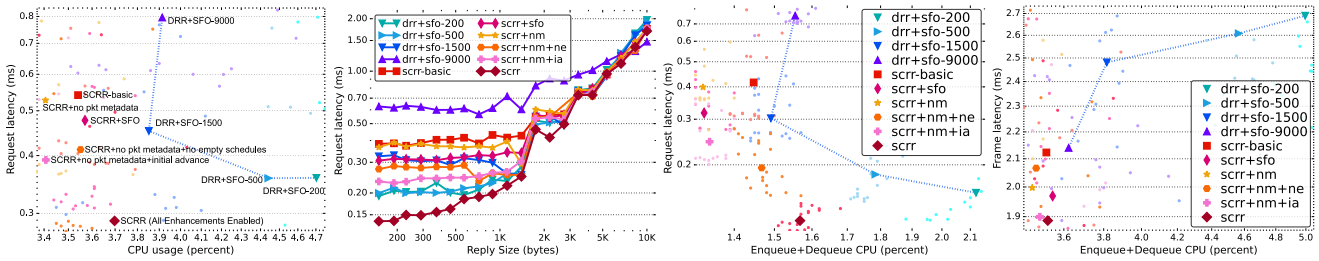
D.1.3 *SP-PIFO* causes packet reordering

We implement *SP-PIFO* using the semantics outlined in [17] and compare its performance against our representative packet schedulers. Fig. 17a presents the TCP re-transmission count for all schemes for the TSO experiment in §5.3. Even with heavy flows congesting the scheduler, *SP-PIFO* suffers from intense packet re-ordering, resulting in unwanted TCP re-transmissions. This in turn impairs the large receive offload functions to save CPU by creating larger packets as depicted in Fig. 17b, ultimately resulting in higher CPU utilization. Hence, *SP-PIFO*'s flow migration across priorities, comes at the cost of heavy re-ordering, starvation, TCP re-transmissions and higher CPU consumption for heavy flows.

Next, we repeat the fairness experiments previously reported in Fig. 9a on a testbed with similar configuration but faster CPUs and report the results in Fig. 17c (§5.4). With faster CPUs, all schedulers except *SP-PIFO* can achieve line rate regardless of the incast scale, even in the case of resource-hungry *DRR+SFO-200*. Similar to the above case, *SP-PIFO* suffers from unwanted TCP re-transmissions that result in reduced throughput.

Fig. 17d presents the request-response workload performance under various packet schedulers; it is an extract of the experiments previously reported in 10a (§5.5). The vertical violins in Fig. 17d represent the distribution of latencies for

(a) *No. TCP re-transmissions* (b) *Mean packet size with TSO*



(c) *Aggregate throughput* (d) *Request latency*

Figure 17: *SP-PIFO performance with heavy flows and TSO (top row), under heavy flows (bottom left), and under request-response workloads (bottom right).*

each reply size and each scheduler. Other schedulers have a tight distribution of latency, whereas the latency distribution of *SP-PIFO* is wide and mostly bimodal when the reply size spans multiple packets. Although many requests are lucky to benefit from the highest priority band and are quickly completed with a latency even lower than *STFQ* and *SCRR*, some requests are heavily penalized and lead to poor average performance. This is because, while the first response packet will have a high chance of using the highest priority band, the consecutive packets will have a larger virtual time and will be inserted into lower bands, hence facing starvation.

D.2 *SCRR* Component Analysis

Fig. 18a compares the CPU utilization and response latency of different *SCRR* components for the request-response experiment reported in §5.5. The basic *SCRR* algorithm (without bursty flow enhancements) offers lower CPU utilization compared to DRR alternatives. The *no packet metadata* variant offers even better CPU performance due to imposing less memory pressure. The *No Empty Schedule* enhancement prevents the *Sparse Flow Optimization* in *SCRR* from performing unwanted visits into stale flow entries in the old flows list by immediately kicking the flows out of the schedule and re-inserting them back when they become active. This results in improved responsiveness by lowering the latency by 23% compared to the basic algorithm. The *initial advance* enhancement has a similar effect on sparse flows by allowing them to send a slightly larger burst without violating the fairness bounds. When both enhancements come together in *SCRR*, the best response latency results can be seen, improving the basic algorithm by 46% while performing 18% faster than

Figure 18: *Comparing the performance of individual SCRR components for the request-response experiment in §5.5.*

DRR+SFO with 200B quantum configuration. Finally, with increasing reply lengths, the upper hand of Sparse Flow Optimization starts to fade as the latency-sensitive flows become backlogged in the scheduler and exhaust their fair share (Fig. 18b). We repeat this experiment on the Edge switching topology and report the results in Fig. 18c in which similar trends in the CPU utilization and response times can be observed for SCRR variants. Finally, Fig. 18d presents the CPU vs latency trade-off for a VBR traffic on the routing topology. SCRR-basic shows a better adaptation to the VBR traffic compared to DRR by offering 15% lower latency and 8% lower CPU utilization with respect to DRR-1500 setting. Other enhancements of SCRR further increase the latency gap by 16%.

D.3 Application Performance Under BBRv3

Request-response Flow Performance. Small request-response flows are one of the most prevalent traffic patterns of modern applications [22, 62, 71]. We already presented experiments with request-response flows using TCP Cubic in §5.5 and §D.6, this section repeats those experiments with BBRv3 and highlight the differences between using BBRv3 and TCP Cubic. We integrated BBRv3 from its official repository [13] and use a different testbed with identical configuration to Fig. 7 with Linux machines running kernel 6.10. The main difference is that on this testbed the scheduler is running on much faster CPUs (Intel Xeon W5-3435X), and therefore the packet schedulers with high CPU usage are less penalized.

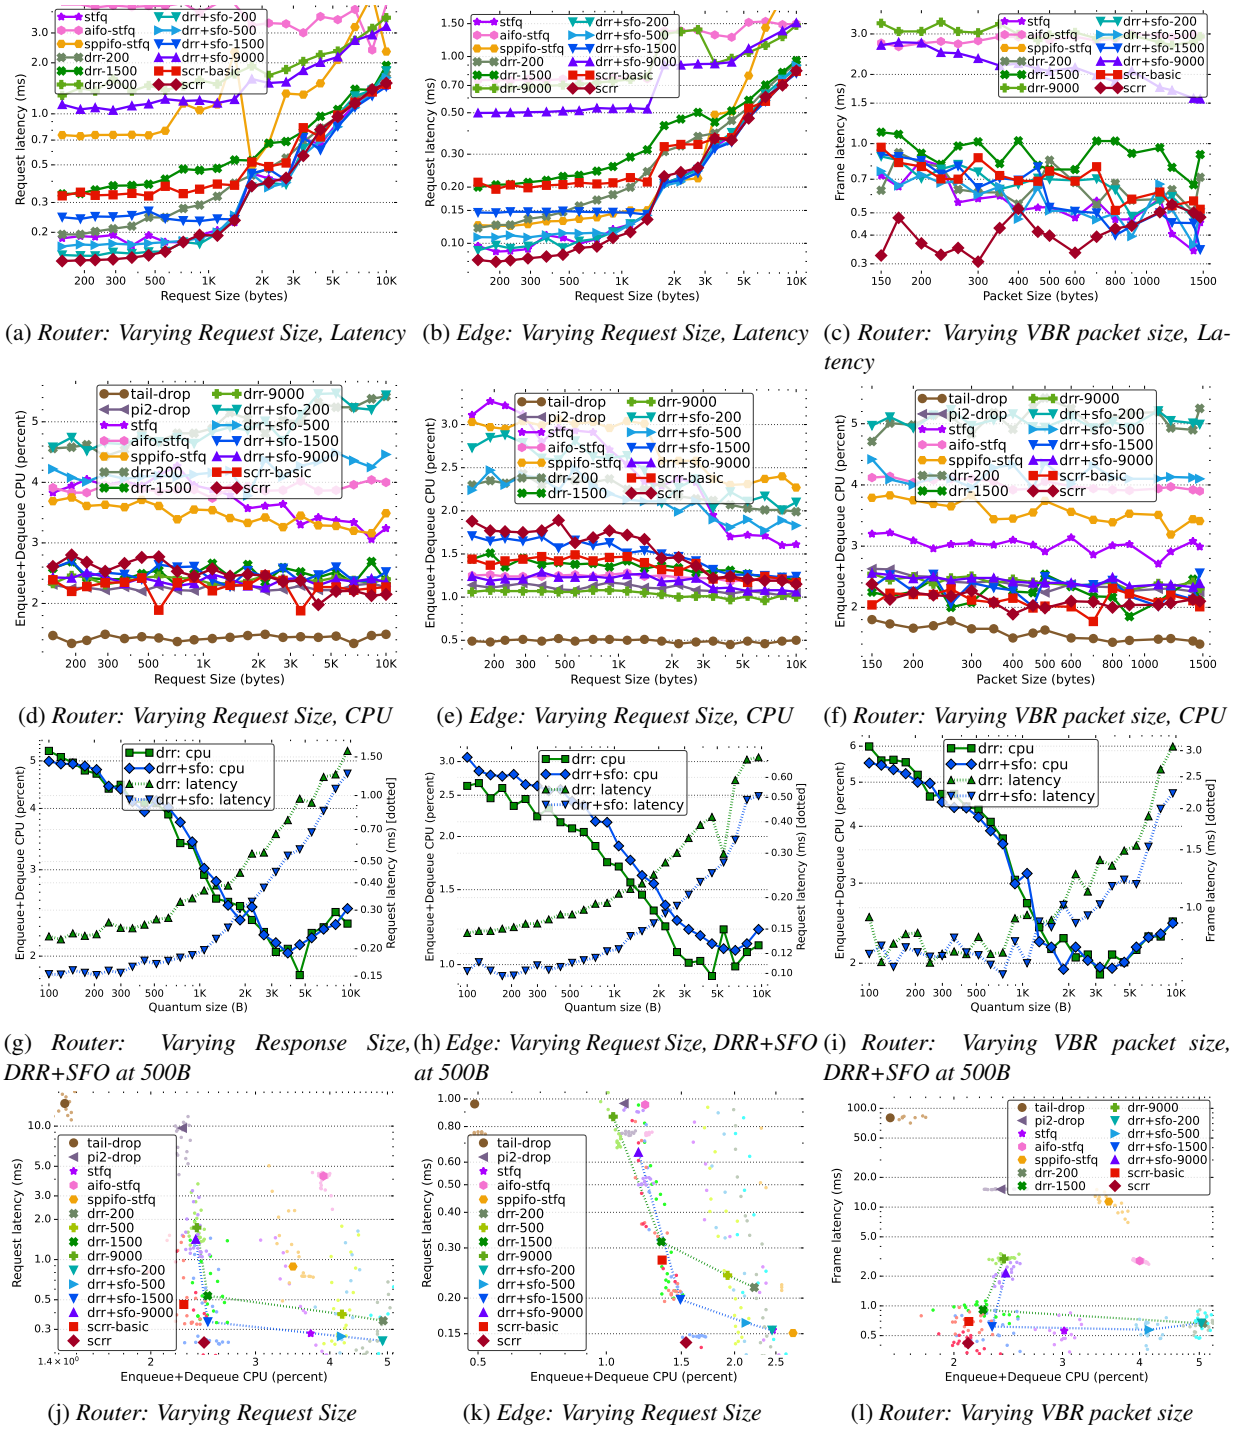

Fig. 19a depicts the application performance as we increase the size of the requests from 100B to 10 kB while the reply size is set to 100B on the router in topology 7b. For this experiment, two sender machines generate 8 latency-sensitive flows each, similar to the Cubic experiments (§5.5). Another two senders generate 64 parallel background long-lived TCP flows each. All flows are configured to use BBRv3. We intentionally opt not to enable Explicit Congestion Notification (ECN) [70] support in BBRv3 as it can arbitrarily impact scheduling performance, and the integration of ECN in *SP-PIFO* and *AIFO* is not trivial and undefined [82, 89].

Fig. 19d shows that with the faster CPU, the CPU utilization of all schedulers is reduced, and has also less jitter. Fig. 19g illustrates that for request-response workloads, the quantum configuration for DRR under BBRv3 offers the usual tradeoff between latency and CPU usage along with the benefits offered by SFO. Finally, BBRv3 offers a tighter control over queue utilization, which causes all single-queue schedulers, i.e., tail-drop, *PI2*, and *AIFO*, to have a smaller average queuing latency. Nonetheless, *SCRR* is able to offer superior latency compared to all alternatives, with low CPU usage (Fig. 19j). *SCRR* has the lowest average latency (0.24 ms), closely followed by *DRR+SFO-200* (0.25 ms), *DRR+SFO-500* (0.27 ms), *STFQ* (0.28 ms) and *DRR+SFO-1500* (0.34 ms).

Figs. 19b, 19e, 19h, and 19k repeat the request-response experiment on the edge topology (7a). Again, the same trends in both application latency and CPU utilization in the face of different request sizes can be observed. Linux's control over the transmit socket buffer size prevents the backlog to exceed 1 ms for tail-drop which significantly improves its application response time. As a result, both *PI2* and *AIFO* do not show any meaningful latency improvements over *Tail-Drop*. Those results are pretty much equal to our results with Cubic (§D.6), indicating again that the congestion control has little effect on overall performance in this setup. *SCRR* has the lowest average latency (0.14 ms), closely followed by *SP-PIFO* (0.15 ms), *DRR+SFO-200* (0.15 ms), *STFQ* (0.15 ms), *DRR+SFO-500* (0.16 ms) and *DRR+SFO-1500* (0.19 ms).

Streaming Flow Performance. The traffic of video conferencing applications is another important traffic pattern of modern applications [52, 61, 79]. We already presented experiments with Variable Bit Rate (VBR) flows using TCP Cubic in §5.5 and more extensively in §D.6, this section repeats those experiments with BBRv3 and highlight the differences between using BBRv3 and TCP Cubic.

VBR experiment results under BBRv3 are depicted in Figs. 19c, 19f, 19i, and 19l. In this experiments, 2 senders generate 32 concurrent VBR UDP flows each, and two other servers generate 64 long-running heavy TCP flows each. Here, the major difference from Cubic experiments (§5.5) is that *DRR*'s overall latency is barely affected when changing the quantum, which is attributed to the faster CPU. The smaller quanta does increase the CPU utilization, and for this experiment, the optimal quantum is around 1500 B. Furthermore, *SFO* improves the latency of *DRR* at little CPU cost. As usual, *SCRR* meaningfully reduces both the latency and the CPU uti-

Figure 19: *Impact of packet schedulers on application response times for latency sensitive workloads with BBRv3 transport.*

lization. In this experiment, *SCRR* has the lowest average latency (0.42 ms), followed by *STFQ* (0.56 ms), *DRR+SFO-500* (0.57 ms), *DRR+SFO-1500* (0.62 ms), *DRR-200* (0.66 ms), *DRR+SFO-200* (0.67 ms), *SCRR-basic* (0.70) and *DRR-200* (0.71 ms).

We observe that scheduling paradigms follow a similar trend under both Cubic and BBRv3. BBRv3 includes advanced techniques to pace packets, to adjust the sending rate, and to try to keep the latency small at the queue, plus a modified slow-start algorithm [13]. However, the bursty requests are too short to show any significant difference compared to Cubic (§5.5). Our results confirm that unlike packet scheduling, congestion control has limited impact on the performance short bursty flows and *SCRR* can complement widely used In-

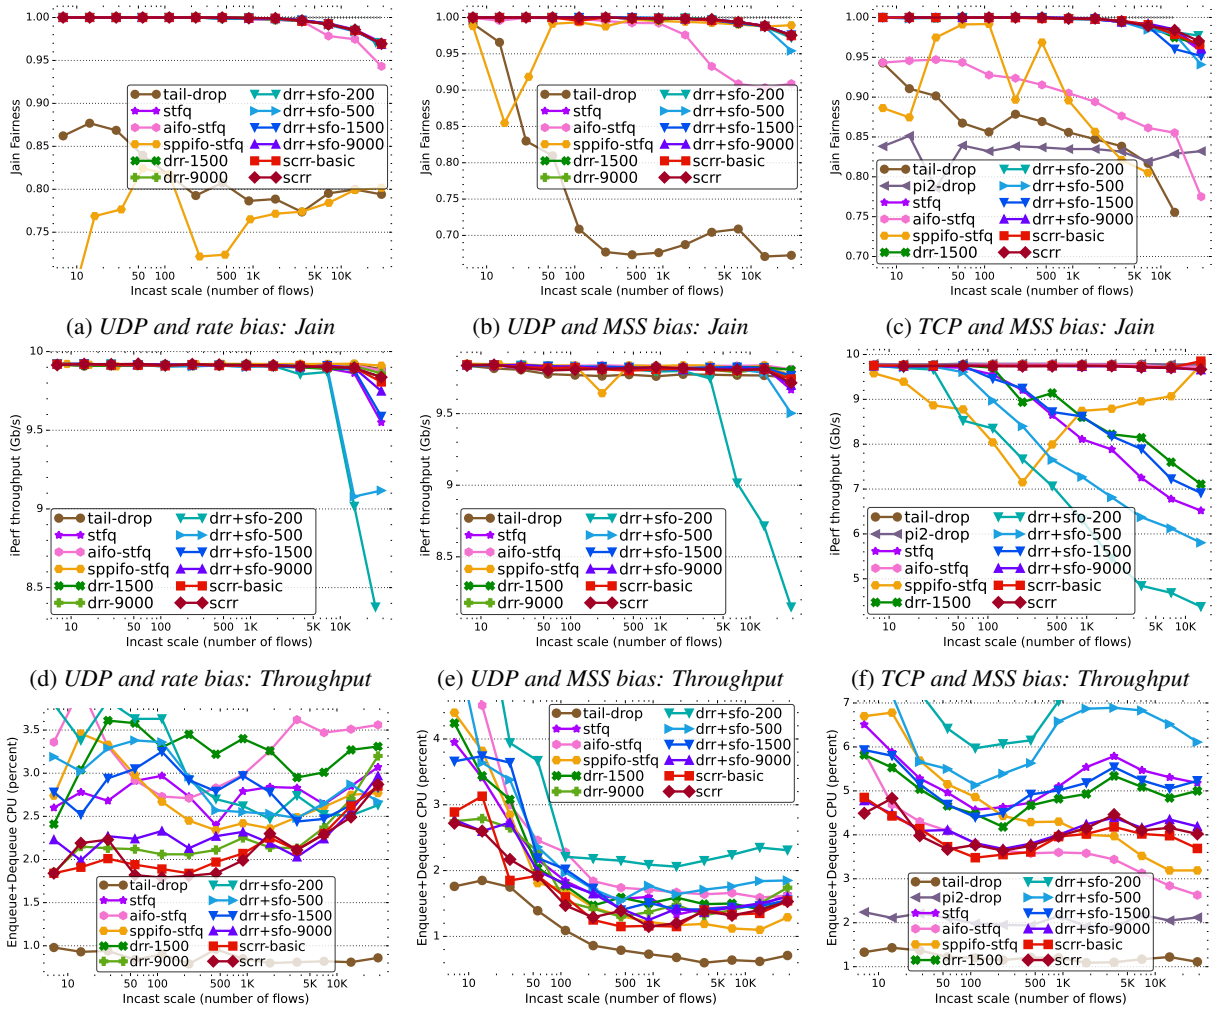
ternet congestion control by providing fairness, low resource consumption and superior application performance for such flows.

D.4 Impact of CPU overhead on throughput



CPU utilization is a good proxy for the overall resource requirements of the packet scheduler. Some software implementations of packet schedulers in Internet gateways result in reduced network throughput due to their high CPU usage [2, 3]. It is usually tricky to estimate the impact of CPU overhead, because different packet schedulers may interact differently with the rest of the networking stack. By changing the quantum of DRR, we can artificially increase the CPU overhead of packet scheduling without changing anything else, and isolate the contribution of the packet scheduler overhead. Further, when the quanta is below 1000 B, packets are scheduled in the exact same order, so only CPU overhead changes. Experiments in Fig. 20 create an incast of heavy flows sharing a bottleneck link serviced by *DRR* and show the increase in CPU overhead due to the reduced the quantum.

Fig. 20a shows the CPU overhead of the packet scheduler and the throughput when using TCP flows. Each of the 7 sender generates 10 flows and each uses a MSS of 1000, 1500, 2000, 3000, 5000, 7000 and 8956 bytes respectively. At higher quanta, the lower per-packet processing time is balanced by the increasing packet rate, and CPU usage is constant. A small 100B quantum makes *DRR* the bottleneck and reduces the aggregate throughput to 5 Gb/s, which is half of the capacity. The CPU usage for *DRR* is less than 7%, however this puts enough pressure on the rest of the networking stack to cause such a slowdown.

Fig. 20b extends this experiment on our new testbed. Each of the 7 senders initiate 100 flows, each using an MSS of 1500, 2000, 3000, 4000, 6000, 8000 and 8956 bytes, respectively. The CPU frequency is downscaled to 1 GHz to mimic the original testbed.[5] The performance of *DRR* is similar to the experiment on the original testbed in Fig. 20a, a small 20B quantum reduces throughput to 3 Gb/s, which is a third of when quantum is 10000B. *SCRR* achieves optimal throughput, however on a slower CPU, *SCRR* could become a bottleneck and cause lower throughput. *SCRR* offers low CPU overhead because every iteration of the dequeue function is guaranteed to dequeue a packet.

Fig. 20c repeats the experiment of Fig. 20b using UDP flows, the flows are constant bit rate and the aggregate rate per sender is 2 Gb/s, for a total of 14 Gb/s. This traffic that the bottleneck can't process is dropped, the ratio of UDP packet drops (not shown) is the inverse mirror of the throughput, a lower throughput means more packets are dropped. The throughput results are broadly similar to the experiment with TCP flows, however the CPU overhead measured is much lower. Also, with the highest quantum, CPU overhead goes up. We repeated these experiments multiple times to eliminate a fluke. We do not have a good explanation for those specific results. The Linux network stack is complex, and cache performance impact and context switch impact can be

[5] In the original testbed, the CPU frequency was not downscaled.

(a) *UDP and rate bias: Jain* (b) *UDP and MSS bias: Jain* (c) *TCP and MSS bias: Jain*

(g) *UDP and rate bias: CPU* (h) *UDP and MSS bias: CPU* (i) *TCP and MSS bias: CPU*

Figure 21: *Fairness of packet schedulers and their CPU overhead as the scale of Incast increases.*

un-intuitive. With UDP traffic, the networking stack has to process a lot more packets and ultimately drop them, causing additional CPU pressure. With TCP traffic, sub-queues may go in and out of the schedule due to the saw-tooth behavior of the TCP congestion control, increasing the amount work for the scheduler. In summary, it's not possible to determine an exact CPU overhead that will cause throughput degradation, this will depend on the traffic and the system.

Fig. 20d shows the the CPU overhead of the various kernel functions in more detail as a FlameGraph for the experiment in Fig. 20b with quantum size 500 B. The call stack for the *enqueue* function starts with the kernel polling Ethernet drivers (__napi_poll), which then passes newly received packet to the networking stack (netif_receive_skb_list_internal), those packets are routed (ip_finish_output2) and then directed to a network device (__dev_queue_xmit) and finally the *enqueue* function is called. Most of the calls to the *dequeue* function are when a packet is directed to a network device (__dev_queue_xmit), effectively after enqueuing some packets, the network stack try to make progress sending packet from that queue. Another call stack for the *dequeue* function is from a periodic timer in the network stack (net_tx_action). As expected, the *dequeue* operations consume more CPU than *enqueue*, because it needs to spin to accumulate quanta for each flow (which is a similar result to Fig. 15). During packet processing many other parts of the Linux network stack must be exercised that respectively consume CPU. With more pressure on the qdisc, the network stack processing also experiences more CPU contention and cache pressure. This explain why even if the qdisc uses a fairly low percentage of the CPU, it can be a bottleneck and lead to throughput decrease.

D.5 Fairness Under Different Biases

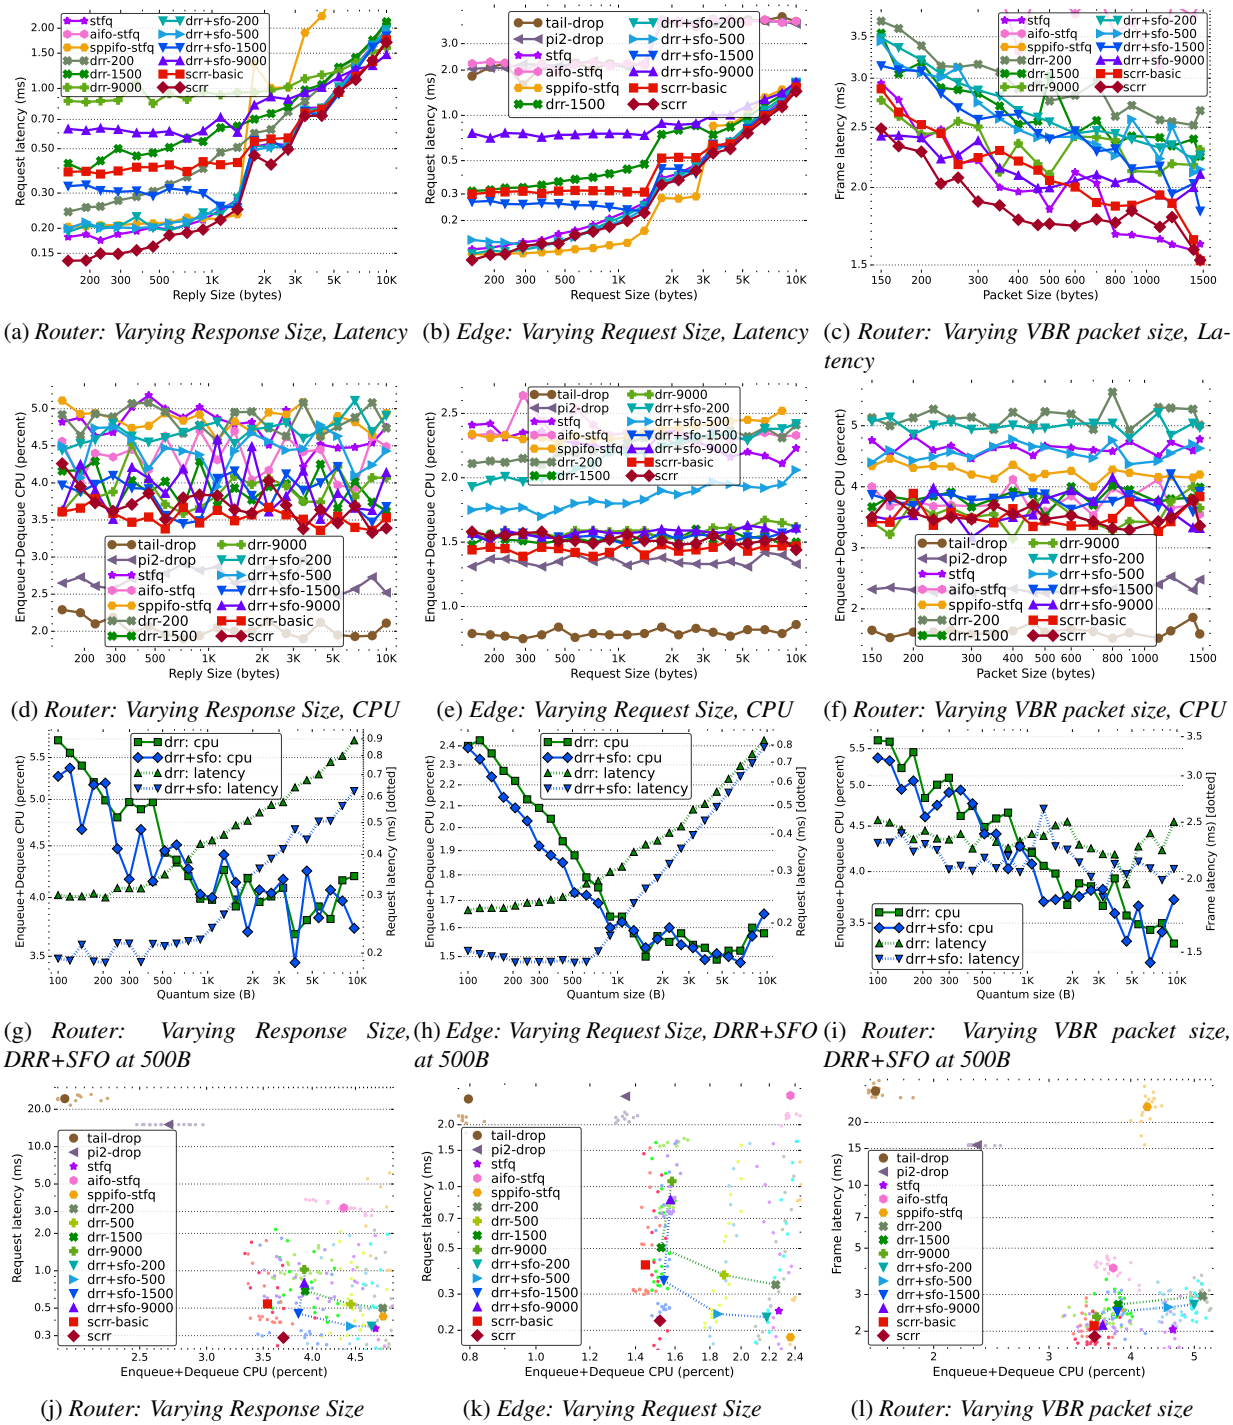
The crucial property of a packet scheduler is enforcing fairness and QoS. This section is an extended version of the fairness experiments already shown in §5.4. Again, to better

scale the experiments, we configured all scheduling classes with identical weights and configured various biases between flows to create potential unfairness. These experiments showcase how the scheduler achieves fairness by overcoming these biases.

The first bias we introduce is the rate at which flows arrive at the scheduler. This is a much-generalized version of the experiments in previous papers [81], where it aims to investigate how well a scheduler deals with incast traffic and a large number of misbehaving flows. The testbed is the original testbed (§5.2) and we are using the routing topology 7b. The seven senders generate UDP traffic, each with different aggregate offered rates of 1.5, 2, 3, 4, 5, 6, and 7 Gb/s, respectively. The number of UDP connections per sender varies from 1 to 4096, for a maximum of 28672 flows. Fig. 21a depicts the Jain Index measuring fairness across the flows. The *tail-drop* and *SP-PIFO* schedulers show poor fairness since it admits packets proportional to their arrival rate, favoring UDP flows with higher rates. All fair queueing schedulers, including *SCRR*, have excellent fairness, as expected, as they enforce byte-level fairness for every flow. At a very high number of UDP flows (28k), the fairness of all schedulers is impacted by hash collisions in the classifier, a well-known caveat of using hashing in flow classifiers. Most QoS classifiers have well-defined QoS classes that do not use hashing, and would not suffer from this issue.

Fig. 21d presents the aggregate throughput of the UDP flows. *DRR-200* and *DRR-500* are methods that waste CPU cycles (§2.4) and they result in decreased throughput at higher flow counts. This is because an increase in flow count increases the cache footprint of the scheduler and the probability of cache misses. Fig. 21g presents the CPU overhead on the router. In general, a higher CPU overhead is more likely to impact throughput (§2.4), however, in this experiment, the relation between the two is not obvious. We believe that the need to drop a very large number of packets distorts the CPU overhead numbers measured. A lower quantum increases CPU consumption for *DRR*, as more scheduling cycles are needed to accumulate enough quantum. All variants of *SCRR* offer lower CPU utilization amongst the schedulers.

The second bias we introduce is the packet size. Varying the packet sizes forces the schedulers to transmit more packets from flows that send smaller packets in order to satisfy the proper byte-level accounting of the schedulers. The seven sender machines generate UDP traffic, each using a different Maximum Segment Size of 2500, 3000, 3500, 5000, 6000, 8500, and 8956 bytes, respectively. Fig. 21b shows the Jain Index measuring fairness across the flows. The *tail-drop* queue yields poor fairness again. This is because the incast traffic causes the single FIFO to always be at its peak utilization. In this state, it becomes more probable for the queue to have enough space for small packets under the byte limit (18 MB, or 15 ms of traffic), which further favors flows with small packets. All other schedulers have excellent fairness, as expected. Fig. 21e shows the aggregate throughput of the UDP flows, again *DRR-200* and *DRR-500* show reduced throughput. Fig. 21h shows the CPU overhead on the router, asserting *SCRR*'s low CPU overhead.



The packet size bias can also be used for TCP traffic. Fig. 21c plots the Jain Index for TCP Cubic flows. At a very high number of TCP flows (28k), some flows experience reduced performance or stalls, especially with schedulers that use the *tail-drop* queue. The TCP congestion protocol is not designed to provide byte-level fairness, therefore *tail-drop* shows only slightly better fairness compared to UDP. However, this time, flows with larger packets are favored. In the congestion avoidance phase, TCP increases the congestion window by one whole packet for each RTT, therefore flows with larger packets can increase their throughput faster. The *PI2* AQM is not designed for byte-level fairness either, which explains why it performs similarly to *tail-drop*. The same applies to *AIFO* and *SP-PIFO*. All fair schedulers provide superior fairness as they enforce byte-level fairness amongst classes. Fig. 21e shows the aggregate throughput of the TCP flows. The TCP flows are much more impacted than UDP flows, as packet drops cause the congestion control to reduce the congestion window. Fig. 21i shows the CPU overhead on the router. In this experiment, the throughput decrease can be directly correlated with the CPU overhead. As expected, the schedulers consume more CPU than the *tail-drop* and *PI2*, and as in previous experiments, the *SCRR* variants are amongst the schedulers with the lowest overhead.

D.6 Application Performance Under Cubic

We present the extended application latency results from §5.5.

Request-response Workloads. Modern networks are filled with small request-response flows [22, 62, 71]. We designed experiments showcasing how schedulers can help those small requests when they are mixed with long-lived heavy flows. Single queues often suffer from BufferBloat, where a few heavy flows can fill the queue and cause high latency for all other flows. It is fairly easy to show how schedulers provide lower latency than a single queue, however, we found it difficult to show the difference between the various schedulers on latency experienced by applications. The main issue is that those differences are mostly visible at very small request sizes, but those small requests magnify the processing overheads and inefficiencies of the packet processing pipelines, especially in the software. Additionally, the difference in scheduling delays is an order of magnitude lower than the latency added by necessary system optimizations such as interrupt coalescence, packet batching and NIC offloads. Consequently, in many cases, those differences are buried in the noise.

Our first experiment mixes small requests with long-lived heavy flows on the router in topology 7b. Two of the receiver machines generate 8 latency-sensitive flows each, the flows

(a) *Router: Varying Response Size, Latency* (b) *Edge: Varying Request Size, Latency* (c) *Router: Varying VBR packet size, Latency*

(d) *Router: Varying Response Size, CPU* (e) *Edge: Varying Request Size, CPU* (f) *Router: Varying VBR packet size, CPU*

(g) *Router: Varying Response Size, DRR+SFO at 500B* (h) *Edge: Varying Request Size, DRR+SFO at 500B* (i) *Router: Varying VBR packet size, DRR+SFO at 500B*

(j) *Router: Varying Response Size* (k) *Edge: Varying Request Size* (l) *Router: Varying VBR packet size*

Figure 22: *Impact of packet schedulers on application response times for latency sensitive workloads with Cubic transport.*

are a sequences of short back-to-back request-response with a request of 100B and varying response lengths. To highlight the difference between schedulers, we need to make them congested, because if there is no packet accumulation, packets are sent as soon as they arrive at the schedulers and they act as a FIFO. To ensure congestion, another two senders generate 32 parallel background long-lived TCP flows each. The requests are initiated on the receivers, so that the replies go from the sender to receiver and get mixed with the background traffic. For all flows, the MSS of TCP set to 1456B (MTU 1500B). LRO is disabled on the software router to minimize the unwanted latency. The latency of the TCP requests and the CPU utilization of the packet scheduler are measured under various request sizes and queue configurations.

Fig. 22a presents the latency of a selected subset of the schedulers. As the size of the replies increases, they are

split across more TCP segments, requiring more scheduling rounds to be forwarded, and we see a corresponding increase in latency. The theoretical optimal quanta for *DRR* is the MTU size, which is 1500B, however *DRR* with smaller quanta can reach the performance of *STFQ*, whereas *DRR-9000* has the worst latency among the schedulers because it always tries to dequeue 9000B worth of packets on every schedule. *SCRR* has a lower latency than *SCRR-basic* due to the combination of *Sparse Flow Optimization* (§3.3.1), *No Empty* (§3.3.3) and *Initial Advance* (§3.3.2) enhancements, which allow, most of the time, to send all the packets of the latency-sensitive flow in one attempt ahead of the background flows.

Sparse Flow Optimization implemented in DRR and SCRR (Algorithm 4) already allows previously idle sub-queues to be scheduled ahead of heavy hitters, giving an advantage to latency-sensitive flows and flows that use less than their fair share bandwidth. The replies are a burst of packets of various length, it usually includes a TCP ack and one or more TCP packets for the reply. The number of packets in the burst depend on the reply size, reply size greater than a MSS need to be broken down. It's also depend on the timing between the TCP ack and the reply. In our experiments, the TCP ack is not deferred into the reply and is sent as a separate packet. The difference in latency between schedulers is due to how they handle those consecutive packets, in particular whether the subsequent packets have to wait for a full scheduling round or not, and how long a scheduling round lasts. *Sparse Flow Optimization* allow those packet train to be scheduled ahead of backlogged flows. *Initial Advance* (§3.3.2 allow SCRR to send multiple of those packets in the same schedule. And *No Empty* (§3.3.3) allows the packets of the train that did not arrive initially to still be scheduled in the current round. Those mechanisms explain the performance of *SCRR*.

Fig. 22d shows the CPU overhead on the router. The SCRR variants are again amongst the schedulers with the lowest overhead. *SCRR* has a slightly higher aggregate CPU utilization than *SCRR-basic* mostly due to higher ratio of small packets processed (increasing the total number of packets) and the *No Empty schedule* (§3.3.3) enhancement, imposing cache pressure by re-inserting sparse flows into the schedule on their arrival.

Fig. 22g presents the performance trade-offs of *DRR* and *DRR+SFO* with 500B response sizes. A smaller quantum enables *DRR* to reduce average latency, however, it causes *DRR* to consume more CPU. In this experiment, 500B looks to be a sweet spot for quantum configuration, offering the best latency improvements.

Finally, Fig. 22j summarizes the average CPU overhead and average latency over all the request sizes. *Tail-drop* and *PI2* use a single queue, therefore, the background TCP flows quickly fill that queue and impose a full queueing delay to the response packets, or more. All fair-queueing schedulers offer much better latency performance by trading off more compute resource usage. *SCRR-basic* and *SCRR* offer the lowest CPU utilization among fair queueing schedulers. *SCRR* and *SCRR-basic* adapt to packet sizes and are therefore able to offer smaller latency than *DRR-1500* while offering a CPU usage even lower than *DRR-9000*. *SCRR-basic* has lower CPU usage than *DRR-1500* mostly because it can decide to schedule the current sub-queue without having to consult the next packet in that sub-queue. *SCRR* has the lowest average latency (0.29 ms), closely followed by *STFQ* (0.34 ms), *DRR+SFO-200* (0.35 ms), *DRR+SFO-500* (0.35 ms) and *DRR+SFO-1500* (0.45 ms).

The bursty flows are using TCP Cubic, however the latency of those flows with per-flow scheduling is mostly independent of the congestion control, and we believe other congestion controls or UDP flows should have similar performance. Our experiments with BBRv3 in §D.3 partially confirm it. With per-flow scheduling, short bursty flows never accumulate enough packets in their sub-queue at the bottleneck to cause congestion and trigger a packet drop (or ECN signal when available). With per-flow schedulers, even under heavy congestion, we did not observe any packet re-transmissions for the request-response flows. Without packet drops, the TCP Cubic never has to throttle the sending rate, and therefore the performance of those short bursty flows is entirely dictated by how they are serviced by the scheduling algorithm at the bottleneck. For similar reasons, Slow-start is not an issue for such small requests, the Initial Window of TCP is usually big enough to send the full request. With *Tail-drop*, we see a very low level of re-transmissions, and some connections that fail to connect entirely. Packets of bursty flows are added at the tail of an already full queue, where they can get dropped, and the congestion control will need to re-transmit them. This is an issue for those short request-response flow : no data is waiting after the missing packet, consequently Fast Recovery [36] usually does not happen and the retry will only happen with the slower Retransmit Time Out (RTO). This explains why with *Tail-drop* in Fig. 22j, some requests have a latency greater than the queuing delay (15 ms). With *PI2*, the number of packet dropped is much lower than *Tail-drop* [73], which helps to reduce latency to the queuing delay.

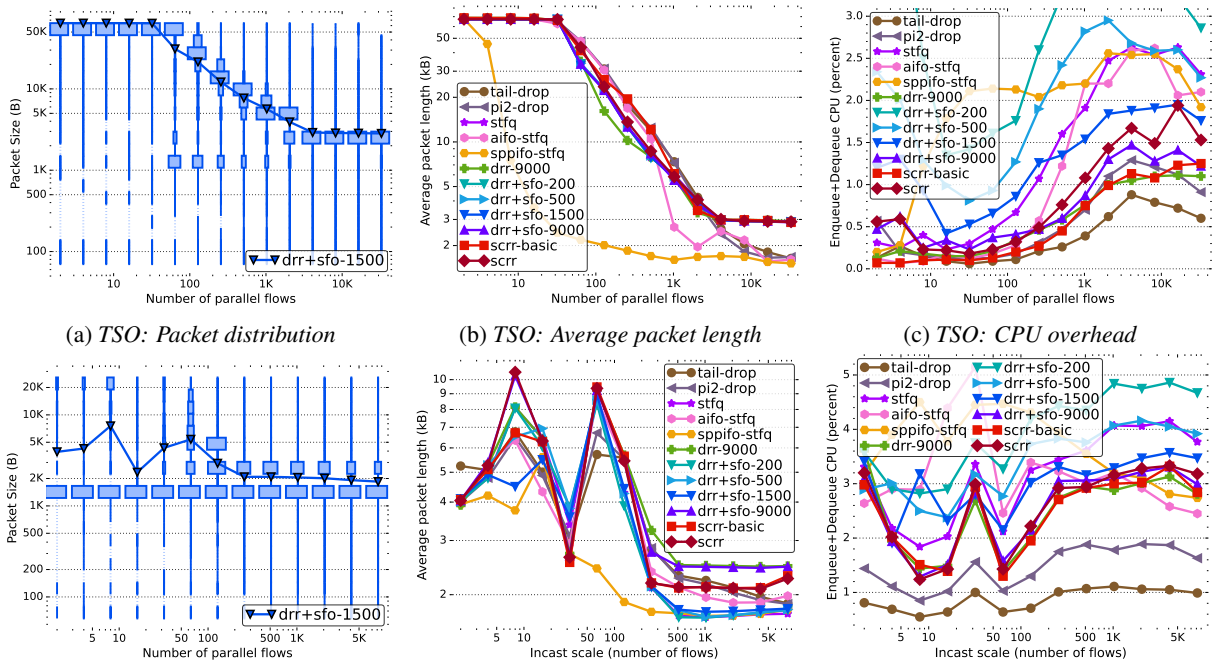
Our second experiment mixes small requests with long-lived heavy flows on the edge-switching topology 7a. This time, the request are varying in size and mixed with the background traffic to resemble applications such as POST and PUT methods in HTTP, Telemetry, Analytics, and Email which send larger chunks of data as a request. Two of the sender machines generate 8 latency-sensitive flows each, the flows are a sequences of short back-to-back request-response with a varying request length and a 50B reply. Another two senders generate 32 parallel background long-lived TCP flows each. Figs. 22b show similar results to our first experiment (fig. 22a). One big difference is *SP-PIFO*, for requests that fit in a single packet, it offers very low latency. However, *SP-PIFO* is unfair and usually has wider variance of latency when requests span multiple packets (§D.1.3). According to Fig.

22e, the CPU utilization is much more stable than our first experiment (fig. 22d) because the arrival of packets is more deterministic in this topology, it is no impacted by processing at the receiver NIC like in topology 7b. Fig. 22h shows the usual tradeoffs of *DRR* and *DRR+SFO*. Again, 500B seems to be a sweet spot for quantum configuration if latency is preferred. The default quantum of the Linux 'sch_fq' module is 3000B [33], i.e., 2× the MTU, which indicates that it was most likely optimized for low CPU utilization. Finally, 22k collects all previous results. *SP-PIFO* has the lowest average latency (0.19 ms), followed by *SCRR* (0.22 ms), *DRR+SFO-200* (0.23 ms), *DRR+SFO-500* (0.24 ms), *STFQ* (0.25 ms), *DRR-200* (0.33 ms) and *DRR+SFO-1500* (0.34 ms).

Tail-drop and *PI2* offer considerably lower latency than expected and than the first experiment. The reason is that the Linux kernel keeps in check the number of outstanding SKB packet buffers for each socket, in order to prevent queue build ups on sender machines and to reduce the latency. We measure much lower queue size in all schedulers, in *DRR* and *SCRR* the sub-queues for heavy flows are much shorter than in the first experiment by almost a factor 10. However, the mechanism to limit outstanding packet buffers reduces the latency only for *Tail-drop*, *PI2* and *AIFO*, in other schedulers it has little impact on the latency of the requests. The smaller queue size also reduce CPU utilization for all scheduler, mostly through reduction of the CPU cache footprint. This mechanism has also the potential of affecting adversely the performance of the packet schedulers, if the sub-queue of a heavy flow does not refill fast enough, it could lose some transmit opportunity, however we believe this is not happening in this experiment. There are also potential issue of CPU starvation and synchronization. We have seen unexplainable results in this topology, and we believe that the performance of *SP-PIFO* in this experiment is one of them.

Streaming Flow Performance. The previous section explores the very short packet bursts created by applications using request-reply. This section explores the longer burst patterns created by streaming applications. The traffic of video conferencing applications is usually composed of short to medium bursts that can saturate the network [79], each burst encoding a video frame. We use the isochronous support in *iperf* to generate Variable Bit Rate (VBR) traffic [8], each VBR flow is a UDP stream at 1.5 Mb/s, bursting at 30 frame per seconds. This emulates a Zoom video session at 720p [52, 61]. The traffic is Variable Bit Rate (VBR), so the length of the burst of packets varies from one frame to the next. The length of the burst of packets also depends on the packet size, it goes from an average of 333 packets (150 B) to 33 packets (1500 B) per burst. 64 streams of VBR traffic are generated on two senders, they are mixed with 128 long lived heavy flows on two other senders on the router in topology 7b.

Fig. 22c shows the average one way latency to transmit a full frame for a selected subset of the schedulers. The delay are much higher than the previous experiments, the size of the burst of packets (50k) means that multiple scheduling rounds are needed to transmit it, even at the highest quantum of DRR (9k). Conferencing often uses small packets to reduce the impact of packet losses [52, 79]. In this case, using smaller packets decreases performance, the reason is that VBR traffic is sensitive to both latency and throughput, and header and processing overheads of small packets hurt throughput of the burst. Fig. 22f shows that *SCRR* has the lowest CPU utilization amongst per-flow schedulers. Fig. 22i shows that the behavior of *DRR* is the opposite of request-response traffic, here the bigger quanta decrease latency as this traffic is more sensitive to throughput than latency. SFO is still effective and does reduce the latency of *DRR*. Fig. 22l averages the latency and CPU utilization over all packet sizes. *STFQ* maintains low latency despite its high processing overhead. *SCRR* has the lowest average latency (1.89 ms), closely followed by *STFQ* (2.04 ms), *DRR+SFO-9000* (2.14 ms), *DRR-9000* (2.34 ms) and *DRR+SFO-1500* (2.48 ms).



SCRR offers a unique proposition, it offers the lowest latency and lowest CPU usage for VBR frames amongst per-flow schedulers. The latency enhancement of *SCRR* enables the burst to start transmitting sooner, and the low CPU utilization allows to expedite the remaining packets of the bursts and those other packets scheduled ahead of the burst.

D.7 NIC Accelerations - TSO & LRO

We present the extended version of the NIC Accelerations results from §5.3.

The commodity acceleration functions of modern Network Interface Cards (NIC) are essential to sustain the high packet rates for high-speed Ethernet in software. TCP segmentation offloading (TSO) [11] and its software counterpart, Generic Segmentation Offload (GSO), allow the sender to defer the segmentation until the very late packet processing stages, resulting in very large packets being passed to the qdisc. Similarly, TCP Large Receive Offload (LRO) and its software counterpart, Generic Large Receive Offload (GRO), allows a NIC to aggregate received packets into larger chunks. In Linux, the current default maximum size of those packets is 64 kB and there are proposals to greatly increase this maximum [34]. This is because, a reduction in packet rate improves software performance by reducing the overhead of context switches, cache misses, and metadata handling. However, as studied earlier in this work, both TSO and LRO make packet size unpredictable for a software packet scheduler.

Fig. 23a and 23b show the impact of TSO on the packets as seen by the sender host's software scheduler in the edge switching topology (7a). This would be a typical packet distribution seen in a virtual switch deployed in a datacenter or the Cloud, or on a busy server. As the number of flows increases, the individual bandwidth share decreases and the average TSO packet size decreases from 64 kB to 1500B. Fig. 23c

(a) *TSO: Packet distribution* (b) *TSO: Average packet length* (c) *TSO: CPU overhead*

(d) *LRO: Packet distribution* (e) *LRO: Average packet length* (f) *LRO: CPU overhead*

Figure 23: *Performance of packet schedulers under TSO and LRO accelerations.*

presents the CPU overhead of the various schedulers. Smaller packets do increase CPU overhead, as expected. This is a scenario where it is difficult to find an optimal configuration for *DRR*. *DRR-1500* is configured based on the MTU and uses a fixed quantum of 1500B, but this causes too many CPU cycles to be wasted on accumulating quantum over multiple scheduling rounds to send packets that are larger than the quantum. *SCRR* lowers CPU usage by adapting to the packet sizes and has a similar CPU overhead as *DRR-9000* which uses a large quantum.

Figs. 23d and 23e show LRO packet sizes received on the router in topology 7b. This would be a typical packet distribution seen in home routers, SD-WAN gateways, access points or middleboxes. Two sender machines produce half of the workload flows, so the LRO packets are aggregated on two separate NICs. The impact of LRO is a lot less predictable than TSO, but there is still a general trend of higher number of flows resulting in smaller packet sizes. DRR with smaller quantum cannot adapt to the dynamics of the traffic, causing CPU wastage. Again, *SCRR* lowers CPU usage by adapting to the packet sizes and has a similar CPU overhead as *DRR-9000* which uses a large quantum.

The default quantum of the Linux 'sch_fq' module is 3000B [33], i.e., 2× the MTU. From the packet distributions in Fig. 23a and 23d, it's a logical choice as it's a very common packet size, and would allow to send most packets without the need to accumulate deficit for LRO and TSO with high number of flows.

Everything Matters in Programmable Packet Scheduling

Abstract

Operators can deploy any scheduler they desire on existing switches through programmable packet schedulers: they tag packets with ranks (which indicate their priority) and schedule them in the order of these ranks. The ideal programmable scheduler is the Push-In First-Out (PIFO) queue, which schedules packets in a perfectly sorted order by "pushing" packets into any position of the queue based on their ranks. However, it is hard to implement PIFO queues in hardware due to their need to sort packets at line rate (based on their ranks).

Recent proposals approximate PIFO behaviors on existing data-planes. While promising, they fail to *simultaneously* capture both of the *necessary* behaviors of PIFO queues: their *scheduling behavior* and *admission control*. We introduce PACKS, an approximate PIFO scheduler that addresses this problem. PACKS runs on top of a set of priority queues and uses packet-rank information and queue-occupancy levels during enqueue to determine whether to admit each incoming packet and to which queue it should be mapped.

We fully implement PACKS in P4 and evaluate it on real workloads. We show that PACKS better-approximates PIFO than state-of-the-art approaches. Specifically, PACKS reduces the rank inversions by up to 7× and 15× with respect to SP-PIFO and AIFO, and the number of packet drops by up to 60% compared to SP-PIFO. Under pFabric ranks, PACKS reduces the mean FCT across small flows by up to 33% and 2.6×, compared to SP-PIFO and AIFO. We also show that PACKS runs at line rate on existing hardware (Intel Tofino).

1 Introduction

Packet scheduling is a classical problem in networking — it defines the time and order at which a buffer drains packets to optimize a given performance metric. Researchers have proposed many scheduling algorithms but most of them have never been deployed in production, due to the cost and time required to implement them on new ASIC designs [4].

Programmable schedulers solve this limitation: they build an abstraction that can represent all possible scheduling algorithms [22, 31–33]. The idea is that, if we find such an abstraction and we can implement it in hardware, then we can run any algorithm on top without need for new ASICs.

Figure 1: PACKS navigates the space between SP-PIFO [6] and AIFO [37], optimizing for both rank ordering and drops.

The first attempt is the "PIFO" abstraction, which relies on the observation that we can split most scheduling functions in: a ranking algorithm that indicates the priority with which each packet should be scheduled, and a queuing structure that can schedule packets in the order of these ranks. Push-In First Out (PIFO) queues serve as a natural candidate since they sort arbitrary packet sequences based on the packets' ranks at line rate — hence the name of the abstraction [32].

PIFO queues "push" packets into arbitrary positions in the queue based on their ranks and serve them from their head. This behavior allows them to satisfy the requirements for programmable packet scheduling: (i) they always *admit* packets with the lowest ranks; and (ii) they *schedule* packets in perfect order of rank. For example, PIFO queues can "push" incoming low-rank packets before higher-rank packets that are already in the queue, even dropping the higher-rank packets (if needed) to accommodate the newly arrived low-rank ones.

However, it is hard to implement PIFO queues in hardware because they need to sort packets at line rate (even after they have been enqueued); and they may have to drop high-rank packets after they have been enqueued (e.g., if a low-rank packet arrives). Recent works *approximate* PIFO's behaviors to provide implementations that can run on existing programmable data planes [6, 16, 28, 35, 37]. But these works *only* approximate *one* of the two key PIFO behaviors (Fig. 1).

For example, SP-PIFO [6], QCluster [35], AFQ [27], PCQ [28], and Gearbox [16], only approximate PIFO's *scheduling behavior*. They map incoming packets to priority queues to minimize the rank inversions at the output. How-

ever, they do not actively control packet drops, which they leave as a byproduct effect of the schedulers' design. As such, even though these schedulers can support a broad variety of scheduling algorithms, their behavior can have a negative impact for loss-sensitive applications (cf. §2).

AIFO [37] only approximates PIFO's *admission behavior*: it executes a rank-aware admission-control policy on top of a FIFO queue that drops incoming packets imitating a PIFO queue. But because it runs on a single FIFO queue, AIFO cannot prioritize packets based on their ranks, which limits the scheduling algorithms that it can accurately approximate.

Our work We propose PACKS, a programmable PACKet Scheduler that approximates *both* the admission and scheduling behaviors of a PIFO queue on programmable hardware. PACKS runs on top of a set of strict-priority queues and combines an admission-control mechanism with a queue-mapping mechanism. Since priority queues cannot drop nor modify the order of enqueued packets, PACKS emulates the behaviors that a PIFO queue follows and executes them at enqueue.

Key insights PACKS derives its admission and queuing decisions from two key sources: the rank distribution of the last packets received (monitored via a sliding window) and the real-time buffer occupancy of each queue. PACKS integrates this data into a quantile-based admission and queue-mapping process that prioritizes packets with lowest expected ranks.

PACKS's *rank-aware* approach allows it to minimize rank inversions and outperforms existing queue-mappers that assume no prior rank knowledge and rely on per-packet heuristics. PACKS's *queue-occupancy-aware* approach ensures efficient resource utilization and reduces packet drops.

Evaluation We implement PACKS in P4 and evaluate it on real workloads and in hardware. Our results under mixed flow scenarios across various loads show that, PACKS consistently outperforms in approximating PIFO's admission behavior and reduces the rank inversions by up to 7× and 15× with respect to SP-PIFO, and AIFO, and the number of packet drops with respect to SP-PIFO by up to 60%. Under pFabric ranks, PACKS reduces the average FCT across small flows by up to 33% and 2.6× with respect to SP-PIFO and AIFO.

Contributions Our main contributions are:

- PACKS, a programmable scheduler that emulates PIFO queues on top of a set of strict-priority queues (§3).
- An admission-control algorithm and a queue-mapping technique that approximate all PIFO behaviors (§4).
- A performance analysis of PACKS on MetaOpt [24] to study its performance gaps and adversarial inputs (§4.5).
- An implementation[1] of PACKS in Java and P4 (§5).
- An evaluation showing PACKS's effectiveness in approximating PIFO using simulations and hardware (§6).

2 Background

We first describe SP-PIFO [6] (§2.1) and AIFO [37] (§2.2), two programmable packet schedulers that represent how prior works approximate PIFO's scheduling and admission control behavior, respectively (Fig. 1). We then motivate PACKS based on where these schedulers fall short (§2.3).

2.1 SP-PIFO

SP-PIFO [6] approximates PIFO's *scheduling behavior* (i.e., forwarding the earliest-arrived lowest-rank packet first) on a set of strict-priority queues. It adapts the mapping between packet ranks and priority queues dynamically to minimize the number of rank inversions (i.e., the number of times a higher-rank packet is scheduled before a lower-rank one).

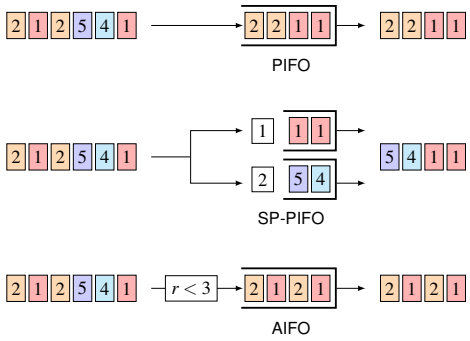
Mapping SP-PIFO maps incoming packets to queues based on the queue *bounds*, which define the lowest rank that the scheduler can admit into each queue. Whenever SP-PIFO receives a packet, it scans the queue bounds from lowest to highest priority, and maps the packet to the first queue with a bound lower or equal to the packet rank.

Adaptation SP-PIFO uses two mechanisms to adapt queue bounds dynamically: a *push-up* stage where it pushes future low-rank (i.e., high-priority) packets to higher-priority queues; and a *push-down* stage where it pushes future high-rank (i.e., low-priority) packets to lower-priority queues. The push-up stage occurs whenever a packet is admitted into a queue. Then, SP-PIFO updates the queue's bound to the rank of the new packet. In the push-down stage, SP-PIFO decreases the queue bounds of *all* queues when it detects a rank inversion in the highest priority queue. With these two mechanisms, SP-PIFO spreads packet ranks across queues, reduces rank inversions, and approximates PIFO's scheduling behavior.

2.2 AIFO

AIFO [37] approximates PIFO's *admission behavior* (i.e., only admitting the earliest-arrived lowest-rank packets) on a FIFO queue. It maintains a sliding window of the most recent ranks and it decides whether to admit each incoming packet based on the packet's rank and the buffer-occupancy level.

Admission AIFO uses the distance of the packet rank to the rank of the packets already in the queue and the time-discrepancy between the incoming and outgoing rate of the FIFO queue to admit packets. It increases the probability of dropping a packet as the distance between it's rank and that of the recently-admitted packets increases; and it increases the probability of dropping packets as the space available in the FIFO queue decreases (the reduction of space in the queue indicates the incoming rate is higher than the outgoing rate).



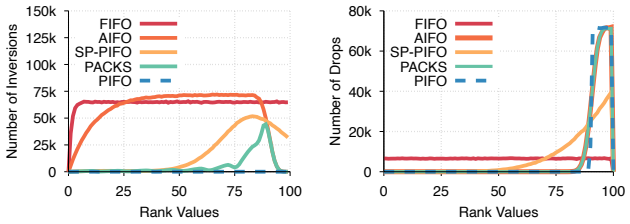


Figure 2: SP-PIFO and AIFO cannot fully approximate PIFO.

(a) Scheduling inversions (b) Packet drops

Figure 3: Scheduling performance, uniform rank distribution.

2.3 Limitations

We analyze the limitations of existing schedulers and motivate the need for PACKS with an example and a simple experiment.

Example Fig. 2 shows how PIFO, SP-PIFO and AIFO serve the packet sequence 2 1 2 5 4 1 (first packet on the right). All schedulers have capacity for 4 packets. SP-PIFO has two priority queues of two packets each, and fixed bounds with values of 1 and 2 for the highest- (resp. lowest-) priority queue. AIFO has a fixed admission control that admits ranks $r < 3$.

PIFO "pushes" the first four packets into the queue according to their rank order: 5 4 2 1. When the fifth packet arrives (1), PIFO "pushes" it into the queue between packets with ranks 1 and 2 and drops the highest-rank packet in the queue (5). When the last packet arrives (2), PIFO "pushes" it between packets of rank 2 and 4 and drops packet 4. PIFO's outgoing sequence is therefore 2 2 1 1.

SP-PIFO maps packets 1 1 to the highest-priority queue, and packets 2 2 5 4 to the lowest-priority queue (c.f., §2.1). Since the lowest-priority queue only has room for two packets, it drops the last packets to arrive (2 2). The output sequence is 5 4 1 1, which has sorted ranks (it approximates PIFO's scheduling), but does not contain the packets with rank 2 that PIFO accepted (it fails to approximate PIFO's admission).

AIFO admits the packets with rank $r < 3$, same as PIFO. However, since it runs on top of a FIFO queue, it does not prioritize any packet, which results in an output sequence not sorted by rank (i.e., 2 1 2 1 instead of 2 2 1 1).

PACKS preemptively drops packets 4 and 5, anticipating the arrival of packets with rank 2. It then sorts admitted packets across queues, achieving the optimal output (cf. Fig. 5).

Experiment These limitations generalize across ranks. We implement SP-PIFO, AIFO, PACKS and FIFO in Netbench [2, 19], and schedule a stream of packets over a bottleneck link where the ranks are distributed uniformly across $[0, 100]$ (details in §6). We measure the priority inversions generated by each rank and the number of packet drops per rank.

PIFO never causes inversions and schedules packets in perfect order (Fig. 3a). SP-PIFO approximates this behavior, especially for lower-rank packets: it maps packets with lower ranks to higher-priority queues. AIFO and FIFO generate a high number of inversions across most ranks because they run on a single queue and cannot prioritize lower-rank packets.

PIFO only drops packets with the highest ranks and has the best performance (Fig. 3b) since it prioritizes low-rank packets. AIFO closely approximates PIFO's behavior [2] by proactively dropping the highest-rank packets. SP-PIFO leaves drops as a by-product effect of its design (it just drops higher-rank packets more often because they are mapped to lower-priority queues that drain less frequently) and performs poorly. FIFO drops packets across all ranks, due to its tail-drop policy (which is rank agnostic) and has the worst performance.

PACKS's behavior is the closest to PIFO in *both* scheduling inversions and packet drops because it combines the best of both worlds: an admission-control scheme, similar to AIFO, and a queue-mapping scheme, similar to SP-PIFO.

The inefficiencies of existing works in approximating PIFO behaviors ultimately lead to performance degradation. Not exempting low-priority packets from occupying buffer space when high-priority ones are present, or not sorting packets by rank, results in increased latency, reduced bandwidth for priority applications, and longer flow completion times (§6.2).

3 Overview

We now provide an overview of how PACKS approximates the behavior of a PIFO queue on existing hardware. PACKS runs on top of a set of strict-priority queues, and incorporates: (i) an *admission-control* mechanism that decides which packets to admit, and (ii) a *queue mapper* that decides how to map admitted packets to the different priority queues (see Fig. 4).

PACKS uses this setup to approximate two PIFO behaviors: it *admits* packets with the lowest ranks; and *schedules* packets in order of their rank. What enables PIFO to achieve these behaviors is that it can map packets to any position in the queue, and it can drop packets (based on their ranks) even after it has admitted them into the queue. Unfortunately, we do not have this functionality (by default) on existing hardware.

[2] Note that the curve for AIFO and PACKS significantly overlap.

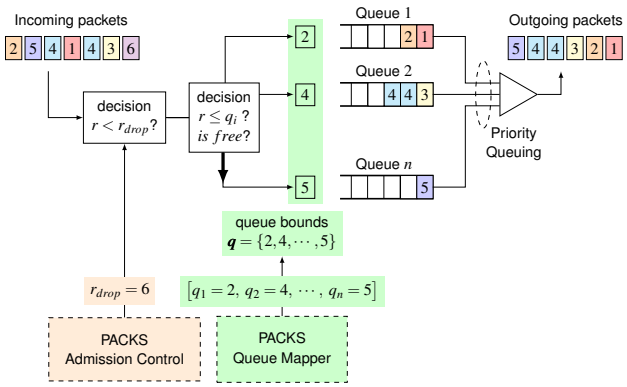

Figure 4: Overview of PACKS data-plane pipeline.

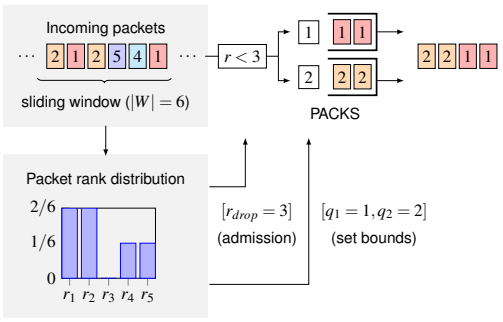

Figure 5: PACKS closely approximates PIFO's behavior.

PACKS approximates these behaviors by estimating the distribution of packets expected to arrive during a given scheduling interval. It then uses this information to compute the admission and scheduling decisions that a PIFO queue would follow and it executes them as each packet arrives. Based on the estimated rank distribution, PACKS identifies the set of lowest-ranked packets that fit into the available buffer space and proactively drops any arriving packets with a higher rank. PACKS also uses the estimated distribution to compute how to best map admitted packets into each priority queue in order to approximate the correct rank order at the output.

Rank-distribution estimation: PACKS uses a sliding window to dynamically monitor the distribution of the ranks of recently arrived packets — it considers this estimate of the rank distribution to be the best possible up-to-date estimate.

Admission control PACKS uses the distribution it estimates (see above) to decide which packets it should admit into the queue. Intuitively, PACKS should only admit the packets with the lowest ranks that can fit in the available buffer space (to mimic PIFO). Whenever a packet arrives, PACKS measures the available buffer space (as a percentage of the total buffer space) and computes a rank r_{drop} that represents a threshold such that all packets with rank $r \geq r_{drop}$ should be dropped. This rank is the lowest rank for which the quantile of the rank distribution exceeds the percentage of the remaining buffer space. This policy ensures that PACKS only admits the *lowest-rank* packets that it *expects* to arrive and fit in the available buffer space, which emulates PIFO's admission behavior.

Queue mapping PACKS then uses its estimate of the rank distribution to find the best mapping of expected packets to priority queues, to maximize the rank order at the output of the scheduler. Intuitively, the best mapping assigns packets with lower-ranks to the higher-priority queues (to prioritize low-rank packets) and minimizes the number of different-rank packets assigned to the same queue (to reduce the probability of higher-rank packets arriving before lower-rank ones, thereby generating a rank inversion in the output sequence).

PACKS defines a set of rank values $\boldsymbol{q} = (q_1, ..., q_n)$ that drive how it maps packets to priority queues (in the same way that r_{drop} drives admission control). The queue bound q_i for each queue describes the highest rank that the scheduler can admit to the queue such that these packets (i.e. those with rank $r < q_i$) are the lowest rank packets that fit in the available queue space. PACKS scans queue bounds top-down (i.e. from highest- to lowest-priority) and maps each incoming packet to the first queue where the packet rank is lower or equal to the queue bound — in this way it maps the low-rank packets to the high-priority queues: PACKS prioritizes *expected* packets of low rank over higher-rank ones (similar to PIFO).

Example Fig. 5 shows how PACKS schedules the sequence 2 1 2 5 4 1. We assume the sequence repeats, and configure PACKS with two priority queues of two packets each and a sliding window of size $|W| = 6$. After receiving the 6-th packet, PACKS has estimated the rank distribution, where the probability of receiving a packet of ranks 1 to 5 are $p(1) = 2/6$, $p(2) = 2/6$, $p(3) = 0$, $p(4) = 1/6$, $p(5) = 1/6$. Given the available buffer space (i.e., 4 packets), and based on the monitored rank distribution, PACKS sets r_{drop} to 3, since the expected 4 packets with lowest rank are those with rank 1 and 2. Then, PACKS sets q_i based on the available buffer space at each queue (i.e., 2 packets each). As such, it sets $q_1 = 1$ to map the two expected packets with lowest rank to the highest-priority queue, and $q_2 = 2$, to map the two expected admitted packets with highest rank to the lowest-priority queue. As a result, the output sequence of PACKS is 2 2 1 1, the exact same one as in the PIFO queue (see Fig. 2).

4 PACKS design

We now describe the theoretical basis supporting the design of PACKS. First, we frame the problem and introduce the design space (§4.1). Second, we provide the high-level intuition behind PACKS's design by studying the case in which it schedules a batch of packets (§4.2). Third, we generalize the algorithm to the online setup (§4.3). Finally, we formalize the PACKS's algorithm (§4.4), and analyze it both theoretically and with MetaOpt [24], an heuristic analyzer (§4.5).

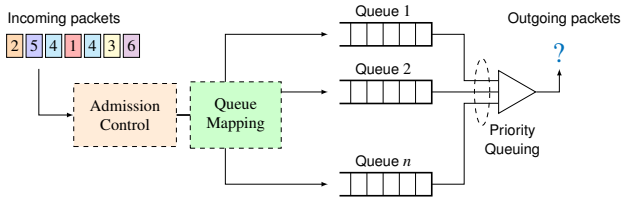

Figure 6: PACKS's design space.

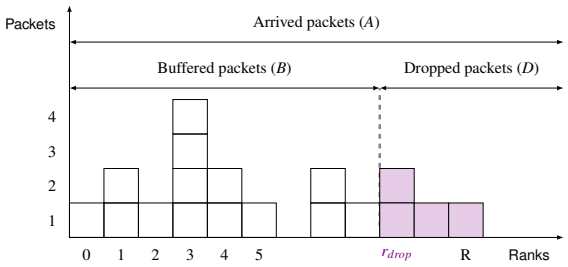

Figure 7: Admission control for a rank distribution, $\mathcal{W}$.

4.1 Design space

Let us consider the scheduling design space in Fig. 6, which represents the available resources in existing data planes [1,3]. Packets arriving at the scheduler are already tagged with ranks, either specified by the end hosts or at prior stages of the switch. The scheduler is composed by a set of strict-priority queues of fixed sizes, an *admission-control* mechanism that decides which packets to admit, and a *queue mapper* that decides how to map admitted packets to the priority queues. [3] After a packet is mapped to a queue, it is enqueued *only* if the queue has sufficient buffer space; otherwise, the packet is dropped. The scheduler continuously drains queues in decreasing order of priority, scheduling packets from low-priority queues only when higher-priority queues are empty, and schedules packets within each priority queue in a first-in first-out fashion.

Problem *How can we best approximate the behavior of a PIFO queue on top of the PACKS abstraction in Fig. 6?* The PACKS abstraction only allows for two design decisions: an admission-control and a queue-mapping algorithm. Our objective is to design such two mechanisms in a way that their overall behavior approximates the one of a PIFO queue. This is, an admission-control mechanism that (ideally) admits the earliest-arrived lowest-rank packets, and a queue-mapping algorithm that (ideally) prioritizes packets with lower rank.

4.2 High-level intuition

We introduce the high-level intuition behind PACKS's design by analyzing the case in which a PIFO queue schedules a batch of A packets. We assume, for now, that all packets have the same size, and that the PIFO queue has a capacity of B packets. For each incoming packet, the PIFO queue decides whether to admit or drop the packet. Only after processing *all* the packets, the PIFO queue schedules the admitted packets.

Approximating PIFO's admission In this setup, the PIFO queue admits the B (earliest-arrived) lowest-rank packets to the buffer, dropping the rest. Considering the rank distribution of the packets in the batch, $\mathcal{W}$, the admitted packets are the first B packets that we find when reading the distribution from left to right (see Fig. 7). As such, we can define a rank r_{drop}, such that all packets with rank equal or higher than r_{drop} are dropped by PIFO. Formally, computing r_{drop} is finding the highest rank in the distribution, for which the quantile of the distribution is below the fraction of the available buffer, B/A:

$$\begin{aligned} &\text{maximize } r_{drop}, \text{ where } 0 \leq r_{drop} \leq R, \\ &s.t., \ \mathcal{W}.quantile(r_{drop}-1) \leq B/A \end{aligned} \tag{1}$$

Once we know r_{drop}, approximating PIFO's admission on top of the PACKS abstraction is straightforward: we just have to configure PACKS's admission-control to drop all incoming packets from the batch with ranks higher or equal than r_{drop}.

So far, our model assumes that PIFO treats all packets with the same rank equally (i.e., either admitting or dropping them). In practice, however, since the PIFO queue has limited size, PIFO may only admit the earliest-arrived subset of them. To support this behavior, we extend the model by defining a time, t_{drop}, above which PIFO drops all the packets of the highest-admitted rank (i.e., $r_{drop}-1$). We can approximate this behavior on the PACKS abstraction by configuring its admission-control mechanism to drop packets based on both, r_{drop} and t_{drop}. Specifically, PACKS should drop packets if $r \geq r_{drop}$ or if $\{r = r_{drop}-1$ and $t \geq t_{drop}\}$.

Approximating PIFO's scheduling Once PIFO has decided whether to admit or drop each packet, it schedules the B buffered packets in a earliest-arrived, lowest-rank-first fashion. This requires packet sorting at line rate. We can approximate this behavior in the PACKS abstraction using priority queues.

For each priority queue, i, we define a rank, q_i, such that we only admit to the queue packets with rank lower or equal than q_i (c.f., Fig. 8). We call these ranks *queue bounds*. Formally, we let $\boldsymbol{q} = (q_1, \ldots, q_n) \in \mathbb{Z}^n$ be the set of bounds for queues 1 to n. We define a mapping strategy that uses queue bounds to map packets to their *highest-possible* priority queue, based on their rank. For each incoming packet with rank r, we scan queues top-down (i.e., from highest- to lowest-priority) and map the packet to the first queue, i, that satisfies $r \leq q_i$.[4] With this definition, we convert the problem of sorting packets at line rate based on their ranks to the problem of finding the optimal queue bounds that maximize rank order at the output of the scheduler. We define a loss function $\mathcal{U}_S : \mathrm{R}^n \times$

[3] Some devices allow extra functionalities such as flexible priority-queue configuration, round-robin scheduling, or buffer management. We use Fig. 6's abstraction for generality and to guarantee line-rate processing for *all* packets.

[4] Note that PACKS scans queues top-down, while SP-PIFO bottom-up [6].

$R_{\geq 0} \rightarrow R_{\geq 0}$, which stands for *scheduling unpifoness*, such that $\mathcal{U}_{\mathcal{S}}(\boldsymbol{q}, r)$ quantifies the approximation error of scheduling a packet with rank r based on queue bounds $\boldsymbol{q}$ compared to an ideal PIFO queue. Intuitively, it estimates the probability that a packet with rank r is scheduled after a packet with higher rank, r'. In the PIFO queue, $\mathcal{U}_{\mathcal{S}} = 0$, since packets are scheduled in perfect order. Thus, in the PACKS abstraction, a lower $\mathcal{U}_{\mathcal{S}}$ leads to a better approximation.

Our goal is to find the optimal queue bounds, $\boldsymbol{q}^*_{\mathcal{S}}$, that minimize $\mathcal{U}_{\mathcal{S}}$. Let Q be the space of all valid queue-bound vectors and $\mathcal{W}$ the distribution of packet ranks. Then, $\boldsymbol{q}^*_{\mathcal{S}}$ are:

$$\boldsymbol{q}^*_{\mathcal{S}} = \arg\min_{\boldsymbol{q} \in Q} \mathcal{U}_{\mathcal{S}}(\boldsymbol{q}, r) \tag{2}$$

Given that queue bounds are *fixed* during the enqueue process, scheduling errors cannot occur between ranks mapped to different priority queues. Thus, we can compute the total scheduling unpifoness as the sum of the individual losses at each priority queue. Letting $\mathcal{U}_{\mathcal{S}}(q_i)$ be the loss function corresponding to the queue with bound q_i, this is:

$$\mathcal{U}_{\mathcal{S}}(\boldsymbol{q}, r) = \sum_{1 \leq i \leq n} \mathcal{U}_{\mathcal{S}}(q_i) \tag{3}$$

Finally, letting $p_{\mathcal{W}}(r)$ and $p_{\mathcal{W}}(r')$ be the probability of ranks r and r', respectively, both mapped to the queue i, we can define the scheduling unpifoness of the queue as:

$$\mathcal{U}_{\mathcal{S}}(q_i) = \sum_{\substack{q_{i-1} < r \leq q_i \\ r < r' \leq q_i}} p_{\mathcal{W}}(r) \cdot p_{\mathcal{W}}(r') \tag{4}$$

With this formulation, given that we know the exact rank distribution, $\mathcal{W}$, we can easily compute the optimal queue bounds, $\boldsymbol{q}^*_{\mathcal{S}}$. For instance, [34] proposes a modified version of the Bellman-Ford algorithm that does so in polynomial time.

To provide a high-level intuition about the optimal queue bounds, we derive an upper-bound of $\mathcal{U}_{\mathcal{S}}(q_i)$ by setting $p_{\mathcal{W}}(r') = 1$. In doing so, we assume the worst case scenario in which, for each rank r, there is always a higher-rank packet, r' in the queue that can produce a scheduling error. As such:

$$\begin{aligned} \hat{\mathcal{U}}_{\mathcal{S}}(q_i) &= \sum_{q_{i-1} < r \leq q_i} p_{\mathcal{W}}(r) \\ &= \mathcal{W}.quantile(q_i) - \mathcal{W}.quantile(q_{i-1}) \end{aligned} \tag{5}$$

We can see how the optimal bounds are those that minimize the quantiles of the rank distribution for the set of ranks mapped to each priority queue. In other words, the optimal bounds are those that result in the least amount of different-rank packets mapped to each queue (i.e., those that minimize the colored area within each priority queue in Fig. 8).

Since we have to map all the admitted ranks, $0 \leq r < r_{drop}$, to some queue, removing a rank from a queue implies adding it to the adjacent queue. Thus, any reduction of unpifoness in a queue, increases the unpifoness of the adjacent queue.

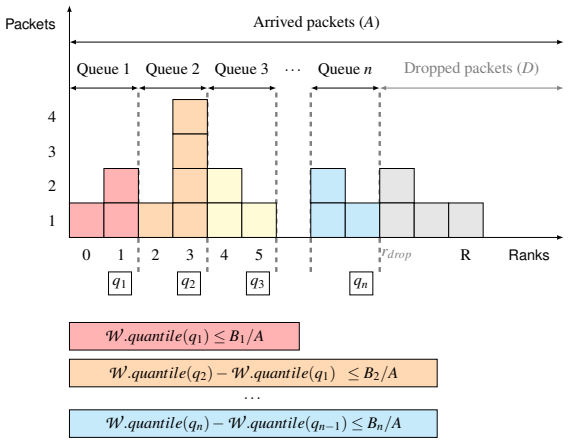

Figure 8: Queue mapping for a rank distribution, $\mathcal{W}$.

Therefore, we can only perform such an optimization step as long as there is a queue that can absorb the cost of taking in more ranks without becoming a new, greater maximum-cost queue. The optimum is achieved when the estimated scheduling unpifoness in each priority queue is balanced out.

PACKS's collateral drops Unlike in PIFO, the admission-control in the PACKS abstraction (i.e., drop if $r \geq r_{drop}$) is not its only source of packet drops. Indeed, an admitted packet can still be dropped by the priority-queue's enqueue mechanism if the available buffer space in the selected queue is not sufficient to accommodate the packet. As such, in order for the PACKS abstraction to fully approximate PIFO's admission behavior, it should not only control which packets are admitted; it should also make sure that the admitted packets are not dropped at enqueue when they are mapped to the priority queues. This brings us to the third part of the PIFO-approximation problem: approximating PIFO's efficient usage of the buffer space.

In the following, we compute the optimal queue bounds that minimize the drops that occur when mapping packets to priority queues, $\boldsymbol{q}^*_{\mathcal{D}}$, and compare them to the optimal bounds that optimize rank order at the output of the scheduler, $\boldsymbol{q}^*_{\mathcal{S}}$.

Let B_i define the buffer capacity of the i-th priority queue in the PACKS abstraction. Let $\boldsymbol{B} = (B_1, \ldots, B_n) \in \mathbb{Z}^n$ describe the buffer allocation across queues, where the sum of the buffer space of each queue is the total buffer space: $\sum_{i=1}^{n} B_i = B$. Let $\boldsymbol{q} = (q_1, ..., q_n) \in \mathbb{Z}^n$ be the set of queue bounds defining the mapping strategy, where $0 \leq q_1 \leq q_2 \leq , \ldots, \leq q_n = r_{drop} - 1$. With this strategy, we can compute the number of packets mapped to the i-th priority queue, m_i, as:

$$\begin{aligned} m_1 &= [A \cdot \mathcal{W}.quantile(q_1)] \\ m_2 &= [A \cdot \mathcal{W}.quantile(q_2)] - m_1 \\ m_n &= [A \cdot \mathcal{W}.quantile(q_n)] - m_{n-1} \end{aligned} \tag{6}$$

We define a loss function $\mathcal{U}_{\mathcal{D}} : R^n \times R_{\geq 0} \rightarrow R_{\geq 0}$, which stands for *dropping unpifoness*, such that $\mathcal{U}_{\mathcal{D}}(\boldsymbol{q})$ measures the number of packets dropped when mapping packets to queues

based on queue bounds $\boldsymbol{q}$. In the PIFO queue, $\mathcal{U}_{\mathcal{D}} = 0$, since there is no queue mapping, and drops only occur at admission. In PACKS, a lower $\mathcal{U}_{\mathcal{D}}(\boldsymbol{q})$ leads to a better approximation.

Our goal is to find the optimal bounds, $\boldsymbol{q}^*_{\mathcal{D}}$, that minimize $\mathcal{U}_{\mathcal{D}}(\boldsymbol{q})$. Let $\mathcal{Q}$ be the space of valid queue-bound vectors and $\mathcal{W}$ the distribution of packet ranks, then the bounds $\boldsymbol{q}^*_{\mathcal{D}}$ are:

$$\boldsymbol{q}^*_{\mathcal{D}} = \underset{\boldsymbol{q} \in \mathcal{Q}}{\arg\min}\ \mathcal{U}_{\mathcal{D}}(\boldsymbol{q}) \tag{7}$$

Since queue bounds are fixed during the enqueue process, and packets are dropped in each queue independently of the other queues, we can compute the total unpifoness as the sum of the individual losses at each queue, $\mathcal{U}_{\mathcal{D}}(q_i)$:

$$\mathcal{U}_{\mathcal{D}}(\boldsymbol{q}) = \sum_{1 \le i \le n} \mathcal{U}_{\mathcal{D}}(q_i) \tag{8}$$

The loss at queue i, $\mathcal{U}_{\mathcal{D}}(q_i)$, is either the difference between the number of packets mapped to the queue, m_i, and the queue space, B_i, if the number of packets mapped to the queue is greater than the queue space, or 0, otherwise:

$$\mathcal{U}_{\mathcal{D}}(q_i) = \begin{cases} m_i - B_i & \text{if } m_i > B_i \\ 0 & \text{otherwise.} \end{cases} \tag{9}$$

As such, the optimal bounds $\boldsymbol{q}^*_{\mathcal{D}}$ are the ones that minimize the difference between the number of packets mapped to each queue and the buffer size of the queue. Since all packet drops contribute equally to the loss function, there may exist multiple queue-bound vectors, $\boldsymbol{q}^*_{\mathcal{D}}$, that result in an optimal number of drops. In fact, any set of queue bounds is optimal as long as the packets mapped to each queue is lower or equal than the buffer space allocated to that queue (i.e., $m_i \le B_i$):

$$\forall i : A \cdot (\mathcal{W}.quantile(q_i) - \mathcal{W}.quantile(q_{i-1})) \le B_i \tag{10}$$

Given that PACKS's admission control already ensures that the total number of packets admitted can fit within the total buffer space (i.e., $A \cdot \mathcal{W}.quantile(r_{drop} - 1) \le B$), we can guarantee that there exists at least one set of queue bounds, $\boldsymbol{q}^*_{\mathcal{D}}$, that leads to zero drops at queue-mapping time. We can find such optimal bounds by computing the ranks for which the quantile of the rank distribution stays below the allocated queue sizes. This is $\forall i$: maximize q_i s.t. the eq. 10 is satisfied.

Same as it happened in the admission-control counterpart, there may be rank distributions for which the number of packets of a certain rank exceeds the queue capacity (even when that rank is the only one mapped to the queue). In that case, we need finer granularity than the rank-level to perform the queue mapping. Same as we did for admission control, we can overcome this limitation by introducing an enqueue-time value t_i, for each priority queue, i, such that packets are only admitted to the queue if: $r \le q_i - 1$ or if $\{r = q_i \text{ and } t \le t_i\}$. Packets not admitted to the queue i are carried over to the next queue, $i+1$, which has to account them as part of its quantile.

Sorting vs. dropping Having computed the optimal queue bounds that best approximate PIFO in optimizing rank order at the output, $\boldsymbol{q}^*_{\mathcal{S}}$, and in minimizing packet drops at queue-mapping, $\boldsymbol{q}^*_{\mathcal{D}}$, we can see that they are not always the same. Indeed, $\boldsymbol{q}^*_{\mathcal{S}}$ minimizes the quantiles of the rank distribution for the ranks mapped to each priority queue, and $\boldsymbol{q}^*_{\mathcal{D}}$ minimizes the difference between these quantiles and their respective queue sizes. Thus, which queue bounds should we use?

In general, we could pick any of the two options based on e.g., which of the two behaviors we believe is more important. However, since our goal is to design a *programmable* scheduler, we select the option that *generalizes* the most. We realize that $\boldsymbol{q}^*_{\mathcal{D}}$ are not only the best bounds for minimizing packet drops at queue-mapping time, but *also* the optimal bounds for *scheduling* in case the rank distribution is not known a priori (see eq.5 and eq.10). Indeed, if the rank distribution of incoming packets is not known, the optimal queue mapping that minimizes rank reordering is the one that distributes packets across queues proportionally to the queue sizes. Thus, $\boldsymbol{q}^*_{\mathcal{D}}$ can be seen as a worst-case bound for $\boldsymbol{q}^*_{\mathcal{S}}$, leading to a good performance in both dimensions, as we show in §6. As a result, we leverage $\boldsymbol{q}^*_{\mathcal{D}}$, as the queue bounds for our design.

4.3 Online adaptation

So far, we have assumed a simplified scenario where packets arrive to the scheduler in a *batch*-basis, all packets have the same size, and we know the complete rank distribution of the batch at enqueue. In practice, however, packets arrive in a *stream*, and the scheduler needs to perform the admission and enqueue decisions *per-packet, at line rate*. In the following, we translate our high-level intuition to an algorithm design that is practical and which we can deploy to existing hardware.

Sliding window to monitor rank distribution In the online setup we do not know the rank distribution of incoming packets, $\mathcal{W}$, in advance. Instead, the best estimation that we can make is based on the rank distribution of recently-received packets. As such, same as previous approaches [34, 37], we monitor this distribution, W, using a sliding window, and use it to drive the admission and queue-mapping decisions.

Queue occupancy to estimate congestion In the online case, packets arrive in a *continuous* stream and not in a batch basis. Thus, instead of computing the quantiles over the number of packets arrived in the batch, A, we do so over the number of packets sharing the buffer in a scheduling interval, B. At the same time, while in the batch case we could assume empty queues at start, in the online case we have to consider dynamic buffers which should absorb the short-term mismatches between traffic arrival and departure rates. We do so by measuring the buffer occupancy of the queues, and using them as an estimate of their congestion levels. [5] As a result, given b, the buffer-occupancy level at a certain packet's enqueue time, we decide to admit the packet if $W.quantile(r_{drop} - 1) \le \left[\frac{1}{1-k} \cdot \frac{B-b}{B} \right]$, where k is an optional

[5] This is a common approach in queue-management [18, 25, 37]. We could also have used the *sojourn-time* of packets, as proposed by CoDel [25].

parameter to give room for burstiness. Similarly, given b_i, the buffer-occupancy level of queue i, we perform the queue-mapping process based on queue bounds, $\boldsymbol{q}$, satisfying:

$$
\begin{aligned}
q_1 &:= \max_{r_1 \in \mathbb{N}} s.t.\ W.quantile(r_1) \leq \frac{1}{1-k} \cdot \left[\frac{(B_1 - b_1)}{B} \right] \\
q_2 &:= \max_{r_2 \in \mathbb{N}} s.t.\ W.quantile(r_2) \leq \\
&\qquad \leq \frac{1}{1-k} \cdot \left[\frac{(B_1 - b_1)}{B} + \frac{(B_2 - b_2)}{B} \right] \qquad (11) \\
&\quad \ldots \\
q_n &:= \max_{r_n \in \mathbb{N}} s.t.\ W.quantile(r_n) \leq \frac{1}{1-k} \left[\frac{\sum_{j=1}^{n} (B_j - b_j)}{B} \right]
\end{aligned}
$$

Since $q_n = r_{drop} - 1$, the lowest-priority queue's mapping policy already implies the admission control at the scheduler, which simplifies the algorithm implementation (cf. alg. 1).

Minimizing collateral drops Same as in the batch case, packets of a certain rank may exceed a queue's capacity. In the batch case, we relied on t_i to map packets to a lower-priority queue if the higher-priority queues were full. In the online case, we assess queue occupancy during mapping; if the selected queue for a given packet is full, we direct the packet to the next queue with available space. This approach addresses a key limitation of queue-mappers like SP-PIFO, which excessively drop incoming packets when mapped to the same queue (e.g., during bursts of packets with the same rank or with monotonic rank increase). As such, PACKS prevents drops and ensures an efficient usage of the buffer resources. Additionally, PACKS's *top-down* scanning process ensures that PACKS preserves the scheduling order of such packet sequences, despite mapping them to different priority queues.

4.4 PACKS algorithm

Algorithm 1 PACKS

Require: An incoming packet pkt with rank r

1: **procedure** INGRESS
2: Update sliding window W with r
3: $B \leftarrow$ buffer.total $B_i \leftarrow$ buffer(q_i).total
4: $b_i \leftarrow$ buffer(q_i).used
5: **for** $Queues(i) : i = 1$ **to** n **do** ▷ Scan top-down
6: **if** $W.quantile(r) \leq \frac{1}{1-k} \cdot \left[\frac{\sum_{j=1}^{i} (B_j - b_j)}{B} \right]$ **then**
7: **if** $b_i < B_i$ **then** ▷ Queue i not full
8: $Queues(i).enqueue(pkt)$ ▷ Select queue
9: **return;**
10: $Drop(pkt)$ ▷ Drop packet

We detail the PACKS algorithm in alg 1. For each incoming packet, PACKS decides whether to admit the packet or drop it, and how to map admitted packets to priority queues.

Admission control Whenever an incoming packet arrives, PACKS performs two main operations. First, it updates the sliding window, W, with the rank of the new packet, r. Then, it measures the current buffer occupancy, b and uses it to compute the portion of the buffer space, B, that is still free: $\frac{B-b}{B}$. PACKS admits the incoming packet if the quantile of its rank for the monitored rank distribution is lower than the fraction of available buffer space: $W.quantile(r) \leq \left[\frac{1}{1-k} \cdot \frac{B-b}{B} \right]$. Note that we weight the admission condition by an optional parameter, k, to allow for some burstiness. Also, note that in alg. 1, the admission condition is *implicit* in the queue-mapping process. Indeed, the drop action in line 10, executed when the packet has *not* been mapped to the lowest-priority queue, already serves the purpose of admission control.

Queue mapping For the admitted packets, PACKS scans priority queues top-down (i.e., from highest- to lowest-priority) and maps the packet to the first queue with available space that satisfies the condition: $W.quantile(r) \leq \frac{1}{1-k} \cdot \left[\frac{\sum_{j=1}^{n} (B_j - b_j)}{B} \right]$. If a packet is not admitted to any of the queues, because its rank is too high, or because all queues are full, it is dropped.

4.5 PACKS analysis

Similarly to other networking algorithms [7, 18, 20, 25, 34, 37], PACKS uses a window-based approach instead of a per-packet heuristic. As a result, PACKS outperforms under a stable rank distribution, if the window size is large enough to capture it.

While the window-based approach generally makes PACKS less vulnerable to adversarial packet workloads (PACKS's bounds are updated more smoothly, making them harder to disrupt, cf. Fig. 15), it also represents PACKS's Achilles' heel.

We evaluated PACKS on MetaOpt [24]–a recent heuristic analysis tool–, to understand its performance gap relative to SP-PIFO, AIFO and PIFO, and to identify adversarial inputs (cf. Appendix B). We found that PACKS is robust against adversarial sequences that make SP-PIFO drop more than 60% of high-priority packets, or make AIFO delay highest-priority packets by more than 60% of the total queue size.

We also found that PACKS's adversarial inputs consist of bursts of either very high or very low rank packets, which "pollute" the monitored distribution and prevent the well functioning of the algorithm (cf. B.3). In §6.1 we study the impact of such behaviors in depth and show how PACKS can react faster to such distribution changes by using smaller window sizes and higher burstiness allowances. In these cases, PACKS relaxes its admission criteria and its behavior converges to the one of per-packet heuristics such as SP-PIFO (cf. Fig 10).

In Appendix A, we study PACKS's optimality theoretically. We prove that, for certain window and buffer-size conditions, the departure rate for all ranks in PACKS converges to that of a PIFO queue (cf. Theorem. 1). We also suggest an upper bound for the number of inversions that PACKS produces for a generic packet sequence, with respect to PIFO (cf. Claim. 1).

5 Implementation

We implemented PACKS in P4$_{16}$ for Intel Tofino 2 [1] using 439 lines of code. Our implementation uses 12 stages and the resources outlined in Table 1. For each incoming packet, PACKS: (i) monitors the distribution of recent ranks; (ii) computes the quantile of the packet's rank on this distribution; (iii) measures queue occupancies; and (iv) uses this data to decide the packet's admission, dropping, and queue mapping.

Rank-distribution monitoring We track the rank distribution of the packets received by implementing a sliding window over a set of $|W|$ registers. Each register stores the rank of one packet, and we use a circular packet counter, from 0 to $|W|-1$, to track the position of the oldest update. Upon the arrival of a new packet, we check the counter's value and update the register pointed to by the counter with the value of the new packet's rank. In our prototype, the sliding window has a size of 16 (which can be extended by using sampling [37]). It uses 4 stages and accesses 4 registers in parallel at each stage.

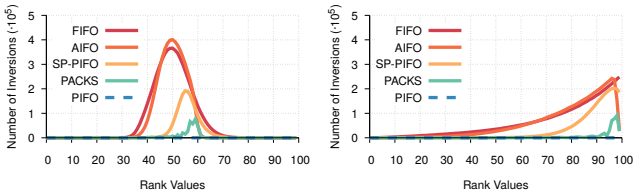
Quantile computation We compute the quantile of each incoming packet's rank based on the monitored distribution. Specifically, we count how many times the packet's rank is lower than a rank in the sliding window and then divide the result by the window size. We perform the count by accessing each register of the sliding window and comparing the packet's rank with the register's value using the register's stateful ALU. We output the result of each comparison into a binary metadata field, $output_j$, which is set to 1 if the packet's rank is smaller than the register value and 0 otherwise. We aggregate the output values by progressively summing pairs of them at each stage using non-stateful ALUs, requiring $\log_2 |W|$ stages. Finally, we divide the sum of the output values by the window size, $|W|$: $W.quantile(r) = (\sum_j output_j)/|W|$. We select the window size to be a power of 2, and implement the division through bit-shift operations.

Queue-occupancy monitoring We use a *ghost thread* [5], available in Tofino 2, to monitor queue occupancy levels at enqueue. Normally, this information is only available in the *egress* pipeline, since packets need to traverse the traffic manager to access it. We address this limitation by setting up a ghost thread that periodically writes the queues' occupancy levels (from the egress) to a register accessible from the ingress pipeline. The ghost thread takes two clock cycles to update the state of each queue and handles one queue per invocation. This results in 8 clock cycles to update the state of 4 queues. To scale PACKS across a larger set of queues and ports, we approximate the admission and queue-mapping conditions by considering the overall buffer occupancy instead of individual per-queue occupancies (i.e., $W.quantile(r) \leq \frac{1}{1-k} \cdot \frac{B-b}{B} \cdot \frac{i}{n}$). Alternatively, we could use traditional packet recirculation to convey queue-occupancy information to the ingress pipeline (as done in [37]). The first option sacrifices accuracy, while the second, throughput.

Admission and queue mapping After obtaining the quantile of the packet's rank based on the monitored rank distribution, $W.quantile(r)$, and the available buffer, b, we combine them to derive the admission and mapping conditions. We rewrite them as: $B \cdot (1-k) \cdot n \cdot W.quantile(r) \leq (B-b) \cdot i$. We compute the right side of the equation by using the math unit and bit-shift operations. Simultaneously, we compute the left side of the equation by picking a k value strategically such that the operation can be performed by a bit shift on the quantile. Finally, we compute the comparison between the two terms using the *minimum* operation of the math unit, and execute the corresponding drop or enqueue action based on its result.

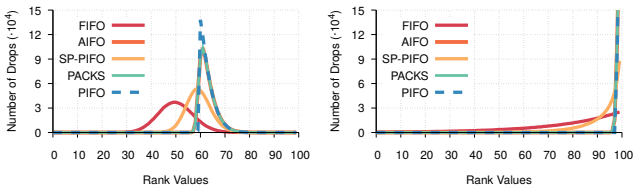
6 Evaluation

We evaluate PACKS's performance in approximating PIFO for various rank distributions and configuration parameters (§6.1), its practicality under complex traffic workloads (§6.2), and its bandwidth allocation when deployed on hardware (§6.3).



6.1 Performance analysis

First, we analyze PACKS's behavior across different rank distributions to assess its performance in approximating PIFO.



Methodology We implement PACKS, PIFO, FIFO, SP-PIFO and AIFO in Netbench [2], a packet-level simulator. We study the performance of a switch scheduling a constant bit-rate flow of 11Gbps over a 10Gbps bottleneck link for one second. We assign each packet a rank within [0-100), drawn from an exponential, Poisson, convex, or inverse-exponential distribution. We set up PACKS and SP-PIFO with 8 priority queues of 10 packets, and AIFO and FIFO with a queue of 80 packets. We set PACKS's and AIFO's window size to 1000 packets and the burstiness allowance, k, to 0. We measure the number of scheduling inversions produced by each rank (i.e., how often a packet with the rank is scheduled *before* a lower-rank packet in the queue) and the number of dropped packets per rank.

Uniform case In §2.3, we have seen how PACKS outperforms existing schemes under a uniform rank distribution (cf. Fig.3) in both the number of scheduling inversions and the drop distribution across packet ranks. Indeed, PACKS reduces the number of inversions by more than 3×, 10× and 12× with respect to SP-PIFO, AIFO and FIFO. While all schemes drop a similar percentage of packets (within ±0.03%), PACKS achieves the closest-to-PIFO drop distribution across packet ranks. PIFO only drops packets with ranks larger than 90. FIFO deviates furthest from PIFO by dropping packets across *all* ranks. It is followed by SP-PIFO, which drops packets with ranks as low as 20. AIFO and PACKS perform best, only dropping packets with ranks above 77 and 79, respectively.

Alternative distributions (inversions) We obtain similar results for non-uniform rank distributions. Fig. 9 shows the

(a) Poisson (inversions) (b) Inv. Exponential (inversions)

(c) Poisson (drops) (d) Inv. Exponential (drops)

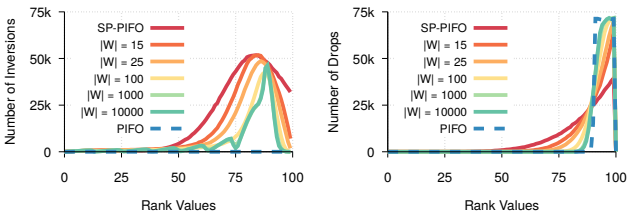


Figure 9: PIFO approximations for various rank distributions.

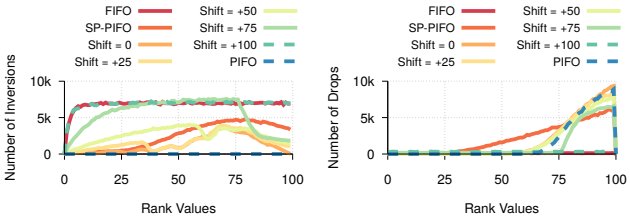
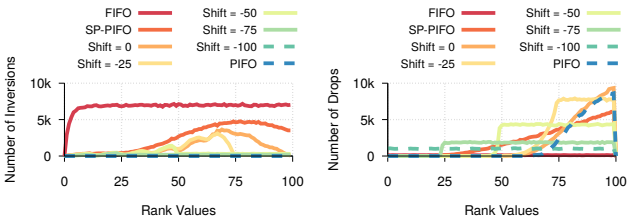
scheduling inversions and the packet drops across ranks for the Poisson and inverse-exponential rank distributions (we see similar results for the convex and exponential distributions). In all cases, PACKS outperforms SP-PIFO and AIFO, and gets closest to PIFO in inversions and packet drops. For the Poisson distribution, PACKS reduces the number of inversions by 5× and more than 15× and 17× compared to SP-PIFO, AIFO and FIFO, respectively. Similarly, for the inverse-exponential distribution, PACKS prevents over 7×, 14× and 15× more inversions than SP-PIFO, AIFO and FIFO, respectively. Notably, PACKS predominantly prevents inversions among lowest-ranked packets, which have higher priority.

Alternative distributions (drops) Under the Poisson distribution, all schemes drop overall a similar number of packets (within ±0.04%), being SP-PIFO the one with the highest drop rate. When considering the distribution of dropped packets across ranks, PACKS and AIFO are the schemes most closely approximating PIFO. Specifically, the lowest rank dropped by PIFO is 59, while PACKS and AIFO drop packets starting at rank 56 [6]. Conversely, SP-PIFO and FIFO show notably worse performance, dropping packets with ranks as low as 36 and 20, respectively. We observe similar results for the inverse-exponential distribution. In this case, however, while the total number of packets dropped by PACKS and AIFO is similar to the one of PIFO (+0.1% and +0.4%, respectively), SP-PIFO drops 42% more packets than them. This is due to the highly skewed nature of the distribution, which is hard for SP-PIFO to manage without admission control (cf. §4.4).



Sensitivity to window size Fig. 10 illustrates the impact of window size on PACKS's performance. Given that the rank distribution ranges from 0 to 100 and the overall buffer space is of 80 packets, PACKS performs best with window sizes above $|W| = 100$, which capture the entire distribution.

[6] Note that PACKS's and AIFO's drop distribution significantly overlap.



(a) Window size (inversions) (b) Window size (drops)

Figure 10: PACKS's window-size sensitivity (UDP, uniform).

(a) Positive shift (inversions) (b) Positive shift (drops)

(c) Negative shift (inversions) (d) Negative shift (drops)

Figure 11: Rank-distribution sensitivity (TCP uniform).

Since the rank distribution is stable, a higher window size consistently leads to more stable queue bounds and better performance, as indicated by the bumps in the distribution reflecting the behavior of priority queues. For example, with $|W| = 1000$, PACKS performs very close to optimal, reducing inversions by 22% compared to $|W| = 100$ and increasing the lowest-dropped rank from 69 to 78. Further increasing the window to $|W| = 10000$ doesn't improve performance so significantly, only reducing inversions by 1% and raising the lowest-dropped rank from 78 to 80, compared to $|W| = 1000$.

Window sizes below $|W| = 100$ lead to worse performance since the window cannot capture the entire distribution. Interestingly, as we reduce the window size, PACKS's behavior approaches that of SP-PIFO. Nevertheless, even with very small window sizes, PACKS still outperforms. For instance, with $|W| = 15$, which barely captures a 15% of the distribution, PACKS still produces 30% less inversions compared to SP-PIFO and starts dropping packets at rank 34 instead of 18.

Sensitivity to distribution shifts PACKS's design follows a window-based approach and, thus, relies on a predictable future packet distribution. Since real-world packet distribu-

tions are not always predictable, we now assess how PACKS performs when the monitored rank distribution differs from that of incoming packets. To do so, we modify PACKS's algorithm to consistently shift *all* ranks *in the sliding window* by a factor. This approach does not reflect a real-world scenario since, even under a drastic distribution shift in practice (e.g., a microburst), packets from the "new distribution" would arrive in a continuous stream, allowing the sliding window to adapt gradually as each packet arrives. Still, it helps us understand PACKS's performance boundaries. We run TCP flows at 80% load, with packet ranked uniformly at random from 0 to 100.

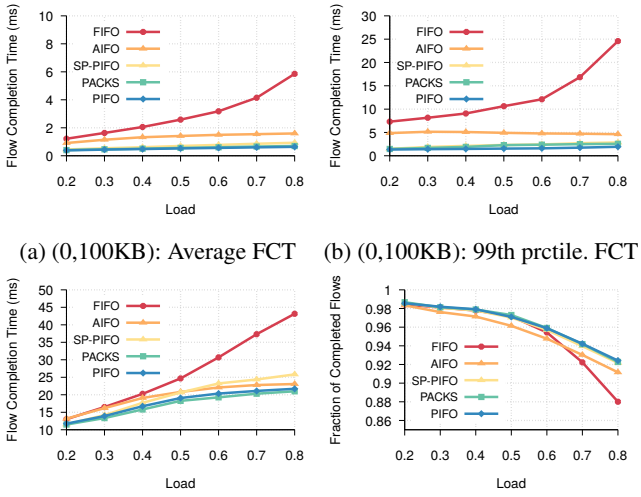


Fig. 11a and Fig. 11b show the impact of shifting the ranks of the sliding window by *positive* factors. This leads to more permissive admission and queue-mapping decisions, as if we increased the priority of incoming packets. When the shift reaches 100, all arriving packets have higher priority than the ones in the sliding window, causing PACKS to admit all packets and behave like a FIFO queue. Despite the extreme scenarios with shifts $\geq$75, PACKS exhibits significant robustness to positive distribution shifts. For instance, with a shift of +25, PACKS vastly outperforms SP-PIFO by reducing inversions by 34% and with a lowest-rank dropped of 46, as opposed to 12 in SP-PIFO. Even with a shift of +50, PACKS performs comparably to SP-PIFO in terms of total inversions while dropping 162$\times$ fewer packets below the rank of 58.

Fig. 11c and Fig. 11d show the impact of shifting the ranks of the sliding window by a *negative* factor. This is equivalent to decreasing the priority of incoming packets, which has a more detrimental impact on performance than positive shifts, and affects packet drops. Indeed, admission control drops a percentage of packets equal to the magnitude of the shift. With a -100 shift, PACKS drops all incoming packets. Similarly, a -75, -50 and -25 shift lead to dropping 75%, 50% and 25% of packets with the lowest priority, respectively. For the subset of admitted packets, PACKS maintains ideal behavior in terms of scheduling inversions. We can counteract the effect of negative distribution shifts by increasing the burstiness allowance, k, or decreasing the window size to speed up reaction time.

6.2 Performance in typical use cases

We now study PACKS's performance under two common scheduling objectives: minimizing flow completion times and enforcing fairness [6, 8, 37, 38]. These scenarios are challenging for PACKS because they involve large and non-stationary rank distributions, which are difficult to monitor accurately.

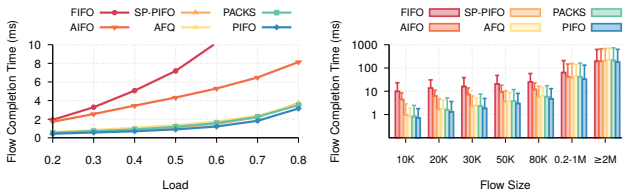
Methodology We use a leaf-spine topology with 144 servers connected through 9 leaf and 4 spine switches, and set the access and leaf-spine links to 1Gbps and 4Gbps, respectively. We generate traffic flows following the pFabric web-search workload [8]. Flow arrivals are Poisson-distributed and we adapt their starting rates for different loads. We use ECMP and draw source-destination pairs uniformly at random.

(a) (0,100KB): Average FCT (b) (0,100KB): 99th prctile. FCT

(c) [All flows]: Average FCT (d) Fraction of completed flows

Figure 12: pFabric: FCT statistics across different flow sizes.

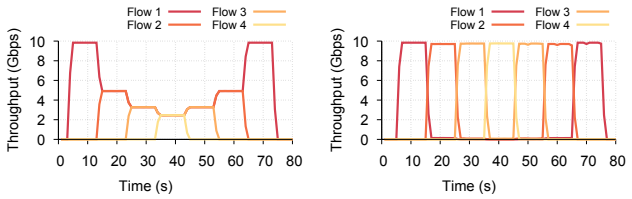
Setup pFabric We run pFabric [8] (without starvation prevention [7]) on top of PIFO, AIFO, SP-PIFO and PACKS, and assess their efficacy in minimizing flow completion times. pFabric assigns ranks to packets based on their remaining flow sizes. As suggested in [8], we approximate pFabric's rate control using standard TCP with an RTO of 3 RTTs. We configure PACKS and SP-PIFO with 4 queues$\times$10 packets and PIFO, AIFO and FIFO with 1 queue$\times$40 packets. For PACKS and AIFO, we set $|W|$ to 20 packets, and k to 0.1.



Results pFabric Fig. 12 shows the mean and 99th percentile FCT of small flows, the average FCT across all flows, and the fraction of completed flows. AIFO produces longer FCTs for small flows due to the lack of packet sorting. SP-PIFO results in longer FCTs at high loads due to queue inversions. PACKS combines the strengths of both, performing best overall.

In terms of average FCTs for small flows, PACKS achieves FCTs just 5% to 9% longer than PIFO, which is remarkable given its use of just 4 queues. In turn, PACKS outperforms SP-PIFO by 11% to 33%, AIFO by a factor of 2.25$\times$ to 2.6$\times$, and FIFO by 3.2$\times$ to 9.2$\times$ (biggest benefits under heavy loads).

At the 99th pctl., PACKS achieves FCTs 8% to 49% longer than PIFO, but remains better than SP-PIFO (from 2.2% to 12% better), AIFO (1.8$\times$ to 3.3$\times$), and FIFO (5$\times$ to 10$\times$).



Regarding the mean FCT across all flows, PACKS achieves on-par performance with PIFO (the mean FCT of PACKS is even a bit lower–from 2% to 5%–due to long flows not completing transmission, cf. Fig. 12d). Once again, PACKS consistently outperforms SP-PIFO across all loads (with improvements ranging from 0.2% at the lowest load to 23% at the highest load), AIFO (9% to 21%) and FIFO (13% to 2$\times$).

[7] Starvation [8] is a limitation inherent to PIFO, and therefore of all its approximations. Previous works have already proposed solutions to the starvation problem (e.g., PDA [35]) which can also run on PACKS.

(a) (0,100KB): Average FCT (b) FCT breakdown for 70% load

Figure 13: Fairness: FCT statistics at different loads.

(a) FIFO Bandwidth-split (b) PACKS Bandwidth-split

Figure 14: Bandwidth allocation for increasing-priority flows.

Finally, PACKS's fraction of completed flows closely matches that of PIFO (± 0.01% to 0.2%). Moreover, PACKS achieves higher completion rates than SP-PIFO, with improvements from 0.06% to 0.2%, and AIFO (resp. 0.3% to 1.2%).

Setup fair queuing We run the Start-Time Fair Queueing rank design [17] on top of the schedulers and evaluate their performance at enforcing fairness across flows. We compare to FIFO and AFQ [27] for reference. We set the bytes-per-round of AFQ to 80 packets. We use 32 queues×10 packets in SP-schemes and 1 queue×320 packets for single-queue schemes. Same as [6,37], we generate traffic from the pFabric web-search distribution, and assess fairness by measuring the flow completion time of short flows. For PACKS and AIFO, we set the window size to 10 and the burstiness margin to 0.2.

Results fair queuing Fig. 13a depicts the average flow completion time for small flows across loads from 20% to 80%. PACKS stays within 10–24% of the ideal PIFO, and consistently outperforms FIFO, AIFO and AFQ across all loads. Specifically, PACKS reduces the average FCTs for short flows by 2.5–5.5×, 1.12×–2.4×, 9–27% with respect to FIFO, AIFO and AFQ, respectively. PACKS performs similarly to SP-PIFO (within ±6%), underperforming at lower loads, but outperforming by 6% at the highest load (80% utilization).

Fig. 13b illustrates the average and 99th percentile flow completion times across flow sizes at 70% utilization. PACKS's performance consistently stays within 17–26% of the ideal PIFO in terms of average FCT and within 15–54% for the 99th percentile across all flow sizes. It shows comparable performance to SP-PIFO (within ±10% for average FCTs and ±20% for the 99th percentile) and AFQ for average FCTs (within ±15%). However, AFQ outperforms at the 99th percentile, by up to 31%. For the smallest flows, PACKS achieves the lowest average FCT, closely trailing AFQ by 5%.

6.3 Hardware testbed

We show that PACKS performs at line rate on actual hardware by running it on the Edgecore Networks DCS810 (AS9516-32D) Intel Tofino2 Switch [1]. Same as previous works [6, 37, 38], we measure the bandwidth that PACKS allocates to different priority flows over a bottleneck link. We generate traffic between two servers, connected by a Tofino2 switch, using interfaces of 100 Gbps (sender→switch) and 10 Gbps (switch→receiver). We run four UDP flows of 20 Gbps each using MoonGen [13, 14]. We start flows sequentially (one flow at a time), in increasing order of priority with a time gap of 10 seconds between starts. We stop them sequentially in decreasing order of priority, with 10 seconds between stops.

Fig. 14 depicts the flows' bandwidth and how PACKS manages to effectively prioritize traffic from lower ranks. While the FIFO queue distributes the bandwidth uniformly across flows (failing at prioritizing traffic), PACKS successfully allocates the available bandwidth to the highest-priority flow.

7 Related work

Packet scheduling has been extensively studied for decades [8, 10–12, 17, 21, 22, 26, 27, 29]. The concept of programmable scheduling was introduced by [31, 32], which proposed the PIFO queue as an enabling abstraction. While promising, implementing PIFO queues in hardware proved challenging. Hence, a subset of follow-up works have suggested new hardware designs such as PIEO [30], BMW-Tree [36], BBQ [9], and Sifter [15]. Other works have focused on approximating PIFO behaviors on existing programmable data planes: SP-PIFO [6], QCluster [35], PCQ [28], AIFO [37], Spring [34], and Gearbox [16]. PACKS falls into the latter category.

8 Conclusions

We present PACKS, the first programmable packet scheduler that emulates PIFO queues on existing data planes in *both* rank ordering *and* packet drops. PACKS runs on top of a set of priority queues and leverages packet-priority information and queue-occupancy levels during enqueue, to schedule packets in order of priority. We show that PACKS is practical, achieves close-to-PIFO behavior, and outperforms the state-of-the-art.

Acknowledgments

We are grateful to the reviewers and our shepherd, Hyojoon Kim, for their comments. This work was partly supported by the OTKA #135606 and #135074 projects of the National Research, Development and Innovation Fund of Hungary.

A Theoretical analysis of PACKS

Comparison with PIFO In the following, first, we show that, under certain conditions, the departure rate for *all* packet ranks in PACKS is the same as for a PIFO queue. Moreover, under these conditions, there is only a small difference between the sets of packets forwarded by PIFO and PACKS.

Let the set of packets forwarded (up to time t) by PIFO and PACKS be PIFO(t) and PACKS(t), respectively. Then, to measure the difference in drops between PACKS and PIFO, we define:

$$\Delta(t) = \frac{|\text{PIFO}(t) \setminus \text{PACKS}(t)| + |\text{PACKS}(t) \setminus \text{PIFO}(t)|}{|\text{PIFO}(t) + \text{PACKS}(t)|}.$$

We have $\Delta(t) \in [0,1]$, where a small value of $\Delta(t)$ indicates a small difference between PACKS and PIFO. In the following, we denote the the maximal and minimal rank probabilities with $\delta_+ := \max_i p(i)$ and $\delta_- := \min_i p(i)$.

Theorem 1 *Assume that the window size $|\mathcal{W}|$, buffer spaces $B_1, \ldots, B_n$, and the number of arrived packets, T, tend to infinity. Furthermore, assume that the maximal and minimal rank probabilities δ_+ and δ_- are bounded between two positive constants. We denote the ratio of the outgoing and incoming packet rate by v, and suppose $v < 1$ (otherwise, both PIFO and PACKS behave like a FIFO). We claim that the difference between the drops of PIFO and PACKS is at most δ_+, i.e., $\Delta(T)_{T\to\infty} \leq \delta_+$. Moreover, for each packet rank, the admission rate of PACKS is identical to the one of PIFO.*

Proof: Since the window size, $|\mathcal{W}|$, is considered very large, the empirical rank distribution in $\mathcal{W}$ tends to the real packet rank distribution. In other words, after waiting a long time, we can know the rank probabilities with high precision, that is $|p(i) - p_{\mathcal{W}}(i)| \xrightarrow[T \geq |\mathcal{W}|]{|\mathcal{W}|\to\infty} 0$. Thus, empirical quantiles, $\mathcal{W}.quantile(i)$, tend to the quantiles according to the real distribution, i.e., $\mathcal{W}.quantile(i) \to \sum_{i=1}^{r} p_i$.

Intuitively, since the buffer space B is very large, the relative queue occupancy b/B changes smoothly over time. More precisely, let $b(t)$ denote the queue occupancy after the arrival of the t^{th} packet (or, for short, 'at time t'), and let $q_n(t) = \frac{1}{1-k}\frac{B-b(t)}{B}$ denote the highest queue bound at time t. At time T, we have queue bound $q_n(T)$ as the admission bound. Let r_T be the maximum rank such that $\mathcal{W}.quantile(r_T) \leq q_n(T)$. This means that the ratio of the admitted packets is $\sum_{i=0}^{r_T} p(i)$ Thus, after the arrival of the next packet, $\mathbb{E}(b(T+1) - b(T)) = \sum_{i=0}^{r_T} p(i) - v$ (recall that, for every incoming packet, the number of drained packets is v on average). This means the following.

1. If $\sum_{i=0}^{r_T} p(i) > v$, the queue occupancy likely increases, ultimately triggering a drop in q_n and in the rate of admitted packets.
2. If $\sum_{i=0}^{r_T} p(i) < v$, the occupancy likely decreases, triggering a rise in q_n and in the rate of admitted packets.
3. Finally, in the event of $\sum_{i=0}^{r_T} p(i) = v$, the queue occupancy makes a motion very similar to the one-dimensional random walk, eventually, after a while likely triggering q_n to either drop or rise for a short time period, before bouncing back to r_T.

We note that, since the buffer spaces are considered to be very large, and the minimum rank probability δ_- is lower bounded by a positive constant, these events happen with probability 1 based on the law of large numbers. Furthermore, in case 3, $q_n(T+t) = r_T$ for any $t \geq 0$ with probability 1.

This also means that, in case 3, $\Delta(T) \xrightarrow{T\to\infty} 0$, since after a while PIFO and PACKS forward the same packets with probability 1. In cases 1 and 2, there is a single rank 'on the border' that either gets forwarded or dropped by chance both in PIFO and PACKS; thus, in these cases, $\Delta(T)_{T\to\infty} \leq \delta_+$. Note that the overall forwarding rate of this rank (and thus of all ranks) is the same for both PIFO and PACKS.

An alternative *intuitive* reasoning supporting the statement that the forwarding rates coincide for PIFO and PACKS is the following. In both cases, there are three classes of ranks: (i) small ranks that are always forwarded; (ii) large ranks that are always rejected; and (iii) a borderline rank r^* that is either forwarded or rejected by chance. Since draining is continuous both for PIFO and PACKS, the leftover bandwidth after the small-ranked packets is given to the borderline rank, r^*, as it is the only choice, again both for PIFO and PACKS. □

Next, we present an asymptotically tight upper bound for the number of inversions that PACKS produces for a packet sequence with respect to PIFO.

Claim 1 *On a sequence of S packets, given a buffer size of B, PACKS cannot cause more than $\Theta(B \cdot S)$ inversions with respect to PIFO.*

Proof: A bad sequence for PACKS: Take a sufficiently large S, with the packet ranks in the sequence being $S, S-1, \ldots, 1$. Then, PACKS will enqueue all the packets to the highest priority queue $Queues(1)$. In this setting, the behavior of PACKS basically transforms to being a FIFO using $Queues(1)$. We assume that after a brief period, when the rate of packet arrivals exceeds the departure rate, $Queues(1)$ gets full. Oversimplified, e.g., while enqueuing the first B_1 packets, none is dequeued. Then, packets are enqueued and dequeued in an alternate fashion. In this simplified example, the PIFO output rank sequence will be (first dequeued on the left): $O_P = [S-B_1, S-B_1-1, \ldots, 1, S-B_1+1, S-B_1+2, \ldots, S]$. In the meantime, the output of PACKS is the same sequence as the input was: $[S, \ldots, 1]$. We can see that PIFO forwarded

a number of $S - B_1$ packets B_1 time slots faster than PACKS. If $S \gg B_1$ and $B_1 \geq c \cdot B$ for some constant $c > 0$, then the number of inversions produced by PACKS compared to the PIFO output is $\Omega(SB)$. We can see that the same asymptotic bound hold in the more realistic scenario when some packets are dequeued in the initial phase when the queue gets full.

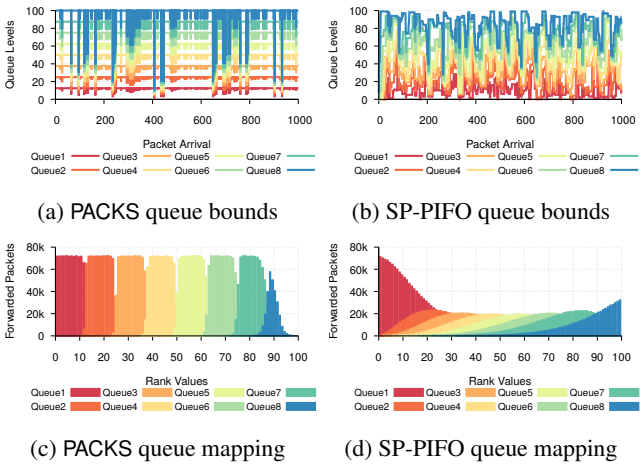
Upper bound if the same packets are admitted as PIFO: obviously, one packet cannot get ahead more packets than the buffer size B, hence in the output sequence of PACKS there could be not more than $O(BS)$ more inversions than in the output of PIFO. □

We note that, after a short initialization period, an ever-decreasing sequence of ranks (like in the proof of Claim 1) makes AIFO and SP-PIFO suffer similarly as PACKS in terms of the number of rank inversions.

Comparison with AIFO The next theorem states that PACKS admits the same packets as AIFO. This notable since AIFO was designed to mimic the admission behavior of PIFO.

Theorem 2 *Given the same window size, buffer size, and burstiness allowance, PACKS drops the same packets as AIFO.*

Proof: Following the notations of the AIFO paper [37], we denote the total buffer size of AIFO by C, and its queue occupancy by c. AIFO admits a packet r if $W.quantile(r) \leq \frac{1}{1-k} \cdot \frac{C-c}{C}$. Assume indirectly that there exists an $t \in \mathbb{N}$, for which the t^{th} arriving packet is enqueued in exactly one of PACKS and AIFO. We choose t as the minimum of such values. We denote the rank of this packet as r_t.



Case 1: PACKS enqueued r_t, while AIFO did not. Here we have the following inequalities explained below, yielding a contradiction:

$$W.quantile(r_t) \overset{(a)}{>} \frac{1}{1-k} \cdot \frac{C-c}{C} \overset{(b)}{=} \frac{1}{1-k} \cdot \frac{\sum_{j=1}^{n} B_j - b_j}{B} \overset{(c)}{\geq}$$

$$\overset{(c)}{\geq} W.quantile(r_t).$$

Here, we get (a) from the fact that AIFO does not enqueue r_x. For (b), we just match the notations of AIFO and PACKS. Finally, (c) holds because PACKS enqueues r_t. Combined, (a), (b), and (c) clearly yield a contradiction.

Case 2: AIFO enqueued r_t, while PACKS did not. Since AIFO enqueued r_t, we have $W.quantile(r_t) \leq \frac{1}{1-k} \cdot \frac{C-c}{C} = \frac{1}{1-k} \cdot \frac{\sum_{j=1}^{n} B_j - b_j}{B}$. Let $i \in \{1, \ldots, n\}$ be the minimal number such that $W.quantile(r_t) \leq \frac{1}{1-k} \cdot \frac{\sum_{j=i}^{n} B_j - b_j}{B}$. We know that such an i exists. Since PACKS did not enqueue r_t at all, we can deduce it did not enqueue r_t in the i^{th} queue either. This is possible only if $b_i = B_i$. If $i \geq 2$, this contradicts the minimality of i, since this means $W.quantile(r_t) \leq \frac{1}{1-k} \cdot \frac{\sum_{j=i-1}^{n} B_j - b_j}{B}$. If $i = 1$, and $n \geq 2$, then PACKS will enqueue r_t to the first queue having free space; note that such a queue exists, since before the arrival of r_t, AIFO had spare buffer space. Finally, The case of $i = 1$, and $n = 1$ also yields contradiction, since then, the AIFO would not have enqueued r_t either. The proof follows. □

(a) PACKS queue bounds (b) SP-PIFO queue bounds

(c) PACKS queue mapping (d) SP-PIFO queue mapping

Figure 15: Queue-bounds evolution and rank mapping for PACKS and SP-PIFO under a uniform distribution (8 queues).

Finally, we argue that, for the highest priority packets, PACKS causes no more rank inversions than AIFO.

Theorem 3 *For any packet sequence, given the same window size, total buffer size, and burstiness allowance, PACKS causes no more priority inversions than AIFO for the highest priority packets.*

Proof: The theorem follows from two statements: (a) AIFO and PACKS admit the same set of packets (under the same configuration, see Theorem. 2), and (b) The quantile estimate of the highest priority packet is always the smallest (equalling 0). Let t denote the index of the packet in the input sequence. Let I_{PACKS} and I_{AIFO} denote the number of higher-ranked packets that t follows in the output sequence of PACKS and AIFO, respectively. From (b), we can show that for a given packet with the highest priority and index t, there is no packet that arrives after t (having an index greater than t), and is going to be dequeued before packet t. Rephrased, this means that $I_{\text{PACKS}} \leq I_{AIFO}$. This is true for each packet of highest priority. Thus, PACKS always has at most the same total number of priority inversions as AIFO for the highest priority packets. □

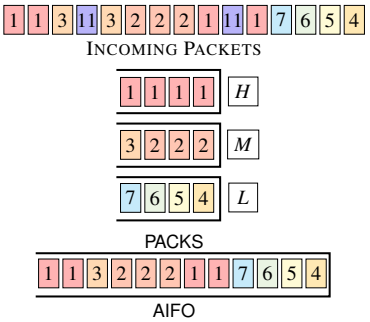


Figure 16: Adversarial input that maximizes the gap between weighted priority inversion of AIFO compared to PACKS. AIFO can delay the highest priority packet by more than 60% of the queue length. (Starting window = [1, 1, 1, 1]).

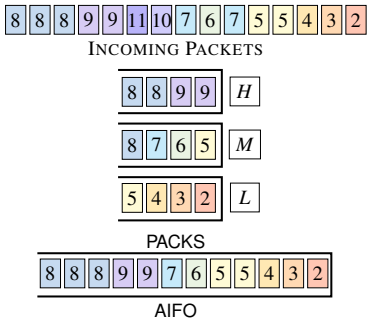

Figure 17: Adversarial input that maximizes the gap between weighted priority inversion of PACKS compared AIFO. (Starting window = [1, 1, 1, 1]).

B PACKS's analysis with MetaOpt

MetaOpt [23, 24] is a tool to compare the performance of two competing heuristics or a heuristic and an optimal solution. It identifies adversarial inputs that cause the maximum difference between the performance of the two algorithms.

We model PACKS in MetaOpt and compare it to AIFO [37], SP-PIFO [6], and PIFO [32]. Our goal is to understand *when and under what inputs* PACKS performs substantially better or worse than them. We focus on two performance metrics. The first metric is the number of packets dropped weighted by the packet's priority (where the priority is defined as the difference between the maximum rank in the distribution and the packet rank: max. rank - packet rank). The second metric is the number of priority inversions weighted by the packet's priority. These metrics help us identify the adversarial inputs that cause the heuristics to disrupt the performance of lower-rank packets (which are most important in the PIFO context).

Experiment setup We let packets take ranks between 1 and 11. We consider *all* the 15-packet traces possible with these ranks. We set the buffer size to 12 packets, and assume it empty at start. We configure PACKS and AIFO with a window size $|\mathcal{W}| = 4$ and a burstiness allowance $k = 0$. We configure SP-PIFO and PACKS with 3 priority queues of 4 packets each.

B.1 Comparison with AIFO

Packet drops We find that PACKS and AIFO always admit the same set of packets when they use the same configuration. This is expected, as we prove in Theorem. 2.

Rank inversions Fig. 16 and Fig. 17 illustrate the adversarial inputs that MetaOpt discovered for AIFO with respect to PACKS and vice versa. We find that:

> AIFO can delay the highest priority packets by more than 60% of the total queue size compared to PACKS.

AIFO only has an admission policy and suffers when the input sequence is not sorted. In Fig. 16, we show an input sequence where AIFO causes 24 priority inversions for lowest-rank packets, whereas PACKS is able to fully sort the packets.

> Adversarial inputs to AIFO consist of lower ranked packets compared to the adversarial inputs to PACKS.

PACKS underperforms when a distribution shift happens, and packets in the window are not a good estimate of the newer incoming packets. The worst case of PACKS compared to AIFO is on a packet sequence that is approximately sorted (Fig. 17). Due to the distribution shift, PACKS ends up mapping higher-priority packets to lower-priority queues and lower-priority packets to higher-priority queues.

Note that, in practice, the impact of scheduling such packet sequence with PACKS would not be significantly detrimental. Since queues are empty at start, PACKS would start sending the lower-rank packets while higher rank packets arrive.

This adversarial sequence (Fig. 17) consists of packets with higher ranks than the adversarial input to AIFO (Fig. 16), which have lower importance. This indicates that AIFO can cause higher average delays for important sensitive packets compared to PACKS. Our results show that PACKS never causes more priority inversion for the lowest ranked packets than AIFO (as we also prove theoretically in Theorem. 3).

B.2 Comparison with SP-PIFO

Packet drops Fig. 18 and Fig. 19 show the adversarial inputs that MetaOpt discovered for SP-PIFO with respect to PACKS and vice versa. We find that:

> SP-PIFO can drop more than 60% of high-priority packets while leaving 66% of the total queue size empty.

SP-PIFO lacks an admission policy and underperforms when we have a stream of packets with the highest priority (all with rank 1). In this case, SP-PIFO maps all the packets to

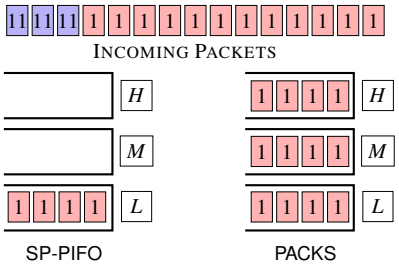

Figure 18: Adversarial input that maximizes the gap between weighted packet drop of SP-PIFO compared to PACKS. (Starting window = [1, 1, 1, 1]).

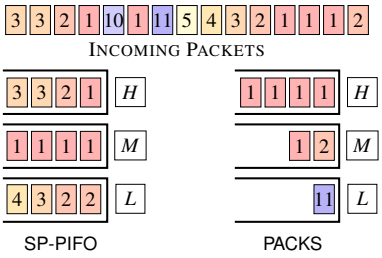

Figure 19: Adversarial input that maximizes the gap between weighted packet drop of PACKS compared to SP-PIFO. (Starting window = [1, 2, 1, 1]).

its lowest-priority queue and ends up dropping many of them while the other queues are empty. PACKS, however, fills the queues one by one from highest to lowest priority, efficiently using the buffer resources and preventing packet drops.

> PACKS drops at most 3 high-priority packets whereas SP-PIFO can drop up to 8 high-priority packets (2.33× more).

PACKS underperforms when the input sequence meets two conditions: (i) the rank of most of the packets increases, and (ii) a few of the packets in the middle of the trace have a higher rank than the ones received before or after them. Condition (i) describes an adversarial case for both SP-PIFO and PACKS, but condition (ii) helps SP-PIFO mitigate this by moving to a higher priority queue. Even with this, PACKS drops at most 3 high-priority packets more than SP-PIFO (2.33× less than the packet drop of SP-PIFO on its adversarial input).

Rank inversions In order to capture only the impact of rank inversions, we set the queue sizes long enough so that packet drops do not occur. Fig. 20 and Fig. 21 show the adversarial inputs that MetaOpt discovered. We see that:

> The adversarial input to PACKS is only slightly worse than the adversarial input to SP-PIFO.

The worst-case input for SP-PIFO with respect to PACKS causes 20 priority inversions for the highest priority packet, while the worst-case input for PACKS only causes 24 of them.

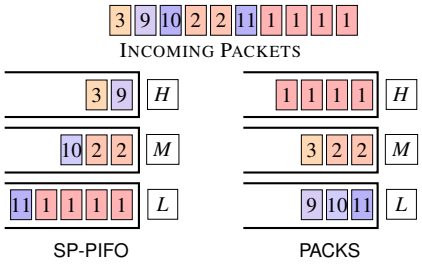

Figure 20: Adversarial input that maximizes the gap between weighted priority inversion of SP-PIFO compared to PACKS. (Starting window = [1, 1, 1, 1]).

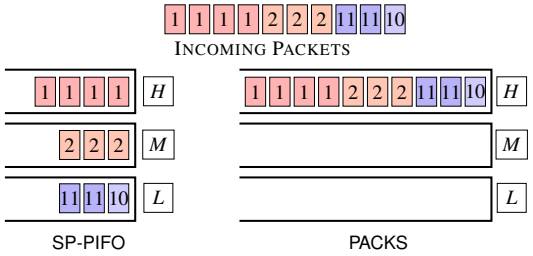

Figure 21: Adversarial input that maximizes the gap between weighted priority inversion of PACKS compared to SP-PIFO. (Starting window = [1, 1, 11, 11]).

SP-PIFO performs poorly when the rank of most of the packets is sorted, but there are a few packets in between with higher ranks than the ones received before or after them. These higher ranks cause SP-PIFO to push the rest of packets to higher-priority queues, leading to priority inversions. This pattern is the same as the one that causes PACKS to drop numerous packets compared to SP-PIFO.

PACKS underperforms when we can split the packets into multiple batches that meet two conditions: (i) the packets in each batch are in the non-decreasing order of their ranks, and (ii) all the packets in a given batch have higher rank than the packets in a subsequent batch. SP-PIFO would put each batch in one of its queues, achieving perfect sorting, whereas PACKS does not perform any sorting across batches of packets.

B.3 Comparison with PIFO

Fig. 23 and Fig. 22 show the adversarial inputs that MetaOpt discovered. We see that:

> The worst-case input to PACKS (with respect to PIFO) is the same as the worst-case input to AIFO (with respect to PIFO).

Packet drops The worst-case input is an increasing sequence of packet ranks. PACKS (similar to AIFO) computes the quantile using a sliding window. In this sequence, the quantile estimate of every packet is large, so PACKS (similar to AIFO)

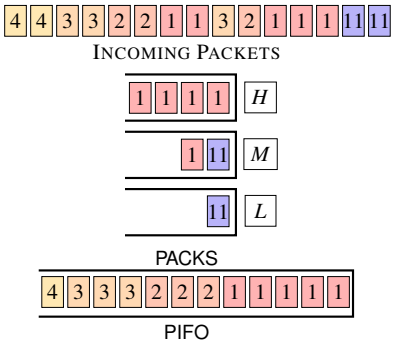

Figure 22: Adversarial input that maximizes the gap between weighted packet drop of PACKS compared to PIFO. (Starting window = [1, 1, 1, 1]).

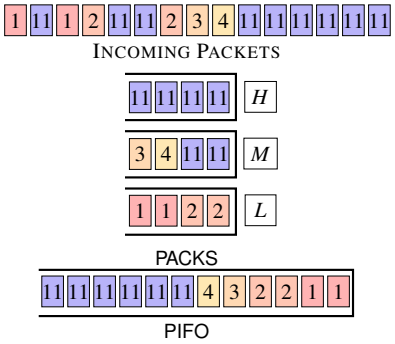

Figure 23: Adversarial input that maximizes the gap between weighted priority inversion of PACKS compared to PIFO. (Starting window = [1, 11, 1, 11]).

will drop the packets. The fact that both worst-case inputs to PACKS and AIFO, with respect to PIFO are the same, is expected, since PACKS and AIFO drop the same packets, as proved in Theorem. 2.

Rank inversions The worst-case input is a decreasing sequence of packet ranks. In that case, PACKS does not do any sorting and performs the same as AIFO (putting every packet in the highest priority queue with available space). This is also expected (cf. Claim 1 and the quick insight after its proof).

C PACKS's resource usage

We describe the resource requirements of our implementation of PACKS on Intel Tofino 2 [1] in Table. 1.

Resource Type	Usage (Average per stage)
Exact Match Crossbar	3.4 %
Gateway	3.4 %
Hash Bit	1.3 %
Hash Dist. Unit	4.2 %
Logical Table ID	10.9 %
SRAM	2.4 %
TCAM	0 %
Stateful ALU	23.8 %

Table 1: Resource requirements of PACKS on Intel Tofino 2.

When P4 Meets Run-to-completion Architecture

Abstract

P4 programmable data planes have significantly accelerated the evolution of various network technologies. Although the P4 language has gained wide acceptance, its further development encounters two obstacles: limited programmability and the cessation of the next-generation Tofino chip. As a hardware manufacturer, we try to address the above dilemmas by opening the P4 programmability of our run-to-completion (RTC) chips. At present, there is no publicly available experience in this field. We introduce P4RTC, a comprehensive consolidation of our experiences applying the P4 language to RTC architecture. P4RTC introduces a new P4 architecture model and a set of beneficial extern constructs to fully leverage the RTC architecture's programmability. Besides, we share the insights we have gained from designing and implementing compilers. We also provide a performance model to facilitate profiling P4RTC's performance on user-customized P4 code. We prototype P4RTC on an RTC chip with 1.2 Tbps bandwidth. Case-oriented evaluation demonstrates that P4RTC can enhance P4 programmability and reduce the burdens of RTC development. The performance model can provide substantial insights into optimizing P4RTC programs.

1 Introduction

P4 programmable data planes have significantly accelerated the evolution of various network technologies, such as in-network computing [1, 2], congestion control [3, 4], load balancing [5], and network measurement [6–8]. As a domain-specific language (DSL) for data-plane programming, P4 has earned widespread recognition in academia and industry for its excellent abstraction. It makes network packet processing more accessible and easier to program. Empirical evidence demonstrates that P4 has become the de facto standard for data plane programmability [9, 10].

Although the P4 language has gained wide acceptance, its further development currently encounters two obstacles. Firstly, its programmability is limited, making implementing many practical designs and algorithms challenging. Currently, P4 is inherently tied to pipeline architectures (*e.g.*, RMT [11]), in which hardware constraints make many algorithms and designs have to make compromises on accuracy or performance [6, 7, 12, 13]. For instance, updating the minimum counter among multiple counters cannot be implemented directly in pipeline architectures since the stage where the minimum counter is located cannot be reaccessed unless recirculation. Secondly, Intel has announced that they will stop developing the next generation of the Tofino series [14], which currently stands as one of the most popular P4 programmable ASICs. To conclude, the P4 community urgently needs a successor hardware platform with Tbps-level throughput and more flexible programmability.

As a hardware manufacturer, we try to overcome the above dilemmas by opening the P4 programmability of our run-to-completion (RTC) chips. RTC is another packet processing architecture significantly different from the pipeline architecture, allowing different packets to have independent processing times. Packets can achieve line-rate forwarding when simple processing is sufficient, while others can be processed below line rate to enable more complex logic. Adapting the P4 language to the RTC architecture carries significant implications for the evolution of the P4 programmable data plane. On the one hand, P4 developers can use RTC devices to implement the functionalities that are difficult to implement in the pipeline architecture. In particular, RTC devices can perform any number of memory read/write operations. Thus, the 'updating the minimum counter' function can easily be implemented. On the other hand, P4 can facilitate the rapid development of the RTC-based data plane. P4 can effectively abstract away the underlying hardware details. Moreover, the recent advancements in the P4 programmable data plane can be easily applied to RTC devices with minimal effort, such as in-network computing [1, 2, 15–17], verification [18–21], packet scheduling [22–24], and formal foundations [25].

At present, there is no publicly available experience in adapting P4 to high-speed RTC devices. Existing extensions to the P4 language [26, 27] focus on reducing the complexity of developing functions and improving resource utilization. They cannot overcome the programmability limitations

of P4 inherent in pipeline architectures. Some efforts (*e.g.*, P4TC [28], P4-DPDK [29], T4P4S [30]) have successfully adapted P4 for CPU platforms. However, they haven't yet extended or optimized P4 for specialized RTC packet processors capable of Tbps throughput. Existing high-level programming languages for high-speed RTC devices are predominantly C-like languages [31]. Their API interfaces are specialized around their hardware and closed to the public community, making it challenging for researchers to understand the underlying architecture and detailed usage.

We propose P4RTC, a comprehensive summary of our experience in applying the P4 language to the RTC architecture. Our contributions can be summarized as follows:

Firstly, we present a new $P4_{16}$ architecture model, which bridges the P4 language and RTC architecture, providing a unified RTC programming abstraction. Based on the architectural model, we introduce a series of novel extern constructs to exploit the flexibility of RTC devices. We show the similarities and differences between P4RTC programming and traditional P4 programming and show how P4RTC can be used to develop functions that are challenging to realize in the pipeline architecture. We also discuss how parallel safety issues are appropriately handled in the P4 code.

Secondly, we share our insights while designing compilers, including table deployments and microcode generation. When deploying P4 tables, we must balance the read/write load among memory banks to improve performance. We develop an integer programming (ILP) model and leverage Profile-Guided Optimization (PGO) [32] strategies to improve the performance of the memory system. When generating microcode, we first transform P4 intermediate representation (IR) to microcode IR rather than directly to microcode instructions. This approach greatly enhances the correctness and efficiency of the generated microcode and makes it easier for the compiler to adapt to different microcode versions.

Thirdly, we provide a performance model to facilitate profiling the performance of P4RTC programs. Due to the resource sharing of the RTC architecture, bottlenecks can occur when many packets simultaneously access the same channel or hardware components. P4 programs no longer have deterministic throughput and delay as they are in the pipeline architecture. The performance model can provide various performance metrics (*e.g.*, pps, latency) to help users identify the bottlenecks of their P4 code under specific traffic patterns.

We prototype P4RTC in Huawei NetEngine 8000 F1A-C routers with 1.2 Tbps bandwidth. The adaptation to higher-throughput RTC chips is ongoing. We conduct several practical use cases. The first case is accurate per-flow monitoring. With the help of P4RTC, the chip can monitor up to 50M concurrent flows at near line rate, and reduce the bandwidth overhead by 86% to 90% compared with an existing Tofino-based solution [33]. The second case demonstrates that P4RTC reduces users' burdens on developing RTC devices. In five projects we examined, P4RTC can reduce lines of code (LOC) by 4.6x to 7.7x compared to microcode programming. This efficiency is comparable to another specialized high-level language developed for the chip. Additionally, using P4RTC, researchers can reproduce the functionalities of existing advances by modifying only 4.3% to 13.0% of the code. In the last case, we show how the performance model guides us in optimizing P4 programs.

This work does not raise any ethical issues.

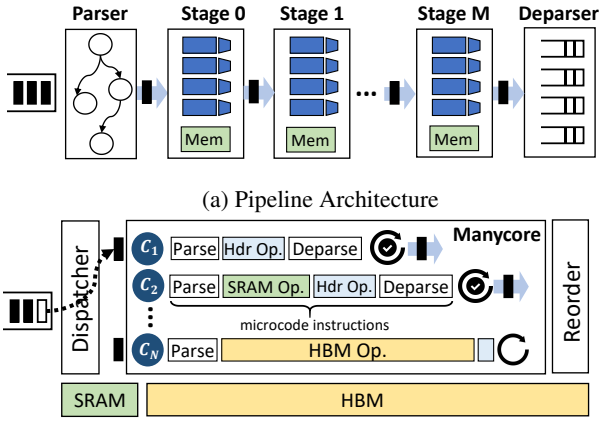

Figure 1: Difference between pipeline and RTC architectures.

2 Background and Motivation

2.1 Architecture Flavors of Dataplane

Packet processing is typically divided into a data plane and a control plane. The data plane, also known as the fast path, is responsible for the processing and forwarding of packets, whereas the control plane handles management logic (*e.g.*, adding routing entries). Developers utilize various hardware platforms, such as CPUs, FPGAs, and ASICs, to implement the data plane for fast packet processing. However, despite significant differences among the hardware platforms, the architecture for the data plane can be fundamentally categorized into pipeline and run-to-completion (RTC) [34].

As shown in Figure 1a, packets orderly pass through several stages in the pipeline architecture. A packet executes part of the processing logic at each stage and then moves to the next stage. Multiple packets can be processed simultaneously in different stages to achieve the 'pipelined' processing. This compact processing is highly efficient when handling high-speed packet arrivals [34]. However, it also introduces some limitations. Firstly, the physical pipeline length is limited in ASICs, which restricts its ability to handle complex logic. Secondly, to ensure the pipeline's efficiency and maximize throughput, resources such as memory are distributed in each stage and cannot be shared between different stages [12].

In the RTC architecture, many cores can independently parse, process, and forward packets. When a packet arrives, a dispatcher assigns the packet to an idle core, and then the

Table 1: Comparison of pipeline and RTC ASICs

Feature	Pipeline ASIC	RTC ASIC
Throughput	(Serial) High	(Parallel) Moderate
Latency	O(100) ns	O(100) ns - ?
Memory Capacity	10's MB	10's - 1000's MB
Logic Length	Limited	Unlimited

packet completes the entire processing on that core. This design allows different packets to have independent processing time, which overcomes the limitations introduced by the pipeline architecture. In particular, packets can perform unlimited read and write operations to a shared memory to implement complex algorithms at the expense of increasing processing time. As for the forwarding performance, RTC devices adopt a manycore architecture to improve the overall throughput to the Tbps level [31]. However, this can lead to memory conflicts and packet disorders.

Table 1 provides an overview of the distinct features of the two architectures. The pipeline architecture typically achieves high throughput under serial processing, while the RTC architecture needs to increase the number of forwarding cores (*i.e.*, parallelism) to improve throughput. Regarding latency, the pipeline architecture generally exhibits deterministic low latency in forwarding, whereas RTC devices' latency depends on the specific processing logic of the packets. As for memory capacity, RTC supports large-capacity memory such as high-bandwidth memory (HBM). Finally, both architectures have the potential for programmability.

2.2 Dataplane Programmability and P4

Reconfigurable Match-action Table (RMT [11]) is a famous programmable switch architecture. It is a typical pipeline architecture consisting of several reconfigurable match-action units (MAU). Developers program the data-plane logic by reconfiguring the structure of tables within the MAUs, including the match-phase key and the action-phase instructions. However, as mentioned earlier, its programmability is constrained, including the limited number of MAU stages, limited capacity and isolated memory. As another crucial packet processing architecture, some RTC devices [31] are also programmable by reloading microcode into chips. Regarding programmability, RTC devices offer more flexibility because they remove the constraints imposed by physical stages (*i.e.*, fixed lengths and isolated memory). This significantly bridges the gap left by the pipeline architecture.

For chip users, configuring the pipeline hardware or developing microcode can be laborious. P4 is a high-level language for data-plane programming, which was initially proposed in 2014 [35]. The P4 data plane consists of a series of programmable blocks, mainly including `parser`, `ingress`, `egress`, and `deparser`. These programmable blocks compose a logical pipeline named a top-level `package` or pipeline package. As an instance, the `main` object in Figure 2 is a

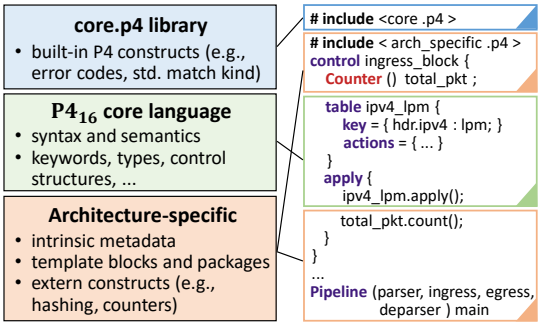

Figure 2: P4$_{16}$ language structures

pipeline package. Developers can customize programmable blocks within the pipeline package. P4 enables developers to implement diverse packet processing logic using only general-purpose operations and table look-ups. More importantly, P4 provides a general packet processing abstraction to shield developers from the underlying hardware details.

However, the original P4$_{14}$ language is complex, mainly attributed to the integration of architecture-specific features into the language, making it hard to adapt to other architectural models [36]. P4$_{16}$, as an improved version of P4$_{14}$, separates the architecture-specific features from the P4 core language. As shown in Figure 2, the basic syntax, semantics, and keywords (*e.g.*, `table`, `apply`) are defined in P4$_{16}$ core language. In contrast, the programmable blocks, extern constructs (*e.g.*, `Counter`), and pipeline packages are architecture-specific. P4$_{16}$ makes the P4 language relatively stable, leaving the architecture-specific parts to be implemented by target manufacturers. However, all existing P4 architecture models are based on the pipeline architecture, such as the PISA [37] used in P4$_{14}$, Portable Switch Architecture (PSA) [36], and Tofino native architecture (TNA) [38] introduced after P4$_{16}$. The adaptation of P4 to the RTC architecture remains unexplored, leaving a gap in the current research community. As a result, when researchers consider utilizing the P4 programmable data plane for designing new network features, they commonly regard the pipeline architecture as their primary target.

Providing a publicly available RTC programming model based on P4 is highly essential. Firstly, introducing the RTC architecture will enhance the programmability of the P4 programmable data plane. As discussed earlier, the pipeline architecture sacrifices programmability to enhance overall forwarding efficiency, which forces many algorithm implementations to make compromises. For instance, some systems execute their algorithm through recirculations, albeit at the cost of reduced bandwidth [4, 39]. Others [6, 40] opt to compromise on the design of their algorithms, implementing an approximate version instead, which inevitably results in a decrease in the algorithm's accuracy. Fortunately, the RTC architecture can make up this aspect, thanks to their unlimited logical length and large-capacity shared memory. With this

flexibility, P4 programmers can implement network features previously unachievable in the pipeline architecture. On the other hand, P4 can facilitate the rapid development of the RTC-based data plane. P4 abstracts away the tedious hardware details for users, while ongoing support for P4 allows existing advancements from the P4 community to remain valuable within the RTC architecture.

3 P4RTC Overview

As shown in Figure 3, the workflow of P4RTC consists of four stages: P4 programs, compilation, firmware, and targets.

Firstly, users define their customized data plane and control plane programs. In the compilation stage, a P4 compiler transforms the P4 code into microcode instructions, and a microcode compiler further generates a binary file according to it. The deployment of P4 tables is also completed at this stage. The binary file and configuration files generated during the compilation stage are collectively called the chip's firmware. Finally, the firmware is loaded onto the target hardware.

Given that both P4 and our RTC chip have reached mature stages individually, we strive to maximize component reuse during the implementation of P4RTC. As shown in Figure 3, the grey components are reused components. Specifically, P4 has public specifications and open-source compilers [41]. The chip used is not a brand-new design but was chosen from our existing RTC chips, previously used for fixed-function routers. Therefore, some legacy components exist, such as the microcode compiler and software development kit (SDK). However, we still encounter the following three challenges:

How to extend P4 to fully leverage the flexibility of RTC without altering P4$_{16}$ core language? Since the P4 language was initially designed around the pipeline architecture, directly referencing the existing architecture models cannot fully utilize the flexible programmability of RTC devices. To this end, we propose a new P4 architecture model for the RTC architecture. Under this architecture model, we provide a set of novel extern constructs (in `RTC.p4`) rather than modify the syntax and semantics of P4. We will introduce the new P4 architecture model and extern constructs in §4.

How does the compiler map the P4 language to the RTC architecture? Due to architectural differences in the hardware, the compiler needs to be designed explicitly for the RTC architecture, especially in table deployments and microcode generation. We implement a new backend for the open-source P4C compiler to generate RTC-specific microcode and table structures. We will introduce the novel issues in the table deployments of the RTC architecture and the experience in the microcode generation process in §5.

How do we verify the performance of the chip after loading customized P4 code? Unlike deterministic performance in the pipeline architecture, the flexibility of the RTC architecture makes it easy to introduce poor performance code. Conducting real machine experiments takes a lot of time and effort. It involves setting up connections, generating traffic, and collecting and analyzing results. More importantly, it is hard to accurately capture the performance details of the chip's internal components. To this end, we introduce a performance model to help users verify their P4 code in §6.

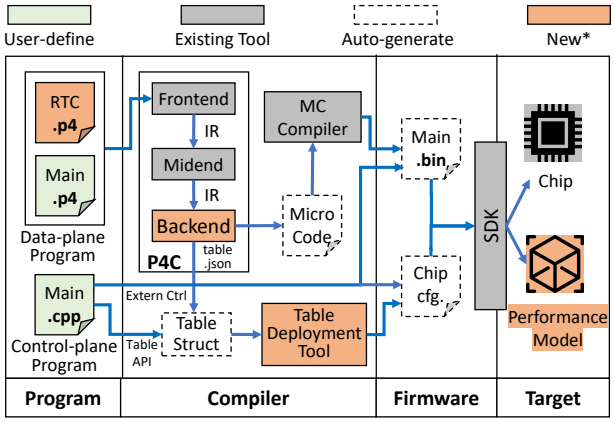

Figure 3: P4RTC system overview. The newly introduced components to address the challenges are colored orange.

4 P4RTC Programming

4.1 New P4 Architecture Model

Figure 4 illustrates the new P4 architecture model introduced by P4RTC. Considering a regular packet forwarding path, a packet enters the chip through the RX MAC and is dispatched to an idle core, where each core can be understood as a thread. Once a packet is handled by a core, all operational logic is executed on that core, where P4 programs define how to process and forward the packet. After processing, the packet is sent to a reorder engine for flow-level sequencing. Then, the packet is sent to the output queue of the destination port through the traffic manager (TM). After leaving the TM, the packet bypasses egress processing by default and is directly sent to TX MAC. If egress processing is necessary, it will again be assigned to a core. In general, the processing logic of the cores is the programmable part of the RTC architecture, while the other parts are non-programmable.

When programming RTC devices with the P4 language, the programmable blocks that users must write reserve those in the pipeline architecture, including the parser, ingress/egress control flow, and deparser. In other words, in the perspective of packets, packets are still processed by a logical pipeline composed of the traditional P4 programmable blocks. At the same time, the user's programming habits are also preserved. However, the concept of 'pipeline' in P4RTC has the following three main differences.

Many-core programming model. Packets are no longer serially processed by a single pipeline of physical stages. In contrast, there are many cores in RTC devices, and each packet is processed by an independent 'logical pipeline' operating on a dedicated core. Users define a pipeline package consisting of P4 programmable blocks, and then the cores run this package to process the packets in parallel. As shown

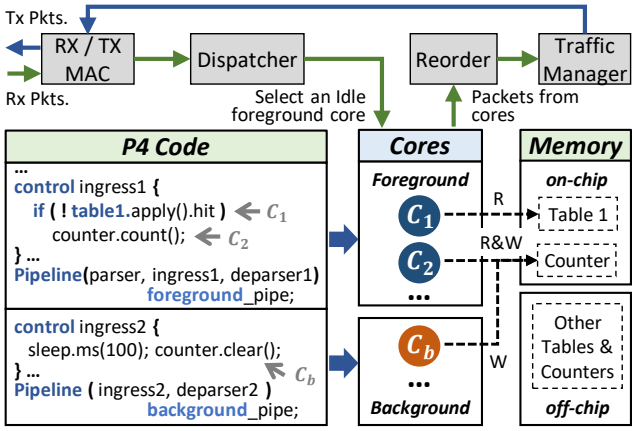

Figure 4: P4 programming abstraction for RTC architectures

in Figure 4, both the core C_1 and the core C_2 are running the *foreground_pipe* package defined in the P4 code. While C_1 is accessing `table 1`, C_2 updates a counter.

Unlimited logical length. In the RTC architecture, packet processing is performed by a dedicated core executing microcode instructions. The logical length is no longer constrained by the number of physical stages, as is the case in the pipeline architecture. This feature dramatically enhances chip programmability, but at the same time, it can easily lead to inefficient code, which degrades overall throughput.

Shared memory subsystem. Packets are no longer sequentially processed by multiple physical stages. Thus there is no need to access separate memory on these stages. Multiple cores can simultaneously access a shared memory system through on/off-chip memory controllers and crossbars. Given the shared nature of the memory, any memory location (*e.g.*, match-action tables, counters, and registers) can be accessed multiple times during the packet processing. As an instance, both C_1 and C_2 can access the counter extern in Figure 4.

4.2 Extensions for Pipeline Package

In the RTC architecture, the running instructions of each core can be defined separately. To provide a simplified view of P4 programming, the pipeline packages are grouped into two roles: foreground pipeline and background pipeline. By default, most cores run the foreground pipeline package, responsible for parsing, processing, and forwarding received packets. The other cores step back into the background. As shown in Figure 4, foreground cores C_1 and C_2 are running the P4 code in the 'foregound_pipe'. C_b is running the 'backgound_pipe' independently as a background core, which resets the counter every 100 ms.

A core running the background pipeline is stuck in an infinite loop of ingress $\rightarrow$ deparser $\rightarrow$ ingress $\rightarrow \cdots$. The background pipeline has no parser block since it does not require packet reception. However, it does not mean that background pipelines cannot process packets. Like standard P4 programming, users can use a `setValid()` method to enable protocol headers within the ingress block. When the control flow reaches the deparser, protocol headers marked as valid will be emitted. Therefore, the background pipeline can also generate customized packets.

To further exploit the programmability of the background pipeline, we introduce the following P4 extern constructs:

```
extern Foreach{
  void apply(in bit<32> start,in bit<32> end);
}
extern void break();
extern void continue();
extern Sleep{
  void us(in bit<32> value);
  void ms(in bit<32> value);
}
```

The `Foreach()` extern allows iteratively access to table entries by binding with a table. It can also be bound to a virtual table to implement a generic range for loop. The reason why we do not introduce a 'for loop' syntax like C/C++ is to retain the P4 core language, which is a crucial design philosophy of $P4_{16}$ for its target-independent feature. The `Sleep()` extern controls the activation frequency of background cores. The following example shows how to use the *Foreach* extern:

```
control back_ingress{
  action __for_act0(KEY_T k, DATA_T data)
  { /* loop body */ }
  @tbl("t")
  @methods(act0="__for_act0")
  Foreach() foreach_t;
  Sleep() sleep;
  apply{
    sleep.ms(10);
    /* setValid() related headers. */
    foreach_t.apply();
  }
}
control back_deparser {
  apply { pkt.emit(hdr); }
}
Pipeline(back_ingress, back_deparser) back_pipe;
```

In the above code, the `Foreach` extern binds a table called `t` and a loop body (*i.e.*, `__for_act0`). The core running the `back_pipe` will traverse each row of `t`, read the match key and action data of that row, and pass them to the loop body to perform the user-customized operations. Once the table traversal is complete, the control flow is transferred from `back_ingress` to `back_deparser`, and the `back_deparser` block sends a packet if any headers are valid. The `Sleep` extern can control the loop frequency.

It seems that the background pipeline is similar to traditional control plane threads. The main differences are that (i) it runs directly on the data plane and has a shorter control loop, and (ii) it has better performance scalability.

Inter-pipeline communication. To better assist in functional decoupling between different pipeline roles, we propose a `Queue` extern construct.

```
extern Queue<T> {
    Queue(bit <32> depth);
    bool push(in T value);
    bool pop(out T value);
    bool popWait(out T value);
}
```

The pipelines running on different cores can implement message push, pop, and a blocking pop through a parallel-safe queue extern. For example, the `Queue` extern can be used to implement messages passing between the foreground pipeline and the background pipeline. In the measurement project outlined in §7.1, we implement a background pipeline to periodically age out expired flow entries (*i.e.*, those that need to be reported to an analyzer). Nevertheless, employing a linear scan of the flow table proves inefficient, as the flow entries accessed by the background pipeline frequently do not meet the aging criteria. We adopt a smart aging technology to improve aging performance. When a foreground pipeline receives the FIN or RST flagged packet, it pushes the corresponding flow information into a `Queue` extern. The background pipeline just needs to pop flow IDs from the queue and directly complete the aging of the flows, which can significantly improve the aging performance. The corresponding P4RTC pseudocode can be found in Appendix A.

4.3 Extensions for Match-action Table

In P4RTC, we expand the types of match-action tables. According to the deployment location, tables can be divided into on-chip tables and off-chip tables. The on-chip tables have lower accessing latency, but the capacity is only a few tens of MB. In contrast, off-chip tables have GB-level capacity, but the access latency is an order of magnitude higher.

According to the memory layout, tables can be classified into content addressing tables (CAT) and linear addressing tables (LAT). The CAT tables perform exact matching and longest prefix matching (LPM) by storing keys in SRAM or specialized memories like content-addressable memory (CAM). In comparison, the LAT tables directly utilize the key as the memory index and then perform the action phase based on the action ID and action data stored in the memory address. LAT tables are more efficient than CAT tables, while it is limited by the capacity of the address space. They are commonly used for short-bit-width matching operations, such as Port-VLAN mapping.

The default definition of the P4 table is an on-chip CAT table. Users can use annotations to change the attributes of the table, including deploy locations, table layouts, and bank group size in the following format:

```
@linear
@offchip(x4)
table offchip_linear { ... }
```

The first annotation, `@linear`, indicates that a LAT table is required instead of CAT table. Another annotation, `@offchip`, signifies that the table needs to be deployed in off-chip memory to accommodate a larger table size. Additionally, users can specify the size of the bank group in the format `@offchip(x<group_size>)`, which improves memory read performance for off-chip tables.

In the RTC architecture, packets can operate table entries directly in the data plane, both for CAT tables and LAT tables. Compared with existing pipeline architecture that can only add or delete CAT entries from the control plane, the in-data-plane table operations have a shorter control loop, thus reducing the delay from milliseconds to hundreds of nanoseconds. To utilize this feature, we introduce a new P4 extern construct:

```
extern TableOperation {
  TableOperation();
  bool entryDel<KEY_T>(in KEY_T k);
  bool entryAdd<KEY_T, DATA_T>(in KEY_T k,
                               in bit<8> act,
                               in DATA_T data);
  bool entryGet<KEY_T, DATA_T>(in KEY_T k,
                               out bit<8> act,
                               out DATA_T data);
}
```

Table operations enable much of the logic that needs to be initially executed on the control plane to be efficiently offloaded to the data plane. A typical use case is to use the on-chip memory as a cache for off-chip big tables. We can dynamically add frequently hit entries to the on-chip memory. The code below shows an implementation example:

```
control foreground_ingress{
  table onchip_cache { ... }
  @offchip
  table offchip_tbl  { ... }
  apply{ /* Only apply the off-chip table
    when a cache miss occurs. */
    if(onchip_cache.apply().hit == false)
      offchip_tbl.apply();
  }
}
control background_ingress{
  @tbl(onchip_cache)
  TableOperation() cache_op;
  @tbl(offchip_tbl)
  TableOperation() tbl_op;
  apply{
    /* Find a heavy key, denoted as 'hk' */
    bool re = cache_op.entryAdd(hk, act, data);
    if(re == false)
      { /* The cache is full. Make eviction. */}
  }
}
```

In the above code, we implemented a simple caching strategy for an off-chip large table named `offchip_tbl`. The `foreground_ingress` only accesses `offchip_tbl` in case a cache miss happens. The `background_ingress`, which is packaged in a background pipeline, periodically loads hot entries into the `onchip_cache` through the `entryAdd()` table operation. Note that we omit the selection of the heavy key and the cache eviction strategy in the code. Through the `Foreach` extern, users can customize their heavy-key selection and idle-key eviction strategies.

Furthermore, we introduce a `lastRowIndex()` extern method. If the `lastRowIndex()` method is called after applying table or executing table operations, it returns the row id of the operated table entry. An important use of `lastRowIndex()` is attaching counters and registers with match-action tables, thereby constructing some advanced data structures. For example, suppose we have an exact matching table with size n and a counter array with size $2n$. With the `lastRowIndex()` extern, the counters can serve as a one-to-two supplement for the exact matching table, which

can implement packet&byte counters for each table entry.

```
control foreground_ingress{
  table tbl {... size=64}
  Counter() cnt(128);
  apply{
    table_1.apply();
    bit<32> row_index  = lastRowIndex();
    bit<32> pkt_index  = row_index << 2;
    bit<32> byte_index = (row_index << 2) + 1;
    cnt.count(pkt_index, 1);
    cnt.count(byte_index, getPktLength());
  }
}
```

4.4 Parallel Safety

A non-negligible concern is the handling of parallel safety of the RTC architecture. Most data-plane operations are stateless operations, which will have no parallel contention issues. However, some stateful operations involve modifying the device state. If not handled, it will lead to unpredictable errors.

The first type of stateful object is the `Counter` extern. The counter operations including `count`, `get`, and `set`, are implemented as atomic operations in hardware. The second type of stateful operation is the `TableOperation` extern that makes addition and deletion of flow tables. These operations involve inserting items into a hashing structure, such as cuckoo hashing [42] or d-left hashing [43], which incurs parallel issues when handling hash conflicts. Fortunately, users can regard the entire operation as an atomic transaction because efficient hardware locks guarantee parallel security.

However, when the above operations are combined to implement read-modify-write operations, it can lead to race conditions if not correctly synchronized. The key to ensuring parallel safety in read-modify-write operations is to prevent all other cores from initiating the same operation until the first core has completed its task. In P4RTC, we provide a `Lock` extern construct to solve this problem.

```
extern Lock {
  Lock(bit<32> size);
  bool acquire(in bit<32> idx, in bool blocking);
  bool release(in bit<32> idx);
}
```

The underlying of the `Lock` extern is the test-and-swap (TAS) atomic instruction. A core obtains a lock that can either be blocking or non-blocking. The distinction is whether the core chooses to spin and wait if it cannot acquire the lock immediately. A `Lock` extern can contain multiple lock instances, and users can implement row-level locking by utilizing the `lastRowIndex()` extern method mentioned before.

5 P4RTC Compilation

This section will discuss our experience in developing the P4RTC compiler, focusing on two main aspects: table deployments and generating microcode instructions.

5.1 Table Deployments

Table deployment entails strategically allocating P4-defined tables (*i.e.*, match-action tables, counters, registers) to the chip's physical memory resources. In the RTC architecture, there is no need to consider table dependencies as in a pipeline architecture; only capacity constraints and performance optimization issues need to be addressed.

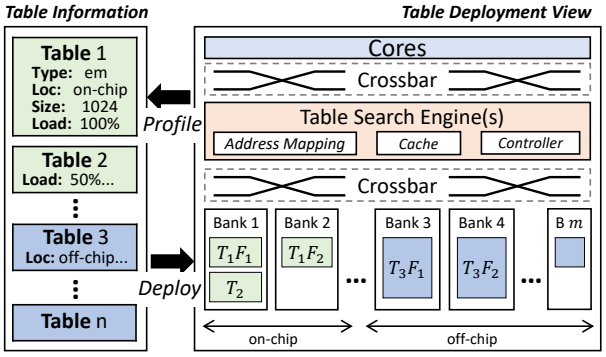

Figure 5: Table deployment view in P4RTC

Problem Constraints and Optimization Objective. The table deployment problem in the RTC architecture can be modeled as a variant of the bin packing problem (BPP), where the bins are the memory banks, and the items are the P4-defined tables. There are two main differences from the standard BPP. Firstly, in the shared memory subsystem, read and write requests caused by table matching and `TableOperation` extern will be queued in the channel of corresponding memory banks. Specific memory banks may suffer congestion due to simultaneous access by multiple cores, and the negative effect is more evident for off-chip deployed tables with higher latency. Therefore, the optimization goal is not to minimize the number of memory banks used but to minimize the maximum load among the memory banks to optimize the performance of the memory subsystem [1].

Secondly, P4RTC allows table fragmentation to utilize memory capacity fully. Specifically, we can fragment a table to satisfy capacity constraints or to reduce the load the table imposes on a single bank. However, each table fragmentation occupies an address mapping entry in table search engines (TSEs [2]), and the number of mapping entries available is limited. Consequently, this introduces a constraint that the quantity of table shards must be less than the number of supported mapping entries.

Based on the above considerations, we use an integer linear programming (ILP) model to solve the problem. Given n tables and m memory banks, each table i has a size of s_i, where $i = 1, 2, \ldots, n$. For each memory bank j, it has a capacity of c_j, where $j = 1, 2, \ldots, m$. We define an integer variable x_{ij} to represent the size of the fragment of the table i put in the memory bank j. We consider this variable as an integer (included between 0 and s_i). We also define a decision variable y_{ij} that equals 1 if the fragment of the table i is deployed

[1] Note that the load balancing of memory requests involves more hardware components (e.g., table search engines). Our experience is that as long as the load balancing of memory banks is done well, it is straightforward to handle the balancing of other upper-layer components.

[2] Table search engines are specialized memory controllers optimized for table operations, efficiently managing table search, read, and write requests.

on memory bank j, and 0 otherwise. Then, the total number of fragments of table i can be expressed as $\sum_{j=1}^{m} y_{ij}$. The following ILP model formalizes the table deployment problem:

$$\text{minimize} \quad \max_{j\in\{1,\ldots,m\}} \sum_{i=1}^{n} x_{ij} \cdot l_i \tag{1}$$

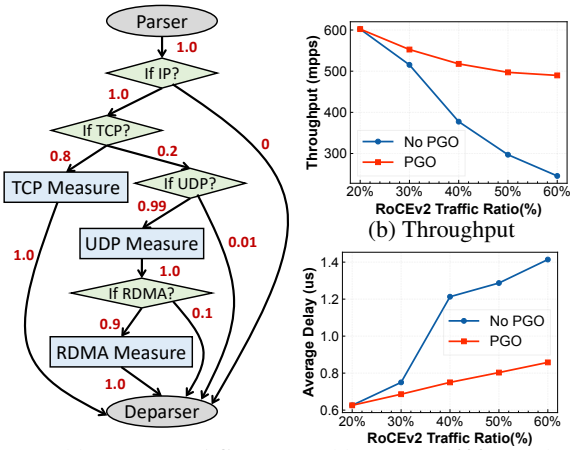
$$\text{subject to} \quad \sum_{j=1}^{m} x_{ij} = s_i, \quad \forall i \in \{1,\ldots,n\} \tag{2}$$

$$\sum_{i=1}^{n} x_{ij} \le c_j, \quad \forall j \in \{1,\ldots,m\} \tag{3}$$

$$\frac{x_{ij}}{s_i} \le y_{ij}, \quad \forall i \in \{1,\ldots,n\},\ j \in \{1,\ldots,m\} \tag{4}$$

$$\sum_{i=1}^{n}\sum_{j=1}^{m} y_{ij} \le T \tag{5}$$

$$x_{ij} \in \mathbb{N}, \ \forall i \in \{1,\ldots,n\},\ j \in \{1,\ldots,m\} \tag{6}$$



$$y_{ij} \in \{0,1\}, \ \forall i \in \{1,\ldots,n\},\ j \in \{1,\ldots,m\} \tag{7}$$

Here, l_i denotes the load incurred by the unit size of table i, while T denotes the maximum number of available mapping entries. The optimization objective (Equation (1)) is to minimize the maximum access frequency among all memory banks. Equation (2) is the table assignment constraint, ensuring that each table is fully deployed. Equation (3) guarantees that the capacities of the memory banks are not exceeded. Equation (4) mandates that the variable y_{ij} must be equal to 1 as soon as the variable x_{ij} is strictly greater than 0. Finally, Equation (5) ensures that the maximum number of mapping entries does not exceed.

Profile-guided optimization on table deployments. The above model relies on load information for each table. However, table access's read/write frequency is determined by runtime traffic and specific table entries. We employ a profile-guided optimization (PGO) compilation strategy. Initially, we adopt a profile where each branch evenly shares the load of its parent node. Then, after running the switch, a new table load information can be obtained [3], and we use the new profile to solve the table deployment problem again. Empirically, we perform PGO 2-3 times in the early stages of deployment to gradually adapt to the traffic of the new environment. In the subsequent stages, we will only proceed with a new round of PGO iteration if there is a significant change in the workload and it stabilizes in the new state.

The PGO's performance maintenance and enhancement are especially noticeable in scenarios with significant workload changes. For instance, within our traffic measurement project, we employ distinct off-chip tables to measure TCP, UDP, and RoCEv2 traffic, enabling the collection of protocol-specific metrics. The DAG graph of the program is shown in Figure 6a. Initially, TCP traffic predominated; however, with the gradual integration of RDMA technology across the network, RoCEv2 traffic has steadily gained prominence over the past years, as it also occurs in Microsoft Azure Storage [44]. We are comparing the performance of two strategies: one utilizing PGO optimization and the other not

[3]The compiler will automatically insert counter instrumentation.

(a) Program DAG (b) Throughput (c) Latency (400 Mpps)

Figure 6: Effect of PGO on performance.

using PGO. The PGO optimization strategy employs the optimal configuration based on the latest workload, whereas the non-PGO strategy consistently utilizes the initial configuration with RDMA traffic at 20%. As shown in Figure 6, as the proportion of RoCEv2 traffic increases to 60%, the non-PGO strategy's throughput drops by 64.7%, and its latency increases by 2.3x. In contrast, the performance of the PGO strategy remains good, with a slight performance degradation as RoCEv2 traffic needs to access more off-chip tables.

5.2 Microcode Generation

P4 is a high-level language that cannot be run directly on chips. Microcode are the closest language to the RTC chip's machine code, usually built from a specific instruction set designed by manufacturers. We must implement a compiler to generate the microcode instructions from P4 code. We reuse the open-source P4C project [41] but rewrite the compiler's backend. Due to space constraints in the paper, we provide an overview of the compilation process and our experiences. A detailed example of compiling P4 to microcode and intermediate representations (IR) is elaborated in Appendix B.

Define Microcode IR. Lowering P4 IR (*i.e.*, generated by P4C) directly into the microcode would increase the coupling between the compiler and microcode, making the compilation process difficult to control. We introduce a Microcode IR, enabling detailed control, optimization, and validation, considering the specific characteristics and constraints of the target hardware, as we will discuss further. Figure 7 shows part of Microcode IR definition for the `Foreach` extern:

Transform the P4 IR to Microcode IR. This is the most complex step in the compilation process. An example of the `Foreach` extern translation is shown in Figure 8.

1. *Align P4 IR with Microcode IR.* Specific Microcode IR nodes can be directly mapped from the equivalent nodes in P4 IR, such as assignment and logical operations shown in the right part of Figure 7. This step identifies the corresponding operations and control flow constructs within

```

          :Statement;
class Lss
          :Expression;
...
```

Figure 7: Microcode IR Definition

the Microcode IR that align with those in the P4 IR. During this process, the compiler must carefully handle type translation, including endianness, padding, and bit width.

2. *Implement P4-specific and architecture-specific constructs.* Handle complex P4 constructs such as match-action tables by mapping them to corresponding Microcode IR nodes. New extern constructs introduced by P4RTC are implemented in this step. As shown in Figure 8, the `Foreach` extern is mapped to an assembly-like loop control flow, including a series of label statements, jump instructions (*i.e.*, Branch), and loop body. This process reads relevant information from multiple parts of the P4 IR based on the desired loop structures in microcode.
3. *Manage Dependencies.* Ensure that the semantic properties and constraints of the P4 program are preserved in the Microcode IR. Consider the dependencies between P4 IR operations and ensure they are correctly accounted for in the Microcode IR. This includes preserving data dependencies, control flow dependencies, and ensuring the proper ordering of instructions in the microcode to avoid hazards or incorrect behavior.
4. *Validate and Verify.* Ensure the correctness and integrity of the transformed Microcode IR. This includes maintaining correct packet processing behavior, adherence to P4 language rules, compliance with micro-architectural restrictions or limitations, and checking for potential errors and inconsistencies.

Emit Microcode Instruction. After completing the previous phases, the lowered Microcode IR can be directly mapped to the microcode instructions (please see Appendix B). The more details are lowered in the Microcode IR level, the less complexity there is in the emission stage, resulting in fewer introduced bugs. Besides, when facing different versions of microcode, Microcode IR allows developers to reuse existing compilation logic, especially target-independent compilation passes, such as assignment and logical operations.

6 Performance Model

In the RTC architecture, P4 codes and actual workloads significantly impact the chip performance. Therefore, strict performance testing must be conducted on P4 programs before deployment. Besides standard functionality models like BMv2 [45], we introduce a performance model for P4RTC to explore potential bottlenecks and optimize users' programs.

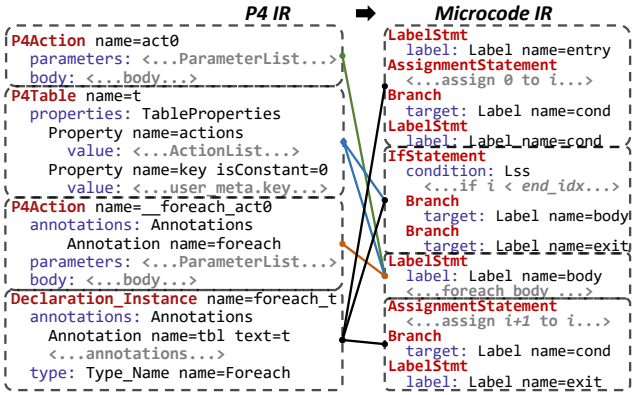

Figure 8: An example of P4 IR to Microcode IR

In general, performance models are utilized to evaluate metrics such as the throughput and latency of a chip under specific programs and workloads [46, 47]. We build a system-level model utilizing the Electronic System Level (ESL) methodology, leveraging the robust capabilities of the SystemC library [48]. We model main hardware components, encompassing cores, the traffic manager (TM), TSEs, the memory subsystem (MSS), and their interconnections (*e.g.*, FIFOs and back-pressure mechanisms). The model employs a global clock (*i.e.*, `sc_clock` in SystemC) to synchronize the chip components, define their operational frequencies, govern instruction execution, and regulate packet rates. As a result, the model can simulate cycle-level behaviors across a range of packet processing scenarios, enabling a more granular real-time depiction of each chip component's status.

As shown in Figure 9, our performance model uses four steps to obtain the performance metrics:

Step 1. Given a P4 program and a specific workload (*i.e.*, a packet trace), we perform functional simulations [45, 49] to process packets, record the microcode paths that each packet traverses, and then save the paths to a *codepath* file. For instance, the sequence `Parser` → `TCP Measure` → `Deparser` in Figure 6a represents an execution path. To realize the system-level simulation, we must also model the hardware behaviors. Specifically, when applying a P4 table, packets access various table entries, thus generating different microcode instructions that interact with multiple memory banks. However, for large P4 projects, recording all different microcodes for an extensive number of packets may result in the *codepath* file becoming excessively large. To deal with these scenarios, we use a probabilistic approach to construct the *codepath* file. We summarize all microcode paths in the *codepath* file as multiple *branches* and *sub-branches* of microcodes, each bearing distinct probabilities. The below example illustrates a sample *codepath* file:

```
<codepath name="demo" bw="1000Mpps">
  <microcode percentage="90%">
    <!-- microcode branch 1 -->  ...
    <io type="read" table="IPv4", tse="0", ...>
      <!-- sub-branch -->
```

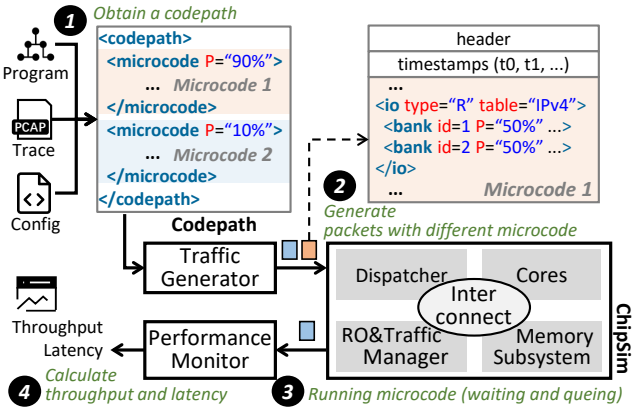

Figure 9: Workflow of performance model

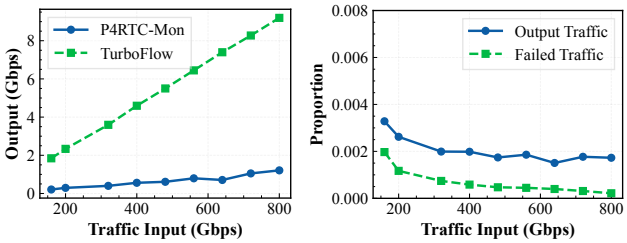

```
      <bank id="31" percentage="50%", .../>
      <bank id="32" percentage="50%", .../>
    </io>
    <action>
      <!-- sub-branch -->
      <alu name="l3_fwd" percentage="90%", .../>
      <alu name="drop" percentage="10%", .../>
    </action> ...
  </microcode>
  <microcode percentage="10%">
    <!-- microcode branch 2 --> ...
  </microcode>
</codepath>
```

There are two microcode *branches*, each with several *sub-branches*. The selection of the *branches* and *sub-branches* is performed dynamically in the following steps.

Step 2. After obtaining a *codepath* file, we upload it to a traffic generator. The traffic generator then interprets the *codepath* and generates traffic at a specified rate. Specifically, the traffic generator creates packets based on the probability of each microcode *branch*. Each packet includes a reference to the relevant microcode instructions, an identifier, and a metadata space for storing timestamps, which are used to calculate the latency experienced in each chip component.

Step 3. The chip simulator receives packets and navigates the microcode instructions. For each instruction, the simulator only emulates the performance behavior rather than executing it precisely. Take an IO instruction as an example: it will generate specific IO requests for the memory subsystem and emulate behaviors, including addressing and queuing a particular memory bank. Each behavior costs specific cycles, consistent with the chip's microarchitecture [50]. When encountering a *sub-branch*, the simulator dynamically employs a probabilistic process to execute the selected instruction, such as bank selection. When a component is over-stressed, a back-pressure signal is sent to upstream components, triggering chip-wide performance impacts.

Step 4. A performance monitor receives the packet output from the chip simulator and summarizes various performance metrics, including throughput and latency. Moreover, the performance monitor can acquire load or utilization information on each hardware component by inserting monitoring probes

(a) Bandwidth Cost (b) Traffic Proportion

Figure 10: Accurate Per-flow Monitoring

(*i.e.*, codes for monitoring) into the chip simulator.

In §7.3, we demonstrate how the performance model can guide performance optimization and assess its accuracy by comparing its outputs with those of a hardware chip.

7 Case Study

We prototype P4RTC on a 1.2-Tbps RTC chip with 8 GB high-bandwidth memory (HBM), used in Huawei NetEngine 8000 F1A-C (NE8000F1AC) routers. The adaptation to higher-throughput chips with the same architecture is ongoing. We evaluate P4RTC through several use cases and summarize the following findings:

P4RTC benefits P4 programmability. It incorporates RTC architectures into the P4 community, enabling previously unsupported functions in P4. A comprehensive case on accurate per-flow monitoring demonstrates that P4RTC can monitor up to 50 million concurrent flows at a near line rate. When the input traffic surpasses 800 Gbps, the report traffic sent from the data plane to a collector occupies less than 0.06% of the total input bandwidth (see case 1).

P4RTC benefits RTC-based devices. Besides existing C-like high-level languages, P4RTC offers another efficient method for data plane development. It reduces the lines of code (LOC) by 4.6x-7.7x compared with microcode programming. Besides, existing P4 functions can be migrated to P4RTC with minimal effort (see case 2).

The performance model benefits P4RTC optimization. It details the performance impact of different P4 codes on the chip under specific traffic inputs. In case3, we employ the performance model iteratively to identify system bottlenecks and implement targeted optimizations. Finally, we enhance the throughput to 14.4 times that of the baseline program.

7.1 Case#1: Accurate Per-flow Monitoring

Accurate per-flow monitoring is helpful for network performance analysis since it completely records flow-level traffic information. Due to the limitation of memory capacity and programmability, the task is challenging to implement on existing pipeline ASICs. Existing efforts employ a sampling strategy to monitor packets with general-purpose servers [51]. Nevertheless, this sampling strategy can lead to imprecise statistics and result in substantial information loss.

With P4RTC, implementing accurate per-flow monitoring

becomes straightforward and flexible. Specifically, we can define an off-chip big table as a flow measuring table (FMT) and the matching key as a flow key (*e.g.*, 5-tuple). Then, some counters and registers are defined to record the size, times-tamps, and other flow attributes. When a packet arrives in the foreground pipeline, it first tries to match a table entry. If a table miss occurs, we use `TableOperation` to add a new flow entry for recording. On the other hand, the FMT needs to age in time to make room for new flows. We complete the aging function by combining the foreground pipeline and background pipeline. In the foreground pipeline, we identify end-of-flow signals such as TCP's FIN and RST flags. In the background pipeline, we use the `Foreach` extern to traverse table entries, and we also use the `Queue` extern to accelerate the performance (see Appendix A). If a flow record is marked as finished or there is no packet access after a certain timeout, the flow will be reported and deleted from the FMT. This background pipeline can be bound to multiple cores to improve aging performance, where each core is responsible for aging a portion of the FMT.

We implement the above function with P4RTC. We connect a NE8000F1AC device to two ToR switches of a storage cluster (with a mix of client traffic and backend traffic) and mirror the truncated upstream packets to the device. With 4 GB of memory, it can measure up to 50M concurrent flows. It is lower than ideal (*i.e.*, 4 GB / the size of a flow record) due to hardware details such as memory alignment and redundancy of hash tables to reduce conflicts. We compare the performance with TurboFlow [33], a state-of-the-art accurate per-flow monitoring system based on Tofino. Turboflow evicts older flow records to the control plane when a hash collision occurs. In contrast, P4RTC can use the *TableOperation* extern to add flow records to an exact match table, automatically handling hash conflicts in the data plane. Therefore, it can continue to measure flows regardless of conflicts, reducing the additional bandwidth overhead caused by hash conflicts. As shown Figure 10a, our solution reduced the bandwidth overhead for sending measurement data by 86% to 90%. Note that packets will fail when multiple packets of a flow add entries simultaneously (*i.e.*, there is a row lock when adding table entries). In Figure 10b, we find that the bandwidth occupied by the failed packets is less than 0.2% of the input traffic. This is because packet failures occur only during the creation of flow entries due to lock contention. Once the table entries for the flows are established, subsequent packet counter updates proceed normally. Since the time taken to build entries in the data plane is short, the number of failed packets is minimal.

7.2 Case#2: Reduce RTC Developing Burden

Table 2 shows the comparison of the number of P4 code lines required for developing functions such as accurate flow monitoring in case 1 and SpaceSaving algorithm in Appendix C. We find that P4 can reduce the LOC development by 4.6x-7.7x compared with microcode programming in the five projects. This efficiency is comparable to NPC++, a C-like programming language developed for the chip. The NPC++-related projects are still under development. We estimate the LOC needed to replicate the same functionality using pseudo code written in NPC++ syntax. NPC++ will take about O(100) LOC and the error comes from the constant-level discrepancies between P4RTC and NPC++ languages (*e.g.*, table definition, 'for loop' syntax). Additionally, we successfully compile CocoSketch [6], ONTAS [53], and AES encryption [15] by only modifying 4.3%-13.0% of P4 code. These modifications mainly involve the architecture-specific extern constructs (*e.g.*, RegisterAction), and similar extern constructs can be easily found in P4RTC.

Table 2: Lines of Code (LOC). 'Modification (Mod.)' denotes the P4 code modifications required to migrate the original project to P4RTC. The required LOCs are comparable to NPC++, in the O(100) range.

Project	Microcode	$P4_{16}$ (Mod.)
Accurate Flow Mon.	2825	547 (N/A)
SpaceSaving [52]	1166	152 (N/A)
CocoSketch [6]	1244	270 (35)
AES Encryption [15]	2883	561 (41)
ONTAS [53]	3029	637 (27)

7.3 Case#3: Using the Performance Model

This case specifically aims to evaluate how the performance model can identify bottlenecks within the memory subsystem and guide optimization. Figure 11 is a sample P4 code we use when opening up the system process. The baseline deployment does not take any optimization. As shown in Table 3, its throughput is less than 40 Mpps. Then, we repeatedly used the performance model to guide the optimization.

Firstly, observing the status of memory banks in the baseline, we find that the utilization gap among the banks is significant. The maximum utilization is 0.99, the minimum is 0.03, and the average is low. This prompts us to adopt table fragments and use the load-aware table deployment strategy discussed in §5. After this optimization (O1), the system's performance increased 7.2 times.

After O1, we further find that load imbalance also existed among the table search engines (TSEs). We use a similar load-aware strategy to rebind the P4 tables to multiple TSEs (O2), balancing the loads of multiple TSEs. This performance optimization increases performance by 1.38 times.

Thirdly, when the bottleneck of TSEs is eliminated, the bottleneck point is once again transferred to the memory subsystem. We find all memory banks' utilization is above 90%. This reveals that the off-chip deployment of the P4 tables limits the system throughput. We offloaded a small number of hotspot table entries to on-chip memory (O3). This further improves performance to 1.45x over O2.

The Accuracy of the performance model. In the above

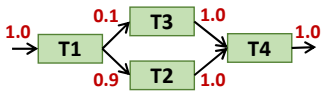

Figure 11: Case 3 P4 program. All off-chip tables.

Table 3: Performance analysis with the performance model.

Opt.	Banks Util. (Min / Max) Avg	TSEs Util. (Min / Max) Avg	Throughput Model (Mpps)	Throughput Hardware (Mpps)
Baseline	0.03 / 0.99 0.09	0 / 0.09 0.04	39.4	38.3
+ O1. Table Redeploy	0.63 / 0.90 0.68	0.03 / 0.63 0.32	283.9	279.4
+ O2. TSE Rebind	0.90 / 0.99 0.95	0.44 / 0.44 0.44	392.7	401.9
+ O3. Table Caching	0.77 / 0.96 0.82	0.63 / 0.63 0.63	569.5	561.0

experiments, the overall error of the performance was less than 3%, which is sufficient for the optimization scenario. We discuss the lessons and current limitations about the accuracy of the performance model in §8.

8 Lessons and Discussion

P4 language design for the run-to-completion architecture. The expressiveness of the RTC architecture is not limited to the externs proposed in this paper. In practice, we also developed some more specialized P4 extensions based on application requirements, such as using `@cache` annotation to directly support the table caching mechanism. Considering openness, the ultimate design of the P4 language for the RTC architecture merits discussion within open communities.

Performance challenges introduced by programmability. The NE8000F1A series comprises high-performance commodity routers designed with fixed functions that are optimized for their functional logic and configurations. Upon introducing programmability, we encountered numerous performance challenges. Some early applications consistently achieved throughputs of less than 100 Gbps. Contrasting with conventional deterministic performance switches, both toolchain developers and users need to invest additional effort to achieve the best performance.

Accuracy boundary of the performance model. Replicating all hardware details in a cycle-accurate manner is a monumental engineering challenge. The modeling granularity directly affects the accuracy and execution efficiency of the performance model. Currently, the performance model is built based on actual needs to maintain satisfactory prediction accuracy in the typical (or known) scenarios (*e.g.*, table deployments). Due to the probabilistic execution of the *codepath*, the current model cannot simulate some detailed behaviors, such as complex locking mechanisms and scenarios where the specific order of packets matters. Our ongoing development is focused on refining the model's traffic generator and chip simulator to support a richer array of scenarios and performance behaviors.

Parallel safety issues in P4RTC. Users must use the `Lock` extern reasonably according to their scenarios and consider potential performance risks. Better-performance concurrency management methods are worthy of future research, especially case-by-case optimizations and trade-offs. Our exploration in Appendix C provides an optimization case.

Future work. We will enrich P4RTC and adapt it to our higher-throughput RTC chips. Support for P4 Runtime is also in the planning process. Besides, we are applying P4RTC to more practical projects, such as traffic generators [54], in-network storage [1], and ML training acceleration [55].

9 Related Work

RMT [11] makes the concept of programmable switches a reality. Nevertheless, RMT is plagued by sub-optimal memory utilization due to the coupling between memory and the MAU stage. dRMT [56] enhances memory utilization and improves execution efficiency by moving table memories out of pipeline stages and into a centralized pool. P4ALL [26] and O4 [57] are extensions of P4 that support elastic switch programming and reduce the voluminosity of P4 code, respectively. Lyra [58] is a cross-platform language for data plane programming. Although these efforts simplify function development and enhance resource utilization, they are not designed to overcome the inherent limitations of P4's programmability within pipeline architectures.

There have been some applications and research around RTC architecture devices. Turboflow [59] employs Netronome NFP-4000 for implementing network flow records generation. Trio [31] is Juniper's programmable chipset using RTC architecture. The language design of P4RTC, along with its experience in compiler optimization and performance modeling, can serve as a reference for Trio. P4TC [28] focuses on applying the P4 language to the Linux tc layer. It is still programmed from a pipeline perspective. Designing new externs to extend the P4 language to the RTC architecture and leveraging the RTC architecture are not within the scope of its design.

10 Conclusion

We proposed P4RTC, a comprehensive summary of our experiences in applying the P4 language to the RTC architecture. P4RTC includes a unified programming model with novel extern constructs, compilers, and a performance model. Case-oriented evaluation demonstrates that P4RTC can enhance P4 programmability and reduce RTC development burdens.

A. Example of the Queue extern

In the following example, the foreground pipeline uses the Queue extern to send signals of finished flows to background pipelines. The motivation behind this design is this. First, the foreground pipeline offloads the reported tasks to the background pipeline for better logical separation. In this way, the cores running the foreground pipeline do not need more packet processing time when reporting is required. And the background pipeline can implement advanced reporting logic, such as batching and compression. However, it is inefficient for the backend pipeline to blindly scan the flow table to determine whether it needs to be aged. A simple optimization method is to pass the end-of-flow signal from the foreground pipeline to the background pipeline through the Queue to achieve more intelligent and efficient table aging.

```
Queue<FlowInfo> queue(4096);
control foreground_ingress{
  @offchip
  table FlowTable {...}
  ...
  apply{
    if (hdr.tcp.flags & TCP_FIN
              || hdr.tcp.flags & TCP_RST)
    {
        queue.push( { hdr.ipv4.srcAddr,
                      hdr.ipv4.dstAddr,
                      hdr.ports.srcPort,
                      hdr.ports.dstPort} );
    }
    /* Measurement logic here, store flow data
      in the action data of FlowTable */
  }
}
control background_ingress{
  @tbl(FlowTable)
  TableOperation() tbl_op;
  apply{
     /* Get an expired flow record */
     FlowInfo flow;
     queue.pop(flow);
     /* Read flow infomation*/
     bit<8> action_id;
     FlowData action_data;
     tbl_op.entryGet(flow, action_id,
                           action_data);
     ...
     /* Deleta the flow record*/
     tbl_op.entryDel(flow);
     /* Set valid the report header and send to
      the measurement analyzer. */
  }
}
```

B. Example of Microcode Generation

The following example introduces how to convert the `Foreach` extern into the final microcode step by step. Since the specific microcode cannot be made public for confidentiality reasons, we use LLVM assembly language [60] for demonstration, which is very close to our final microcode.

The P4 language snippet we're working with introduces an extern library for table traversal, named `Foreach`. This library also contains methods such as `continue()` and `break()`, which control the traversal flow. The `Foreach` extern is used in the P4 program as follows:

```
action act0(bit<32> value) {}
action act1(bit<32> value0,
            bit<32> value1) {}
table t {
    key = {
        user_meta.key : exact;
    }
    actions = { act0(); act1(); }
    size = 1024;
}

/* Add '@foreach' annotation to indicate this
   action is a method in 'Foreach' procedure */
@foreach
action __for_act0(bit<32> key,
                  bit<32> val) {
    // ...
    continue();
    /* Use 'continue' extern function to
       continue to the next iteration */
}
@foreach
action __for_act1(bit<32> key,
                  bit<32> val0,
                  bit<32> val1) {
    // ...
    break();
    /* Use 'break' extern function to
       break the loop */
}

// Instantiate a 'Foreach' variable.
// Bind this instance to table 't'
// Bind method '__for_act0'
//      to action 'act0' of table 't'
// Bind method '__for_act1'
//      to action 'act1' of table 't'
@tbl("t")
@methods[act0="__for_act0", act1="__for_act1"]
Foreach() foreach_t;
apply {
    // ...
    foreach_t.apply();
}
```

The `Foreach` extern needs to be bound to a table, and each table action of the table requires a separate `foreach` action (*i.e.*, loop body). This is because different actions usually have various types of action data, and we need to match the function parameter list.

Firstly, the P4C compiler translates the P4 language into the corresponding P4 IR. The P4 IR is a tree structure representing the P4 code in a more abstract form, including information about tables, actions, and extern constructs.

```
P4Action name=act0
  parameters: ParameterList
    Parameter name=value
      type: Type_Bits size=32 isSigned=0
  body: BlockStatement
    <... body ...>
P4Action name=act1
  parameters: ParameterList
    Parameter name=value0
      type: Type_Bits size=32 isSigned=0
    Parameter name=value1
      type: Type_Bits size=32 isSigned=0
```

```
  body: BlockStatement
    <... body ...>
P4Table name=t
  properties: TableProperties
    Property name=actions isConstant=0
      value: ActionList
        <... act0 ...>
        <... act1 ...>
    Property name=key isConstant=0
      value: Key
        <... user_meta.key ...>
P4Action name=__for_act0
  annotations: Annotations
    Annotation name=foreach
  parameters: ParameterList
    Parameter name=key
      type: Type_Bits size=32 isSigned=0
    Parameter name=value
      type: Type_Bits size=32 isSigned=0
  body: BlockStatement
    <... body ...>
P4Action name=__for_act1
  annotations: Annotations
    Annotation name=foreach
  parameters: ParameterList
    Parameter name=key
      type: Type_Bits size=32 isSigned=0
    Parameter name=value0
      type: Type_Bits size=32 isSigned=0
    Parameter name=value1
      type: Type_Bits size=32 isSigned=0
  body: BlockStatement
    <... body ...>
Declaration_Instance name=foreach_t
  annotations: Annotations
    Annotation name=tbl text=t
    Annotation name=methods
      NamedExpression name=act0 value=__for_act0
      NamedExpression name=act1 value=__for_act1
  type: Type_Name name=Foreach
```

We can see that the P4 IR uses the elements in P4 as the main content and is still far away from the final microcode. We first translate the P4 IR to Microcode IR. This transformation involves converting the high-level P4 constructs into lower-level ones that are more suitable for generating microcode instructions. For example, we must build a loop structure, conditions for entering or exiting the loop, and distinguishing the logic of calling different table action's loop bodies (*i.e.*, `SwitchStatement`). Here is the representation of the Microcode IR of the P4 code:

```
BlockStatement
  LabelStmt
    label: Label name=entry
  AssignmentStatement
    left: PathExpression name=i
    right: Constant value=0
  Branch
    target: Label name=cond
  LabelStmt
    label: Label name=cond
  IfStatement
    condition: Lss
      type: Type_Boolean
      left: PathExpression name=i
      right: Constant value=10
    Branch
      target: Label name=body
    Branch
      target: Label name=exit
  LabelStmt
    label: Label name=body
  EntryGet
    table: PathExpression name=t
    key: PathExpression name=idx
    act: PathExpression name=act
    data: PathExpression name=data
  SwitchStatement
    expression: PathExpression name=act
    SwitchCase
      label: Constant value=0
      statement: BlockStatement
        <... body ...>
    SwitchCase
      label: Constant value=1
      statement: BlockStatement
        <... body ...>
  AssignmentStatement
    left: PathExpression name=i
    right: Add
      left: PathExpression name=i
      right: Constant value=1
  Branch
    target: Label name=cond
  LabelStmt
    label: Label name=exit
```

Finally, the Microcode IR is transformed into microcode instructions. After the conversion from P4 IR to Microcode IR, the conversion from Microcode IR to microcode instructions is a straightforward parallel mapping.

```
%union.Data = type { %struct.Act0_Data }
%struct.Act0_Data = type { i32 }
%struct.Act1_Data = type { i32, i32 }

define void @foreach_t() {
     %act_ptr = alloca i8
     %data_ptr = alloca %union.Data
     %idx_ptr = alloca i32
     br label %enter

enter:
     store i32 0, i32* %idx_ptr
     br label %cond

cond:
     %cond_idx = load i32, i32* %idx_ptr

declare i1 @foreach_act1(i32,%struct.Act1_Data*)
```

C. Profiling Complex Algorithms

Algorithms that involve complex memory operations can now be implemented with the help of P4RTC. A typical example is SpaceSaving (SS) [61], which is utilized to detect the top-k flows. SS maintains O(k) slots in memory, where each slot contains a flow key and a counter to track large flows. Upon receiving a packet from flow i, the algorithm employs a loop to verify whether the flow is stored within a slot. If the flow is found, the algorithm increments the corresponding counter. Otherwise, it locates the slot with the minimum counter value and replaces the existing flow with flow i. These kinds of operations cannot be implemented in the pipeline architecture. With P4RTC, we can easily use `Foreach` extern to implement an SS algorithm.

However, parallel safety issues may occur during the updating process. Using locks can lead to significant performance issues as they negate the performance benefits of parallel packet processing. Therefore, we are curious whether SS can be applied directly without the locks. To deeply reveal the impact of the parallel safety issues on algorithm accuracy, we leverage our performance model (in §6) to help us analyze this process. We embed a customized execution environment in the performance model to actually run the actual instructions in the codepath, thus profiling the functional performance in a multi-threaded environment. We input a

(a) SS Accuracy Profiling (b) SS Latency Profiling

Figure 13: Profiling with the performance model

real-world packet trace collected by the WIDE Project in 2020 [62], which contains 10M packets. Figure 13a shows the false negative of the SS algorithm across numbers of cores at 1, 64, 256, and 1024. We detect top-256 large flows ($k = 256$) and the x-axis represents the number of slots allocated for SS. We surprisingly find that we can optimistically neglect the locks. Even when utilizing 1024 cores (parallelism $P = 1024$), the algorithm maintains its accuracy without noticeable degradation. This is primarily due to the stability of the large flow candidates in memory as the algorithm progresses. The accumulation of these atomic counters is parallel safe. The only potential parallel safety concerns arise during the eviction of the smallest flow. Fortunately, this operation does not impact the other slots that contain larger flows, thus the impact of parallel safety issues is limited.

The performance model can also help us balance parameter k (*i.e.*, the number of large flows that need to be identified) and performance overheads. Suppose for each k, we allocate $2k$ slots in memory to obtain a satisfactory recall ratio. Figure 13b shows the variation of average packet latency with the change of allocated slots. Developers can choose the most appropriate parameters k based on their tolerance for delays and the top-k flow requirements.

Table 4: Comparison between P4RTC with regular P4

Language	P4	P4RTC

Abstract

Learning how to control congestion remains a challenge despite years of progress. Existing congestion control protocols have demonstrated efficacy within specific network conditions, inevitably behaving suboptimally or poorly in others. Machine learning solutions to congestion control have been proposed, though relying on extensive training and specific network configurations. In this paper, we loosen such dependencies by proposing *Mutant*, an online reinforcement learning algorithm for congestion control that adapts to the behavior of the best-performing schemes, outperforming them in most network conditions. Design challenges included determining the best protocols to learn from, given a network scenario, and creating a system able to evolve to accommodate future protocols with minimal changes. Our evaluation on real-world and emulated scenarios shows that Mutant achieves lower delays and higher throughput than prior learning-based schemes while maintaining fairness by exhibiting negligible harm to competing flows, making it robust across diverse and dynamic network conditions.

1 Introduction

Years of research on congestion control algorithms for TCP [44] have produced creative solutions departing from TCP Vegas [13], Fast [30], Compound [47], and the more recent BBR [15], to name a few, with improvements in performance results of more than 15% compared to Cubic [25], the default in most Linux systems. BBR, rather than traditionally relying on packet loss to adjust the congestion window, (*cwnd*), uses round-trip time (*rtt*) and throughput data to decide how fast to transmit data packets. TCP Vegas, a delay-based protocol, only looks at the *rtt* to adjust the congestion window. An increasing *rtt*, due, for example, to a packet drop, causes Vegas to reduce its packet sending rate, while a steady *rtt* causes Vegas to increase its sending rate until the *rtt* increases again. These examples highlight that traditional congestion control solutions rely on current network stats such as *rtt*, throughput, and packet loss. As such, they are mostly reactive (not proactive) to sudden network changes. In addition, they rarely look at the past behaviors of the network or their own historical behaviors in their analysis.

With the surge of machine learning performance in recent years, promising approaches using Deep Learning (DL) or Reinforcement Learning (RL) techniques have been proposed to adjust performance, mostly by tuning the congestion window [29]. As an example, Aurora [28], a variant of the Performance-oriented Congestion Control (PCC) [21], uses Deep Reinforcement Learning to adjust the congestion control actions empirically by observing the connection state and the experienced performance. Owl [43], Orca, [2], and Marten [39], three other RL-based congestion control protocols, use Deep Q-Learning to determine the next congestion window using metrics retrieved from the network stack. These approaches share the idea of solving the congestion control problem by instructing an agent to dynamically learn the optimal *congestion window (cwnd)* via the RL framework. Despite their learning ability as the network environments change, their design is inherently limited by the training phase. Congestion control parameters often exhibit complex interactions and dependencies with various network factors, including traffic load, topology changes, and routing dynamics. Even when enough samples of the significant states are collected *offline*, i.e., ahead of time, data drift problems remain, and protocols experience performance degradations for their lack of adaptability under new, unseen, changing conditions.

The good news is that years of research on congestion control protocols have shown that some protocols can learn how to perform well by observing specific network input signals, and even though they fail in scenarios for which they were not optimized, there is often another (existing) protocol that does perform better in such scenarios. *What if we could learn from a team of protocols, each performing well in a few complementary scenarios, without requiring exhaustive and impractical data collections and without requiring the one-size-fits-all protocol?*

In this paper, we propose *Mutant*. While such a design is inspired by the so-called imitation learning [20], deciding

which protocol Mutant should “imitate" or “mutate" into is also a computationally hard problem even if we choose the best-performing k protocols of the team offline. To solve this problem bounding the optimality gap, we use the team selection theory [31]. In particular, our algorithm solves the following problem: *Given a set of congestion control algorithms available, which subset should we input to our online reinforcement learning algorithm, so that our selection is most likely to bring the best performance, i.e., smaller delays, higher throughput, or both, for each network environment and congestion state?* We reduce this problem from the top-k players in cooperating games and discuss the team selection algorithm used by Mutant in Section 5.2. There are tens of CC protocols to choose from and we show that having as many protocols as possible leads to inefficiencies, not only overhead. Similar problems have been applied in the context of supervised machine learning, where individual features are modeled as players and feature subsets as coalitions that yield the best predictive performance [19].

In Section 4 we justify the chosen subsets of protocols per each network scenario and discuss our lessons learned. Among those, (1) the datasets available and the choice of protocols to learn from are more important than the learning algorithm, and (2) learning from too many protocols is counterproductive: the performance degrades because, intuitively, we explore too much and we do not exploit enough.

Aside from algorithmic challenges, to deploy a protocol that mutates its behavior based on the underlying available user-space and kernel implementations, we needed to solve several system design challenges as well (Section 3). For example, our kernel module implementation should be able to quickly mutate into one of the congestion control algorithms used to learn with minimal overhead. For performance reasons, we focused on learning from congestion control protocols already implemented in the kernel, such as Cubic, Hybla, and TCP Vegas, but Mutant can be easily adapted to learn from any transport protocol that uses sockets and returns congestion window updates, including ML-based protocols. Our evaluation results (Section 6), on real network traces and real-world traffic, show that *Mutant* consistently performs among the best protocols in all scenarios analyzed, for both delay-sensitive and bandwidth-sensitive applications. We also analyzed *Mutant*'s fairness using the notion of harm [50], showing promising results. From our evaluation, it is also clear that the choice of which protocol set *Mutant* is programmed to emulate influences its performance, just as humans should not learn from anyone in any scenario. We review existing literature in Section 7 and we present our conclusion in Section 8.

2 Mutant: Motivation and Design Overview

Learning From Existing Protocols. The main insight behind our protocol design is the idea that there is no one-size-fits-all congestion control for all scenarios, as confirmed by our results in Figure 1. These results show the ratio between throughput and delay, and the fairness performance of four widely used TCP protocols. We consider the following six network environments sampled from our experimental sets: *fixed bandwidth*, *low capacity*, *high rtt*, *large queue* i.e., buffer of the bottleneck router, *mixed conditions* i.e., large queue with high RTT, *step* i.e., with regular and abrupt channel bandwidth fluctuations. In Section 6.1, we detail these testing scenarios. We observe that no protocol is dominant in all the cases for single-flow settings. Cubic, for example, performs well in stable conditions but fails across fluctuating bandwidth conditions (step scenario). BBR2 [16], on the contrary, handles these abrupt changes but is suboptimal for networks with low capacity. When we instead consider a multi-flow scenario, focusing on the fairness of these protocols, expressed in terms of *harm*, a notion introduced in [50] and defined in Section 6.4, we can see that, e.g., BBR2 harms others in many use cases but not in all scenarios.

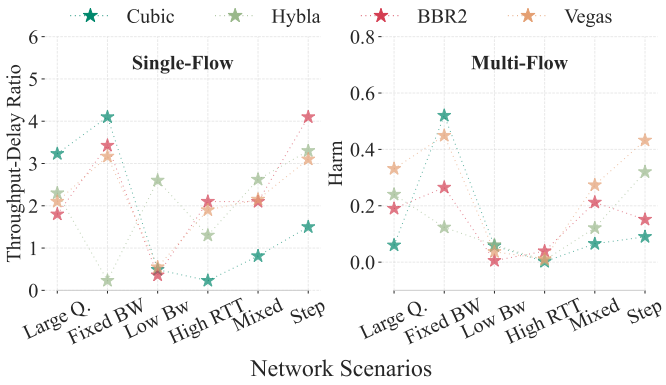

Figure 1: Motivation for our study: Performance of a few protocols in six different network environments, tput/delay on a single-flow (left) and harm [50] in multi-flow scenarios (right): low values translate to high fairness. Every protocol performs well in only a selected group of network scenarios.

The Challenge of Generalization. While adaptive and learning-based solutions have been explored, we believe that learning from past congestion window values is insufficient and poorly adapted to unseen network conditions. Current approaches attempting to achieve adequate model generalization require a long offline training phase, e.g., [42, 43, 55]. In Figure 2, we compare one state-of-the-art model as Sage [55] against our online model. The offline learning process requires vast data collection, expensive resources, and long training sessions. Mutant quickly adapts to the network scenario while achieving comparable or superior performance to the data-driven model. Motivated by these results, we propose a system that quickly adapts to diverse conditions and learns in real-time from ongoing interactions with the underlying network environment. In addition, our design principle is to offer the community a system that, rather than autonomously adapting

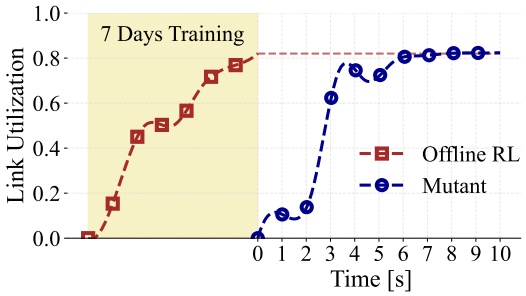

Figure 2: Mutant reduces the learning time overhead compared to pretrained, data-driven ML models for congestion control.

the best *cwnd* update strategy, considers other features to learn what would be the best protocol in a given network state.

Mutant Overview. At the core of our solution, *Mutant*, lies on an online Reinforcement Learning (RL) algorithm that *(1)* quickly learns from existing congestion control schemes by a real-time policy switching mechanism at fine-grained intervals implemented in kernel, *(2)* minimizes the reaction time to network changes, and *(3)* relies mostly on online data with minimal offline adjustments. We present the overview of Mutant in Figure 3, highlighting its main components. Our online learning logic decides on the best CC scheme in real-time during the communication. Two main components dictate the selection of the best scheme at each time step: the *Protocol Manager* and the *Learning Module*. The *Protocol Manager* is a pluggable kernel module implemented following the structure of the existing CC schemes in the Linux kernel. Indeed, Mutant is a kernel module that can be loaded as another kernel-based TCP congestion control protocol (i.e., Cubic, BBR2, Hybla, etc.). This component supports the key low-level functionalities of Mutant's system: *(1)* runs the real-time CC scheme switching logic, *(2)* maintains the state of each protocol during the execution, and *(3)* communicates the network statistics to the user-space *Learning Module* module.

The *Learning Module*, instead, is a user-space component that handles the algorithmic operations within our system. This module is responsible for executing *(1)* the online reinforcement learning process and *(2)* the best starting protocols using a *top-k* selection schema (Section 4). At each step of the RL loop, Mutant switches the CC scheme in real-time, by sampling from a pool of different protocols in the kernel. The user-space module will learn the relationship between the scheme selected and the features collected at each time step, with the primary goal of maximizing the throughput and minimizing the delay.

While designing our solution, we attempted to answer two key questions: *(1)* What pool of CC protocols should we consider in our deployment? *(2)* Which schema should we choose at runtime? To answer the first question, we questioned if all the CC schemes should be kept in the pool or if selecting only a subset of them would benefit the overall performance of our

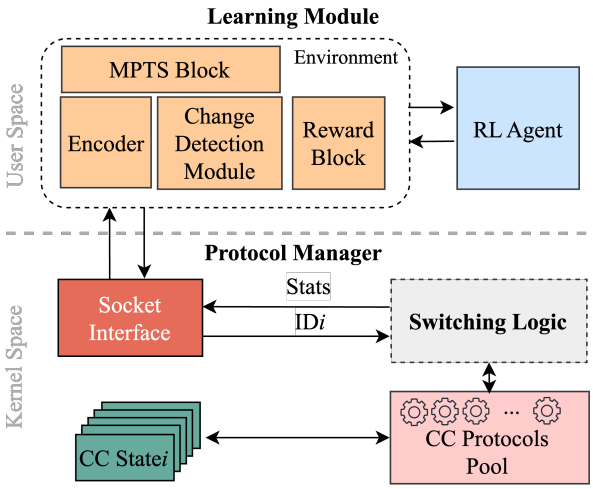

Figure 3: Overall architecture of *Mutant*. Two main components are a kernel module hosting a set of TCP protocols and a user-level module with the learning logic to decide when it is convenient to mutate into another protocol.

solution. Our results show that a subset of the best-performing policies for the specific network scenario leads to higher performance and faster convergence (see Section 6.2). We designed an algorithm that selects the top-*k* policies *per-flow* before running the online learning process (see Section 5.2). Secondly, Mutant runs a reinforcement learning procedure that can quickly learn *its own CC schema over time, based on the pool of existing protocols* (i.e., the CC heuristics in the kernel). By continuously adapting and exploring different protocols, Mutant can dynamically learn the strengths of each protocol. For instance, it might recognize that BBR2 excels in specific scenarios, such as when delays become particularly high or bandwidths change abruptly, while Cubic performs better in different conditions, for example, when packet loss events occur. In such a way, our solution can learn to adapt and refine its own congestion control policy over time, continually assessing and adjusting its strategies based on the evolving network conditions and performance metrics.

3 Design and Implementation

This section details the two main components overviewed in the previous section. First, we highlight the main challenges that originate from the kernel components and operations of the Protocol Manager. Then, we describe the Learning Module with the RL-based algorithm.

3.1 Protocol Manager

Our Protocol Manager seamlessly integrates in-kernel functionalities with the Linux kernel's TCP source code. The Mutant kernel module acts as a versatile meta-protocol for congestion control. The kernel utilizes a modular and extensible framework for implementing TCP congestion control

algorithms, with the struct `tcp_congestion_ops` at its core. This structure consists of function call pointers that define an interface for congestion control algorithms. Each function can be seen as a handler for a specific TCP event. Examples of events can be congestion avoidance (i.e., a congestion event has been triggered), receipt of a TCP ACK, or the adjustment of the TCP sender's state. Each function is designed to promptly respond to these events by executing the necessary actions that facilitate congestion management and update the internal state variables of the CC scheme. Each congestion control algorithm encapsulates its functionalities within this structure, enabling effortless pluggability into the system.

In our implementation of Mutant, we have created an independent and flexible *meta-protocol*. This module acts as a wrapper for the `tcp_congestion_ops` of the protocols in the pool and can dynamically plug and unplug them for live switching. Our live switching procedure functions as follows: when the Protocol Manager receives a new CC scheme to select from the Learning Module, it performs two important operations. Firstly, it stores the current state of the active CC scheme, which can be restored if selected again later. Secondly, it plugs the `tcp_congestion_ops` of the selected CC scheme, seamlessly replacing the previous one. Each CC scheme's state variables are maintained over time, and they are frozen and unfrozen when the scheme is selected. Additionally, upon every switch, the next protocol starts from the `cwnd` value of the preceding one. To communicate with the RL module in the user space, the protocol manager uses the *netlink* socket family. After receiving every ACK, it sends the network features to the Learning Module, which predicts the CC scheme to be selected for the next step.

3.2 Learning Module

This module hosts the online learning capability using a Reinforcement Learning (RL) approach. In RL, an *agent* performs an action, *a*, in a particular state, *s*, of an *environment* and receives a reward, *r*, for having performed this action [46]. An *agent* learns a *policy* to maximize its reward over time, where such a reward value indicates how successful the agent's action has been. This motivates the agent to seek for a series of state-action pairs that eventually maximizes its overall reward via a process of exploration and exploitation, with varying degrees.

In this work, we design an online learning algorithm based on contextual Multi-Arm Bandits (MAB) [36]. Similar to the more popular *Q-Learning*, *MAB* is an RL algorithm that makes decisions under uncertainty by balancing between exploration and exploitation of several actions, known as *bandits*. Simply, the algorithm observes a context, makes a decision by selecting one action from a set of alternative actions, and then observes the outcome of that decision. However, unlike traditional RL, bandit problems only observe the outcome of a selected action for a given state, and it does not have

Table 1: Raw input statistics used in the learning process. For each feature in **bold**, we also compute the mean, minimum, and maximum values across three observation windows of different sizes: *short* (10), *medium* (200), and *long* (1000).

`snd_cwnd`	Sender's congestion window size
`rtt_us`	Round-trip time in microseconds
`srtt_us`	Smoothed round-trip time
`mdev_us`	Mean deviation of round-trip time
`min_rtt`	Minimum round-trip time
`advmss`	Advertised maximum segment size
`delivered`	Number of packets delivered
`lost_out`	Rate of packets lost
`in_flight`	Number of packets sent
`retrans_out`	Number of retransmitted packets
`rate`	Delivery rate
`prev_proto`	ID of the previous protocol
`crt_proto`	ID of the selected protocol
`throughput`	Throughput
`loss_rate`	Loss rate

Q-tables to look up past performances and decide the best action to take [36]. By being simple in the learning nature, this approach can be used to learn *online* among possible choices and, thus, leads to faster adaptability to new network conditions.

Environment. It acts as the interface through which the agent interacts with its surroundings, offering feedback to the agent's actions and shaping its learning trajectory. The environment runs in our *Learning Module*, which collects the network parameters from the kernel at runtime and provides the observation at each time step. The duration of this time interval is customizable, but it impacts the switching frequency between different congestion control (CC) schemes within the pool. We explored various time intervals through empirical experimentation to understand their impact on model performance in Section 6.1.

Agent. The agent interacts with the Mutant environment by observing states, taking actions, and receiving rewards. The agent aims to learn the best mapping between states and actions to maximize cumulative rewards over time. In contextual MAB, the agent faces a set of actions (*arms*) and must choose the next action based on observed contexts or features. As each action yields an uncertain reward, the agent aims to learn which action maximizes cumulative rewards given different contexts. In multi-arm bandits algorithms, the agent employs a policy to balance the trade-off between exploration and exploitation. In Mutant, we implement the Upper Confidence Bound [32] as the exploration-exploitation policy (see Section 5.1).

State. In our work, we consider a diverse set of network statistics from the kernel during the communication between two hosts as our input features (Table 1). For a subset of these features, we additionally consider three observation windows to extract temporal dynamics varying the time granularity

across *short* (10 samples), *medium* (200 samples), and *long* (1000 samples) durations. This leads to a total of 55 input features collected at each step from the kernel. To efficiently manage this input space, we employ a pre-trained encoder to map these features in the latent space to achieve dimensionality reduction (see Section 5.1), resulting in a total of 16 embedding input signals.

Actions. The arm or action determines what an agent observing an environment can do to influence the environment. In our context, *Mutant* has the following set of actions represented as $A = tcp_proto_i \; \forall \; i$, where i is the index of the CC scheme deployed on the host machine. According to the learning agent, Mutant selects the next scheme based on the network conditions it has seen. For every network scenario and before the agent starts learning, we run our MPTS protocol to determine the pool of *top-k* schemes, given a fixed k. However, k is a parameter of *Mutant*, and we designed our solution with the aim of providing the flexibility of including other (future) protocols in the kernel thanks to an extensible and versatile interface [1]. Our prototype tested in this paper supports 11 different in-kernel CC schemes: Cubic [25], Hybla [14], BBR2 [15], Westwood [17], Veno [24], Vegas [13], YeAH [9], Bic [53], HTCP [33], Highspeed [23] and Illinois [35]. Selecting the best scheme at each time interval is a non-trivial problem. We discuss such a problem and solution in Section 4.

Reward. A reward is a utility function that allows us to calculate the effectiveness of the action by measuring a reward value for an agent observing an environment. In our context, we want our agents to maximize the network throughput while minimizing the delay. We express this objective as an attempt to maximize the Power metric, a well-known quantity defined as $pw = \frac{Throughput}{Delay}$. At the same time, we also aim to minimize the number of packet losses. As such, our agents seek to maximize their overall reward at time step t, R_t defined as:

$$R_t = \frac{(thr_t - \zeta \cdot l_t)^{\kappa}}{d_t}, \tag{1}$$

where thr_t, d_t, l_t are the delivery rate, average delay, and loss rate observed at timestep t. ζ and κ are coefficients that determine the impact of the loss rate over the throughput and the importance of the throughput over the delay, respectively. We compute the throughput as the delivery rate during the communication directly in the kernel, defined as $thr_t = \frac{r_t}{s_t}$, where r_t is the number of packets delivered and s_t the time interval in *us*.

Algorithm 1: Mutant's Online Learning Algorithm

```
Let δ represent the step duration

        Update state with z_t
        Update thr_max and del_min
    Compute μ_a = θ*^T z_t
    Compute UCB_a = μ_a + sqrt(2 log(t) / n_a)
    Update MAB policy parameters
R_max = thr_max / del_min
R_t = ((thr_t − ζ·l_t)^κ / d_t) · (1 / R_max)
```

4 Problem Statement: Selecting the Best Protocols to Learn From

A cooperative game is characterized by a pair (N, ν) containing a set of players $N = \{p_1, ..., p_n\}$ and a value function $\nu : \mathcal{P}(N) \rightarrow \mathbb{R}$, where $\nu(\emptyset) = 0$ by definition. The players can form coalitions $S \subseteq N$ and obtain a combined benefit given by $\nu(S)$, which is called the worth of S.

Our problem is characterized by a set of strategies, or arms $\mathcal{A} = \{a_1, ..., a_n\}$ and at each discrete time step t, the learner can *pull* an arm a_i. To each arm i there is an associated probability distribution $p_i \in [0, 1]$. The observed reward for arm i is drawn from p_i. We model our congestion control protocol set selection in Mutant as a multi-armed problem.

In particular, the resolution of the top-k arms identification problem determines the protocols to use. The Mutant agent selects the k arms with the highest mean rewards to form a coalition at the end of T evaluations. In the multi-arm bandit literature, the parameter T is denoted *fixed budget*. Such budget is given beforehand, and once exhausted, the learner returns its guess about the top-k arms. The learner's performance is hence measured by the probability of returning a correct output. Formally, the objective of the learner is to select the set $\{a_1, ..., a_k\}$ corresponding to the set of arms with the k highest mean rewards, $\mu_1, ..., \mu_k$. In the rest of this section, we assume that the final set of arms is ordered by the reward, i.e., $\mu_1 > ... > \mu_k$. This ordering assumption preserves the generality, while the assumption that the means are all distinct is made for the sake of notation (the complexity measures differ slightly if the top k means are ambiguous).

We assess the effectiveness of the Mutant agent's strategy by using the probability of misidentification, i.e.:

$$e_T = \mathbb{P}(\{a_1, ..., a_k\} \neq \{1, ..., k\}). \tag{2}$$

Considering the following complexity measure for the single

[1] Mutant code is publicly available at https://github.com/lorepap/mutant

best arm identification:

$$H_1 = \sum_{i=0}^{n} \frac{1}{\Delta_i^2} \quad \text{and} \quad H_2 = \max_i \frac{i}{\Delta_i^2}, \tag{3}$$

where $\Delta_i = \mu_1 - \mu_i$ for $i \neq 1$ and $\Delta_1 = \mu_1 - \mu_2$ (difference in mean rewards). Prior work [7] showed that these two complexity measures are equivalent up to a log factor, i.e.,

$$H_2 \leq H_1 \leq \log(2n) H_2. \tag{4}$$

Intuitively, H_1 represents a lower bound on the number of evaluations necessary to identify the best arm. To verify if an arm has mean $\mu^* = \max_i \mu_i$ or μ_i, and agent needs to sample $\frac{1}{\Delta_i^2}$ times. The surprising fact shown in [7], that we reuse in our analytical result, is that the order of H_1 evaluations suffices to identify the best arm. As for upper bounds, the quantity H_2 proved to be a useful surrogate for H_1 to express the bounds on e_T.

To model our k-best arms identification problem, we then define the gaps and the complexity measures as follows:

$$\Delta_i^k = \begin{cases} \mu_i - \mu_{k+1} & \text{if } i \leq k \\ \mu_k - \mu_i & \text{otherwise} \end{cases}$$
$$H_1^k = \sum_{i=0}^{n} \frac{1}{(\Delta_i^k)^2}, \quad H_2^k = \max_i \frac{i}{(\Delta_{(i)}^k)^2}, \tag{5}$$

where the notation $(i) \in \{1, .., n\}$ is defined such that $\Delta_1^k \leq ... \leq \Delta_m^k$. In our case, the H_1^k replaces the H_1 as the lower bound of the k-best arms identification problem.

5 Mutant Online Learning Logic

After the team selection process, we oversee the ultimate lineup and dynamically choose the protocol responsible for controlling congestion. We formulate the online learning procedure in Mutant (Algorithm 1) - which changes the CC scheme in the pool based on the real-time collection of network features - as a Contextual Multi-Armed bandit problem (CMAB) [36]. Unlike the traditional multi-armed bandit problem, where the rewards of each arm are independent of the context, in CMAB, the reward of each arm (i.e., the CC schemes) depends not only on the arm chosen but also on a set of contextual features (i.e., the network parameters) associated with the current state of the environment. Formally, at each time step t, the agent observes a context vector $\mathbf{x}_t$ that describes the current state of the environment and selects an arm i based on a policy $\pi(\mathbf{x}_t)$. The policy maps each context vector to a probability distribution over the arms, indicating the likelihood of selecting each arm given the context. The agent then receives a reward $r_{t,i}$ associated with the chosen arm.

To address this trade-off problem, we leveraged the Linear Upper-Confidence Bound policy, which we combine with an algorithm to preliminary select the policies in the pool (Section 5.2). We design our algorithm as a cooperative game. Unlike competitive games, where players compete to maximize an often selfish utility, cooperative games foster teamwork and coordination among participants [41]. In our system, all players (protocols) aim to reach "high throughput and low delay" for all flows. An intriguing question in the context of cooperative games concerns the importance of a single player's contribution. In particular, one crucial question is: What are the top players performing in this game?

5.1 Challenges to Achieve an Online Learner

Exploration vs. Exploitation Trade-Off. One main challenge in online RL is balancing the trade-off between exploration, i.e., trying out new actions or strategies to gather information about the environment, and exploitation, i.e., leveraging known information to maximize short-term rewards. While too much exploration may lead to sub-optimal performance, excessive exploitation can result in missed opportunities for discovering better solutions, given the uncertainty surrounding the efficacy of the chosen protocol and the varying network conditions. This difficulty arises because achieving quick and cost-effective convergence becomes impractical without investing significant time and resources. As an online RL approach, our model must minimize the exploration time and ensure consistently good performance by selecting the best-performing protocol for the underlying network settings.

The key challenge in the CMAB problem is to learn an effective policy that balances the exploration of different arms with the exploitation of arms that are likely to yield high rewards, considering the contextual information. To this end, we use the LinUCB (Linear Upper Confidence Bound) algorithm [34], which extends the classic Upper Confidence Bound algorithm [8] to the contextual setting.

LinUCB assumes a linear relationship between the expected reward of an arm and associated contextual information. Specifically, the expected reward for pulling arm a at round t, given a context feature vector x_t with dimensionality d, can be expressed as $\mu_a = \theta^{*T} x_t$, where θ^{*T} captures the weights associated with each feature. However, since we do not have direct access to θ^*, LinUCB employs an estimate $\hat{\theta}_t \in \mathbb{R}^d$ that is updated over time based on observations. Our approach entails Bayesian linear regression [12] to model such a relationship between the contextual features and the expected rewards for each action, thus forecasting the weights θ^{*T}. This linear relaxation simplifies the traditional RL process, making the learning policy a more lightweight process suitable for our purpose of learning online.

In addition to predicting the reward, LinUCB computes an upper confidence bound (UCB) for each action's expected reward. This bound represents a trade-off between the estimated mean reward and the uncertainty in that estimate. In conclusion, by selecting actions with higher UCB values, LinUCB can balance exploration (selecting actions with uncertain re-

wards) and exploitation (selecting actions with potentially high rewards), aiming to maximize cumulative rewards over time.

Reduce the Input Representation. From the raw network features indicated in Table 1, we compute maximum, minimum, and mean values for some metrics over short, medium, and long-size sliding windows. While this approach allows to extract temporal dynamics at runtime, it also leads to a total of 55 different network features. Such a large state space is hardly managed by LinUCB, which approximate a linear relationship between the context (i.e., network features) and the reward of each arm (i.e., the protocols in the pool). If, on the one hand, such a linear algorithm enables a more lightweight policy, on the other hand, this simplistic assumption poses new challenges as it needs more representational power, especially with a large context vector.

Inspired by [40], to overcome this limitation, we design an *encoder* network to represent a large network feature vector into a smaller latent space. On top of that, this operation should be done in an online fashion. At each step, the high-dimensional raw observation x_t is processed by a pre-trained encoder that outputs the low-dimensional embeddings z_t. We use a Gated-Recurrent Unit [18] layer with two fully connected (FC) layers as our encoding network architecture to capture the sequence-level information from the online network data. Thus, the expected reward for each arm becomes $\mu_a = \theta^{*T} z_t$, where z_t is the output of the last hidden layer of the encoding network for the context x_t.

Dynamic Reward Normalization. Since the reward defined in Equation 1 captures the ratio between the throughput and the round-trip time, as the bandwidth can change over time, the most-rewarded protocol can change accordingly. Because of this, we need to normalize the reward according to the maximum achievable reward for the particular network setting. We adopt an online change detection algorithm based on ADWIN [11]. This algorithm can detect the throughput and the round-trip time shifts during the communication for each selected CC scheme. Every time a change is detected, we recalculate the maximum reward by replacing the throughput and round-trip time values in Equation 1 with each adaptive window's maximum throughput and minimum round-trip time. This approach ensures that the normalized reward reflects the best-performing CC scheme at each step, even when the underlying network setting changes.

5.2 Top-*k* selection with MPTS

We present an algorithm — *Mutant Protocol Team Selection (MPTS)* – to find the best CC algorithms to learn from, and we show that such an algorithm has a bounded error. Before proceeding, we introduce the following notation. For each arm i and for all rounds $t \geq 1$, we have $W_i(t) = \sum_{s=1}^{t} \mathbb{1}_{I_t=1}$ to be the number of times arm i was pulled from rounds 1 to t, and $X_{i,1}, X_{i,2}, ..., X_{i,W_i(t)}$ the sequence of associated rewards. Then,

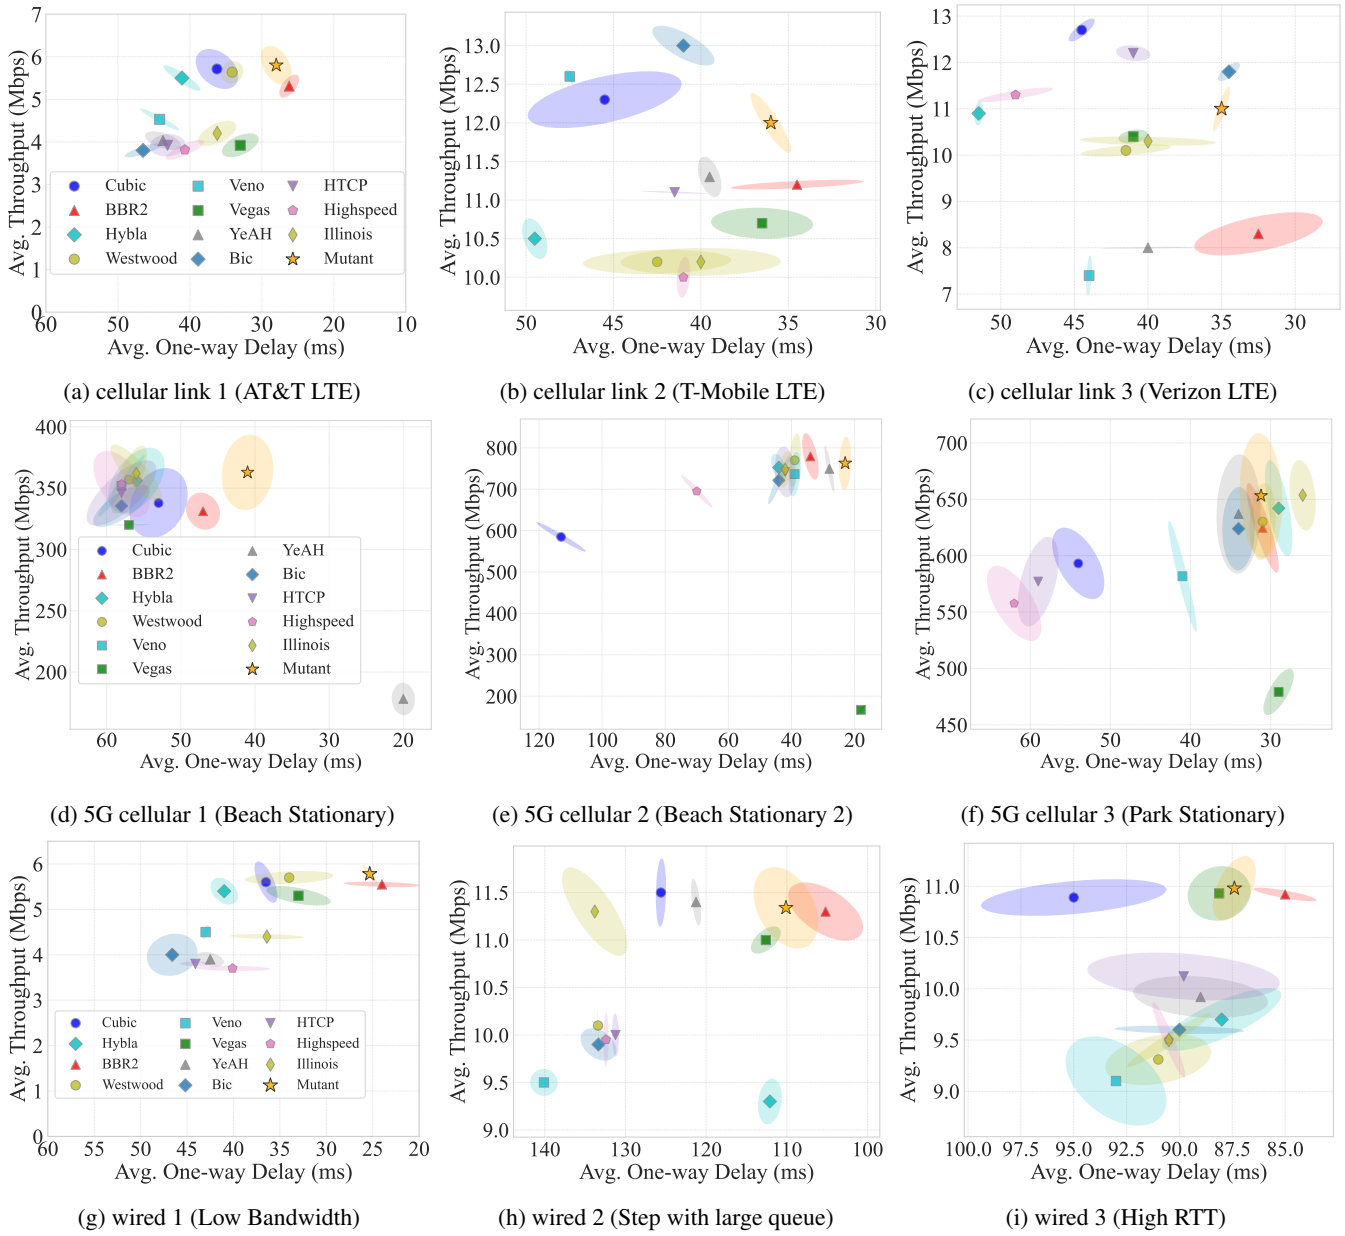
Algorithm 2: Mutant Protocol Team Selection (MPTS) algorithm for k-best protocol identification.

Let $\mathcal{A}_1 = \{a_1, ..., a_n\}, k(1) = k, n_0 = 0$, $\overline{\log}(T) = \frac{1}{2} + \sum_{i=2}^{T} \frac{1}{i}$, and for $j \in \{1, ..., n-1\}$ $n_j = [\frac{1}{\overline{\log}(T)} \frac{T-n}{n+1-j}]$;

Initialize ;

for *each phase* $j \in \{1, ..., n-1\}$ **do**

1. For each active arm $a_i \in \mathcal{A}_j$ select arm a_i for $n_j - n_{j-1}$;
2. Let $\sigma_j : \{1, ..., n+1-j\} \to \mathcal{A}_j$ be the bijection that orders the empirical means by $\hat{\mu}_{\sigma_j(1),n_j} \geq \hat{\mu}_{\sigma_j(2),n_j} \geq ... \geq \hat{\mu}_{\sigma_j(n+1-j),n_j}$. For $1 \leq r \leq n+1-j$, we have these empirical gaps $\hat{\Delta}_{\sigma_j(r),n_j} =$ $\begin{cases} \hat{\mu}_{\sigma_j(r),n_j} - \hat{\mu}_{\sigma_j(k(j)+1),n_j} & \text{if } r \leq k(j) \\ \hat{\mu}_{\sigma_j(k(j)),n_j} - \hat{\mu}_{\sigma_j(r),n_j} & \text{if } r \geq k(j)+1 \end{cases}$;
3. Let $i_j \in argmax \hat{\Delta}_{i,n_j}$ and ties are broken arbitrarily. Deactivate arm a_{i_j} and $\mathcal{A}_{j+1} = \mathcal{A}_j \backslash \{a_{i_j}\}$;
4. If $\hat{\mu}_{i_j,n_j} > \hat{\mu}_{\sigma_j(k(j)+1),n_j}$, then arm a_{i_j} is accepted, i.e., $k(j+1) = k(j) - 1$ and $a_{k-k(j+1)} = i_j$;



return the k accepted arms $a_1, ..., a_k$;

let $\hat{\mu}_{i,s} = \frac{1}{s} \sum_{t=1}^{s} X_{i,t}$ the empirical mean of arm i after s evaluations and $X_{i,s}(k)$ and $\hat{\mu}_{i,s}(k)$ the corresponding quantities in the multi-bandit problem.

The concept behind MPTS is similar to *Successive Rejects*, which was developed to address the single best arm identification problem [7]. However, MPTS has the additional feature of occasionally accepting an arm if it can be conclusively shown to be one of the top k arms.

Informally MPTS evolves following these steps. The time (the T rounds) is first divided into $K-1$ phases. At the end of each phase, the algorithm either accepts the protocol (arm) with the highest empirical mean or dismisses the protocol with the lowest empirical mean. In any of these two cases, the corresponding protocol is deactivated. During the following phase, it pulls each active protocol with the same frequency. During a specific phase j, the key to choosing whether to accept or reject is to rely on estimates for the gaps Δ_i^k.

Assuming, for example, that the algorithm has already accepted $k - k(j)$ protocols, $a_1, ..., a_{k-k(j)}$, it means that $k(j)$ must be still found. At the end of the phase j, MPTS computes for the $k(j)$ empirical best arms (among the active arms) the distance in terms of empirical mean to the $(k(j)+1)^{th}$ empirical best arm among the active arms. For the active arms not among the $k(j)$ empirical best arms, instead, MPTS computes the distance to the $k(j)^{th}$ empirical best arm. MPTS deactivates the arm i_j that maximizes these empirical distances. If i_j is the currently best (empirically) arm, it is accepted and

variables are updated as $k(j+1) = k(j) - 1$, $a_{k-k(j+1)} = i_j$. Otherwise, the arm i_j is rejected. The formal description of MPTS is reported in Algorithm 2. We now show that the error probability of MPTS is bounded, with the following Theorem.

Theorem 5.1. *Let n be the number of available protocols, T the number of evaluations, and H_2^k the complexity measure defined in Equation 5. The error probability of the MPTS algorithm in the k-best protocol identification problem has the following error bound:*

$$e_T \leq 2n^2 \exp\left(-\frac{T-n}{8\overline{\log}(T)H_2^k}\right). \tag{6}$$

Proof. See appendix. □

6 Performance Evaluation

In what follows, we describe Mutant general evaluation using simulated and real-world traffic. In particular, in Section 6.1, we give details about the environments used for our experiments. In Section 6.2, we present Mutant's performance and compare them to state-of-art ML-based schemes. In Section 6.3, we analyze the importance of selecting the best-k protocols in the pool. We elaborate more about Mutant's fairness in Section 6.4. Finally, in Section 6.5 we present an

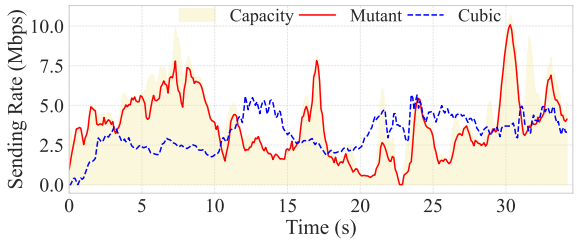

Figure 5: Mutant quickly adapts to highly variable network conditions compared to Cubic, the default congestion control in most Linux implementations. An optimal protocol would follow exactly the available capacity.

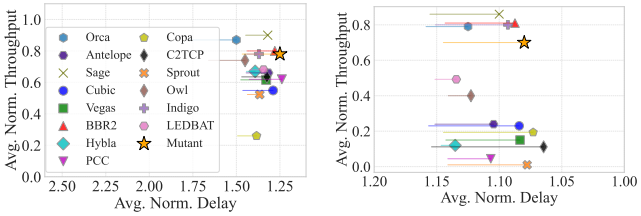
ablation study on Mutant's main components.



6.1 Evaluation Settings

Across our experiments, we test our protocol on publicly available realistic network conditions [2, 6, 37] to emulate *cellular* links even high bandwidths. Additionally, we consider a combination of emulated *wired* network scenarios, i.e., a typical Internet network environment consisting of a fixed bandwidth, delay, and queue size. We range the bandwidth, minimum rtt, and buffer queue size values within [12, 96] Mbps, [10, 120] ms, and [1, 20] $\times$ BDP, respectively.

We collect the performance of other CC baselines using Pantheon testbed [54] and Mahimahi emulator [37]. An experiment involves establishing an `iperf3` session between a single client and a Linux-based host machine. This setup allows us to capture and analyze various network metrics and evaluate the performance of different congestion control algorithms in a controlled experimental environment. For our real-world scenarios, we test Mutant on *(i)* intra-continental and *(i)* inter-continental network environments using Fabric [10] testbed. In our experimental setup, we establish the default quantity of kernel protocols within the pool, denoted as k, to be 6. This decision followed a comprehensive evaluation via a greedy search approach, as detailed in Section 6.3. Additionally, we set $\delta = 10^{-}2$s, i.e., the interval for alternation among CC schemes, (see Section 6.5).

6.2 Throughput-Delay Performance

In our experiments we compared Mutant with the following baseline, divided into four categories: (i) end-to-end TCP designs, e.g., Cubic [25], Vegas [13], Hybla [14] and the schemes in the pool, PCC [21], Copa [5]; (ii) end-to-end cellular, i.e., LTE protocols, e.g., C2TCP [1], Sprout [51]; (iii) ML-based protocols, such as Owl [43], Indigo [54], Orca [2], Sage [55], Antelope [56], and (iv) mixed schemes, e.g., LEDBAT [45]. Figure 4 shows the average throughput and delay across the cellular and wired sets of experiments, where the shaded ellipses represent the standard deviation across experiments from the mean value (i.e., the center of the ellipses). In particular, the *step* scenario (Figure 4h) is obtained by doubling the bandwidth after a defined time period. We compare Mutant against the pool of schemes it learns from. We select different emulated network environments for wired and cellular experiments and run each protocol for 2 minutes. We selected a diverse set of network scenarios with different ranges of bandwidth, from low (i.e., LTE and wired), to high[2] (i.e., 5G cellular). For each environment, we preliminary compute the protocols in the pool by running MPTS with $T = 100$, then running Mutant with the resulting pool. Results prove that Mutant is consistently among the best protocols across all tested scenarios and learns how to adapt to the specific environment. Somehow surprisingly, these findings show that Mutant does not depend on the best-performing protocol but can learn its policy by switching among the protocols pool and adapting quickly to the network scenario to maximize its reward. Indeed, Mutant can learn from the pool of protocols and outperform them. In Figure 5, we present how Mutant's best-k setting can quickly adapt to changing network conditions, while Cubic clearly shows the inability to achieve full link utilization. This shows that Mutant learns to select the protocols based on when they perform at their best over time, even in highly variable network scenarios. We explore further the reward suboptimality in Appendix B.

(a) Intra-Continental (b) Inter-Continental

Figure 6: Average normalized throughput, average normalized delay and 95^{th} percentile (end of lines) on real-world experiments.

We then validate Mutant on real-world network environments. We consider intra-continental and inter-continental experiments by setting up different hosts across the US and Europe using Fabric testbed [10]. To make a fair comparison with the ML baselines, we preliminary run the MPTS algorithm for the top-k protocols on every scenario. For each baseline, we run one flow for 30 seconds and repeat the experiment 10 times. As demonstrated in Figure 6, Mutant consistently achieves high performance levels when compared to other baselines. Most notably, Mutant can surprisingly match or even outperform pre-trained ML-based congestion control protocols (such as Orca, Sage, Antelope, and Indigo), even without extensive offline training. Mutant can also outperform online learning schemes, such as PCC, which show a competitive delay but a low throughput. We also highlight

[2]Due to Mahimahi limitations on traces with bandwidths larger than $\sim$ 200 Mbps, we leveraged a modified version of Mahimahi [6] to test Mutant on real 5G cellular traces with high bandwidth.

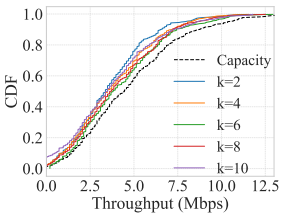


Figure 7: CDF of the throughput over a cellular link varying k.

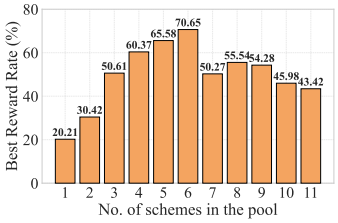

Figure 8: Mutant's performance varying the number of protocols in the pool (k).

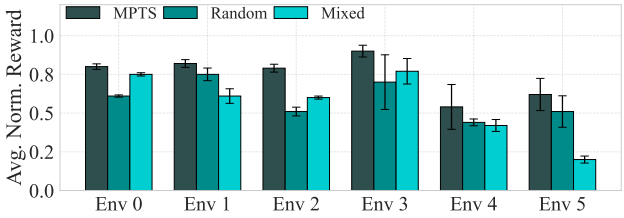

Figure 9: Impact of different protocol selection strategies.

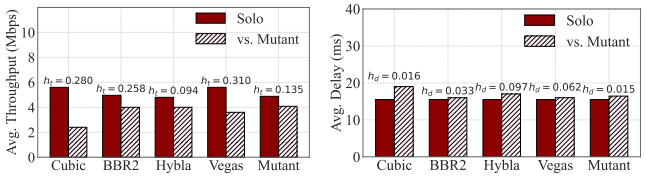
that Mutant is capable of achieving competitive performance even within a short duration of the flow transmission. Overall, Mutant shows a 3.85% lower delay than BBR2 (appearing as the best-performing protocol in the pool) and a 3.60% lower delay than the average delay of other machine learning-based solutions like Sage, Orca, Indigo, and Antelope. Notably, it can achieve this result while maintaining a high throughput. This analysis yields an important result: *it is possible to learn from a pool of protocols in an online fashion and achieve competitive performance compared to offline ML algorithms.*

6.3 MPTS: Top-k Evaluation

To identify the optimal k for our Mutant Congestion Control protocol, we employ our MPTS Algorithm 2 while varying the number of protocol k in the pool, which also defines the action space in the RL model. Empirically, we observe that the inclusion or exclusion of certain protocols significantly influences the performance of the model, leading to either performance improvement or deterioration. Consequently, it is crucial to determine the best-performing configuration, where the k-size "team" in the algorithm effectively represents the protocols that positively contribute to the overall performance of Mutant.

We run an experiment to empirically find the value of k to be set for each network scenario. We run MPTS for a total of $T = 100$ rounds, varying k between 2 and 11. During each round of the MPTS algorithm, the available protocols are selected based on a uniform distribution. This selection process ensures that each protocol has an equal chance of being evaluated. Upon completing the T total rounds of the MPTS algorithm, we compute the best k protocols based on their cumulative mean reward, as defined in Equation 1. Intuitively, the higher the number of protocols in the pool, the more time Mutant must explore to find the best protocol at a given step of the algorithm. We evaluate how the number of protocols in the pool impacts the performance of Mutant on a cellular link in terms of throughput over time, reporting results in Figure 7. While it benefits the exploration of more protocols, we found that with more than $k = 8$, performance degrades without improving, even with more time to explore.



We then test each resulting configuration across all network scenarios and collect the average throughput and delay. We present the overall performance in Figure 8 in terms of *best reward rate*, namely the number of times Mutant results in the top 10% of the best-performing protocols for a given network environment.

Finally, to underline the importance of selecting the best-k protocol preliminary (via MPTS), we run the following experiment: we consider six different network environments sampled from the sets in Section 6.1, and three protocol selection strategies: (i) MPTS with $k = 6$, (ii) a random selection of $k = 6$ initial CC schemes and (iii) a mixed selection of CC schemes for each of the following categories: delay-based (Vegas, BBR2), loss-based (Cubic, Westwood), hybrid (Illinois) and specialized (Highspeed, Hybla). Subsequently, we run Mutant with the resulting pool of CC schemes for each selection strategy for 2 minutes on the six network scenarios. In Figure 9, we present the average normalized reward (Equation 1) for the three selection strategies. Interestingly, the selection of the initial pool of schemes significantly impacts the performance of our model. When a diverse set of CC schemes (i.e., protocols of different natures) is considered, Mutant shows a degradation of performance. The takeaway message is that *the efficacy of Mutant is significantly enhanced by an adequate selection of the starting protocols for the specific network environment, and our MPTS algorithm enables consistently high performance across the test scenarios.*

6.4 Fairness and Harm Analysis

In this section, we evaluate the *harm* [50] that a *Mutant* flow, α, causes another flow, β, considered as another congestion control algorithm, e.g., Cubic. As mentioned by Ware et al. [50], *harm* instead of *fairness* is a better performance metric. If the amount of harm caused by flows using a new algorithm γ on flows using an algorithm ω is within a bound derived from how much harm ω flows cause other ω flows, we can consider γ deployable alongside ω. Therefore, we use this metric to show that *Mutant* can be deployed to real-world systems.

Harm, unlike *fairness*, takes into account that different flows can have different demands. As such, for example, a new CC scheme γ competing against a *Reno* flow on a 10Gbps link would not be flagged as *unfair* because it took advantage of the remainder of the link capacity due to the well-known *Reno's* slow additive increase and aggressive reaction to loss [26], which prevents *Reno* from fully utilizing the link. Also, it is

(a) Throughput. (b) Delay.

Figure 10: Mutant's *harm* [50] to other protocols and *self-harm* (right-most bars) is consistently low, meaning that the protocol *fairness* and *friendliness* are high when competing with other protocols or against other Mutant instances.

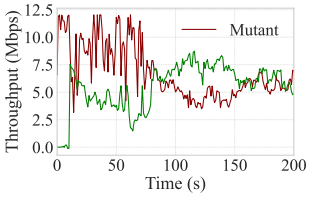


Figure 11: Friendliness competing with a Cubic flow.

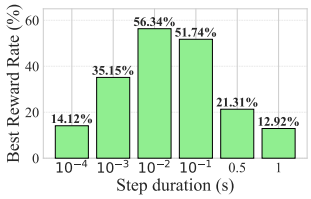

Figure 12: Impact of the step duration δ.

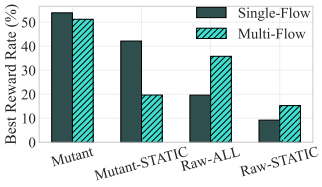

Figure 13: Impact of different groups of input features.

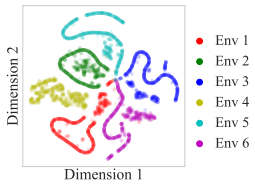

Figure 14: t-SNE [49] of the embeddings extracted from the last layer of the encoder.

multi-metric. It is not based solely on throughput unlike Jain's Fairness Index (JFI) [27]. On the contrary, it also considers performance metrics like latency, flow completion time, etc.

Much like *fairness*, *harm* ranges from [0 - 1] where 1 is maximally harmful and 0 is harmless. We use the following equations to calculate the *harm*, h, caused by *Mutant's* on another CC scheme. For metrics where "more is better" (like throughput), we use $h_t = \frac{x-y}{x}$, where x is the solo performance of β without α and y is the performance of β after the introduction of α. While for metrics where "less is better" (like latency or loss), we use $h_d = \frac{y-x}{y}$ to calculate *harm*.

We evaluated the harm of *Mutant* when competing with other flows. In Figure 10, we report the performance in terms of throughput and delay, where Mutant is used in competition with different CCAs. We also assess the protocol's self-harm. In particular, we tested some protocols in Mutant's pool on an emulated cellular link. First, we run each CC scheme individually in a single-flow scenario (i.e., without interference from Mutant's flow). Then, we run Mutant concurrently with a flow using a different CC scheme to observe their competition. Our results reveal that *Mutant* is friendly (i.e., causes minimal harm) to all the other protocols, with a negligible influence on the flows of other protocols, by just looking at the h_t and h_d values. From these experiments, we can see how, in addition to being friendly, Mutant also has high self-fairness i.e., it minimally harms other Mutant instances.

Additionally, we provide a sample of the Mutant's behavior when competing with a Cubic's flow in Figure 11 on a cellular link. It is worth noticing how Mutant learns to adapt to the new flow and converge to a fair share over time. This is due to the fact that even though Equation 1 does not explicitly include a fairness term, Mutant has the capability to penalize any unfair protocol behavior and promptly switch to an alternative one in response to a sudden surge in packet loss - which is accounted for in the formulation. Over time, Mutant converges to the fair share of the link capacity to maximize the reward.

6.5 Ablation Study

In this section, we validate some of the main Mutant's components and their impact on its overall behavior. First, as Mutant's switching logic is a core feature of the system, we study the impact of different values of δ (i.e., the switching frequency). Second, we evaluate the importance of input features in the online learning process. In particular, we validate the impact of mapping the network features into the latent space. Third, we study the encoder's ability to identify different network conditions.

Impact of switching frequency. We start analyzing the performance of different values of the step duration δ, i.e. the time interval a CC scheme in the pool runs before the next action of the RL algorithm is performed. We report in Figure 12 the *best reward rate* across all our network test environments - i.e., the number of times Mutant results in the top 10% of the best-performing protocols for a given environment. As emerging from the graph, *Mutant benefits from high-frequency transitions between schemes in the pool, instead of selecting a single protocol for extended duration.*

Input Features. To evaluate the effect of different input feature strategies, we run an experiment for single and multi-flow environments to examine the following input feature configurations: Mutant-STATIC, Raw-ALL, and Raw-STATIC. Mutant-STATIC excludes all mean, minimum, and maximum statistics from the input feature set. Raw-ALL removes the encoder from Mutant's workflow and directly feeds the network features into the learning model. Raw-STATIC eliminates both the encoder and the mean, minimum, and maximum statistics. Figure 13 exhibits that Mutant benefits from input features represented in the latent space. These results also reflect Mutant's behavior when only a partial set of features is input to the encoder: indeed, without any historical information given by the different observation windows, there is a clear performance degradation.

Quality of the embeddings. We present a t-Distributed Stochastic Neighbor Embedding (t-SNE) [49] analysis (a

popular technique employed to visualize high-dimensional data) to validate further the importance of encoding the input network features in Mutant. Figure 14 shows such a two-dimensional t-SNE representation of the embeddings in six random network scenarios sampled from the test set indicated in Section 6.1. This visualization highlights that our encoder sharply separates different network scenarios in the latent space, helping Mutant detect diversities among states.

7 Related Work

The problem of congestion control has been extensively discussed in the literature, given its importance for reliable data transmissions. While congestion control has been a popular research topic for over 30 years, new recent solutions have employed machine learning-based algorithms to overcome the limitations of traditional approaches. In the following, we describe how machine learning (ML) has been helpful and how we differ from these recent solutions.

Since TCP congestion control is a fundamental service, it is not surprising that significant improvements and variations have been proposed over the years. Among them, we can mention TCP Vegas [13], Fast [30], BBR [15], and Compound [47]. Several other protocols focus on data centers, e.g. Data Center TCP (DCTCP) [3], but those are not the focus of our approaches. Data centers have been recently departing from TPC-based solutions, moving towards service meshes. Past congestion control protocols have been classified according to the metric they consider. Delay-based protocols consider *rtt* and/or average delivery rate measurements to decide how fast data should be sent over the network. BBR [15], e.g., belongs to such class and is considered to be resistant to the bufferbloat problem, but it frequently exceeds the link capacity, causing excessive queuing delays. On the other hand, loss-based protocols rely on indications of lost packets, and most of the traditional approaches, e.g., Compound [47] and Cubic [25], rely on some predefined functions or rules to handle network conditions.

However, all these solutions are limited by their nature of fixed-rule strategies, and their performance is limited in networks that require rapid adaptations. To address this problem, a plethora of online learning congestion control protocols have appeared, e.g., Remy [52], Performance-oriented Congestion Control (PCC) [21], PCC-Vivace [22], Copa [5]. After defining an objective function to be optimized, the process consists of learning the best actions to take either periodically or upon receiving ACKs.

This learning process can be further optimized by the advances in ML, and in particular in reinforcement learning (RL). RL has permeated many congestion control mechanisms, such as Orca [2], Owl [43], SPINE [48], and Aurora [28]. While Aurora is built upon the previous PCC protocol and then extended with a Deep-RL approach, Owl and Orca extend the Cubic implementation by adding an RL learning model that can work even in unexplored conditions. SPINE, instead, follows the additive-increase/ multiplicative-decrease (AIMD) approach of Cubic, but the parameters of the increment and decrement are the output of the RL model. As these papers, our protocol also leverages past solutions to combine the classical approach with advanced DRL techniques, but with a novel twist. Prior learning solutions suffer from design suboptimalities. If, on the one hand, delay-based protocols cannot avoid starvation, an extreme form of unfairness, in paths with excessive delay variations [4], loss-based ones suffer the bufferbloat problems. To solve this tussle, we bank on the idea there is no one-size-fits-all protocol, as learned from decades of designing congestion control protocols. Our design is based on the notion of learning from existing protocols, and predicting which protocol (set) would perform best in future seen network and congestion scenarios.

The idea of switching among available CCs has been floated before [38, 55, 56]. With them, we share the idea of learning from existing protocols; however, we differ in several ways from these solutions. Firstly, Mutant is not reliant on a data-driven offline procedure, meaning that its learned congestion control policy can adjust to different network conditions over time. Secondly, Mutant can adapt quickly to changes in the network environment with minimal offline adaptations, as its main functions run online. Finally, Mutant can smoothly transition between different CC protocols in the kernel space, regardless of the flow duration, while preserving past TCP information and states for each protocol during the change.

8 Conclusion

In this paper, we presented the design, implementation, and evaluation of *Mutant*, a congestion control scheme that learns from a pool of existing congestion control algorithms online. *Mutant*'s online learning algorithm understands which current state-of-the-art congestion control algorithm can perform well in the near future. Our evaluation shows that our solution can adapt to different network congestion scenarios efficiently if it has the correct pool of CC schemes to learn from. Perhaps surprisingly, we found that more knowledge in terms of protocol choices may hurt performance, given the explorative nature of the protocol. Mutant obtained high throughput and low delays more consistently than our benchmark CC protocols across different network conditions. Additionally, we evaluated *Mutant* fairness by measuring the harm index. Our results confirmed that *Mutant* is fair and causes negligent harm and self-harm to other flows.

Appendix

A MPTS Proof

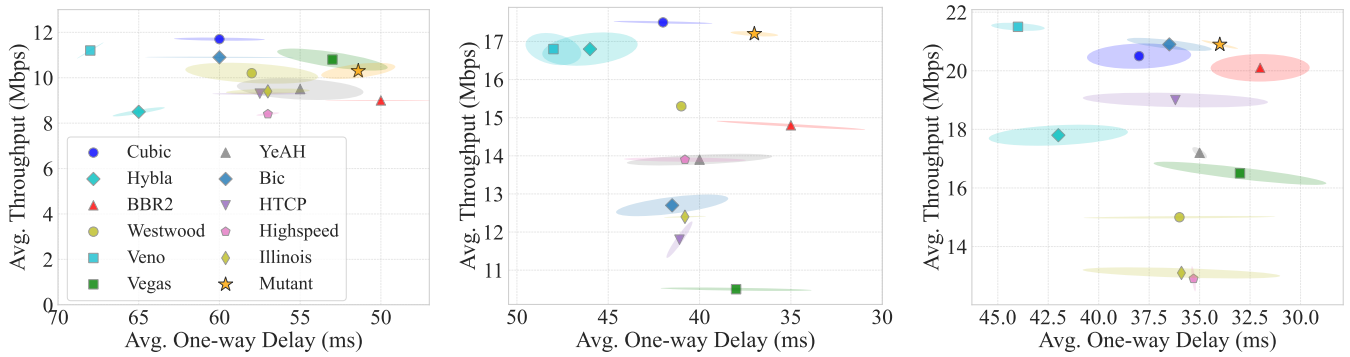
Proof Sketch of Theorem 5.1.

Proof. Let's consider the event ξ defined as:

$$\xi = \{\forall i \in \{1,...,n\}, j \in \{1,...,n-1\}, \left|\frac{1}{n_j}\sum_{s=1}^{n_j} X_{i,s} - \mu_i\right| \leq \frac{1}{4}\Delta^i_{(n+1-j)}\}; \quad (7)$$

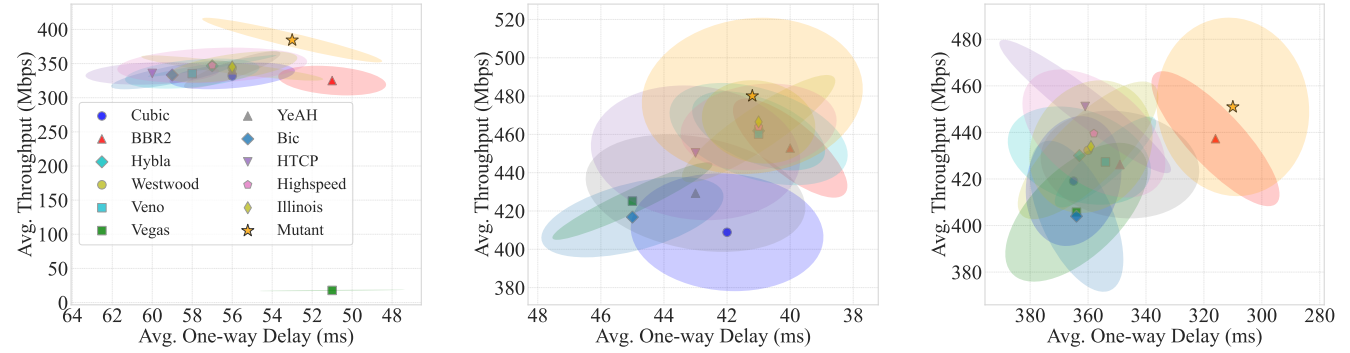
by Hoeffding's inequality and a union bound, the probability of the complementary event $\overline{\xi}$ is bounded by inequality:

$$\begin{aligned}\mathbb{P}(\overline{\xi}) &\leq \sum_{i=1}^{n}\sum_{j=1}^{n-1}\mathbb{P}\left(\left|\frac{1}{n_j}\sum_{s=1}^{n_j} X_{i,s} - \mu_i\right| > \frac{1}{4}\Delta^i_{(n+1-j)}\right) \\ &\leq \sum_{i=1}^{n}\sum_{j=1}^{n-1} 2\exp\left(-2n_j\left(\frac{\Delta^i_{(n+1-j)}}{4}\right)^2\right) \\ &\leq 2n^2\exp\left(-\frac{T-n}{8\overline{\log}(T)H_2^k}\right).\end{aligned} \quad (8)$$



The last inequality is a direct conclusion from the fact that:

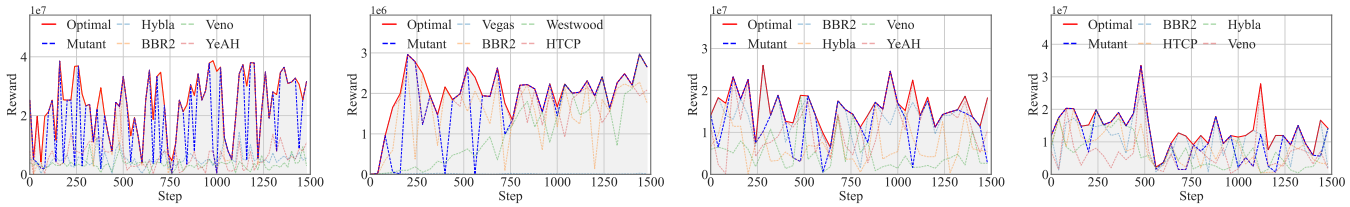
$$\begin{aligned}n_j\left(\Delta^i_{(n+1-j)}\right)^2 &\geq \frac{T-n}{\overline{\log}(T)(T+1-j)\left(\Delta^i_{(n+1-j)}\right)^{-2}} \\ &\geq \frac{T-n}{\overline{\log}(T)H_2^k}.\end{aligned} \quad (9)$$



It is therefore sufficient to show that on event ξ, the algorithm does not make any error. This conclusion can be proved by induction on j. □

B More on Mutant's Performance

Mutant demonstrates higher performance across a wide range of network conditions in terms of both throughput and delay. We extended our evaluation to include additional cellular traces (Figure 15), encompassing both LTE and 5G networks with different ranges of bandwidth, where data are sampled from [2] and [6], respectively. Mutant consistently ranks among the top-performing protocols across diverse scenarios and shows its ability to adapt and maintain optimal performance.



(a) cellular link 4 (Walking in Times Square) (b) cellular link 5 (Bus Riding) (c) cellular link 6 (Stationary Times Square)

(d) 5G cellular link 4 (Corniche) (e) 5G cellular link 5 (Corniche Walking) (f) 5G cellular link 6 (City Drive)

Figure 15: Average throughput and one-way delay over different real cellular network traces.

(a) 5G Cell. (Beach Stat.) (b) 5G Cell. (Beach Stat. 2) (c) 5G Cell. (City Drive) (d) 5G Cell. (Park Stationary)

Figure 16: Performance comparison of Mutant against individual protocols in four distinct 5G cellular scenarios. Mutant's reward performance is also against an idealized system that always chooses the "optimal" protocol.

In Figure 16, we report the reward of our Mutant protocol across four distinct high bandwidth 5G cellular scenarios. The reward function follows Equation 1. We compare Mutant's reward against an optimal system, which selects the best-performing protocol at each step of the run, and the reward of each of the CCAs in the pool. The pool of best-performing protocols is selected via the MPTS algorithm with $K = 4$. Our Mutant model was then trained to convergence and subsequently tested on network traces for 1500 steps and $\delta = 10^{-2}$ (see Section 6.1) in each scenario. We observe that Mutant, consistently achieves high rewards, demonstrating its adaptive capability by dynamically selecting the best-performing protocol at each step and for every network trace It is worth noting that the occasional dips in Mutant's performance, which correspond to intentional exploration (hence suboptimal) steps, are the only instances where it deviates from the optimal choice. However, these exploration phases enable Mutant to continually evaluate and adapt to potential changes in network conditions.

CATO: End-to-End Optimization of ML-Based Traffic Analysis Pipelines

Abstract

Machine learning has shown tremendous potential for improving the capabilities of network traffic analysis applications, often outperforming simpler rule-based heuristics. However, ML-based solutions remain difficult to deploy in practice. Many existing approaches only optimize the predictive performance of their models, overlooking the practical challenges of running them against network traffic in real time. This is especially problematic in the domain of traffic analysis, where the efficiency of the serving pipeline is a critical factor in determining the usability of a model. In this work, we introduce CATO, a framework that addresses this problem by jointly optimizing the predictive performance and the associated systems costs of the serving pipeline. CATO leverages recent advances in multi-objective Bayesian optimization to efficiently identify Pareto-optimal configurations, and automatically compiles end-to-end optimized serving pipelines that can be deployed in real networks. Our evaluations show that compared to popular feature optimization techniques, CATO can provide up to 3600× lower inference latency and 3.7× higher zero-loss throughput while simultaneously achieving better model performance.

1 Introduction

Machine learning (ML) models have grown to outperform traditional rule-based heuristics for a variety of traffic analysis applications, such as traffic classification [36, 44], intrusion detection [73], and QoE inference [15, 47]. Over the past few years, researchers have explored various approaches to developing more accurate models, ranging from better feature selection to employing sophisticated model types and traffic representations [4, 12, 25, 29, 37, 46, 51, 55, 57, 62, 76, 81]. However, the predictive performance of ML-based solutions often overshadows an equally critical aspect—the end-to-end efficiency of the serving pipeline that processes network traffic and executes the model.

For traffic analysis, a significant challenge lies not just in developing accurate models, but in meeting the performance demands of the network. Many network applications must operate in real time with sub-second reaction times and/or process hundreds of gigabits per second of traffic without packet loss [72]. Unfortunately, models developed without consideration of the associated systems costs of serving them in real networks often turn out to be unusable in practice [14]. Current approaches to this problem typically rely on lightweight models [43], programmable hardware [36, 74], or early inference techniques [11, 54], but many of these unnecessarily compromise on predictive performance [16, 64, 74].

Recent studies have stressed the need to balance both the systems costs and predictive performance of ML-based traffic analysis solutions [14, 64]. However, achieving this balance is difficult. The end-to-end latency and throughput of a serving pipeline, which includes packet capture, feature extraction, *and* model inference, are difficult to approximate without in-network measurements. Furthermore, the search space over optimal feature representations is exponential in the number of candidate traffic features, and also depends on how far into a flow to wait before making a prediction. The added complexity of not just considering one objective, but two, makes end-to-end optimization of such systems an open challenge.

In this work, we present CATO, a generalizable framework that systematically optimizes the systems costs and model performance of ML-based traffic analysis pipelines. We start by formalizing the development of ML models for traffic analysis as a *multi-objective* optimization problem. We then combine multi-objective Bayesian optimization, tailored specifically for traffic analysis, with a realistic pipeline profiler to efficiently construct end-to-end optimized traffic analysis pipelines. CATO simultaneously searches over the selected features and the amount of captured traffic needed to compute those features, factors which have been shown to significantly impact both efficiency and predictive performance [14, 34]. During this search, CATO performs direct end-to-end measurements on the resulting serving pipelines to both *optimize* and *validate* their in-network performance.

We evaluate CATO on live network traffic and offline traces across a range of classification and regression traffic analy-

sis tasks. Our experimental results show that compared to popular feature optimization methods, CATO can reduce the end-to-end latency of the serving pipeline by up to 3600×, from several minutes to under 0.1 seconds, while simultaneously improving model performance. Additionally, CATO can increase zero-loss classification throughput by up to 3.7×.

We hope that our work helps to realize the potential impact of using machine learning to manage and improve networks. Code is available at: https://github.com/stanford-esrg/cato.

2 Background and Motivation

The networking community has long attempted to use machine learning (ML) to perform traffic analysis tasks like QoE inference [15, 26, 39, 47, 48], traffic classification [36, 44, 65], intrusion detection [73], and load balancing [18]. As traffic increasingly becomes encrypted, ML has also been shown to be a promising technique for understanding otherwise opaque network traffic, replacing traditional deep packet inspection and other rule-based heuristics [12, 53, 63].

While significant progress has been made in improving the predictive capabilities of models used for traffic analysis [12], the real-world deployability of a model is based not just on conventional notions of ML performance (e.g., accuracy, F1 score), but also on the associated systems-level performance (e.g., latency, throughput) of the entire serving pipeline [14]. Given the real-time demands of network operations, any applications that rely on ML must nonetheless operate within tight performance budgets. Even small delays can cause substantial packet loss and render a model ineffective [15, 31], making systems performance even more crucial for traffic analysis. As a result, ML-based traffic analysis cannot solely target high predictive performance—the end-to-end efficiency of the entire serving pipeline must be jointly optimized as well.

2.1 ML-Based Traffic Analysis

ML-based traffic analysis typically begins with the ingestion of raw traffic and ends with a prediction of a traffic property, such as a service quality metric. While traffic analysis applications are diverse, we focus on the class of problems that involves per-flow or per-connection inference, such as traffic/device classification, QoE inference, or intrusion detection. These applications typically make a prediction about an entire flow or connection, then initiate an action such as triggering an alert, blocking or rerouting the flow, or performing further analysis downstream (Figure 1).

Traffic inference extends beyond merely executing the model; it also involves packet capture, connection tracking, flow reassembly, and feature extraction. Raw traffic undergoes multiple operations, including header parsing, computation, and encoding before arriving at the representation that is used as input to the model. The final model inference step makes the prediction, with its predictive performance determined

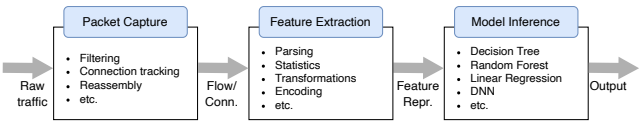

Figure 1: A typical serving pipeline for ML-based traffic analysis. Usability of a model hinges on both its predictive accuracy and the systems performance of the entire pipeline.

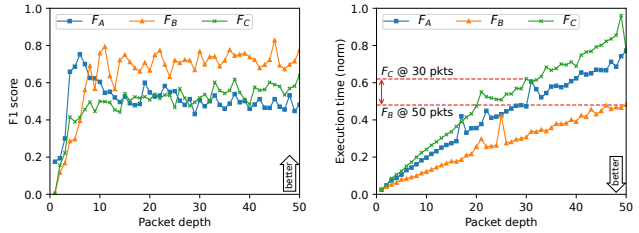

by the model type (e.g., random forest, neural network), the computed features, and the amount of data captured from the flow. The end-to-end systems performance depends on *all* of these aspects together.

For traffic analysis in particular, the choice of features computed from the network traffic is often as important, if not more so, than the model itself [29, 34, 55]. While many previous works have focused on the model inference stage [43, 46, 57, 64, 74, 81], design decisions made in the earlier stages of the serving pipeline are crucial to its performance and practicality, and warrant careful consideration.

Optimizing Predictive Performance. Many techniques have been proposed to accurately make predictions about network traffic. These approaches range from popular feature selection methods that choose highly predictive features based on summary statistics [51], packet lengths [11], timing [37], and/or frequency domain characteristics [25], to new techniques like GGFAST [55], which generates specialized "snippets" to classify encrypted flows.

Following advancements in domains like computer vision and natural language processing, network researchers have also proposed sophisticated deep learning models [46, 57, 81] and traffic representations [29, 62] designed to further optimize the predictive performance of traffic analysis applications. However, most of these machine learning techniques are evaluated using offline packet traces on metrics like accuracy, precision, recall, or F1 score, overlooking the need to both *optimize* and *validate* their in-network systems performance. As a result, ML-based traffic analysis solutions that have been demonstrated to have high accuracy in controlled laboratory experiments often turn out to be unusable in real-time deployments because of the systems costs associated with running them [14].

Optimizing Serving Efficiency. To address the systems requirements of traffic analysis on modern networks, some works propose using lightweight models [43, 74] or choose features that reduce model inference time [69]. However, these techniques can over-compromise on predictive performance for speed, and often overlook the efficiency of other pieces of the serving pipeline like packet capture and feature extraction. Other approaches aim to optimize serving efficiency by making predictions as early as possible [10, 11, 21, 60]. While many traffic analysis solutions implicitly rely on the entire network flow or connec-

(a) Packet Depth vs. F1 Score. The best feature sets differ at varying packet depths.

(b) Packet Depth vs. Exec. Time. It can be cheaper to extract low-cost features at greater depths.

Figure 2: Effects of different (feature set, packet depth) configurations on F1 score and execution time. We highlight the size and complexity of the search space.

tion [7, 9, 15, 40, 62], these "early inference" techniques make predictions after observing a predefined number of packets. However, there is no ideal *packet depth* (i.e., the number of packets to use from any given flow) that is universally effective across applications. Choosing an appropriate value typically requires prior domain-specific knowledge or resorting to manual trial-and-error [54]. Consequently, existing works that do explicitly choose a packet depth often opt for values such as 10, 50, or 100 packets with little justification [5, 29, 30, 45, 50, 55, 56, 64]. As we will show in Section 5.2, this approach can miss significant opportunities for gains in both efficiency and model performance.

2.2 Challenge of End-to-End Optimization

Despite progress towards individually optimizing the predictive performance or serving efficiency of ML-based traffic analysis, improvements to either area in isolation often result in solutions that fail to achieve optimal combined model and systems performance objectives. Systematically designing traffic analysis pipelines that jointly optimize both of these objectives remains an open challenge.

We illustrate this challenge by attempting to design an IoT device classifier using the dataset published by Sivanathan et al. [65]. Our goal is to construct a serving pipeline that is *Pareto-optimal* across both its execution time and F1 score. In other words, it should not be possible to further reduce the execution time without also reducing the F1 score, or vice versa. We combine techniques from prior work by experimenting with different features and early inference, both of which have been shown (and we confirm) to significantly impact multiple aspects of the pipeline, including predictive performance, model inference time, and feature extraction time [14, 34, 51, 54]. For this example, we choose from six candidate flow features (Appendix A, Table 4) and vary the packet depth collected in each flow from 1 to 50, which is consistent with values used in prior work [11, 45, 54, 55]. We train the model, compile the complete serving pipeline, and exhaustively measure the F1 score and execution time for all $2^6 \times 50 = 3{,}200$ (feature set, packet depth) combinations.

As seen in Figure 2, F1 score and execution time vary with the chosen features and packet depth. For readability, we plot only three (labeled $F_A/F_B/F_C$) out of the 64 possible feature sets, but find qualitatively similar results across those not shown. We can see in Figure 2a that the best feature sets by F1 score differ dramatically at different packet depths. While F_A has the highest F1 score within the first 10 packets, the ranking flips at higher packet counts. Interestingly, the predictive performance of F_B and F_C increase with packet depth, whereas the opposite is true for F_A. In Figure 2b, we observe that for the *same* feature set, execution time generally increases with packet depth. However, the overall cost of waiting 50 packets to extract F_B is lower than the cost of waiting 30 packets for F_C. This reveals that having the flexibility to optimize the timing of feature extraction can significantly enhance serving efficiency, but is not always as straightforward as simply minimizing analyzed packets. If we look across both figures, we see that over-optimizing on execution time can also adversely affect F1 score and vice versa. The non-linear trade-offs between objectives further highlight the challenge in identifying Pareto-optimal solutions without exhaustive measurement.

The trade-offs between predictive performance and systems costs form a multi-dimensional and multi-objective search space that extends beyond merely identifying which features result in more accurate models. It also includes considerations for features that are efficient to extract, as well as how much data must be captured to compute and represent the features. While exhaustive measurement of end-to-end systems costs and model performance is feasible for just six candidate features, it quickly becomes impractical when scaling up to the dozens to hundreds of flow features typically considered by developers. In our example, it took 5 days to train, compile, and measure all 3,200 serving pipelines, but it would take over 7,000 years with 25 candidate features. The size and complexity of the search space, coupled with the need to consider and validate both model performance and systems cost objectives, makes end-to-end optimization challenging. Addressing this challenge is the central contribution of our work.

3 Cost-Aware Traffic Analysis Optimization

We introduce CATO (Cost-Aware Traffic Analysis Optimization), our solution for cost-aware ML-based traffic analysis optimization. The goal of CATO is to automatically construct traffic analysis pipelines that jointly minimize the end-to-end systems costs of model serving while maximizing predictive performance. At its core, CATO combines a multi-objective Bayesian optimization-guided search with a novel pipeline generator and feature representation profiler to produce serving pipelines suitable for deployment in real networks.

Symbol	Description
$\mathcal{F}$	Set of candidate network flow features
N	Maximum connection depth
$\mathcal{P}(\mathcal{F})$	Power set of $\mathcal{F}$
$\mathbb{X}$	Search space defined as $\mathbb{X} = \mathcal{P}(\mathcal{F}) \times N$
F	Set of features in a feature representation
n	Connection depth from which F is extracted
x	Feature representation $x = (F, n)$
$\texttt{cost}(x)$	Systems cost objective function
$\texttt{perf}(x)$	Predictive performance objective function
Γ	Set of Pareto-optimal solutions

Table 1: Summary of Variables

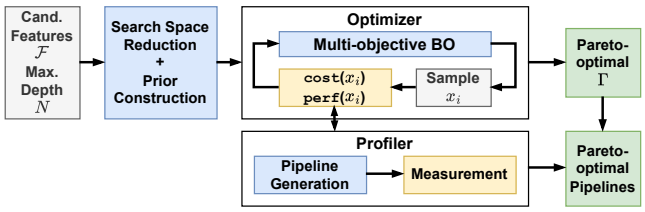

Figure 3: CATO combines a multi-objective BO-based Optimizer and a realistic pipeline Profiler to construct and validate efficient ML-based traffic analysis serving pipelines.

3.1 Problem Definition

CATO takes as input a set of candidate network flow features, denoted by $\mathcal{F}$. In line with conventional machine learning practice, these are typically derived from domain expertise or determined by the capabilities of the traffic collection tool. Common examples for traffic analysis include mean packet size, bytes transferred, connection duration, etc. [51], but can also include more complex features like frequency domain [25,77] and application-layer characteristics [15]. CATO also takes as input a maximum connection depth $N \in \mathbb{R}$, which serves as an *upper bound* on the amount of data in the connection that is considered for inference. Concretely, this can be the number of initial packets (i.e., packet depth), bytes, or time into the connection prior to feature extraction. These inputs define the *search space* $\mathbb{X} = \mathcal{P}(\mathcal{F}) \times N$, where $\mathcal{P}(\mathcal{F})$ is the power set of $\mathcal{F}$, i.e., the set of all possible subsets of $\mathcal{F}$, from which CATO selects feature representations.

A *feature representation* $x = (F, n)$ consists of a set of features $F \subseteq \mathcal{F}$ and a value $n \leq N$ that indicates the connection depth from which F is extracted. Each feature representation gives rise to a serving pipeline with an associated end-to-end systems cost and predictive performance, denoted by the functions $\texttt{cost}(x) : \mathbb{X} \to \mathbb{R}$ and $\texttt{perf}(x) : \mathbb{X} \to \mathbb{R}$. We note that these functions are general and can be user-defined according to the specific objectives of the traffic analysis problem. For instance, $\texttt{cost}(x)$ can refer to the end-to-end inference latency, execution time, (negative) throughput, etc., while $\texttt{perf}(x)$ can be defined as F1 score, accuracy, (negative) mean-squared-error, etc. We list a summary of variables in Table 1.

Multi-objective Optimization. We formalize the development of ML models for traffic analysis as a multi-objective optimization over the search space $\mathbb{X}$. The aim is to identify the Pareto front $\Gamma \subseteq \mathbb{X}$, which consists of all non-dominated points in $\mathbb{X}$. In other words, Γ contains the maximally desirable feature set / connection depth configurations, where no further improvement in systems cost or model performance can be achieved without compromising the other objective.

We deliberately choose a multi-objective optimization over a single-objective approach. Unlike a single-objective problem that aims to maximize model performance while satisfying system constraints, or vice versa, a multi-objective solution offers several advantages. The first is that the exact system and model performance requirements may not be known a priori (e.g., due to variable traffic rates or shared system resources), making it difficult to precisely define constraints. Second, if requirements change, a single-objective approach would necessitate redefining and rerunning the optimization with new objectives and constraints [68]. By expressing the problem as a multi-objective optimization, CATO identifies multiple Pareto-optimal solutions that each achieve a different balance between systems cost and model performance, providing the flexibility to accommodate changing application needs (e.g., adjusting accuracy thresholds or imposing new latency constraints) without re-optimization.

3.2 CATO Overview

CATO constructs end-to-end optimized traffic analysis pipelines according to the systems cost and model performance objective functions. It does so by efficiently identifying Pareto-optimal feature representations, and generating ready-to-deploy serving pipelines for a given model from those feature representations. Figure 3 depicts the high-level design, which consists of the Optimizer and the Profiler:

- The Optimizer takes the set of candidate features and maximum connection depth, and performs a multi-objective Bayesian optimization-guided search over the feature representation space. It periodically queries the Profiler for the systems costs and model performance of its sampled feature representations, which it uses to further refine the search for the Pareto front.
- The Profiler accepts queries from the Optimizer, compiles binaries for the end-to-end serving pipeline, and runs them to accurately measure $\texttt{cost}(x)$ and $\texttt{perf}(x)$. These measurements serve the dual purpose of guiding the Optimizer towards Pareto-optimal solutions and validating the in-network performance of the generated pipelines.

3.3 The CATO Optimizer

In general, measuring $\texttt{cost}(x)$ and $\texttt{perf}(x)$ for an arbitrary feature representation is computationally expensive. It involves generating the serving pipeline, training and evaluating the ML model, and measuring performance costs either through simulation or in physical testbeds. The massive size

of the search space and the computational cost of evaluating the objective functions precludes the possibility of exhaustively searching all possible configurations. To handle this intractability, CATO leverages Bayesian Optimization (BO), building on recent developments in multi-objective design space exploration [52] and sample-efficient BO [32] to efficiently estimate the Pareto front in $\mathbb{X}$.

Why Bayesian Optimization? Bayesian optimization is a technique designed for global optimization of black-box objective functions [35], and has seen success in domains like hyperparameter tuning [66, 70], compiler optimization [28, 52], and robotics [17]. It is particularly useful for expensive-to-evaluate, non-linear objectives, as in our case with $\texttt{cost}(x)$ and $\texttt{perf}(x)$. Moreover, the discontinuous nature of these objective functions make the use of traditional gradient-based or linear optimizers a poor fit for our problem.

BO works by building a probabilistic surrogate model for the objective function(s), and uses it to make decisions about which points (e.g., feature representations) in the search space to evaluate next. Typically, BO begins by sampling an initial number of points at random to build the surrogate model. Each subsequent iteration involves generating a set of candidate points, using the surrogate model to predict the objective function's output on the candidate set, and choosing the next "best" (e.g., maximizing Expected Improvement) point to evaluate using the real objective function. The surrogate model is then updated to include the newly evaluated point, and the process repeats until some stopping criteria is met, such as a maximum number of iterations or a satisfactory level of convergence [24, 35]. While BO is not guaranteed to work well in high-dimensional, multi-objective spaces [61], we describe how we augment it for our context later in this section. We compare the performance of BO against other search techniques in Section 5.3 and show that our approach is efficient at approximating the Pareto front.

BO Formulation. We formulate CATO's search process as a multi-objective Bayesian optimization problem with $|\mathcal{F}|+1$ dimensions: one dimension per feature in $\mathcal{F}$ and one for the connection depth n. Each feature parameter is represented by a binary indicator variable, which denotes whether or not the feature is included. The connection depth parameter is separately encoded as an integer or real-valued variable upper bounded by the maximum connection depth N. This setup lets CATO *concurrently* search over both features and connection depth while optimizing for systems cost and model performance. We define this search as a minimization of the two functions $\texttt{cost}(F,n)$ and $-\texttt{perf}(F,n)$. These objective functions are managed by the Profiler (Section 3.4), which generates complete serving pipelines according to the feature representations sampled by the Optimizer, and returns the end-to-end systems cost and model performance metrics.

Tailoring BO for Traffic Analysis. In its basic form, BO has several limitations. Conventional applications of BO typically involve single-objective, low-dimensional (fewer than 20) search spaces [24, 61]. However, our traffic analysis problem is inherently multi-objective, high-dimensional, and involves a complex search space with mixed categorical (features) and numerical (connection depth) variables. To address this, we augment the CATO Optimizer with two preprocessing techniques to improve its sample efficiency (Figure 3). The first is a dimensionality reduction step that strategically discards candidate features that are unlikely to improve the model's predictive performance regardless of its impact on the end-to-end systems costs. By default, we exclude features with a mutual information [71] score of zero, which indicates no direct informational relationship with the target variable.

The second technique incorporates prior probabilities into the BO formulation, accelerating the search by providing the Optimizer with "hints" about the approximate locations of Pareto-optimal feature representations. To account for both objectives, CATO constructs two sets of priors: one over the feature space that targets $\texttt{perf}(x)$, and one over the connection depth that targets $\texttt{cost}(x)$. The set of priors over the feature space encodes each feature's relative contribution to the model's performance, and are derived from the mutual information scores computed in the dimensionality reduction step. Formally, we define the prior probability of whether a feature f is part of a Pareto-optimal feature representation $x=(F,n)$ as $\mathbb{P}(f \in F | x \in \Gamma) = (1-\delta)\frac{I(f)}{I_{max}} + \frac{\delta}{2}$, where $I(f)$ represents the mutual information of f with respect to the target variable, I_{max} is the maximum mutual information among all candidate features, and δ is a damping coefficient. The damping coefficient is used to adjust the priors to prevent the feature with the highest mutual information from always being included. $\delta = 0$ signifies no damping, while $\delta = 1$ results in uniform priors for all features. These probabilities encourage CATO to more frequently explore regions of the search space that include features with higher predictive power.

The prior over the connection depth is represented by a probability mass function that decays linearly as the connection depth increases. The rationale is that for the same feature set, waiting longer to capture more packets or bytes before feature extraction correlates with worse systems performance. This prior encourages CATO to more frequently explore representations that require fewer packets or less data, despite not requiring domain-specific knowledge about the optimal connection depth at which to collect features. As we will show in Section 5.5, CATO is robust to reasonably large connection depth ranges.

We emphasize that these preprocessing steps can be performed efficiently without needing to evaluate the objective functions. Despite the term "prior," no prior knowledge about the optimal features or connection depth needs to be supplied by the user. CATO automatically derives the priors used to accelerate its search, thereby streamlining its usability.

3.4 The CATO Profiler

The CATO Profiler evaluates the feature representations sampled by the Optimizer based on the concrete definitions of $\texttt{cost}(x)$ and $\texttt{perf}(x)$. To accomplish this, it generates code for the packet capture and feature extraction stages of each sampled point, trains the model, and runs the full serving pipeline to *directly measure* its end-to-end systems costs and model performance. This measurement serves two purposes: (1) guiding the search process of the Optimizer, and (2) validating the in-network performance of identified solutions.

Why Measure? Using heuristics to estimate the end-to-end systems cost of a traffic analysis pipeline is difficult. Much like how existing heuristics that approximate model performance often fail to capture interdependencies and correlations among features [6, 34, 71], systems cost heuristics can similarly fail to capture the complexities of packet capture and feature extraction. Traffic analysis is particularly sensitive to this, since the processing steps during feature extraction often overlap in non-trivial ways. For instance, computing mean TCP window size and the number of ACKs sent in a connection require parsing each packet down to its TCP header, a shared task that must be factored into the end-to-end cost. Likewise, computing the mean window size also involves calculating its sum, the latter of which can then essentially be used for free. Other factors like resource contention and characteristics of the network traffic (e.g., bursty vs. non-bursty) can also unpredictably affect the end-to-end systems cost [58].

We argue that rather than trying to model or predict these complex systems-level interactions, it is both more accurate and useful to perform direct measurement. With direct measurement, CATO captures the actual end-to-end cost of the serving pipeline, encompassing all critical components including packet capture, feature extraction, and the model inference itself. Accurate measurement not only helps the Optimizer make well-informed decisions, but also helps users build confidence in validating whether identified solutions are operationally viable. Although this approach can be computationally expensive, the cost of training the model, generating the full serving pipeline, and measuring its performance is balanced by the sample efficiency of the Optimizer.

Pipeline Generation. To evaluate different feature representations during the search process, we require an *automated* way to measure $\texttt{cost}(x)$ and $\texttt{perf}(x)$ for any $x \in \mathbb{X}$. With a search space size of $O(2^{|\mathcal{F}|} \times N)$, manually implementing packet capture, feature extraction, and model inference for each evaluated point is impractical. One approach that enables flexible evaluation is "runtime branching," which uses branching logic at runtime to determine which paths in the code should be executed to extract a given feature representation. However, runtime branching introduces additional overhead that can contaminate the cost measurements of performance-sensitive traffic analysis pipelines. Instead, CATO employs *conditional compilation* to build and run customized end-to-end serving pipelines tailored to each configuration. The resulting binary matches the performance of a manually implemented pipeline, containing only the set of operations needed to collect traffic data up to the specified connection depth, extract the corresponding features, and execute the model inference. This technique not only constructs fully operational traffic analysis pipelines, but also provides the flexibility to accurately measure any point in the search space.

Pipeline Measurement. CATO presents a testbed interface that replicates a real-world deployment scenario of the pipeline. For model performance measurements, the Profiler trains a fresh model for each representation sampled by the Optimizer and directly measures its predictive performance to account for any interaction effects between features. The final performance metric is derived from a hold-out test set. We note that CATO operates on pre-labeled datasets, meaning it does not focus on automatic labeling or ground truth generation. The framework is designed to optimize model accuracy and system performance based on this labeled input. For systems cost measurements, CATO either simulates traffic inputs from the training data, or, when feasible, deploys the full serving pipeline in its target network environment (e.g., a passive monitoring or bump-in-the-wire deployment model) for end-to-end measurements. While each measurement can be expensive, the Optimizer is intentionally designed to minimize the number of measurements needed to approximate the Pareto front. We report wall-clock times for several of our evaluated use cases (Section 5.1) in Appendix E.

4 Implementation of CATO

We detail our implementation of CATO, covering the Optimizer, Profiler, model training, and objective functions.

Bayesian Optimization. We implement the CATO Optimizer using HyperMapper [52], a Bayesian optimization framework for design space exploration. HyperMapper supports multi-objective optimization with mixed-variable search spaces, but is not tailored specifically for high-dimensional BO. We use πBO [32] for prior injection, but adapt its implementation to incorporate CATO-generated priors in multi-objective use cases. We use a random forest as the surrogate model, which has been shown to perform well compared to more traditional Gaussian processes for discontinuous and non-linear objective functions [52]. The prior over the packet depth is constructed using the Beta distribution with $\alpha = 1$ and $\beta = 2$. We initialize the Optimizer with three iterations of random search space exploration and choose $\delta = 0.4$ based on empirically tuned values (Section 5.5).

Pipeline Generation. The CATO Profiler generates serving pipelines using a modified version of Retina [72], a Rust framework that compiles traffic *subscriptions* into efficient packet processing pipelines. A subscription defines the rules for how incoming traffic should transformed into a specific

```
1  fn on_packet(&mut self, packet: Packet) {
2      #[cfg(any(feature="iat_sum"))]
3      {
4          let pkt_timestamp = packet.timestamp();
5          self.iat_sum += pkt_timestamp - last_timestamp;
6          let last_timestamp = pkt_timestamp;
7      }
8      #[cfg(any(feature="ttl_min",feature="winsize_max"))]
9      let eth = packet.parse_eth();
10     #[cfg(any(feature="ttl_min",feature="winsize_max"))]
11     let ipv4 = eth.parse_ipv4();
12     #[cfg(any(feature="ttl_min"))]
13     self.ttl_min = self.ttl_min.min(ipv4.ttl());
14     #[cfg(any(feature="winsize_max"))]
15     {
16         let tcp = ipv4.parse_tcp();
17         self.winsize_max = self.winsize_max.max(tcp.winsize());
18     }
19 }
20
21 fn extract(&mut self) -> Vec<f64> {
22     vec![
23         #[cfg(feature="iat_sum")]
24         self.iat_sum,
25         #[cfg(feature="ttl_min")]
26         self.ttl_min,
27         #[cfg(feature="winsize_max")]
28         self.winsize_max,
29     ]
30 }
```

Figure 4: An example portion of the CATO Profiler's template subscription module. Each operation is predicated on its associated features and conditionally compiled with the `cfg` macro. For instance, if the evaluated feature set consists of `ttl_min` and `winsize_max`, then only lines 9, 11, 13, 16, and 17 will execute on each new packet, and only those two features will be extracted in the final feature representation. This enables dynamic cost profiling that matches the characteristics of a manually implemented feature extraction stage.

representation, and invokes a callback on the returned data. We implement the model inference stage in the callback, and subscribe to a template feature representation that can be modified at compile-time to the specific representation being evaluated. To dynamically generate the custom packet capture and feature extraction stages, we create a Retina subscription module that implements the processing steps needed to extract *all* candidate features. Each operation (e.g., parse an IPv4 header, add to a cumulative sum of packet inter-arrival times, etc.) is then annotated with a configuration predicate that specifies the subset of features necessitating its execution. If the feature representation being evaluated contains at least one of the predicated features, the predicate evaluates to true and the operation is conditionally compiled into the binary. This technique avoids redundant computation in shared steps, such as parsing headers, and ignores operations associated with features that are not included. For packet capture, we annotate the subscription with an early termination flag that stops data collection once the connection depth is reached.

Figure 4 shows pseudo-code for an example portion of the template subscription module. We implement 67 candidate features (Appendix A, Table 4) in 1,600 lines of Rust code. We note that the chosen candidate features are not specific to any use case: they are widely used in traffic analysis applications and are common features exposed by open source tools [3, 15, 16, 23, 51, 64, 72, 77]. We use number of packets into the connection to measure connection depth.

We note that our Profiler implementation uses Retina [72] to target commodity servers. However, CATO's core design principles remain applicable to optimizing and validating hardware-based traffic analysis pipelines, which we discuss further in Section 6.

Model Training. As an optimization framework, CATO is general to the specific type of model used in the traffic analysis pipeline. We implement support for three model types: decision trees (DT), random forests (RF), and deep neural networks (DNN). For DT and RF, we use scikit-learn's DecisionTreeClassifier and RandomForestClassifier, with 5-fold nested cross validation and grid search for hyperparameter tuning. We tune the maximum tree depth from 3–20 and set the number of estimators to 100 for RF. To match the speed of the Rust-based feature extraction stage, we retrain the best-performing DT and RF models in Rust using the SmartCore [1] library and evaluate the final Rust model on a hold-out test set containing 20% of the data.

For DNN, we implement a fully connected feedforward neural network in TensorFlow, consisting of three hidden layers with ReLU activation and L2 regularization. We apply dropout to prevent overfitting and use the Adam optimizer for training. Since Rust lacks mature DNN libraries, we train and evaluate the DNN models entirely in Python/TensorFlow. Additional details are provided in Appendix C.

Objective Functions. We use end-to-end inference latency, zero-loss classification throughput, and pipeline execution time as three different metrics for systems cost. End-to-end inference latency measures the duration from the arrival of the first packet in the connection to the model's final prediction. This includes the time spent extracting features from raw traffic, the model inference time, and time spent waiting for packets to arrive. Zero-loss throughput is the highest ingress traffic rate that can be sustained by the serving pipeline with no packet drops, which we negate to match the sign of $\texttt{cost}(x)$ minimization. The execution time measures the total CPU time spent in the serving pipeline, excluding time between packets. This metric is less dependent on the specific characteristics of the input traffic, and is an indirect measure of both latency and throughput. Although these can be combined into a single cost metric, we evaluate them separately to show CATO's flexibility. Depending on the traffic analysis use case, which we detail in the next section, we use either the F1 score or root-mean-squared error, calculated from the predictions on the hold-out test set as the model performance metric.

5 Evaluation

We evaluate CATO over a variety of configurations and use cases. Section 5.1 details our datasets and testbeds. In Section 5.2, we show that CATO can help traffic analysis applications achieve substantially lower inference latency and higher

Use Case	Type	Traffic	Model
app-class	Classification	Live	Decision Tree
iot-class	Classification	Dataset	Random Forest
vid-start	Regression	Dataset	Deep Neural Network

Table 2: Evaluation Use Cases

throughput without compromising model performance, and in many cases improve upon both metrics. We also compare it with Traffic Refinery [14], a recent system for cost-aware ML on network traffic. Section 5.3 compares the efficiency of the CATO Optimizer to alternative Pareto-finding approaches, and Section 5.4 performs an ablation study of the Profiler. In Section 5.5, we run micro-benchmarks on CATO's sensitivity to various search space sizes and hyperparameters.

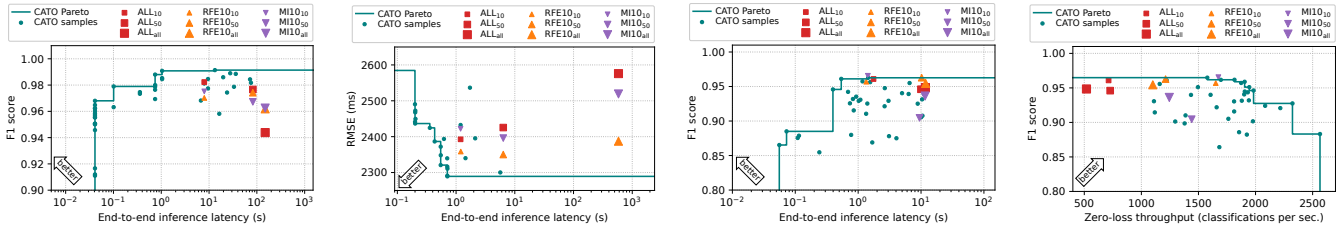
5.1 Datasets and Testbeds

We consider three use cases in our evaluations: web application classification (app-class), IoT device recognition (iot-class), and video startup delay inference (vid-start). These are typical analysis tasks of varying complexity that are representative of the type of ML-based inference performed on network traffic. Table 2 summarizes them, with more details provided in Appendix B.

Web Application Classification. While open-source traffic classification datasets exist, replaying them at modern line rates is challenging without duplicating flows. To evaluate serving pipelines against real traffic at high speeds, we develop a use case that identifies one of six common web applications from live traffic on a large university network. This type of classification is typically used by web application firewalls or in the early stages of network QoE inference pipelines [2, 15]. For ground truth, we label connections using the server name in the TLS handshake. We train and evaluate decision tree models using flow statistics captured from the network, then deploy them to the same network for real-time serving using Retina [72].

IoT Device Recognition. To help make our results reproducible, we also consider an IoT device recognition use case based on the dataset published by Sivanathan et al. [65]. We use a random forest to classify connections as belonging to one of 28 IoT device types. Although real-time throughput experiments are not feasible without duplicating flows, we use this dataset to report micro-benchmarks and evaluate CATO's ability to approximate the true Pareto front.

Video Startup Delay Inference. We further demonstrate CATO's generalizability to different traffic analysis tasks and model types through a regression use case that predicts the startup delay of video streams. Startup delay inference is widely used in analysis of encrypted video traffic as a measure of QoE [8, 15, 49]. We choose startup delay (rather than other QoE metrics) to provide a regression task that complements the previous two classification use cases. We also adopt a more complex DNN instead of a tree-based model, using the YouTube dataset published by Bronzino et al. [15].



5.2 Model Serving Performance

We first examine the end-to-end inference latency, zero-loss throughput, and predictive performance of CATO-optimized serving pipelines. Note that CATO itself is not a classifier, but a general framework for optimizing ML-based serving pipelines for real-time traffic analysis. Therefore, instead of directly comparing CATO with existing classifiers or models, we evaluate it against optimization strategies commonly used in prior work to build those models. We use the following feature optimization methods and combine them with early inference techniques as our baselines:

- ALL: Use all available features.
- RFE10: Select the top ten features by recursive feature elimination [27]. RFE trains a model using all available features, then iteratively removes the least important feature and retrains until the desired number remains.
- MI10: Select the top ten features based on mutual information [71]. This is a model agnostic algorithm that measures how much information each feature contributes to the target variable and picks the most relevant ones.

Prior traffic analysis solutions typically wait until the end of the connection before making a prediction [7, 9, 15, 40, 62] or use a fixed packet depth for early inference [5, 10, 11, 29, 45, 50, 56]. For example, Peng et al. [54] collects up to the first 10 (including TCP handshake) packets, while recent work like GGFAST [55] use the first 50. For a thorough analysis, we compare against these strategies by running each baseline at packet depths of 10, 50, and all packets. CATO does not assume a predefined optimal packet depth, but searches over the entire feature representation space as part of its optimization process. We choose a maximum packet depth of 50 and run for 50 iterations, which is consistent with common machine learning practices [13, 32]. We show how CATO reacts to different packet depth ranges in Section 5.5.

End-to-End Inference Latency. Figures 5a, 5b, and 5c show the end-to-end inference latency and predictive performance (F1 score or RMSE) for iot-class, vid-start, and app-class, respectively. Each CATO sample represents a candidate point explored during the optimization process, with CATO's Pareto front constructed from the set of non-dominated points. For iot-class and vid-start, all points on CATO's Pareto front dominate the baseline solutions, achieving equal or better predictive performance with lower end-to-end latency. For iot-class, CATO can reduce the inference latency by 11–79× compared to solutions that use the first 10 packets in the connection, 817–2000× compared to those that use the first 50, and over 3600× (from several minutes to under 0.1 seconds) compared to those that wait until the end of the connection. Likewise for vid-start, CATO generates solutions that can infer video startup delays

(a) `iot-class` latency (b) `vid-start` latency (c) `app-class` latency (d) `app-class` throughput

Figure 5: Comparison of F1 score / RMSE vs. end-to-end inference latency / zero-loss throughput (single-core) for `iot-class`, `vid-start`, and `app-class` serving pipelines. CATO identifies multiple solutions on its Pareto front that dominate those found by traditional optimization techniques, and can achieve significantly better systems and predictive performance.

in less than one second (a 2.2–2900× speedup, depending on baseline) while also reducing the mean squared error of its predictions.

Since end-to-end inference latency is largely dominated by packet inter-arrival times, this improvement can be attributed to CATO's ability to find alternative sets of features using the fewest packets necessary without compromising the predictive performance of these popular feature selection methods. For example, RFE10 using the first 10 packets (RFE10_{10}) in `iot-class` achieves an F1 score of 0.970 with an inference latency of 7.9 seconds. However, CATO identifies a different set of features using just the first 3 packets for a better F1 score of 0.979 and an inference latency of 0.1 seconds.

We find a similar pattern for `app-class`, where CATO-optimized pipelines outperform most baseline methods across both objectives. While MI10_{10} and RFE10_{50} achieve slightly higher F1 scores (0.963 and 0.962), CATO produces a solution with a nearly identical F1 score (0.960) and a latency of 0.54 seconds—2.6× and 19× faster than MI10_{10} and RFE10_{50}, respectively. These results reinforce that for traditional feature optimization methods, it is not always clear a priori which feature set at which packet depth results in the best model performance or serving efficiency. Through end-to-end optimization of both objectives over the entire feature representation space, CATO is able to automatically derive and validate the performance of faster and more accurate traffic analysis pipelines.

Zero-Loss Classification Throughput. We compare the predictive performance and classification throughput of solutions found by CATO with those found by the baseline methods for `app-class`. We exclude `iot-class` and `vid-start` due to limitations in replaying the traces at high speeds without repeating flows. For a realistic assessment, we use live traffic from our campus network, but restrict all experiments to a single core to avoid saturating our network's maximum ingress throughput. In an actual deployment scenario, the throughput can be easily scaled up by adding more cores, owing to the per-core scalability of Retina [72]. More details about our throughput experiments can be found in Appendix D.

Figure 5d shows that CATO's solutions outperform the baselines in both throughput and F1 score, with the exception of MI10_{10}. Despite this, CATO successfully identifies the feature representation with the highest overall F1 score and the one with the highest zero-loss throughput. For a decrease in F1 score from 0.96 to 0.93, CATO can increase throughput by 37%. Compared to solutions that wait until the end of the connection, CATO can improve the zero-loss throughput by a factor of 1.6–3.7×, and 1.3–2.7× for those that require the first 50 packets while also achieving higher model performance. Notably, CATO achieves these results after exploring just 50 feature representations out of $2^{67} \times 50 = 7 \times 10^{21}$ (67 candidate features, up to a maximum packet depth of 50).

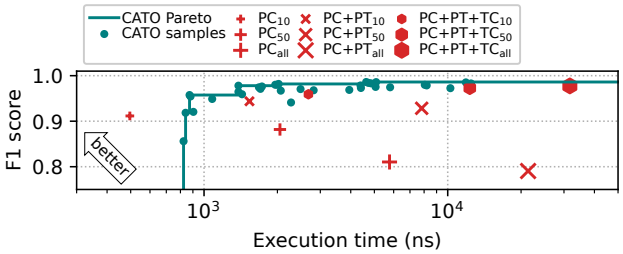


Figure 6: F1 score vs. pipeline execution time for `iot-class` using CATO and Traffic Refinery (in red). While PC_{10} achieves a strong trade-off due to its low cost, CATO more consistently finds solutions closer to the Pareto front.

Comparison with Traffic Refinery. We further compare CATO with Traffic Refinery [14], a recent traffic analysis framework that also facilitates joint evaluation of model performance and system costs. Unlike CATO, Traffic Refinery requires manual exploration of flow features and connection depth. We simulate Traffic Refinery's cost profiler using CATO's execution time cost metric and replicate its built-in packet counter (PC), packet timing (PT), and TCP counter (TC) feature classes. While Traffic Refinery defaults to making an inference after ten seconds into the flow, we evaluate it at packet depths of 10, 50, and all packets for consistency with the above baselines (see Appendix F for more details).

Figure 6 plots F1 score vs. execution time for `iot-class`

using CATO and Traffic Refinery. The results show that Traffic Refinery's macro-aggregation of standard feature classes is less efficient than CATO at finding optimal trade-offs. CATO achieves better accuracy at lower cost across all sampled points except PC_{10}. Even in this case, it is still able to identify an alternative representation with a similar F1 score and a modest 344 ns increase in pipeline execution time. While packet counters alone at a packet depth of 10 happen to perform well for `iot-class` at minimal cost, adding packet timing and TCP state information further improves accuracy but incurs a much higher execution time. Identifying such configurations with Traffic Refinery requires trial-and-error, as it is not clear which combinations perform best at which packet depths. In contrast, CATO more efficiently explores the feature representation space, clustering solutions closer to the Pareto front and more effectively balancing predictive performance and systems cost across a broader range of configurations.

5.3 Optimizer Efficiency

In this section, we evaluate the efficiency of the CATO Optimizer by measuring the quality of its computed Pareto front and the speed at which it converges to the true Pareto front. Since it is infeasible to exhaustively measure all points in $\mathbb{X}$ to obtain the true Pareto front for the default candidate feature set size of 67, we evaluate on a smaller candidate set of six features (Appendix A, Table 4) for the `iot-class` use case in order to obtain the ground truth. We compare the Optimizer with three alternative Pareto-finding algorithms:

- SIMA: Use simulated annealing [38], a metaheuristic for solving optimization problems with a complex search space. We provide details of our multi-objective implementation in Appendix G.
- RAND: Sample a random subset of features at a random packet depth without replacement.
- ITERALL: Use all available features but increment the packet depth on each iteration, starting from one.

We remark that these algorithms differ from the baseline methods described in the previous section in that they attempt to estimate the Pareto front rather than a single point solution. In N search iterations, each of these alternative approaches makes exactly N calls to $\texttt{cost}(x)$ and $\texttt{perf}(x)$.

Pareto Front Quality. We compare the quality of the Pareto front estimated by each algorithm using Hypervolume Indicator (HVI). HVI is a common metric used to compare multi-objective algorithm performance, and measures the area between the estimated Pareto front and the true Pareto front bounded by a reference point [41]. We use pipeline execution time as our chosen systems cost metric and F1 score for model performance. Since F1 score and execution time have different raw value ranges, we normalize the data before computing HVI to assign similar importance to both objectives.

We run each search algorithm for 50 iterations at a maximum packet depth of 50. In Figure 7, we plot the feature representations sampled at each iteration alongside the corresponding Pareto front constructed from the non-dominated points. These sampled points represent candidate solutions explored during optimization and do not directly impact the end-to-end traffic analysis pipeline. While many intermediate samples overlap between algorithms due to inherent randomness, they primarily serve to illustrate the regions explored by each algorithm and are not included in the final solution. For reference, we also show the true Pareto front computed from exhaustively measuring all $2^6 \times 50 = 3{,}200$ feature representations in the search space.

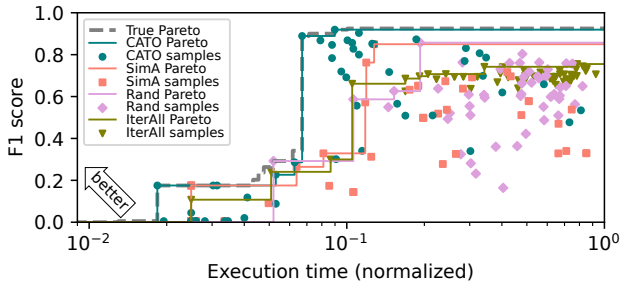

Figure 7: Estimated Pareto fronts after 50 iterations. CATO outperforms other Pareto-finding approaches, especially in regions with high F1 scores and low execution times. The sampled points illustrate the candidate solutions explored by each algorithm during the optimization process, while only the Pareto-optimal points are included in the final output.

We observe that CATO's Pareto front closely approximates the true Pareto front while sampling less than 1.6% of the search space. Using a worst-case reference point (F1 score of 0 and normalized execution time of 1), CATO achieves an HVI of 0.98, compared to 0.88, 0.86, and 0.77 achieved by SIMA, RAND, ITERALL, respectively. We note that CATO does not entirely dominate all alternative search algorithms, especially around F1 scores of 0.3. However, it performs better at higher and lower extremes. This behavior can be attributed to CATO's tendency to explore representations that require very few packets (due to the decay-shaped prior placed over connection depth), while also injecting priors based on each feature's relative importance. If we only consider solutions with an F1 score of at least 0.8, the HVI is 0.95 for CATO, 0.39 for SIMA and RAND, and 0 (no solutions found) for ITERALL.

Convergence Speed. Figure 8 compares the sample efficiency of CATO with alternative search algorithms. We extend the 50 sample explorations commonly used by ML practitioners [13, 32] to 1,500 to examine the convergence rate towards the true Pareto front as most of the search space is explored. We also plot the performance of CATO's baseline BO formulation without dimensionality reduction and prior injection (CATOBASE). We exclude ITERALL from

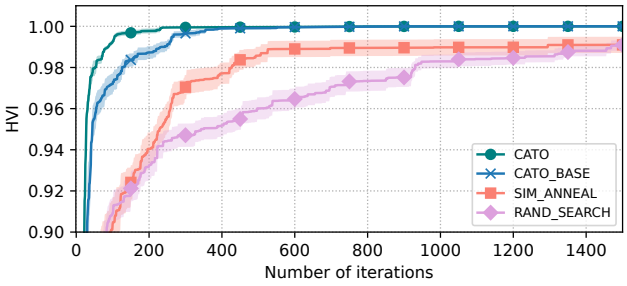

Figure 8: CATO efficiently converges to the true Pareto front. We show the mean and standard error of the HVI with a worst-case reference point across 20 runs.

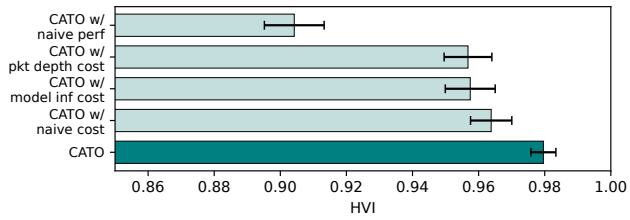

Figure 9: CATO with alternative Profiler metrics. End-to-end measurements prove useful for estimating the Pareto front and validating the performance of identified solutions.

this analysis since more than 50 iterations would exceed the maximum packet depth covered by the ground truth Pareto front. Moreover, we find that the HVI for ITERALL does not show significant improvement beyond this point.

We can see that CATO converges to the true Pareto front fastest, demonstrating a more sample-efficient approach to optimizing ML-based traffic analysis pipelines. CATO surpasses 0.99 HVI (using a worst-case reference point) within 87 iterations on average compared to CATOBASE's 240 iterations, demonstrating a speedup of 2.76×. This speedup can be attributed to the incorporation of priors on the optimization parameters as described in Section 3.3, which helps CATO emphasize more promising regions in the search space. SIMA and RAND are less sample efficient, surpassing 0.99 HVI at 1,295 iterations and 1,469 iterations for a CATO speedup of 14.9× and 16.9×, respectively.

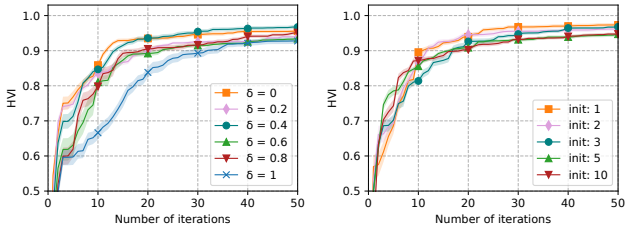
5.4 Ablation Study of the Profiler

We assess the impact of the Profiler on the estimated Pareto front found by CATO. We retain the Optimizer, including dimensionality reduction and prior injection, and perform an ablation study by replacing $\texttt{cost}(x)$ and $\texttt{perf}(x)$ measurements with heuristic metrics. We devise four variants of CATO. The first is CATO W/ NAÏVE COST, which replaces the original cost metric with the sum of the costs of each feature in isolation. This design captures the end-to-end systems costs of individual features, but fails to account for shared processing steps during packet capture and feature extraction. The second is CATO W/ MODEL INF COST, which measures the model inference speed but ignores the cost of packet capture and feature extraction. CATO W/ PKT DEPTH COST directly uses packet depth as the cost. CATO W/ NAÏVE PERF retains the original $\texttt{cost}(x)$ metric but replaces $\texttt{perf}(x)$ with the sum of each feature's mutual information with respect to the target variable. This version does not account for the effects of feature interactions.

We run each variant for 50 Optimizer iterations using the smaller candidate feature set, then measure (using the Profiler) the true $\texttt{perf}(x)$ and $\texttt{cost}(x)$ of each sampled point in a post-processing step to compare HVI. Figure 9 reveals that CATO comes closest to the true Pareto front, demonstrating that there is value to incorporating real model performance and systems costs measurements as feedback for the Optimizer. Furthermore, we note that none of the variants provide a means to *validate* the expected in-network performance of their identified solutions. In particular, CATO W/ NAÏVE PERF and CATO W/ PKT DEPTH COST do not yield meaningful performance metrics. CATO W/ NAÏVE COST and CATO W/ MODEL INF COST are better, but may overestimate or underestimate the true systems cost, respectively. Depending on the concrete definition of $\texttt{cost}(x)$, this could lead to the deployment of an unrealizable model (e.g., by overestimating the throughput or underestimating the latency of the pipeline).

5.5 Microbenchmarks

In this section, we evaluate CATO's robustness to varying search space sizes and its sensitivity with respect to its BO initialization and damping coefficient hyperparameters.



Varying Maximum Connection Depth. Previously, we showed that CATO is highly effective across both large (67) and small (6) candidate feature sets, but limited the search space to a maximum connection depth of 50 packets. Here, we explore the impact of maximum connection depth and the size of the search space on CATO's ability to identify Pareto-optimal feature representations.

In general, limiting the search space inherently restricts the number of possible feature representations, potentially compromising the quality of the estimated Pareto front. Conversely, expanding the search space offers a richer set of feature representations, but makes locating the true Pareto front more challenging. Table 3 shows CATO's performance across different maximum packet depths for `iot-class` using the full 67 candidate features. Since it is difficult to compare HVI across configurations without a ground truth, we report metrics for the estimated Pareto-optimal representations with the highest F1 score and lowest overall execution time.

We can see that restricting the packet depth to very small values (e.g., less than 5) limits CATO's ability to find a so-

Max Depth N	Highest F1 Score n	F1 score	Time (μs)	Lowest Execution Time n	F1 score	Time (μs)
3	3	0.959	1.37	1	0.310	0.2
5	4	0.983	1.30	1	0.520	0.26
10	7	0.994	2.04	1	0.520	0.26
25	7	0.989	2.61	1	0.520	0.26
50	7	0.993	2.10	1	0.461	0.27
100	10	0.990	3.01	1	0.005	0.24
∞	42k	0.984	28.2	52k	0.944	16.5

Table 3: Estimated Pareto-optimal solutions with the highest F1 score and lowest execution time for different maximum packet depths. CATO is able to identify high quality solutions, even when expanding the maximum connection depth.

(a) Damping coefficient δ. (b) BO initialization samples.

Figure 10: Effects of varying the damping coefficient and the number of samples used to initialize the BO surrogate model.

lution that yields an F1 score above 0.99, likely because not many feature sets can achieve such high model performance using only the first few packets in a flow. However, if we expand the search space to include features extracted from *up to* the first 10–100 packets, CATO is still able to identify feature sets that only need the first 7–10 packets to achieve good model performance despite the larger maximum packet depth. However, if the search space over packet depth is unbounded, CATO struggles converge to a feature representation with low cost since the Optimizer has too much flexibility to explore any value between 1 and the maximum number of packets across *all* flows in the training set. These results reinforce that concurrently searching over different features and when to collect those features, rather than predefining a fixed connection depth, can lead to more optimal traffic analysis pipelines. CATO can identify highly efficient and predictive feature representations within a wide range of connection depths, even without prior knowledge of its optimum.

Sensitivity Analysis. We analyze the sensitivity of CATO with respect to its hyperparameters. We again use the smaller candidate feature set to measure HVI against the true Pareto front with a worst-case reference point. Figure 10a shows the impact of varying the damping coefficient δ between 0 and 1. Recall that $\delta = 0$ represents a prior probability equivalent to the normalized mutual information, while $\delta = 1$ represents uniform priors for each feature. Using uniform priors performs the worst with an HVI of 0.93 after 50 iterations. With less damping, CATO converges faster in earlier iterations. We find that a $\delta = 0.4$ results in the highest performance at 50 iterations, while $\delta = 0$ also performs well overall.

In Figure 10b, we vary the number of samples used to initialize the BO surrogate model. Initialization samples are chosen at random but weighted according to the priors. We observe little difference in CATO's performance for small initialization values, but find that initializing with just 1 point empirically results in the highest HVI after 50 iterations. We choose to go with a more conventional value for BO [35], and choose 3 initialization samples by default.

6 Related Work

Efficient Inference. Several systems have been proposed for efficient traffic analysis inference. However, many of these efforts focus only on increasing the speed of the final model inference stage, rather than that of the end-to-end serving pipeline [22, 43, 69]. Such approaches overlook the effects of the packet capture and feature extraction stages, both of which CATO considers in its end-to-end optimization. AC-DC [34] and pForest [16] are similar in that they explicitly consider the preprocessing costs of extracting features. AC-DC performs inference under dynamic memory constraints while pForest targets programmable hardware. Both of these differ from CATO in that they generate pools of models and dynamically switch between them based on inference requirements.

There is a growing body of research that proposes the use of programmable hardware for traffic analysis [9, 16, 33, 36, 59, 64, 67, 68, 74, 75, 80, 82]. For example, N3IC [64] uses binary neural networks to implement traffic analysis models on FPGAs and SmartNICs, while BoS [75] enables RNN inference on programmable switches. These approaches focus on the trade-off between accuracy and efficiency of the *model* under the constraints of dataplane hardware, such as limited memory and lack of support for floating-point operations, multiplications, and loops. Our work, by contrast, focuses on the choice of *traffic* representation—spanning both feature selection and connection depth—to co-optimize systems performance and predictive accuracy. CATO can complement hardware-focused techniques: by applying the CATO Optimizer and extending our Profiler implementation to target programmable hardware, we can identify traffic representations that are cheaper to collect while also validating the end-to-end performance of the hardware pipeline. This combined strategy can further boost the efficiency and predictive performance of ML-based traffic analysis, which we leave for future work.

Balancing Systems and Model Performance. There exist general-purpose serving frameworks that aim to balance efficiency with model performance through techniques like caching [20], adaptive model selection [20, 58], autoscaling [19, 58, 78], and scheduling for resource-quality tradeoffs [42, 79]. Unlike CATO, these frameworks primarily fo-

cus on optimizing resource allocation and are less suited for real-time traffic analysis, where even small inefficiencies in end-to-end systems performance can cause not just delayed results, but also potentially invalidate the model due to packet loss. Additionally, CATO explicitly considers the optimal point in the flow (i.e., connection depth) for making predictions, which previous frameworks do not address. Traffic Refinery [14] considers joint optimization of model and system performance for ML-based network traffic analysis. However, it relies on manual exploration of data representations and focuses only on individual feature costs, whereas CATO performs automated end-to-end optimization of the entire analysis pipeline.

Bayesian Optimization for Traffic Analysis. Bayesian Optimization is a popular technique for compiler optimization [28], FPGA design [52], and hyperparameter tuning [66, 70], but has seen limited use in optimizing ML-based traffic analysis pipelines. Most similar is Homunculus [68], which uses Bayesian optimization to generate ML models for datacenter network applications under the resource constraints of data-plane hardware. Homunculus optimizes over different model architectures and their hyperparameters, but is single-objective and does not consider the effects of different feature sets, connection depths, and their associated systems costs. CATO, on the other hand, uses multi-objective BO over the entire feature representation space to simultaneously optimize serving efficiency and predictive performance.

7 Conclusion

In this work, we introduced CATO, a framework for end-to-end optimization of ML-based traffic analysis pipelines. By leveraging multi-objective Bayesian optimization coupled with a realistic pipeline generator and profiler, CATO efficiently builds and validates serving pipelines that balance both model accuracy and systems performance. Our evaluations on live traffic and offline traces showed that CATO can improve end-to-end inference latency, throughput, and pipeline execution time across diverse traffic analysis tasks, while also maintaining or enhancing model performance. Future work includes broader model selection strategies and extending performance profiling across heterogeneous serving hardware.

A Candidate Features

Table 4 lists the set of candidate features used in our evaluations. We aggregate common network flow features used throughout networking research for ML-based traffic analysis [3, 15, 16, 51, 64, 68, 72]. These are also commonly supported by open source tools, and are not specific to any particular use case. However, for privacy reasons related to our live traffic experiments, we restrict these to various types of summary statistics to avoid saving packet payloads to disk.

B Dataset Collection

All experiments with live traffic are performed on a server running Ubuntu 20.04, with a dual Xeon Gold 6248R 3GHz CPU, 384 GB of memory, and a 100GbE Mellanox ConnectX-5 NIC. All experiments using offline datasets are performed on a server with a dual Xeon Gold 6154 3GHz CPU and 384 GB of memory, running Ubuntu 20.04.

Web Application Classification. For `app-class`, we classify the following applications: Netflix, Twitch, Zoom, Microsoft Teams, Facebook, Twitter, or "other." Connections are labeled using the SNI from the TLS handshake, and only statistical features listed in Table 4 are collected (see Appendix H for ethical considerations involving live traffic). We

Table 4: Candidate feature set $\mathcal{F}$ containing 67 commonly used flow features. We indicate the six that are used in the smaller candidate set for ground truth analyses.

use Retina [72] for data collection, which we run for 30 seconds with 12.5% flow sampling, and an additional 10 minutes with 50% flow sampling filtered on the target applications to help collect a more balanced dataset. Flow sampling reduces the effective ingress network throughput while maintaining per-connection consistency, and is done entirely in the NIC using hardware filters [72]. We avoid collecting at full network throughput to ensure that no packets are dropped in the data collection phase. In total, we collected 2M samples of connection data over 50 different packet depths.

IoT Device Recognition. For `iot-class`, we classify one of 28 IoT device types using the UNSW IoT dataset [65]. We use the September 2016 traces in our evaluations, which include approximately 134K connections. Models are trained and evaluated using data from eight days of packet traces.

Video Startup Delay Inference. We use the dataset collected by Bronzino et al. [15] for `vid-start`, focusing exclusively on YouTube traffic, where each video session consists of a single TCP connection. The final dataset comprises 4,287 connections, capturing a wide range of startup delay times. Delay times range from 315 ms to 54 seconds at P99, with the maximum observed delay being 14 minutes.

C Model Training

For DT and RF model training, we use scikit-learn's DecisionTreeClassifier and RandomForestClassifier with default parameters and tune the maximum tree depth from the set {3, 5, 10, 15, 20}. The RandomForestClassifier is configured with 100 estimators. To integrate with the Rust-based packet capture and feature extraction stages, the tuned DT and RF models are retrained in Rust using the SmartCore [1] library.

DNN hyperparameters are tuned over the following values: batch size {16, 32, 64}, learning rate {0.001, 0.01}, dropout rate {0.2, 0.4, 0.6, 0.8}, L2 regularization {0.1, 0.5}, and number of neurons in each hidden layer {4, 8, 16}.

D Measurement Details

End-to-End Inference Latency. We implement two versions of inference latency measurement, depending on the use case. For `app-class`, we record the arrival timestamp of the SYN packet, and subtract it from the timestamp of the final prediction output by the model. Since we do not have access to live traffic from the `iot-class` dataset, we compute the end-to-end inference latency by taking the sum of the pipeline execution time, model inference time, and packet inter-arrival times up to the specified connection depth. The inter-arrival times are calculated from packet timestamps in the traces.

Zero-Loss Throughput. Since we are unable to control the input traffic rate on our live network, we choose to restrict our serving pipelines to a single core to differentiate the performance of each optimization method. This ensures that we

can find an upper bound on the throughput since no solution will be able to saturate the input traffic rate. To measure the zero-loss throughput, we leverage Retina's flow sampling capabilities by starting at the full traffic rate and slowly decreasing the percentage of flows randomly dropped by the NIC until we observe zero packet loss for 30 seconds. We repeat this for multiple trials and take the average zero-loss throughput sustained by the traffic analysis pipeline.

Execution Time. Pipeline execution time is a measure of total CPU time spent in the serving pipeline, excluding time spent waiting for packets to arrive. We measure this by inserting calls to query the Read Time-Stamp Counter register at the start and end of each packet processing step and the model inference stage.

E Optimization Wall-Clock Time

Wall-clock time depends heavily on the application use-case, model type, number of samples explored, and the concrete definitions of $\texttt{cost}(x)$ and $\texttt{perf}(x)$. For reference, Table 5 reports the breakdown in time elapsed for CATO to compute the Pareto fronts depicted in Figure 5d and Figure 7, which target different use cases and system cost metrics. As expected, execution time is mostly consumed by the Profiler, which, on each iteration, generates a fresh serving pipeline, trains and evaluates the model, and measures the end-to-end systems costs. We deem this a worthwhile trade-off because the time spent by the Profiler to validate the systems cost of each sampled solution ensures that the resulting Pareto-optimal pipeline can meet real-time performance requirements. The BO-guided sampling that determines the next feature representation for the Profiler to evaluate adds between 1.4 and 55 seconds per iteration depending on the search space.

F Reproducing Traffic Refinery

We reproduce key components of the Traffic Refinery [14] framework for evaluation. Traffic Refinery defines several feature classes that contain features commonly used in ML-based traffic analysis. Specifically, we replicate the PacketCounter (PC), PacketTiming (PT), and TCPCounter (TC) feature classes using subsets of our candidate feature set. PC includes all packet and byte counters, PT includes all packet inter-arrival statistics, and TC includes all flag counters, window size statistics, and RTT. We simulate using Traffic Refinery by manually aggregating feature classes, varying the packet depths, and measuring the predictive performance and pipeline execution time using CATO's Profiler. While Traffic Refinery also has the ability to profile state and storage costs, we focus on execution time in our evaluation since it is a shared cost metric in both frameworks.

Use case / # cand. features **Systems cost metric:**	`app-class` / 67 zero-loss throughput	`iot-class` / 6 processing time
Preprocessing	22.4 s	4.1 s
Opt. Iteration (50×)		
BO sample	55.5 s	1.4 s
Pipeline generation	53.1 s	46.5 s
Measure $\texttt{perf}(x)$	29.6 s	26.4 s
Measure $\texttt{cost}(x)$	546.7 s	70.3 s
Total elapsed	9.5 h	2 h

Table 5: CATO optimization wall-clock times. BO is well-suited for expensive-to-evaluate objective functions, such as $\texttt{perf}(x)$ and $\texttt{cost}(x)$.

G Simulated Annealing Details

We describe our simulated annealing [38] implementation SIMA from Section 5.3. SIMA starts with a random feature representation x as the current "best" point. On each iteration i, it samples a neighbor point x_i and measures $\texttt{cost}(x_i)$ and $\texttt{perf}(x_i)$. Neighbors are sampled by randomly perturbing either the feature set or the packet depth with equal probability:

- Feature set perturbation: Add, remove, or replace a feature at random.
- Packet depth perturbation: Move up to some maximum step size away from the current packet depth, with the maximum step size decreasing linearly from the maximum packet depth as more samples are explored. This allows for more exploration earlier in the search.

Since our optimization is multi-objective, we adjust the standard simulated annealing neighbor acceptance criterion as follows: If the neighboring point dominates the current point across both objectives, it is accepted as the new current point. Otherwise, it is still accepted with probability $\mathbb{P}(x, x_i, T_i) = \exp(f(x) - f(x_i))/T_i$, where $f(x)$ is an equal weighted combination of $\texttt{perf}(x)$ and $\texttt{cost}(x)$, and T_i is the temperature at iteration i. Consistent with simulated annealing algorithms, the temperature gradually decreases as the search space is explored. This mechanism allows for non-dominating solutions to still be accepted with higher probability at the beginning of the search process, preventing SIMA from getting trapped in local minima. We empirically tune SIMA with different initial temperatures and cooling schedules, and choose $T_0 = 1$ and $T_{i+1} = 0.99T_i$.

Figure 8 (Section 5.3) reveals that while SIMA is less sample efficient than CATO, it is generally more efficient than RAND. However, RAND catches up after approximately 1500 sample explorations, likely due to SIMA's reduced ability to explore new feature representations as the temperature decreases.

H Ethical Considerations

As part of our experiments with high-speed network traffic, we evaluated the performance of models against live campus

network traffic. The candidate flow features we use included only aggregate flow statistics and an application name derived from the SNI field in TLS handshakes. We never captured or analyzed client IP addresses, viewed any individual flows or connection records, stored any packets to disk, or investigated human behavior; our IRB has ruled that this type of analysis does not constitute human subjects research. Nonetheless, we took steps to ensure the security and privacy of campus users. All live traffic experiments were isolated to a single hardened server that was deployed in partnership with our campus networking and security teams in order to not increase the attack surface for users.

Resolving Packets from Counters: Enabling Multi-scale Network Traffic Super Resolution via Composable Large Traffic Model

Xizheng Wang[1,2], Libin Liu[2], Li Chen[2], Dan Li[1], Yukai Miao[2], Yu Bai[2]

[1]*Tsinghua University* [2]*Zhongguancun Laboratory*

Abstract

Realistic fine-grained traffic traces are valuable to numerous applications in both academia and industry. However, obtaining them directly from devices is significantly challenging, while coarse-grained counters are readily available on almost all network devices. None of existing work can restore fine-grained traffic traces from counters, which we call network traffic super-resolution (TSR). To this end, we propose ZOOMSYNTH, the first TSR system that can achieve packet-level trace synthesis with counter traces as input. Following the basic structure of the TSR task, we design the Granular Traffic Transformer (GTT) model and the Composable Large Traffic Model (CLTM). CLTM is a tree of GTT models, and the GTT models in each layer perform upscaling on a particular granularity, which allows each GTT model to capture the traffic characteristics at this resolution. Using CLTM, we synthesize fine-grained traces from counters. We also leverage a rule-following model to comprehend counter rules (*e.g.* ACLs) when available, guiding the generations of fine-grained traces. We implement ZOOMSYNTH and perform extensive evaluations. Results show that, with only second-level counter traces, ZOOMSYNTH achieves synthesis quality comparable to existing solutions that takes packet-level traces as input. CLTM can also be fine-tuned to support downstream tasks. For example, ZOOMSYNTH with fine-tuned CLTM outperforms the existing solution by 27.5% and 9.8% in anomaly detection and service recognition tasks, respectively. To promote future research, we release the pre-trained CLTM-1.8B model weights along with its source code.

1 Introduction

Fine-grained traffic traces are valuable to numerous applications in both academia and industry. Packet-level traces can benefit performance evaluation of systems and algorithms in all layers of the networking stack, from packet scheduling to congestion control. Realistic traffic traces are also useful in optimizing various tasks, such as traffic engineering [48], network telemetry [53, 54], anomaly detection [75], and service recognition [27]. However, obtaining fine-grained traffic traces from devices is challenging due to factors such as business confidentiality, device processing/capacity limits, and privacy constraints [77].

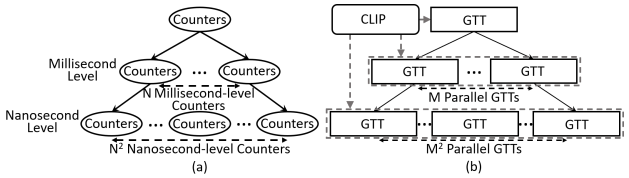

Figure 1: CLTM is a tree of Granular Traffic Transformers (GTTs).

Meanwhile, counters are readily available on almost all network devices and can be collected by network management systems (NMSs) [26, 43] (§2.2). On any network interface, we can easily find counters that accumulate byte-count or packet-count statistics. Counters are usually deeply embedded in the chip registers of the networking hardware; thus, they are high-performance, accurate, and reliable. Networking engineers frequently use them to monitor network behaviors or diagnose failures. But the problem with counters is that they are coarse–grained — the frequency at which NMSs collect them is typically in tens of seconds or even minutes. Without involving deep modification using SDK of the networking chip, a typical operating system of a networking device can only report counters on the scale of seconds. This is far from enough for the collection of packet-level fine-grained traces.

Given the abundance of counter statistics in NMSs and the scarcity of fine-grained traffic traces, we seek to answer a natural research question: *Can we restore fine-grained traffic traces from coarse-grained counters?* Although there have been continuous efforts in the synthesis of packet traces [28, 42, 50, 51, 71, 74, 77], none of them can recreate packet-level traffic from coarse-grained counter statistics.

Recent advances in generative artificial intelligence give us hope: for computer vision, image super-resolution (ISR) is a similar and well-studied task [35, 49]. ISR is the task of recreating high-resolution images (*e.g.* 1080p) from low-resolution ones (*e.g.* 360p), and it has many existing algorithms and models that achieve high-quality results [78, 79].

However, our experiments show that ISR algorithms and models cannot be applied directly to network traffic super-resolution (TSR) (§2.3). We summarize the unique challenges of TSR:

C1 **Input Format**: ISR and TSR work on different domains

of data. A TSR system should take in a time-series (counters), and output a time-series (packets), while an ISR system deals with images (grids of pixels).

C2 **Extreme Upscaling Ratio**: The required upscaling ratio of TSR is many orders of magnitude larger than that of ISR. Packet-level traces have timestamps at resolutions of nanoseconds. To recreate a packet trace from a per-second counter trace, the upscaling ratio is 10^9. In contrast, the maximum ISR upscaling ratio of the popular Stable Diffusion model is only 16 [21].

C3 **Generality**: Network traffic in different network environments, such as the Internet, data centers, and access networks, exhibits diverse characteristics. For TSR, even when the coarse-grained traffic statistics remain consistent, the features of the corresponding fine-grained traffic should be different.

In addition, we define three more design requirements that serve to broaden our scope of application.

R1 **Multi-scale Synthesis**: Some downstream tasks do not require nanosecond-level timestamps, and a coarser-grained trace would suffice. For example, traffic engineering systems do not need traces with granularity of nanoseconds but will benefit if we can upscale a trace's resolution from 1 hour to 1 minute. Thus, we intend to generate traces with different upscaling ratios.

R2 **Understanding Counter Rules**: Due to the finite number of registers in network devices, operators often use user-defined rules (*e.g.* ACL) to specify which flows to track. Understanding the semantic meaning of these rules can guide the TSR to generate traces adhering to the rules. The rules can be accessed by operators from their configuration databases or network devices [76], and shared with researchers anonymously [72].

R3 **Real-time Synthesis**: Recreating high-resolution traffic from counters in real time can enable various downstream tasks such as network telemetry, failure diagnosis, and network digital twins [25].

Clearly, tackling these challenges and requirements simultaneously is ambitious, and an added difficulty is that we also need to design a new base model architecture for TSR, given that the existing models for ISR are unsatisfactory. We draw inspiration from the basic structure of the problem: A coarse-grained trace is the summary of many fine-grained traces. For example, the trace of a second-level counter is the *summary* of ten 100ms-level counters. This summarizing relationship forms a tree structure (Fig. 1), and we design the base model for TSR in the same way, which we name the Composable Large Traffic Model (CLTM).

The core of CLTM is a tree of Granular Traffic Transformers (GTTs). Each layer of the tree consists of the same GTT modules only look at the traffic characteristics at this particular granularity. Concentrating on a particular scaling phase (e.g. 1s to 100ms) better captures the characteristics of traffic at this granularity. For instance, with the same $10\times$ upscaling factor, ten 100ms-level counters generated from a second-level counter may have relatively average values, whereas the subsequent 10ms-level counters may show a more uneven distribution.

With CLTM, we design and implement ZoomSynth, the first network traffic synthesis system that supports TSR. ZoomSynth effectively tackles the aforementioned challenges and meets the specified requirements through a strategic combination of innovative ideas in addition to CLTM. Firstly, the tree of GTTs in CLTM addresses **C1**, **C2**, and **R1**, simultaneously. For **C3**, to adapt to new synthesis scenarios, we incorporate the Low-Rank Adaptation Model (LoRA) [40]. This adaptation model borrows the concept from domain adaptation in large language models (LLMs). Furthermore, we develop a rule-following model based on Contrastive Language-Image Pre-training (CLIP) [59], linking counter rules with the generation of traffic traces, to understand counter rules (**R2**). Finally, to achieve real-time generation (**R3**), we introduce pipeline-parallelism to accelerate CLTM's inference.

In summary, we make the following contributions.

- We illustrate the practical need for TSR and the availability of counters, underscoring the importance of resolving fine-grained traces from coarse-grained counters (§2).
- We design and implement ZoomSynth[1], the first TSR system that facilitates multi-scale TSR based on counters, with counter rules available as optional input (§3, §6).
- We propose CLTM, a novel base model architecture for TSR, which breaks down the TSR process into multiple phases, each employing a GTT tailored to the specific upscaling stage (§4).
- We evaluate ZoomSynth with extensive testbed experiments (§7) and confirm it meets the design goals. Notably, across all distributional metrics and traces [6, 7, 9, 22, 31, 55, 57, 63], ZoomSynth achieves packet trace synthesis with up to 25.8% JSD and 20.1% EMD improvements compared to the state-of-the-art schemes [46, 77]. ZoomSynth can also achieve real-time generation with over one billion packets per second with pipelined inference.

This work raises no ethical concerns. All traces used in this paper contain no personally identifiable information (PII).

2 Background and Motivations

In this section, we first introduce the applications of TSR (§2.1). Then, we demonstrate the wide availability of counters (§2.2) and show that existing approaches cannot be applied to TSR (§2.3). Finally, we motivate the design choices of ZoomSynth for TSR (§2.4).

[1] https://github.com/wxzisk/ZoomSynth_NSDI2025

2.1 Applications of TSR

We believe that any application that requires realistic fine-grained traffic traces can benefit from TSR, because TSR can turn counter traces into fine-grained packet traces, and counter traces are much easier to collect. Previous works [44, 50, 71, 74, 77] have explored a range of applications, including telemetry algorithms, the evaluation of machine learning models [77], and service recognition [46].

Accurate and real-time TSR can also enable new applications. One example is failure diagnosis using counters. Previously, counters could only offer operators a low-resolution view of network state. With TSR, operators can *expand* the counter trace into a high-likelihood packet trace, which can help understand and diagnose network events. TSR is also a potential enabling technology for network digital twins (NDTs) [25]. A major roadblock for NDT is the large amount of data that needs to be transferred from the physical network to the NDT system to realistically recreate the traffic in the digital twin, especially when physical networks today have interfaces $\geq$100Gbps. Using TSR, NDT systems can collect only the coarse-grained data from the physical network, and restore high-resolution traffic.

2.2 Availability of Counters

Counters are almost available on all network devices and network operating systems (NOS) and software. We conclude this by surveying the device configuration manuals of Cisco, one of the mainstream vendors, and widely used open-source NOS and software, such as software for open networking in the cloud (SONiC) [20], Linux kernel, and data plane development kit (DPDK) [10].

In the survey, we find 41 out of 42 categories of router products of Cisco listed at its official site [5] exactly declare supporting packet counters in their configuration manuals. Only the virtual router emulator states that some hardware counters are not supported by it [8]. We summarize the router products, configuration commands to display counters, and the corresponding online configuration manuals, in Table 6 in appendix §.5. Also, the vendor NOS, such as Cisco IOS XR [1, 2] and Cisco IOS XE [3, 4], that these routers run support the standard management protocols, such as SNMP [43] and NetFlow [26], which is commonly used to collect counters by the network management systems.

Besides, existing open-source NOS and software [10, 12, 20] support multiple types of counters as well. Taking SONiC as an example, its switch abstraction interface (SAI) defines eight types of counters [17] in its router interface API [19], which include the ingress or egress byte counters, ingress or egress packet counters, byte or packet counters for packets having errors on router ingress, and byte or packet counters for packets having errors on router egress. And Linux kernel implements 25 types of counters including packet and byte counters [12], while DPDK supports packet and byte counters in its packet framework library [15, 18].

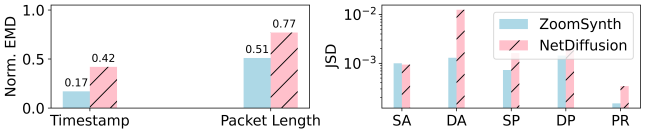

Figure 2: NetDiffusion's performance for TSR to achieve 10^9 end-to-end upscaling.

2.3 Applicability of ISR to TSR

Recent advances in ISR [35, 49] address a similar research question to TSR, aiming to restore high-resolution images (*e.g.*, 1080p) from low-resolution images (*e.g.*, 360p). Many ISR algorithms and models have achieved high-quality results [78, 79]. This prompts us to investigate whether existing ISR algorithms and models can be applied directly to TSR.

We notice a recent pioneering work that applies ISR to traffic synthesis [45]. NetDiffusion utilizes Stable Diffusion 1.5 [65] as the base model, which is recognized as one of the state-of-the-art ISR models. We deploy the open-source implementation of NetDiffusion [13] and evaluate its performance for TSR, *i.e.*, synthesizing packet-level traces from counters. To ensure consistency, we download the model and follow the same fine-tuning process as NetDiffusion, while employing the same datasets as those used by ZOOMSYNTH. Fig. 2 illustrates the experimental results in terms of Jensen-Shannon Divergence (JSD) [56] and Earth Mover's Distance (EMD) [66], and we also show the performance of ZOOMSYNTH. For these two metrics, lower is better, and we observe that NetDiffusion has worse performance than ZOOMSYNTH.

We dive into the implementation of NetDiffusion and identify two primary reasons. First, there is a mismatch between input formats (or data representation) required by the Stable Diffusion model and the inherent nature of traffic data, which is naturally represented as time series. NetDiffusion needs to fold the time series into matrices, which may induce the ISR model to capture unwanted or non-existent relationship between data points. Second, NetDiffusion directly uses the pre-trained model based on image datasets as the basic model and only fine-tunes it for traffic synthesis. Thus, the direct application of an ISR model for TSR, without sufficient customization to the characteristics of traffic data, results in unsatisfactory performance.

2.4 ZOOMSYNTH Design Motivations

We first summarize the challenges and requirements in §1 into five design goals, and then we motivate the design choices of ZOOMSYNTH to achieve these goals.

Design goals. Based on §1, we summarize the goals for ZOOMSYNTH.

G1 **Counter-to-packet Synthesis**: This goal ensures practical applicability, given that many downstream tasks necessitate packet-level traces and coarse-grained counters are widely available.

G2 **Multi-scale Synthesis**: In addition to packet traces

(nanosecond trace), ZoomSynth should generate traffic traces with varying upscaling ratios.

G3 **Counter-rule-based Synthesis**: ZoomSynth should comprehend the semantic meaning of these rules, such as ACL policies, and generate traces that adhere to them.

G4 **Generality**: Traffic traces in different network environments have different characteristics. ZoomSynth should adapt to the features of these varying environments and generate traces with user-defined granularity.

G5 **Real-time Synthesis**: Real-time synthesis enables ZoomSynth to be used in real-time tasks. We define real-time synthesis as follows: for a counter collected every n seconds ($n \geq 1$), ZoomSynth should generate the corresponding packet-level trace within n seconds.

To achieve the goals, our five design choices for ZoomSynth are as follows:

1. GTT-based TSR: With the unsatisfactory performance of ISR models for TSR, we seek a model which is more suitable to handle time-series data. We choose Transformer [70] for ZoomSynth (§4.1), because Transformer can capture long-range dependencies in time-series sequences, and is well-suited for modeling time-series traffic traces where temporal dependencies span over extended periods [67, 68].

We do not use a single Transformer model for TSR: each Transformer model is responsible for only one upscaling granularity (*e.g.*, 1s to 100ms), and it captures the characteristics of traffic at this particular granularity. We name this type of models the Granular Traffic Transformer (GTT). We use GTT $^{k}_{\delta}$ to denote a GTT with upscaling factor k and generation resolution δ. For example, a GTT $^{10}_{100\text{ms}}$ can transform a trace with 1s resolution to one with 100ms resolution.

2. Tree-structured CLTM Model: A coarse-grained counter summarizes the underlying fine-grained counters, forming a classic tree structure at different granularities, as illustrated in Fig. 1(a). With this observation, we then compose GTTs at different granularities into a tree, which we name the Composable Large Traffic Model (CLTM).

CLTM can achieve high upscaling ratios (**G1**). CLTM contains a tree of GTTs, illustrated in Fig. 1(b). This hierarchical structure allows the upscaling ratios to be multiplied across GTTs in distinct layers of CLTM. Consequently, CLTM can achieve exponential increases in upscaling ratios by incorporating additional layers of GTTs. This enables CLTM to attain high upscaling ratios.

CLTM supports multi-scale traffic synthesis (**G2**). Within the CLTM tree, each layer of GTTs is dedicated to a specific granularity. Each layer can generate traffic traces with the targeted granularity, enabling multi-scale traffic synthesis.

3. Counter Rule Understanding with CLIP: **G3** requires us to use counter rules (*e.g.*, text strings of ACL policies) to guide the generation of traffic traces, which is a multimodality task of two domains: text and time-series. We learn from mainstream multimodal models [32, 52], and use CLIP [59] to develop a conversion model to link counter rules with traffic traces. This ensures that synthetic traffic aligns with specified rules in every layer of the CLTM (§4.2).

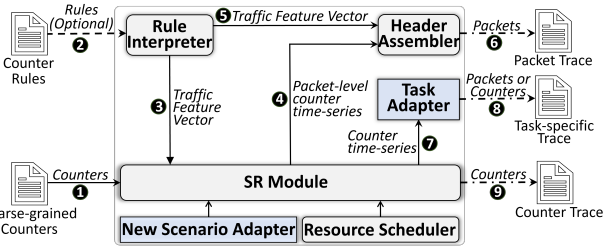

Figure 3: ZoomSynth end-to-end workflow (New Scenario Adaptor and Task Adaptor only run in the training phase). Note that counter rules are not mandatory input but optional.

4. Generality with a LoRA-based Approach: To generalize ZoomSynth, we seek a method that allows users to use their own data to *fine-tune* CLTM, since it is impossible to collect data in all scenarios. Thus, for **G4**, we leverage a LoRA-based approach, borrowing from the LLM literature [40], to facilitate lightweight fine-tuning of CLTM for adapting to new scenarios (appendix §.1.5).

5. Pipeline-parallel Inference: To achieve **G5**, we introduce pipeline paralellism and execute GTTs in different layers of CLTM concurrently. We dynamically allocate computational resources to different layers by scheduling GTTs automatically to ensure efficient inference. We also develop a prefetching technique to further improve the performance (§4.3).

3 ZoomSynth Overview

We present the overview of ZoomSynth in Fig. 3. ZoomSynth is a TSR system designed for fine-grained traffic synthesis using counter traces and counter rules.

3.1 Architecture and Components

ZoomSynth has six key modules, shown in Fig. 3, and we describe them as follows:

- **SR Module**: The SR Module runs the CLTM model. It takes as input a coarse-grained counter time-series. Through the application of the SR module, each counter within the time series undergoes an upscaling process, resulting in a more fine-grained counter time series. Users' required upscaling ratio can be achieved by composing the GTT models to the target number of layers. We set the upscaling factor of each layer to a fixed value of 10 and justify this in appendix §.1.2.
- **Rule Interpreter**: The Rule Interpreter runs a CLIP-based rule-following model. It takes counter rules as input and outputs a feature vector representing the traffic traces complying with the rules. As shown in Fig. 3, the output vector of the Rule Interpreter is fed into each layer of CLTM to help align the time-series features of counters, while in

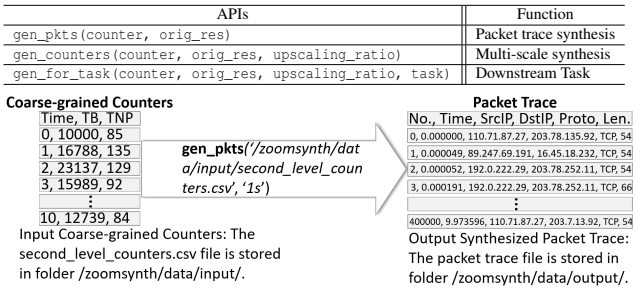

Figure 4: APIs of ZOOMSYNTH's applications and an example for packet trace synthesis from second-level counters using the API `gen_pkts(·)` of ZOOMSYNTH (TB: Total Bytes, TNP: Total Number of Packets).

the header generation process, it is used by the Header Assembler to constrain the scope of the packet headers.

- **Header Assembler**: The Header Assembler runs a GPT-2 based header generation model. As shown in Fig. 3, it takes the outputs from both CLTM and Rule Interpreter as input and generates packet headers to synthesize packet traces.
- **Resource Scheduler**: This module allocates resources to run the above modules. We use pipeline parallelism (a type of model parallelism) to accelerate the inference of CLTM. For the other models, running Rule Interpreter, Header Assembler and Task Adapter is trivial as their model is small and do not need model parallelism, while New Scenario Adaptor only runs offline and does not affect the inference performance of real-time traffic synthesis.
- **Task Adaptor**: This module runs task-specific model with domain knowledge. It can take fine-grained traces with various granularity as input, and leverages task-specific model to align the traces to the domain of the downstream task. Taking an ML-based anomaly detection task as an example, the Task Adaptor uses the ML-based anomaly detection model trained with real traffic data to align the type labels of the fine-grained traces.
- **New Scenario Adaptor**: This module aims to make ZOOMSYNTH adapt to new scenarios efficiently. It leverages a LoRA-based approach to update the CLTM with a small amount of traffic traces of the new scenarios, while purely retraining the models of Header Assembler and Task Adapter as they are small and quick to train. We explore the efficiency of this module in appendix §.4.1.

3.2 Workflow

User of ZOOMSYNTH can programmatically determine their desired resolution by configuring the CLTM. In this way, ZOOMSYNTH supports arbitrary upscaling ratios and can also act as *base model* for many downstream tasks. For each application, ZOOMSYNTH needs to adapt its relative components to synthesize required traces from coarse-grained counters. ZOOMSYNTH provides APIs summarized in Fig. 4 to run the applications. We summarize the workflow of ZOOMSYNTH in Fig. 3 and describe its applications as follows.

Packet Trace Synthesis: The finest-grained traces that ZOOMSYNTH can generate are packet trace synthesis with nanosecond resolution. ZOOMSYNTH utilizes Rule Interpreter, SR Module, and Header Assembler to compose the assembly line for packet trace synthesis. It takes the ❶ counters or both ❶ counters and ❷ counter rules as input, and processes them with ❸ ❺ the Rule Interpreter, ❹ SR Module, and ❻ Header Assembler in succession and outputs packet traces. To run these modules, users can use the `gen_pkts(·)` API, where the parameter `counter` is the path to the file of counters and rules and the parameter `orig_res` is the granularity of the input counters.

Taking Fig. 4 as an example to illustrate packet trace synthesis based on second-level counters by using `gen_pkts(·)` API of ZOOMSYNTH. When invoking the API, users need to specify the input file of the coarse-grained counters with its granularity, ZOOMSYNTH outputs the packet trace after running the API.

Multi-scale Fine-grained Trace Synthesis: Fine-grained counter traces are counter time-series on a finer scale than the input counter time-series. They follow the same counter rules and do not contain packet header information. Therefore, ZOOMSYNTH only takes the ❶ counters or both ❶ counters and ❷ counter rules as inputs, and adopts ❸ the Rule Interpreter and ❾ the SR Module to synthesize fine-grained counter traces. Users can adopt the API `gen_counters(·)` to run the application, where the parameter `upscaling_ratio` is the target end-to-end upscaling ratio.

Downstream Task: Specific downstream network tasks generally require task-specific fine-grained traffic traces. Before synthetic traces are used for a specific task, ZOOMSYNTH leverages Task Adapter to align them to task-specific characteristics with domain knowledge. Therefore, ZOOMSYNTH takes the ❶ counters or both ❶ counters and ❷ counter rules as inputs, and adopts ❸ Rule Interpreter, ❼ SR Module, and ❽ Task Adapter to synthesize counter or packet traces needed by downstream tasks. ZOOMSYNTH provides the API `gen_for_task(·)` for users to specify their input file of coarse-grained counters, counters' original resolution, target end-to-end upscaling ratio, and the downstream task model. In §5.2, we implement three downstream tasks based on ZOOMSYNTH, and evaluate their performance in §7.2.

4 Composable Large Traffic Model

CLTM is composed of GTT models and CLIP-based rule-following model and is the key for enabling multi-scale TSR. In CLTM, GTT is organized as a tree structure, by combining it with the rule-following model, CLTM empowers rule-based synthesis. CLTM supports real-time synthesis with pipelined inference. In the following, we illustrate its design in detail.

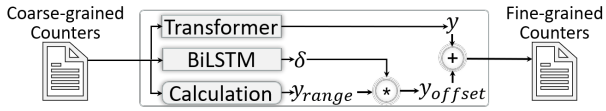

Figure 5: The structure of GTT.

4.1 GTT Model

GTT model consists of two key modules: a Transformer model [70] and a bidirectional LSTM (BiLSTM) [38]. GTT uses Transformer to learn temporal characteristics and leverages BiLSTM to deal with extreme values of counter time series. For each stage of CLTM, a GTT $\frac{k}{\delta}$ make $k\times$ upscaling for counters at a δ resolution. We describe more details about the training data preparation for GTT and the mechanism to determine the upscaling factor k in appendix §.1.1 and appendix §.1.2, respectively.

Handling Extreme Values: The counter time-series displays many extreme values, which are caused by many hidden factors, such as network stack, network functions, and scheduling policies. We observe that a Transformer cannot handle extreme values efficiently, since it tends to evenly distribute packets and byte counts, making upscaled counters tend to favor the means. To address this issue, we use a BiLSTM model to learn the distribution of extreme values, which is borrowed from extreme value prediction methods [33]. GTT integrates Transformer and BiLSTM, as shown in Fig. 5, and uses BiLSTM to learn the distribution frequency of extreme values and their deviations from the means. Unlike Transformer, which directly uses coarse-grained and the corresponding fine-grained counter time-series as training data, we leverage the same input time-series but uses the deviations from the mean of the fine-grained counter time-series as output to BiLSTM in the training phase.

As shown in Fig. 5, in the inference phase, when GTT receives the counter time-series, it feeds the input into both the Transformer and BiLSTM, and calculates the range of the counter time-series. GTT takes the offset ratios (δ) output by BiLSTM to multiply by the calculated range (y_{range}) to obtain the offsets (y_{offset}), and then add them with the output (y) of Transformer to produce the final output.

In order to make GTT models learn counter time-series distributions, we adopt both Mean Square Error (MSE) and EMD in the loss function, while guiding it to satisfy the counter equality constraints described as follows.

Counter Equality Constraints: Clearly, the counters obtained from the fine-grained counter time-series outputted by a GTT should align with the input coarse-grained counters, which relation we call counter equality constraints, denoted as $E(C_{s-1}, \hat{C}_s)$.

$$E(C_{s-1}, \hat{C}_s) = 0,$$
$$\text{where } E(C_{s-1}, \hat{C}_s) = C_{s-1} - F(\hat{C}_s).$$

Here, C_{s-1} represents the realistic input counter time-series of upscaling stage s, and $\hat{C}_s$ is the corresponding counter time-series outputted by the GTT model based on C_{s-1}. F is the counter filtering function.

Loss Function of GTT: We integrate MSE and EMD into our loss function, since MSE can make the means of GTT's output closely align with the target values of the ground truth, while EMD facilitates learning the intrinsic structure of the target distribution. By minimizing both MSE and EMD, the loss function guides GTTs to capture the counter time-series characteristics at each upscaling stage. Thus, the combined loss function can be expressed as:

$$L_{combine} = MSE(\hat{C}_s, C_s) + \lambda EMD(\hat{C}_s, C_s),$$

where $\hat{C}_s$ is the output of a GTT and C_s is the corresponding ground truth at the upscaling stage s, and λ is a hyperparameter to balance MSE and EMD metrics.

Besides finding model parameters that minimize $L_{combine}$ across the training data, GTTs also need to adhere to the counter equality constraints. Formally, we translate it to solving an optimization problem:

$$\min(L_{comibine}),$$
$$\text{s.t. } E(C_{s-1}, \hat{C}_s) = 0.$$

Inspired by Zoom2Net's design for knowledge augmented loss [37], in order to make GTTs learn and respect the constraints during the training phase, we employ the augmented Lagrangian method [34] to establish an augmented Lagrangian loss function:

$$L = L_{combine} + \sigma E(C_{s-1}, \hat{C}_s),$$

where σ is a hyperparameter to balance $L_{combine}$ and $E(C_{s-1}, \hat{C}_s)$. Training GTTs with the loss function L enables them to capture the consistency between the input and output counter time-series, as enforced by the counter equality constraints. Different from Zoom2Net [37], we do not need to consider inequality constraints, since counters within the same time-series do not have such constraints.

4.2 Composing GTTs and Rule-following Model into CLTM

ZoomSynth automatically composes GTTs in CLTM to the target number of stages based on upscaling ratio parameter in its API summarized in Fig. 4. For instance, when users specify the end-to-end upscaling ratio to 10^9 for a second-level counter time-series, ZoomSynth automatically composes GTT $\frac{10}{100\text{ms}}$, GTT $\frac{10}{10\text{ms}}$, ..., and GTT $\frac{10}{1\text{ns}}$ into CLTM in a hierarchical manner. The number of GTTs increases by a factor of k in each subsequent layer, which guarantees that each GTT processes the same size of counter time-series.

Rule-following Model: The counters are the summarization of traffic traces processed following specific counter rules. Properly understanding the counter rules and applying them to the TSR process benefits the synthesis process when restoring fine-grained trace from counters. This is similar to text-based image synthesis, which utilizes CLIP [59] to align the embeddings of images and their corresponding textural descriptions, thereby establishing an association between them. Inspired by

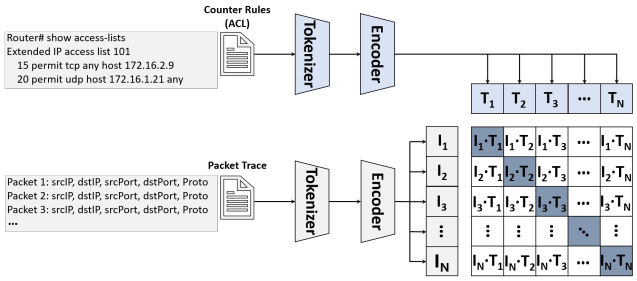

Figure 6: The pre-training process of rule-following model.

this, we employ CLIP to construct a conversion model, called the rule-following model, that bridges counter rules and traffic traces. The rule-following model is fine-tuned using counter rules and traffic traces to understand their relationships in a shared latent space.

Fig. 6 shows the pre-training process of rule-following model. The two Transformer-based encoders with 63M parameters encode counter rules and packet trace to the vectors $T=(T_1,T_2,...,T_N)$ and $I=(I_1,I_2,...,I_N)$, respectively, and map them to the same latent space. Here, we set N to 256. In the training phase, we minimize the cosine similarity of T and I and obtain a similarity matrix of counter rules and packet trace. In the inference phase, we encode the counter rules with the encoder to its vector representation T and convert T to another vector representation using the similarity matrix.

In order to prepare the training data for the rule-following model, we process the original pcap data with specific counter rules and generate packet traces which adhere to them. After finishing the training, we compose the model into CLTM as shown in Fig. 1. We compose GTTs and the pre-trained rule-following model into CLTM for training and inference to achieve multi-scale synthesis based on both counters and counter rules.

4.3 Pipelined Inference of CLTM

Fig. 7 showcases the task scheduling of ZOOMSYNTH on 4 GPUs for pipelined inference of CLTM, which is for packet trace synthesis from second-level counters. A task is defined as a GTT model for processing a fixed size of counter time-series. We use a block to represent a task in Fig. 7, and the number within the block indicates the specific GTT model a task runs. For instance, task belongs to stage 1 of CLTM run GTT $^{10}_{100ms}$. The number of tasks increases by multiplying by the upscaling factor k along with the increase of CLTM's stages. Here, we assume k=10.

ZOOMSYNTH follows two simple rules to schedule tasks on GPUs. (1) Prioritize tasks running GTT models with coarse-grained generation resolutions, because finer-grained tasks depend on them. (2) Prioritize tasks whose GTTs have input data affinity with preceding tasks running on the same GPU. As shown in Fig. 7, ZOOMSYNTH can fully utilize all GPUs after the first stage.

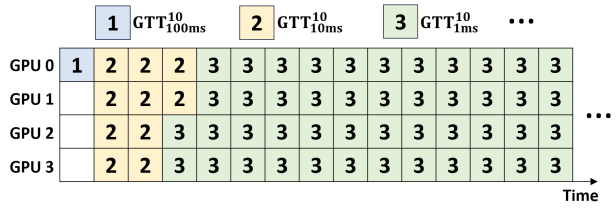

Figure 7: The task scheduling of ZOOMSYNTH on 4 GPUs for pipelined inference of CLTM. Each block represents a task, which is a GTT model for processing a fixed size of counter time-series. The number within each block represents the stage of CLTM the task belongs to. The ratio for the number of tasks between neighbouring CLTM stages is 1:10 assuming upscaling factor k=10.

5 Enabling Downstream Applications

CLTM enables downstream applications of ZOOMSYNTH, and we describe them in this section.

5.1 Header Generation

The final step of packet traces generation is to provide headers for the packets. Similarly to the existing work [62, 77], we use an embedding model to encode the header fields of the packet. Unlike previous work, the header generation model only takes care of the synthesis of five tuples (*i.e.*, source IP, destination IP, source port, destination port and protocol), since CLTM has provided the other information of packets, such as packet timestamp and size.

Packet Header Encoding: We use an embedding model similar to IP2Vec [62] to encode the categorical fields of the packet header, such as IP address, port, and protocol. The embedding is trained on packet traces collected from public datasets. Considering that the IP, port, and protocol fields in our datasets are finite, we utilize an embedding layer with a vocabulary size of 50000 and embedding dimension of 128 to serve as our header encoder. Users can retrain it to cover any additional fields with their new datasets.

Header Generation Model: Building upon the success of previous studies [30, 58] that utilize GPT-2 [60] for packet header generation, we adopt this model to reconstruct packet headers using the finest-grained counter time series from CLTM. We retrain the model using public packet traces. We detail the model training process in appendix §.2.

During the inference phase, the header generation model populates the header fields of packets using the information extracted from the raw training packet traces, alongside the timestamps and sizes derived from the synthesized finest-grained counter time-series. This ensures that the generated packet headers adhere to the traffic semantics and preserve the traffic distribution characteristics. However, this approach has limitations with respect to the generalization of packet headers, which we discuss in §9.

5.2 Task Adaptor

The Task Adaptor fine-tunes CLTM for downstream tasks, allowing the end-to-end upscaling model to be trained with a loss function that is more conducive to downstream tasks. This is similar to *fine-tuning* in the LLM literature [41]. As for most downstream tasks, packet header traces are needed, since the discrete nature of packet header information guarantees that the Task Adaptor does not entail predicting extreme values when synthesizing header fields. As a result, we do not need BiLSTM here. We use a Transformer model for Task Adaptor.

The effectiveness of synthetic traffic used for downstream tasks is the key criterion for evaluating the Task Adaptor. For this, we implement three classic downstream tasks like NetShare [77], including anomaly detection, sketch-based telemetry, and service recognition, and we use the same machine learning (ML) model as NetShare [77].

Anomaly Detection: Existing ML models for this task require packet traces with fields that include packet arrival time, packet size, and five tuples. Based on ZOOMSYNTH, we use five models [77] for anomaly detection: Decision Tree (DT), Logistic Regression (LR), Random Forest (RF), Gradient Boosting (GB), and Multi-layer Perceptron (MLP).

Sketch-based Telemetry: We implement a Count-Min Sketch (CMS) [53] and use it to estimate the proportion of heavy-hitters within the traffic. Sketch-based telemetry commonly uses traffic synthesis as a precursor task, producing a large volume of traffic with consistent characteristics.

Service Recognition: The service recognition task is a more complex ML-based task, different from the above two categories of tasks. It relies on more deep features of traffic to recognize services, instead of looking at IP addresses, port numbers, and protocol types. We adopt the same five models for anomaly detection for this task, and utilize data from CIDDS to train them for service recognition. The services are categorized into three types: email, file copying, and others.

6 Implementation

We implement a prototype of ZOOMSYNTH in Python 3.10. We use PyTorch [16] library to implement all the models in ∼950 lines of code (LOC), except for the header generation model, which we implement using the codes from Hugging Face. And for parsing datasets into packets and multi-scale counters, we implement scripts in ∼230 LOC. Table 5 in appendix §.3.1 lists the hyper-parameter setups of ZOOMSYNTH for each model. Specifically, besides the APIs summarized in Fig. 4, we also implement 6 APIs to support operations of CLTM. Based on these APIs, users can adjust the number of GTTs in each stage of CLTM by considering their hardware and TSR tasks. For the three downstream tasks, we also utilize the PyTorch library to implement the models for anomaly detection and service recognition in ∼420 LOC and implement CMS for sketch-based telemetry in ∼170 LOC.

We implement the Resource Scheduler in ∼130 LOC, which adopts `nvidia-smi` (provided by the GPU driver) to monitor GPU resources and schedule tasks to GPUs.

Datasets: We aggregate seven open-source datasets available online, namely TON (IoT traffic data) [57], CA (data of a cyber defense competition) [6], CIDDS (enterprise traffic) [7], DC (data center traffic) [9], UGR16 (traffic data from Spanish ISP) [55], CAIDA (anonymized trace on backbone network) [22], and MAWI (packet traces from WIDE backbone) [31]. The resulting dataset have a combined size of 16GB, and MAWI and CAIDA predominantly constitute this hybrid dataset, with each accounting for 45% of the data. We obtain counter traces of varying resolutions from this dataset, and the counter traces has a total size of >1.7TB.

Model Size: With k=10, input resolution 1s, and output resolution 1ns (packet-level), the required CLTM has 1.8 billion parameters. We call this model CLTM-1.8B, and release a pre-trained version[1] using the above datasets, accompanied with the source code for its training. We use this model in the evaluations, unless otherwise specified.

7 Evaluation

In this section, we seek to understand: 1) With only counter traces, can ZOOMSYNTH achieve a similar performance in traffic generation as existing traffic synthesizers that take packet-level trace as input? 2) Can the synthesized ZOOMSYNTH traces satisfy the requirements of downstream tasks? 3) Can ZOOMSYNTH achieve real-time synthesis? 4) How does the counter based on the counting bloom filter (CBF) affect TSR? 5) How does each model in ZOOMSYNTH contribute to its performance? We answer the first four questions positively. We summarize the evaluation results below.

Summary of Results:

- For packet-level trace synthesis, ZOOMSYNTH, using only counters, achieves a similar performance as NetShare that takes packet-level trace as input. ZOOMSYNTH achieves up to 25.8% and 20.1% improvements in terms of JSD and EMD, respectively. And across all four datasets, ZOOMSYNTH achieves only 30.6% reduction in JSD.
- ZOOMSYNTH relaxes the requirements for data collection for downstream tasks. With only counter traces, ZOOMSYNTH with fine-tuned CLTM outperforms NetShare by 27.5% and 9.8% in anomaly detection and service recognition tasks, respectively.
- For a CLTM-1.8B on a server with 8× A100 GPUs, for a per-second counter trace, ZOOMSYNTH can generate at most 10^9 packets in 0.966 second. This exceeds the maximum forwarding capacity of modern core network devices [8, 23, 24], proving its real-time synthesis capacity.
- We observe that CBF-based counters have negative impact on TSR performance, and find that ZOOMSYNTH still outperforms NetDiffusion and Zoom2Net, achieving im-

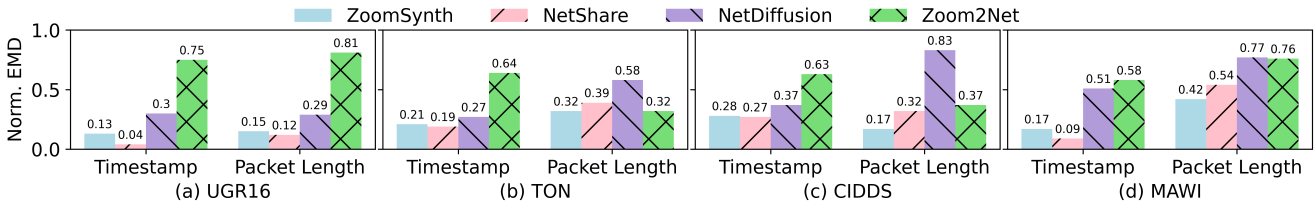

Figure 8: Earth Mover's Distance (EMD) between real and synthetic distributions on UGR16, TON, CIDDS, and MAWI, where the end-to-end upscaling ratio is 10^9.

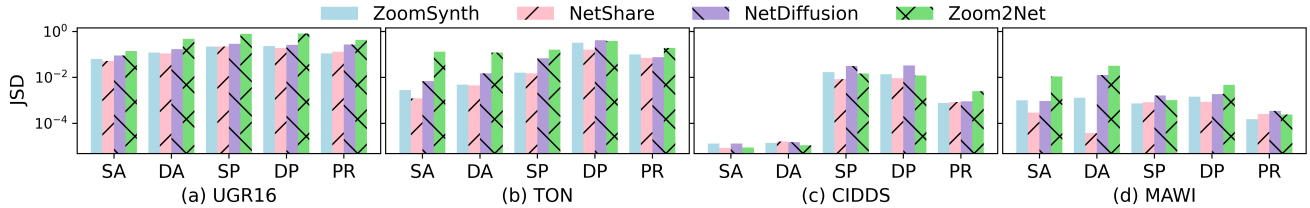

Figure 9: Jensen-Shannon Divergence (JSD) between real and synthetic distributions on UGR16, TON, CIDDS, and MAWI, where the end-to-end upscaling ratio is 10^9.

provements in EMD by 58.3% and 76.0%, and in JSD by 52.3% and 80.1%, respectively.

- We confirm the effectiveness of the header generation and rule-following models in ZOOMSYNTH.

Testbed: We use a machine equipped with 8× NVIDIA A100 GPUs, 2× 64-core 2.90GHz Intel Xeon Platinum CPUs, and 2TB DDR4 RAM. The machine runs Ubuntu 22.04 LTS and PyTorch 2.1.0.

Comparison Targets: We compare ZOOMSYNTH to three existing traffic synthesizers, each of which is the state-of-the-art work in their application scenarios. (1) *NetDiffusion* [45]: This scheme originally uses a stable diffusion model [65] to synthesize the traffic trace from text, such as *generating TCP traffic*. In the TSR scenario, we use it to synthesize traffic trace from counters. (2) *NetShare* [77]: This system must take packet traces as input, and uses the DoppelGANger model [50] with domain-specific insights to generate packet traces. It cannot take counter traces as input. (3) *Zoom2Net*: We extend Zoom2Net [37] for TSR. Following [37], this scheme uses a single Transformer model [70] to complete all tasks for TSR including up-scaling and packet header generation. In addition, we use the same loss function as ZOOMSYNTH to incorporate the domain knowledge in Zoom2Net. Comparison of ZOOMSYNTH with Zoom2Net can demonstrate the performance benefit of ZOOMSYNTH's other design choices. The hyperparameters of Zoom2Net are the same as GTT.

Metrics: We evaluate the fidelity of synthetic traffic traces by computing distance metrics between real and synthetic distributions of packet header fields. Following the common practice in prior work [74, 77], we utilize Earth Mover's Distance (EMD) (also called Wasserstein-1 distance) for continuous fields, such as packet length and timestamp, and Jensen-Shannon Divergence (JSD) for discrete fields, such as source address (SA), destination address (DA), source port (SP), destination port (DP), and protocol (PR).

7.1 Counter-to-Packet Synthesis

Accuracy. To assess the generation quality of timestamp field and packet length field, we employ EMD to compare the generated packet traces with the actual ones, with smaller values indicating closer resemblance. Fig. 8 presents the EMD metrics across four datasets. With only second-level counters, ZOOMSYNTH achieves performance comparable to NetShare (using packet-level traces as input), and significantly outperforms Zoom2Net and NetDiffusion. Specifically, ZOOMSYNTH achieves EMD reductions of 69.5% and 48.4% in the four datasets on average compared to Zoom2Net and NetDiffusion, respectively. In TON, CIDDS, and MAWI datasets, our method surpasses NetShare in terms of packet length's EMD. We further look at the percentiles of deviations for the 1st and 99th synthetic packet lengths generated by ZOOMSYNTH and NetShare in appendix §.4.2, and find that NetShare tries to fit the extreme values, making it perform well in generating packet lengths around the extreme values and also causing it to tend to overfit the variations of the packet length time-series, and thus leading to worse EMD.

For categorical fields such as IP address/port number/protocol in packet headers, we use JSD, a metric that assesses the distribution characteristics of discrete data within the whole set, and a smaller JSD is better. Similarly, we calculate the JSD between the synthetic data and the real data for each scheme, which is shown in Fig. 9. We can see ZOOMSYNTH achieves 49.6% and 35.6% JSD reductions compared to Zoom2Net and NetDiffusion, respectively, and it is slightly inferior to the NetShare scheme, which uses packet-level traces as input.

Error Accumulation. To show how errors accumulate in the multi-level TSR process of ZOOMSYNTH, we assess the results generated at multiple granularities. Counter-level results encompass three dimensions of information: time interval, byte count, and packet count. Since the time interval at the

Table 1: Performance comparison of ZOOMSYNTH, NetShare, NetDiffusion, and Zoom2Net on three downstream tasks.

Downstream Task	Anomaly Detection					Sketch-based Telemetry			Service Recognition				
	MLP	DT	RF	GB	LR	TON_SA	TON_DP	CAIDA_SP	MLP	DT	RF	GB	LR
Real Traces	0.99	1.0	1.0	1.0	0.8	-	-	-	1.0	1.0	1.0	1.0	0.87
ZOOMSYNTH	0.88	0.91	0.81	0.87	0.78	0.22	0.64	0.57	0.87	0.89	0.84	0.84	0.75
NetShare	0.58	0.78	0.64	0.77	0.60	0.14	0.62	0.53	0.83	0.79	0.85	0.78	0.60
NetDiffusion	0.43	0.49	0.43	0.51	0.36	0.29	0.78	0.73	0.60	0.59	0.63	0.55	0.49
Zoom2Net	0.31	0.42	0.32	0.35	0.32	0.41	0.94	0.82	0.58	0.54	0.61	0.49	0.43

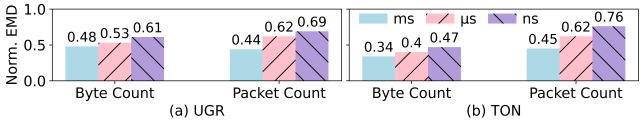

Figure 10: Error accumulation on counters of packets and bytes as the TSR processes.

counter level is fixed that represents the sampling period, we just calculate the EMD for the byte and packet counts. Due to how the EMD is calculated, there are magnitude differences in the EMD across different granularities. Therefore, when comparing the EMD values horizontally, it is necessary to perform normalization. Fig. 10 shows the normalized results. When generating microsecond counters from millisecond counters in the TON dataset, it is evident that even when the EMD values for millisecond data are divided by a thousand (reflecting the granularity difference), they are still significantly lower than the EMD for the microsecond-level results. A similar pattern is observed when nanosecond counters are generated from microsecond counters.

We conclude that, although errors accumulate in multi-level generation, the growth of accumulated error is slow, which has limited impact on overall accuracy, as we observe in Figs. 8 and 9.

7.2 Downstream Task Performance

We evaluate the performance of the three downstream tasks manufactured by ZOOMSYNTH in the following.

Anomaly Detection: We train DT, LR, RF, GB, and MLP with both real and synthetic traces and compare their accuracy with real traces. Table 1 shows that models trained using ZOOMSYNTH's synthetic traces achieve superior accuracy compared to NetShare, especially for DT model, its accuracy is 27.5% higher than that of NetShare, while they improve 93.2% and 149.2% on average accuracy compared to NetDiffusion and Zoom2Net, respectively.

Sketch-based Telemetry: We use E_{real} and E_{syn} to represent the number of errors in identifying heavy-hitters using CMS for real and synthetic data, respectively. If the features of the generated data are closer to those of the real data, these two values are also closer. Therefore, we use the relative error ratio $\frac{|E_{real}-E_{syn}|}{E_{real}}$ to evaluate the similarity between real data and synthetic data, and a lower value means better performance. We calculate the relative error of the heavy-hitters using TON and CAIDA datasets. Table 1 shows that the synthetic traces from ZOOMSYNTH have a performance similar to that of NetShare, with only 23.6% higher average relative error, and reduce the average relative errors with 21.3% and 49.6%, respectively, compared to NetDiffusion and Zoom2Net.

Table 2: The inference time of ZOOMSYNTH for achieving different end-to-end upscaling ratios from second-level counters. The upscaling factor k=10 and the results are obtained using TON dataset.

End-to-end Upscaling Ratio	10	10^2	10^3	10^5	10^9
Inference Time (Seconds)	0.855	0.938	0.951	0.965	0.966

Service Recognition: We compare the trained service recognition models using data from the real dataset and the synthetic ones of the compared schemes. Table 1 presents the results that the synthetic traces of ZOOMSYNTH better represent the characteristics of the real ones. For instance, the models trained with the data from ZOOMSYNTH achieve 9.8%, 46.9%, and 59.7% higher accuracy on average than the models trained with the synthetic data from NetShare, NetDiffusion, and Zoom2Net, respectively.

7.3 Real-time Synthesis

To assess whether ZOOMSYNTH can empower real-time downstream tasks, such as NDT [25], we measure the inference time under various end-to-end upscaling ratios. And to avoid measuring errors that result from inference with insufficient counter time series data, we employ counters of 1-second duration to generate packets and test whether the inference time exceeds 1 second. For example, when evaluating with an upscaling factor of 10^6, we use 1000× ms-level counters and record the end-to-end inference time. We conduct the experiments using CLTM-1.8B and 8× A100 GPUs. Table 2 shows that ZOOMSYNTH can achieve the target upscaling performance goal from second-level counters within 1 second for any end-to-end upscaling ratios, demonstrating that ZOOMSYNTH achieves real-time synthesis for various upscaling ratios.

7.4 Using CBF-based Counters

Due to limited memory and computing resources, many network devices adopt Counting Bloom Filters (CBF) [36] to implement packet or byte counters for obtaining approximate results. To see its impact on TSR performance, we implement a CBF-based counter with an array size of 300 and 2 hash functions, while using packet length as the hash key. Subsequently, we use the CBF-based counter to process the packet traces to obtain the counter time-series data, and then we use

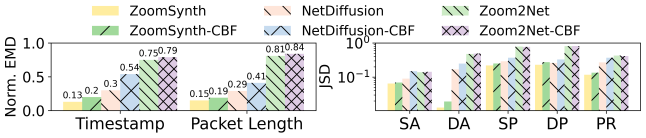

Figure 11: Normalized EMD and JSD between real and synthetic packet traces on UGR dataset using real counters and CBF counters as input, respectively.

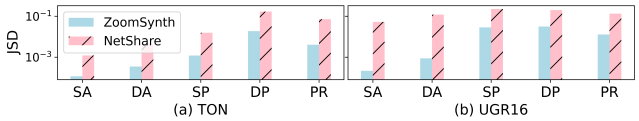

Figure 12: Performance comparison for packet header generation between NetShare and ZOOMSYNTH.

the data to train GTTs. Fig. 11 shows normalized EMD and JSD between real and synthetic packet traces on UGR dataset using real counters and CBF counters as input, respectively. Note that the packet and byte counters obtained using CBF on UGR dataset exceed the actual values by 7% and 12%, respectively. We can see ZOOMSYNTH outperforms NetDiffusion and Zoom2Net, improving EMD by 58.3% and 76.0%, and JSD by 52.3% and 80.1%, respectively. Besides, both ZOOMSYNTH and NetDiffusion have a significant increase in EMD for timestamp (53.8% for ZOOMSYNTH and 80.0% for NetDiffusion) and packet length (26.7% for ZOOMSYNTH and 41.4% for NetDiffusion), indicating that they are more sensitive to the accuracy of CBF.

7.5 Header Generation Model

To solely evaluate the quality of header generation, we use real nanosecond-level counter information as input, as this represents the packet prototype stripped of its header information. Fig. 12 provides an assessment of the capability of the header generation model. Our approach demonstrates an order of magnitude lower JSD values across various fields, proving that our header generation model significantly outperforms NetShare. This also underscores that the effectiveness of header generation is greatly dependent on the TSR results of the counters. We do not compare ZOOMSYNTH against NetDiffusion and Zoom2Net, since they do not have dedicated header generation modules.

7.6 Rule-following Model

We investigate the impact of counter rules on CLTM's header generation process. To do this, we construct multi-scale counter time-series and packet traces by filtering the original traffic traces using the ACL rules and use these data to train CLTM. Subsequently, we gather the packet outputs of ZOOMSYNTH with and without counter rules as input, respectively. Then we quantify the percentage of packets that adhere to the counter rules among all synthetic packets. For instance, when considering a rule like "Deny TCP", if counter rule is absent from the input, ZOOMSYNTH would use CLTM to recreate counters and use the header generation model to generate packet headers purely following the characteristics

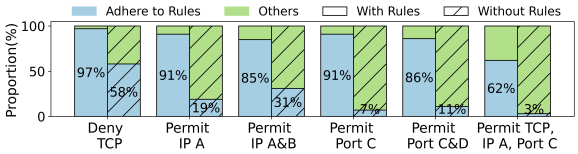

Figure 13: Comparison for the proportion of traffic which adheres to the counter rules with and without them as input.

Table 3: Summary of existing work.

Existing Work	Input	Output	Generality
DYNAMO [28], NS-2 [14]	Config Para.	Packets	✗
Swing [71], Tmix [73], LitGen [64]	Model Para.	Packets	✗
STAN [74]	-	Flows	✓
Redzovic et al. [61]	-	Sizes, Times	✓
DoppelGANger [50], NetShare [77]	Packets	Packets	✓
NetDiffusion [44, 46], PAC-GPT [47]	Prompts	Packets	✓
ZOOMSYNTH	Counters, Counter Rules	Packets, or Counters	✓

of the overall traffic flow.

We conduct this experiment on the CAIDA dataset, and use six counter rules as input to generate packet traces, respectively. Fig. 13 shows the comparison results for the proportion of traffic which adheres to the counter rules with and without counter rules as input. The results demonstrate that using counter rules as input can significantly benefit packet trace synthesis. For example, when the counter rule representing "Deny TCP" is not fed into the model, yet the counters represent traffic filtered by the rules, the proportion of TCP traffic in the final packet trace reaches 42%. In contrast, when we incorporate the "Deny TCP" rule into the packet header generation process, the final packet trace only has 3% TCP traffic. We can filter out the remaining 3% directly in the post-processing process without affecting the whole packet trace, because the proportion of the remaining TCP traffic among all traffic is small enough.

8 Related Work

There has been a large amount of work on traffic synthesis. In Table 3, we compare ZOOMSYNTH against them across three dimensions.

Traffic Synthesis Input: Existing work varies in their inputs. Simulation-/emulation-driven approaches demand detailed configurations, such as workloads and clients, to simulate network traffic in virtual environments. Model-driven approaches require distribution parameters derived from realistic traffic to establish statistical or structural models. ML-based models have diverse needs: some, like STAN [74] and Redzovic et al. [61], require no input, whereas others, such as DoppelGANger [50] and NetShare [77], need packet-level traffic data. In contrast, NetDiffusion [44, 46] and PAC-GPT [47] accept text prompts. Unlike these approaches, ZOOMSYNTH leverages counters to generate fine-grained traffic traces, achieving TSR not natively supported by them.

Traffic Synthesis Output: In addition to the inputs, the outputs of existing approaches also vary. Most approaches can produce packet-level traces, but some of them differ in

the fields generated from the packet headers. Specifically, simulation-/emulation-driven approaches acquire packets via direct packet capture within their environments. STAN [74] is limited to generating flow-level traffic, while Redzovic et al. [61] can only produce the header fields of packet sizes and interarrival times. Besides producing packet-level traces, ZOOMSYNTH further enables multi-scale synthesis of fine-grained counters directly from coarse-grained ones, offering flexibility for supporting various network applications.

Generality: In this regard, simulation-/emulation-driven and model-driven approaches are easy to analyze: they both rely on extracting specific features from realistic traffic to configure simulators, emulators, or models manually, making them inherently tied to specific workloads and thus limiting their adaptability for generalization. To overcome the issue, ZOOMSYNTH supports fast new scenario adaptation.

Cross-Domain Techniques: ZOOMSYNTH applies some techniques from other domains to traffic synthesis. ZOOMSYNTH adapts CLIP [59], a model used to align image and text embeddings in image synthesis, to understand the relationship between counter rules and packet traces. LoRA [40], originally used to fine-tune LLMs for new scenarios, is employed in training GTT layers of CLTM, tailored for the traffic synthesis domain. Moreover, ZOOMSYNTH chooses GPT-2 [11] as the header generation model, considering its generation efficiency.

9 Limitations and Future Work

Although ZOOMSYNTH boosts many network applications by enabling TSR, it faces several limitations that require further investigation. We discuss these limitations in the following.

Lowering Device Fingerprinting Risks: Sharing raw counter datasets from devices can increase the risks of device fingerprinting. Counters vary in type, with some accumulating values over time and others resetting at regular intervals. Public access to these counters could allow adversaries to identify devices according to their types. To reduce risk, operators can process counter data into a uniform format, thereby obscuring the original types.

Extending ZOOMSYNTH to Cases Needing Diverse Inputs: ZOOMSYNTH has limitations in accurately synthesizing traffic for cases that require more than just counters as input. For example, generating traffic for video or audio applications, using only counters may not ensure that the traffic aligns with the specific characteristics of these applications. Future research could explore methods to synthesize traces that capture the characteristics of specific applications, incorporating more inputs such as application descriptions along with counters.

Mitigating Adversarial Misuse Risks: There is a potential for adversaries to exploit ZOOMSYNTH for malicious purposes, such as using synthesized normal traffic patterns to evade detection by security devices like IDS and IPS. Although ZOOMSYNTH focuses on TSR, the potential for misuse presents a significant challenge. This highlights the need for future research on preventing adversarial use.

Reducing Adversarial Effects in Traffic Synthesis: ML-based traffic synthesizers are vulnerable to adversarial traffic [29], which can lead to inaccurate output. Adversaries may tamper with training data, introducing deceptive patterns that result in unrealistic traces. To protect against this, the training datasets for GTTs should be carefully filtered to exclude adversarial samples. Identifying adversarial traffic is a well-established research area [39, 69] and is beyond the scope of our work.

Enhancing Support for More Downstream Tasks: ZOOMSYNTH currently has limited support for downstream tasks requiring precise stateful protocol behaviors, such as congestion control and switch buffer monitoring, in line with existing work [45, 47, 50, 74, 77]. Future work will focus on enhancing packet generation with advanced stateful features (*e.g.* sequence numbers) and improving inter-arrival sequence modeling through better protocol and application behavior understanding.

Enhancing Generalization in Header Generation: ZOOMSYNTH has generalization issue in header generation, as it limits header field values to those found in the training data. This reduces diversity compared to realistic traffic. To enhance generality while maintaining semantic conformity, future research could involve training a packet header model with domain-specific semantic knowledge.

10 Conclusion

We present ZOOMSYNTH, the first TSR system to restore fine-grained traffic traces from coarse-grained counters. We design GTTs to capture traffic characteristics at particular granularities, and compose CLTM as a combination of a tree of GTTs and a rule-following model. ZOOMSYNTH uses CLTM and a header generation model to achieve packet-trace synthesis, and can be adapted to new scenarios with LoRA. We prototype ZOOMSYNTH with PyTorch and evaluate it on a real testbed using public datasets. ZOOMSYNTH can satisfy the requirements for three downstream tasks. Compared to NetShare that takes packet-level trace as input, ZOOMSYNTH can achieve comparable accuracy in terms of JSD and EMD, while obtaining more than 42.1% accuracy improvements compared to NetDiffusion.

Appendix

The appendix describes additional details that we could not fit into the main paper.

.1 Additional Details of CLTM

.1.1 Training Data Preparation for GTT Models

We need traffic data with various resolutions to train GTT $^{k}_{\delta}$ models. To obtain them, we aggregate raw pcap data from public datasets into counter time-series at various granularities, according to k. We have introduced all the public datasets we use in §6. The number of needed training data couple is $\frac{\theta}{k}$, where the overall end-to-end upscaling raito for CLTM is θ. Taking packet synthesis from second-level counters (overall end-to-end upscaling ratio is 10^9) and k=10 as an example, a total nine couples of counter time-series at different granularities are needed, including (1s, 100ms), (100ms, 10ms), ..., and (10ns, 1ns). These counter time-series is structured as `pandas.DataFrame` with the following columns: time, packet count, and byte count. Moreover, CLTM increases GTTs within each stage by k to process different partitions of counter time-series to improve scalability, as the data size increases by k along with the upscaling stages. Considering the temporal dependency between the neighbouring partitions, we intentionally introduce overlap between them, which enhances the ability of GTTs to capture long-term time-series characteristics.

.1.2 Choosing Upscaling Factor k

As analyzed in §2.4, each GTT concentrates on a particular upscaling stage with a fixed upscaling factor k, which is important for the tradeoff between end-to-end traffic synthesis accuracy and model training cost. A GTT with small k can achieve satisfactory end-to-end synthesis accuracy, yet may incur extra training costs as involving more GTTs for more upscaling steps.

The choices of k are different across different datasets. Generally, a GTT having smaller upscaling factor can have better TSR performance. For example, GTT $^{10}_{1ms}$ outperforms GTT $^{100}_{1ms}$. For a fixed end-to-end upscaling ratio, however, smaller k would increase CLTM stages. Each stage may have a degree of synthesis errors, which may accumulate along with upscaling stages. In addition, the performance gains obtained by choosing GTT $^{10}_{1ms}$ over GTT $^{100}_{1ms}$ are not consistent across the datasets, since they exhibit various characteristics at different granularities. Therefore, we employ experimental methods to determine the value of k.

We use TON [57] and CIDDS [7] datasets as an example to show how we experimentally choose the value of k. We restore packet trace from second-level counters and make k equal to 5, 10, 10^2, and 10^3, respectively. These choices of k are enough for us to determine the k values for the two datasets. For each k value, we calculate the normalized EMD and JSD between real and synthetic packet traces. Fig. 14 shows the results. We can see, for the two datasets, the normalized EMD and JSD results have different trends along with the increase of k. For TON dataset, the normalized EMD and JSD results increase along with k, and they are similar for k=5 and k=10, and increase significantly when k>10. However, for CIDDS dataset, from k=5 to k=10^2, both EMD and JSD results of the most packet header fields decrease along with k, and then they increase largely when k=10^3, compared to k=10^2.

Table 4 shows the corresponding end-to-end model training time for different values of k. The measurements are done on the testbed described in §7. We only show the training time using TON dataset, since it is consistent for all the datasets that more CLTM stages with more GTT models would lead to longer training time. Taking accuracy and training time into account, we recommend to set k as 10 and 10^2 for the TON and CIDDS datasets, respectively. Other datasets adopt the same method to choose their k.

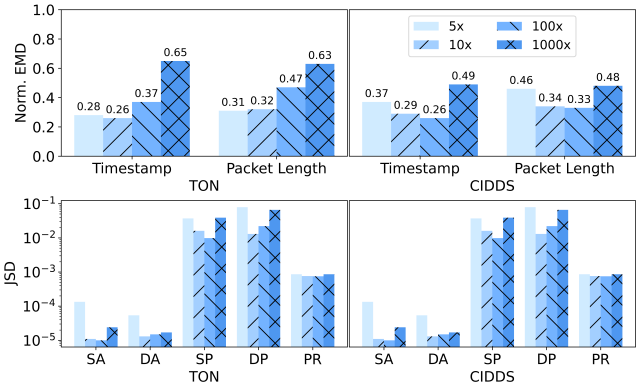

Figure 14: Normalized EMD and JSD between real and synthetic packet traces for different choices of k on TON and CIDDS datasets (SA: source address, DA: destination address, SP: source port, DP: destination port, PR: protocol).

Table 4: The end-to-end training time of ZOOMSYNTH for different values of k using TON dataset.

k	5	10	10^2	10^3
Training Time (GPU Hours)	99.15	61.91	6.77	6.31

.1.3 Training CLTM

In the training phase of CLTM, we combine the output vector of pre-trained rule-following model and the vector of counter time-series at a particular granularity and feed their combinations into GTT to train it. Specifically, when no counter rules are available, its input to GTT is a zero vector. To combine them, we directly copy and extend the output vector of pre-trained rule-following model into 2 dimensions, ensuring that the two vectors are of same shape before concatenating them.

.1.4 Handling Sparsity with Early Stopping

We observe some intermediate fine-grained counter time-series exhibit sparsity. For instance, when upscaling a counter

Table 5: Hyperparameters of ZOOMSYNTH models.

Models	Param.	Value
GTT	Transformer Layers	15
	Multi-Headers	4
	Hidden Size	256
	Dropout	0.1
	Learn Ratio	0.001 - 0.01 (vary with iterations)
	Batch Size	10 - 64 (vary with data volumes)
	λ in Loss Func.	0.1 - 1.5 (vary with iterations)
	σ in Loss Func.	0 - 1 (vary with iterations)
Header Gen. Model	Vocab Size	50000
	Embedding Dim.	128
	Generation Model	GPT2-Small
Rule-following Model	Text Encoder	Transformer-63M
	Similarity Matrix	256*256
Downstream Task Adaptor	Header Generation	Transformer-38M
	Task-specific Model	3-layers DT or MLP

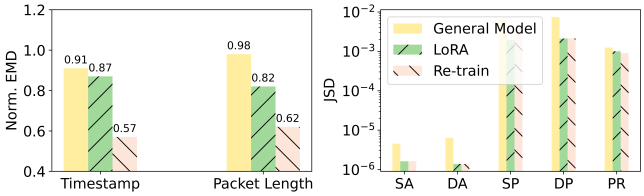

Figure 15: EMD and JSD between real and synthetic distributions on CIDDS using four kind of models: specific model trained on CIDDS, general model trained on combined dataset, LoRA on general model, re-training general model.

time-series from 10ms to 1ms, there are 8 upscaled 1ms-counters whose values are 0; during the inference phase, for these counters, ZOOMSYNTH will stop the upscaling process of the subsequent GTT models in CLTM. In addition, if both the packet count of the other 2 1ms-counters are 1, this represents the 1ms-counter has reached the finest granularity and its byte count is the packet size, we can stop its upscaling process as well. By classifying the sparsity of counter time-series during the upscaling process, ZOOMSYNTH accelerates the inference of CLTM with an early stop mechanism, avoiding useless upscalings.

.1.5 *Fast New Scenario Adaptation*

CLTM is designed to be a general foundation model for TSR and we train it using the common traffic traces, which prevents it from overfitting to the specific features of any specific dataset, while directing the model to focus on the underlying and universal traffic features across various scenarios. However, we also admit that traffic characteristics can vary significantly for different scenarios, and can also change over time. Therefore, we design an approach for adapting CLTM to the new scenarios with low overhead.

We leverage the LoRA-based approach to empower CLTM to adapt to new scenarios quickly. This is a systematic application of LoRA [40] for traffic synthesis building on its success in fine-tuning of LLMs. The core of LoRA is training the low-rank parameter matrices of the whole model with a small amount of data from new scenarios during the re-training phase. After finishing the training, it injects the re-trained parameters to the original model and replaces the corresponding ones. We use the same approach to train the low-rank parameter matrices of CLTM.

We only choose the GTT model layer of CLTM for finer-grained counter synthesis to perform re-training with LoRA approach, which further accelerates the adaptation process. We observe that across various scenarios, coarse-grained traffic statistics remain consistent, the features of the corresponding fine-grained traffic are different. Therefore, as shown in Fig. 1, for GTTs within the upper layers of CLTM, they are similar to perform uniform upscalings, while GTTs within the lower layer vary in capturing the traffic fine-grained features. Based on the observation and analysis, we should re-train GTTs for finer-grained counter synthesis. For instance, we choose GTT $^{10}_{10ns}$ and GTT $^{10}_{1ns}$ in the last two stages of CLTM to be retrained for packet synthesis from second-level counter time-series.

.2 Training Header Generation Model

For preparing the training dataset, we process the raw packet trace to the same granularity of counter time series. We use the processed counter time series and packet trace to train the header generation model. The training method is that we mask header fields randomly and use the model to regenerate the relative fields. We retrain the header generation model on our hybrid dataset, with the training process taking approximately 8 days.

.3 Implementation Details of ZOOMSYNTH

.3.1 *Hyperparameters of* ZOOMSYNTH *Models*

Table 5 lists the hyper-parameter setups of ZOOMSYNTH for each model.

.3.2 *Operation APIs of CLTM*

The six APIs to support operations of CLTM introduced in §6 include `def_TSR_ratio(·)` for defining the end-to-end upscaling ratio, `def_GTT_factor(·)` for choosing the factor k of the GTT, `def_GTT_num(·)` for deciding the number of GTTs in CLTM, `def_GTT_model(·)` for configuring model hyperparameters, `def_training_iter(·)` for setting model training parameters.

.4 Additional Experimental Results

.4.1 *Adapting to New Scenarios*

To simulate adapting to a new scenario, we design two datasets: the D_0 dataset combines UGR16, TON and MAWI datasets; and the D_+ dataset which contains only the CIDDS dataset whose size is 5% of that of D_0. We then train three models: 1) the *General Model* is a CLTM trained on D_0; 2) with the *General Model* as base, we train the LoRA layers on D_+, which is our recommended procedure to adapt CLTM to new scenarios; we denote the combined model of *General Model* and LoRA layers as *LoRA*; 3) Using the *General Model* as a starting point, we run 50 iterations of training using D_+, and we call the resulting model *Re-train Model*.

Fig. 15 shows the results. We observe that the *Re-train Model* achieves the best performance, and *LoRA* can greatly

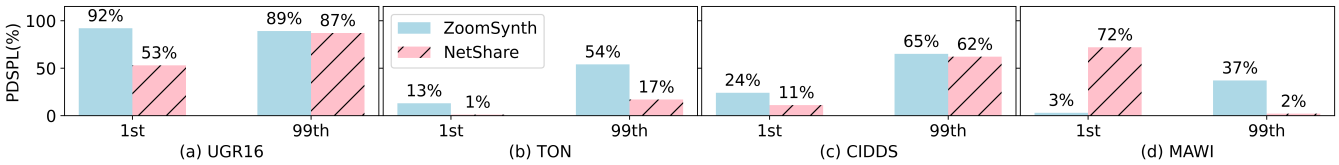

Figure 16: Proportions of deviations for synthetic packet lengths at the 1st and 99th percentile generated by ZOOMSYNTH and NetShare on the UGR16, TON, CIDDS, and MAWI datasets (PDSPL: Proportions of Deviations for the Synthetic Packet Lengths).

improve the *General Model*'s performance in the new scenario. *LoRA* can improve the generation quality of timestamps and packet lengths by 4.3% and 15%, respectively. For header generation, *LoRA* achieves roughly the same performance as the *Re-train Model*. Since re-training the complete CLTM model takes up significantly more resource and time than training a few LoRA layers, we believe adapting to new scenarios with *LoRA* is an attractive alternative for users with limited time, data, and resources.

.4.2 Deviation Proportions of Synthetic Packet Lengths

To further explore the generation performance of ZOOMSYNTH and NetShare in synthesizing packet lengths, we look at the proportions of deviation between the synthetic and realistic packet lengths. This metric, referred to as the proportion of deviations for synthetic packet lengths (PDSPL), is defined as follows:

$$PDSPL_i = \frac{|PL_i^{syn} - PL_i^{real}|}{PL_i^{real}} \times 100\%.$$

Here, PL_i^{real} denotes the packet length at the ith percentile of the sorted realistic packet length time-series, arranged from smallest to largest, while PL_i^{syn} represents the corresponding value of the sorted synthetic packet length time-series. This metric measures how closely the synthetic packet lengths match the realistic ones across different percentiles.

Fig. 16 shows the proportions of deviations for the 1st and 99th percentile synthetic packet lengths generated by ZOOMSYNTH and NetShare on the UGR16, TON, CIDDS, and MAWI datasets. We can see NetShare exhibits lower deviations at both the 1st and 99th percentiles, except for the 1st percentile packet length on the MAWI dataset. We analyze that this is because GAN-based models are sensitive to fluctuations and extreme values in time-series data [46], making NetShare perform better in generating packet lengths around extreme values. However, this sensitivity also causes NetShare to tend to overfit the variations of the packet length time-series, leading to worse EMD performance compared to ZOOMSYNTH, as we observe in Fig. 8.

.5 Cisco Router Products Supporting Counters

Table 6 shows Cisco's router products which support counters, their configuration commands to display counters, and the corresponding online configuration manuals. These routers are the 41 out of 42 ones from 500 series to 12000 series listed at Cisco's official site [5]. Their configuration manuals state that they support counters, which can be obtained via command line interface (CLI) with the corresponding configuration commands. The router product which does not appear in Table 6 is 8000 series virtual router emulator, whose data sheet introduces that some hardware counters are not supported by it [8]. It is not that it does not support counters at all.

We list the links of the online configuration manuals referenced in Table 6 below.

Abstract

This paper presents BFTBrain, a reinforcement learning (RL) based Byzantine fault-tolerant (BFT) system that provides significant operational benefits: a plug-and-play system suitable for a broad set of hardware and network configurations, and adjusts effectively in real-time to changing fault scenarios and workloads. BFTBrain adapts to system conditions and application needs by switching between a set of BFT protocols in real-time. Two main advances contribute to BFTBrain's agility and performance. First, BFTBrain is based on a systematic, thorough modeling of metrics that correlate the performance of the studied BFT protocols with varying fault scenarios and workloads. These metrics are fed as features to BFTBrain's RL engine in order to choose the best-performing BFT protocols in real-time. Second, BFTBrain coordinates RL in a decentralized manner which is resilient to adversarial data pollution, where nodes share local metering values and reach the same learning output by consensus. As a result, in addition to providing significant operational benefits, BFTBrain improves throughput over fixed protocols by 18% to 119% under dynamic conditions and outperforms state-of-the-art learning based approaches by 44% to 154%.

1 Introduction

Byzantine fault-tolerant (BFT) consensus protocols are the core engines powering the state machine replication (SMR) paradigm, ensuring that non-faulty replicas execute client requests in the same order, despite the existence of f Byzantine replicas. The ability to tolerate up to f arbitrary failures makes BFT protocols a key component in various distributed systems, including permissioned blockchains [6, 48], distributed file systems [19, 22], locking services [23], firewalls [33, 34], key-value stores [27, 35], and SCADA systems [9, 45].

While various BFT protocols have been proposed (e.g., PBFT [18, 19], Zyzzyva [46], CheapBFT [43], Prime [4], SBFT [40] and HotStuff-2 [52]), there is no one-size-fits-all solution. The performance ranking of BFT protocols varies significantly depending on client workloads, network configurations, and application needs. For example, protocols that reduce message complexity by increasing communication phases exhibit better throughput but worse latency. In addition, adversarial behaviors in the system also affect the best-performing protocol choice. The lack of a clear "winner" among BFT protocols makes it difficult for application developers to choose one and may invalidate their choice if workloads or attacks change. This is exacerbated in blockchain systems where application workloads and potential attacks are diverse and dynamic [37].

To address this challenge, two prior systems, Abstract [8, 38] and ADAPT [10] have been proposed. Both systems combine multiple protocols under a single framework and switch between protocols adaptively in real-time. Specifically, Abstract creates an adaptive framework whereby there is a predefined switching order of BFT protocols. If one protocol does not make sufficient progress, it is aborted and the next protocol in the predefined order is selected. Such an approach lacks flexibility and is unlikely to work in all scenarios.

ADAPT enhances protocol selection using supervised learning, but it faces operational limitations. First, it relies on a single replica to collect data, train the machine learning model, and then distribute the decision to all other replicas. In a Byzantine environment, such centralized control is not realistic and runs counter to the entire BFT approach. Second, its requirement for prolonged upfront data collection and supervised learning hinders its ability to adapt to unforeseen conditions and workloads. Lastly, as our experiments will demonstrate, ADAPT's incomplete feature space design renders it ineffective under diverse fault scenarios.

To embrace the idea of a multi-protocol BFT engine while considerably enhancing its practicality, we propose *BFTBrain*, a reinforcement learning (RL) based BFT system. At a high level, given a performance metric to optimize, BFTBrain smartly switches between a set of BFT protocols at run-time under dynamic workloads. BFTBrain is *practical* in two aspects — it not only maintains adaptivity under various adversarial behaviors, but also provides significant *operational benefits* when deployed on different hardware and system configurations: instead of manually choosing from multiple alter-

native systems for deployment, or running a prolonged data collection process prior to the deployment, BFTBrain only requires running one system that automatically re-configures itself to implement a top-performing protocol in real-time.

To leverage RL, BFTBrain measures in real-time performance metrics obtained locally by replicas. Beyond standard metrics like commit throughput, BFTBrain employs fine-grained metrics that offer deeper performance insights, such as the ratio of requests that are committed in the fast path of dual-path protocols, the number of received messages per slot, and the interval between consecutive leader proposals. These new metrics are measured in a distributed manner and serve as features for BFTBrain's RL engine. By modeling the selection of a BFT protocol as a contextual multi-armed bandit problem, the RL engine strategically tests different protocols at run-time to learn which ones are well-suited to the current system conditions. BFTBrain coordinates RL in a decentralized manner, where nodes share local features/rewards by consensus and reach the same learning output, achieving resilience to adversarial data pollution. Our extensive evaluation shows that BFTBrain significantly outperforms fixed protocols and existing adaptive systems in dynamic workloads and faults.

Specifically, this paper makes the following contributions.

BFT based on reinforcement learning. To our best knowledge, BFTBrain is the first BFT system that utilizes reinforcement learning to achieve run-time adaptability. It does not rely on a lengthy data collection process prior to every deployment and effectively adapts to unforeseen system conditions.

Adaptivity to fault scenarios. BFTBrain is the first BFT consensus system that not only automatically adapts to dynamic user workloads under a broad set of hardware and system configurations, but also adapts to various fault scenarios.

Dissecting BFT performance. Through a suite of workload and fault parameters, we conducted a large-scale study examining the relationship between protocol algorithmic design and performance, encompassing a wide range of well-known BFT protocols, including PBFT, Zyzzyva, CheapBFT, Prime, SBFT, and HotStuff-2. Our experiments highlight the vast state space, rendering existing solutions impractical.

Prototype and experimental evaluation. We developed a prototype of BFTBrain and integrated it with the six BFT protocols listed above. Our CloudLab evaluation demonstrates that BFTBrain improves throughput by 18%-119% over fixed protocols under dynamic conditions and outperforms the state-of-the-art learning-based approach by 44%-154% depending on how many data are polluted by adversaries.

2 Landscape of BFT Performance

To motivate BFTBrain, we first conduct an in-depth performance study to examine how various BFT protocols perform under different conditions. The key takeaway is that no single BFT protocol is always "better" or "worse" than others, but rather that different protocols perform better/worse than others under different circumstances.

Table 1: Our observed best-performing BFT protocols under different conditions. The advantage over the second-best protocol is shown in the last column.

f	# of absentees	request size	proposal slowness	best protocol
1	0	4KB	0ms	Zyzzyva (15.6%)
4	0	4KB	0ms	Zyzzyva (34.3%)
4	0	100KB	0ms	CheapBFT (8.5%)
4	4	4KB	0ms	CheapBFT (13.1%)
4	0	0KB	20ms	HotStuff-2 (45.4%)
4	0	1KB	20ms	HotStuff-2 (44.8%)
4	0	0KB	100ms	Prime (16.9%)
1	0	0KB	20ms	Prime (71.5%)

2.1 Comparing Representative BFT Protocols

We picked six representative BFT protocols as our exploration targets: PBFT [18], Zyzzyva [46], CheapBFT [43], Prime [4], SBFT [40], and HotStuff-2 [52]. All six protocols are *leader-based*, working in the partial synchrony settings with networks of $n = 3f + 1$ nodes[1]. Detailed background on these protocols is provided in Appendix A. These protocols and the benchmarking tools were implemented under a common software framework Bedrock [5]; hence, our evaluation below focuses on the impact of algorithmic logic of these protocols on performance, rather than the effect of the implementation details of a specific system.

Our experiments were conducted on CloudLab [28] where each replica is an `xl170` bare metal server. We ran these six protocols under diverse workloads and fault scenarios, and compared their average throughput during 120 second runs that were stably reproduced 10 times. For a fair comparison, the common internal parameters (e.g., batch size and view-change timer) of all six protocols were configured with the same values. For simplicity and facilitating protocol switching, as described in later sections, we added f extra replicas to the original CheapBFT acting as *active* replicas (see [43]). This approach affects the hardware resource consumption and scalability of the original CheapBFT, but does not change its performance under our setups. We also emulated the overhead of the trusted subsystem CASH by injecting 60 μs delay for creating and verifying message certificates.

Table 1 summarizes our evaluation results. Importantly, it demonstrates that **no single protocol dominates in all conditions**. The first four columns indicate the workloads and fault scenarios: system size, number of non-responsive nodes, client request size, and slowness of leader proposals; a more detailed description is provided in Section 4.2. The last column shows the best-performing protocol under each condition as well as its relative percentage advantage in throughput over the second-best protocol; the throughput of all six protocols under each condition is provided in Appendix D.1.

It is worth underscoring that a "slowness-attack", capturing the interval between two consecutive leader proposals, ap-

[1] CheapBFT requires only $2f + 1$ with the help of trusted hardware, but was evaluated with $3f + 1$ for simplicity. Correctness is still guaranteed.

pears in many studies [4, 8, 23]. It captures a Byzantine attack where a malicious leader deliberately postpones its proposal before the view-change timer expires. In addition, it could also happen naturally in a heterogeneous deployment, where a leader has weaker compute or network resources compared to other replicas. Below, we navigate through the table and explain the insights behind the results.

Row 1-3. The first three rows are in an ideal world where every replica is benign and responsive, with no obvious slowness in leader proposals, while varying the network and request sizes. When $n = 4$ ($f = 1$) and the request size is 4KB, Zyzzyva outperforms the next best protocol CheapBFT by 15.6%. When increasing the network size to $n = 13$ ($f = 4$), Zyzzyva outperforms CheapBFT by 34.3%. However, when the request size increases to 100KB, a flip of ranking occurs: CheapBFT becomes the best-performing protocol and outperforms the second best protocol HotStuff-2 by 8.5%, which then slightly outperforms Zyzzyva. The comparison of rows 2 and 3 suggests that different protocols have different "sweet spots" depending on the request size and quorum size. When requests are small, optimistically waiting for $3f + 1$ votes is reasonable, but when requests become larger, waiting for the slowest f nodes to vote on a leader proposal takes a long time, especially when f is large. In the latter scenario, protocols that only need $2f + 1$ replicas to vote on the leader proposal perform better, even at the cost of an extra phase of exchanging small hashes and extra computation. Note that due to the separation of transaction dissemination from consensus logic, only the leader proposals contain the actual requests.

Two of the protocols we studied require a $3f + 1$ quorum in their fast paths: Zyzzyva and SBFT. Across rows 1 to 3 in Table 1, Zyzzyva's performance leads or almost equals SBFT since it has fewer phases of communication. However, we found that with weaker clients, SBFT outperforms Zyzzyva in some cases. More specifically, we reran row 1 on a different hardware setup, where the client machine (which hosts multiple client threads) is configured with fewer CPU cores and higher network latency: this is done by limiting the available CPU cores on a 10-core machine to 6 using `taskset` and injecting an extra 20ms RTT. In this new setup, SBFT outperforms Zyzzyva by 8.5%. These two protocols demonstrate a design trade-off between the number of phases and the choice of commit collector. Since SBFT moves the collector role from clients to certain replicas, it is beneficial when clients have weak network connectivity and compute power.

Row 4. Row 4 demonstrates the effect of non-responsive replicas, referred to as absentees in the table. When certain replicas are non-responsive, the performance of dual-path protocols is adversely impacted, since a slow path is activated only after a timer expiration when failing to gather $3f + 1$ votes on the fast path. Conversely, single-path protocols are less impacted and even have better performance due to fewer message validations and less bookkeeping. In this setting, CheapBFT is the best-performing protocol in our evaluation, which outperforms the next best protocol HotStuff-2 by 13.1% since it has fewer phases of communication. Due to their slow paths, Zyzzyva and SBFT become the bottom-performing protocols. It is worth mentioning that in our evaluation, HotStuff-2 is equipped with a reputation-based leader rotation mechanism, Carousel [24], which tracks active replica participation via their signed votes during the committed chain prefix in order to select the next leaders. For a HotStuff-2 implementation without leader reputation mechanisms, CheapBFT will outperform it by an even larger margin, since it suffers from a non-responsive leader periodically.

Row 5-8. Row 5-8 evaluate different degrees of proposal slowness, representing a Byzantine world where malicious leaders might deliberately slow down the system. When the slowness is as low as 20ms and f is large, HotStuff-2 outperforms all other protocols by up to 45.4%. This is due to HotStuff-2's *routine* leader rotation, which is made possible with low cost by its linear responsive view-change and alleviates the impact of slow nodes elected as leaders. Although Prime also replaces slow leaders proactively, it has more phases and higher communication complexity than HotStuff-2 (i.e., 6 phases and quadratic complexity compared to 2 phases and linear complexity), resulting in worse performance. However, when the slowness further increases to 100ms, or when the network size reduces from 13 to 4 ($f = 4$ to $f = 1$), the ranking flips: Prime outperforms HotStuff-2 by 16.9%-71.5%. This happens since Prime replaces any deliberately slow leader with a *stable* benign leader. In Prime, each node measures the actual turnaround time to the leader, which is independent of the system load, and compares it with the acceptable turnaround time, which is a function of the RTT between correct servers. In HotStuff-2, when the network is small or slowness is high, slow nodes are being rotated in as leaders routinely, causing considerable slowness. This outweighs the benefits of HotStuff-2's simpler and linear communication pattern, resulting in sub-optimal performance.

These experiments demonstrate a complex trade-off between design principles of different BFT protocols. Thus, when conditions change dynamically, no single protocol outperforms others in all scenarios.

2.2 The Case for Reinforcement Learning

Since no single BFT protocol is dominant in all scenarios, one could imagine building heuristics or supervised learning models that map conditions to the best-performing protocol, and switching protocols at run-time according to the current perceived conditions. However, such approaches suffer from several drawbacks.

Condition space size. The condition space is too large to search. Table 1 only presents a sample of the space. The complete condition space we monitor consists of 6 dimensions (State 1 and 2 in Section 4.2), where each dimension is either a continuous or discrete variable. Further, each point in the condition space has multiple protocols to experiment with.

Even with coarse-grained sampling and an automated toolkit, it took us more than a week to experimentally explore just a small subset of the condition space. Unfortunately, building good heuristics and supervised models requires *complete* data, which are hard to obtain.

Hardware and time dependence. The mapping from conditions to the best-performing protocol depends on the underlying hardware and system configuration: when changing from `xl170` to `m510` instances on CloudLab, or changing from a 13-node network to a 4-node network, the mapping changes. Additionally, we observe that even with the same hardware instance type but across different launches on shared facilities like CloudLab, the sweet spots (in terms of request size) of Zyzzyva and CheapBFT change due to subtle differences in physical machines and network resource availability. Worse yet, network conditions can change over time, rendering any pre-computed mapping on a specific network less useful.

Growing protocol space. When new BFT protocols emerge (e.g., HotStuff-2) or changes are introduced to existing implementations (e.g., DiemBFT-v1 to v4 [1]), any precomputed mapping would need to be recomputed. In other words, one would need to re-collect data and re-craft the heuristics, or re-collect data and retrain the supervised model virtually every time a new BFT consensus protocol is proposed.

Reinforcement learning addresses this daunting and complex task, and has shown superior performance in other learned systems [20, 53, 54, 62]. Unlike supervised learning, which assumes training data is complete and requires a separate lengthy data collection process prior to deployment, one can simply plug and play an RL-based system — it learns from its mistakes and optimizes long-term rewards through trials in an online fashion. With reinforcement learning, BFTBrain can optimize itself to whatever client workloads, faults, hardware, system configurations and BFT protocols present, providing adaptivity and significant operational benefits.

3 BFTBrain Overview

We provide an overview of BFTBrain, first outlining its system model followed by its overall reinforcement learning based design.

3.1 System Model

In BFTBrain, we assume a system consists of a fixed set of $n = 3f + 1$ *nodes* and a finite population of *clients*, where up to f nodes and any number of clients might experience Byzantine faults. Each node serves two roles simultaneously, *validator* and *learning agent*. A validator is responsible for totally ordering the blocks, while a learning agent coordinates online data collection, trains machine learning models, and periodically instructs the companion validator at run-time to replace the current BFT protocol.

When a node is faulty, it can behave arbitrarily in any of its roles. The faulty validators may exhibit standard malicious behavior such as double voting and message suppression or equivocation. We assume a strong adversary that can coordinate the faulty validators to compromise the replicated service. However, we do assume the adversary cannot break the cryptographic techniques. Given our use of machine learning, faulty learning agents could exhibit additional malicious behaviors related to learning, such as being non-responsive (e.g., refuse to exchange its locally measured data with other learning agents), as well as presenting *arbitrarily manipulated* local data points (i.e., local features and rewards) in order to disrupt the machine learning models on other agents.

Network communication is point-to-point and authenticated. BFTBrain adopts the *partial synchrony model* [29], where there is a known bound Δ and an unknown Global Stabilization Time (GST), such that after GST, all transmissions between two correct nodes arrive within time Δ. For two different roles on the same node, we assume their communication in-between is always synchronous.

3.2 Design Overview

At a high level, BFTBrain contains three key components: (1) a reinforcement learning algorithm (i.e., the core of the learning agent) that guides the choice of BFT protocols according to the perceived underlying dynamic environment, (2) a coordination protocol that collects data distributedly at run-time, and (3) a switching mechanism that allows BFTBrain to seamlessly transition from one BFT protocol to another while ensuring safety and liveness.

BFTBrain operates in *epochs*, where each epoch is marked by the completion of k blocks. Here, k is a predefined constant hyper-parameter. Within one epoch, the protocol remains unchanged. When the learning agent finds a protocol candidate, it instructs the validator to use that protocol for the next epoch. We next introduce BFTBrain's key components and workflow.

Learning agent. BFTBrain's learning agent models the problem of selecting a BFT protocol as a contextual multi-armed bandit (CMAB) problem [67]: periodically, BFTBrain examines the most recent state of the workload and faults in the system (*context*), and then selects one of many BFT protocols (*arms*) in our protocol pool. After making the selection, it observes the performance of the newly selected protocol (*reward*). To be successful, BFTBrain must balance the *exploration* of new, untested protocols with *exploiting* past experience to maximize performance. That is, without a careful balance of exploration and exploitation, BFTBrain risks failing to discover an optimal protocol (too much exploitation), or performing no better than random (too much exploration). We select this CMAB formulation (as opposed to full reinforcement learning) because CMABs are exceptionally well-studied, enable faster convergence, and many asymptotically-optimal algorithms exist to solve them [2, 21]. Details about the learning algorithms are provided in Section 4.

Since BFTBrain operates in a Byzantine environment, a centralized learning agent cannot be trusted. In BFTBrain, each validator process has a companion learning agent run-

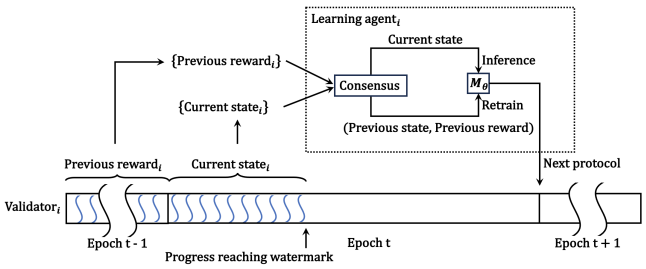

Figure 1: Overview of BFTBrain. For readability, we only present the internals of one node i.

ning on the same node, and accepts instructions only from its companion learning agent. The learning agents themselves also form a state machine replication. Specifically, they start with the same *initial state*, i.e., the same random seed of machine learning models. For the same epoch t, as we will show later, different learning agents agree on the same *sequence of operations*, i.e., training data points where each data point consists of context and reward. With deterministic training, benign learning agents host the same parameters for their machine learning models. As a result, if different learning agents perceive the same context for epoch $t+1$, they will render the same decision (i.e., choice of protocol) for epoch $t+1$.

Distributed online data collection. In a Byzantine environment, no centralized entity could be trusted to collect training data. Therefore, the learning agents in BFTBrain also participate in a protocol that coordinates distributed data collection in an online fashion. At a high level, for every epoch, each learning agent monitors its local context and reward at runtime, then exchanges them with other agents via a separate instance of BFT consensus independent of the consensus that validators are running. For each epoch, agents form agreement over an aggregation of contexts and rewards that include input from at least a quorum of two-thirds of agents. The consensus algorithm used for forming this agreement is left open for the system designer (note that it is invoked only once per epoch, hence does not need to have high throughput). Once an agreed quorum of local contexts and rewards is obtained, each learning agent can apply the same robustness filter to the quorum in order to get a global context and reward, constituting a training data point. Details about this learning-coordination protocol are provided in Section 5.

Switching BFT protocols. After a BFT protocol is selected by the learning agent, the switching mechanism allows each validator to make use of this protocol for the next epoch. Our switching mechanism is an improvement over Abstract [8], which aborts a BFT instance if a certain progress condition is not met. An epoch in BFTBrain is equivalent to a *Backup* instance in Abstract. Due to space limits, details on how we switch BFT protocols are provided in Appendix B.

BFTBrain workflow overview. Figure 1 presents an overview of BFTBrain, where each node in the system follows the same workflow as depicted. In the middle of epoch t, when the number of executed blocks reaches a certain watermark, the validator on node i notifies its local learning agent. The learning agent featurizes its current local state (i.e., context) observed in epoch t, and uses it to approximate the next local state $state_i^{t+1}$ for epoch $t+1$. Each agent exchanges $state_i^{t+1}$ and its locally measured reward of previous epoch $reward_i^{t-1}$ with other agents via the learning-coordination protocol. Therefore, each agent obtains the same global state $state^{t+1}$ and reward $reward^{t-1}$. Subsequently, each agent adds the $(state^{t-1}, protocol^{t-1}, reward^{t-1})$ triplet to its experience buffer, and retrains its predictive model M_θ based on its experience buffer as well as the chosen algorithm to solve CMAB. Once retrained, the predictive model M_θ inferences the performance of each protocol candidate under $state^{t+1}$, and selects $protocol^{t+1}$ that is predicted to have the best performance. The learning agent then informs the validator to switch to $protocol^{t+1}$ for epoch $t+1$, the reward of which is then measured locally upon reaching the end of epoch $t+1$. The validator only starts epoch $t+1$ once it receives a decision for that epoch from the companion agent.

The learning agent is designed in a way such that the BFT system is not delayed due to learning. First, within one epoch, when the model undergoes retraining and inference, the parallel validator process still commits blocks simultaneously. Second, with a lightweight model design and limiting the size of the experience buffer, model training and inference can be viewed as a synchronous process. In other words, with a reasonable epoch length, the learning agent can complete protocol selection before the validator finishes its current epoch, without impeding the start of the next epoch.

4 Learning Algorithms

This section delves into BFTBrain's learning algorithms. We first formalize the learning problem and explain the use of Thompson sampling. The state and action space design is then outlined, followed by the predictive model description.

4.1 Problem Formulation

BFTBrain formulates the learning problem as a contextual multi-armed bandit (CMAB) problem, where an agent periodically makes decisions in a sequence of epochs. In epoch t, the agent selects an action a_t in its protocol pool based on a provided state s_t, and then receives a reward r_t. The agent's goal is to select actions in a way that minimizes *regret*, i.e., the difference between the reward sum associated with an optimal selection strategy and the reward sum associated with the chosen actions. CMABs assume that epochs are independent from each other, and that the optimal action depends only on the state s_t. BFTBrain fits this assumption, since the current choice of protocol does not affect the pattern of workloads and faults in future epochs. Using this CMAB formulation, BFTBrain allows users to specify any performance metric (e.g., throughput or latency) as the reward function to optimize.

Thompson sampling. Amongst different CMAB algorithms, we select Thompson sampling [2, 21] for its simplicity: at the start of each epoch, the learning agent trains a model based on current experience, and then selects the best action as predicted by the model. In Thompson sampling, instead of selecting the model parameters that are most likely given the training data as used by supervised learning, it *samples model parameters proportionally to their likelihood given the training data*. More formally, we can define maximum likelihood estimation as finding the model parameters θ that maximize likelihood given experience E: $\arg\max_\theta P(\theta \mid E)$ (assuming a uniform prior). Instead of maximizing likelihood, Thompson sampling simply samples from the distribution $P(\theta \mid E)$. As a result, if we have a lot of data suggesting that our model weights should be in a certain part of the parameter space, our sampled parameters are likely to be in that part of the space. Conversely, if we have only a small amount of data suggesting that our model weights should be in a certain part of the parameter space, we may or may not sample parameters in that part of the space during any given epoch.

4.2 State and Action Space

We next list factors that affect the performance of BFT protocols, broadly grouped into workloads, faults, and hardware/system configurations categories, jointly constituting the state space. Within each epoch, each learning agent leverages a window of the last w executed requests to featurize such factors, where w is a constant hyper-parameter.

State 1: Workloads (W). The first category consists of factors that are influenced by application and client dynamics.

W1: Request size. The request size is dependent on the application workload, where some requests contain little data while others are more involved and require updating files with large chunks of data. Although all our candidate protocols separate request dissemination from sequencing (i.e., only the leader proposals contain the actual requests while the remaining messages contain the hash of requests), as described in Section 2, request size is still an important factor impacting the performance of different protocols in different ways. We use the average request size to represent this feature.

W2: Reply size. Depending on the application, request and reply size can be asymmetric. Reply size also impacts different protocols in different ways, but with a distinct boundary from that of request size. For instance, in our experiments, when all other factors remain the same, CheapBFT performs best for either 0KB/4KB (request size/reply size) or 40KB/0KB, while Zyzzyva is best with 4KB/0KB. Furthermore, different protocols have different sensitivity to an increase in reply size. For instance, SBFT reduces the per-client linear reply cost to just one message by adding an execution aggregation phase. We use the average reply size to represent this feature.

W3: Load on system. The load on the BFT system is dependent on the number of clients and the rate at which clients send new requests. Specifically, each honest client allows a *quota* of outstanding unacknowledged requests before issuing new ones, controlling the rate at which requests are generated relative to the system's capacity to process them.

In our experiments, we observed that lowering the load affects different protocols in the same direction, but to different extents: for example, there is a sharper drop in the throughput of Zyzzyva and SBFT compared with other protocols. The reason is that lower load increases batching delay, which has a larger impact in terms of both latency and throughput on protocols with fewer phases (i.e., Zyzzyva and SBFT in our protocol pool). BFTBrain derives the per-client sending rate according to the request timestamps, and uses the aggregated client sending rate to represent this feature.

W4: Execution overhead. Execution overhead captures the computational cost of request execution, which impacts the system in two ways. First, it directly affects the execution latency in state machine replication. Second, it indirectly affects other components of the BFT protocol that are also compute-intensive. For instance, requests with high execution overhead compete for CPU resources that are otherwise used to sign and verify messages, especially when machines have limited compute capacity or a small number of cores. Higher compute load results in excessive context switching, and potentially pushes the system towards being compute-bound instead of network-bound. We use the CPU cycles consumed by the executor thread to represent this feature.

State 2: Faults (F). The next category of factors is tied to faulty behaviors. BFT protocols make different assumptions about "steady state" and "common faults", and hence, each protocol is often optimized for specific fault scenarios. The features below enable BFTBrain to tell what type of fault scenarios the system is experiencing and choose the most promising protocol accordingly.

Note that BFTBrain does not aim to defend against *transient* or *broad-spectrum* faults. The reason is, transient faults are already handled timely at the protocol level and require no protocol switching. An example would be a crashed leader or a malicious leader which equivocates, such that no progress is made and a view-change will be triggered to replace the leader. For broad-spectrum faults, effective and orthogonal solutions already exist. Examples of broad-spectrum faults include network flooding which can be resolved via resource isolation [8], and malformed client requests which can be handled by enforcing client signatures (instead of MACs) [23].

F1: Absence from participation. Measuring absence is tricky in a Byzantine environment, since information reported by malicious nodes could deviate from their actual participation. Moreover, a collusion of f malicious participants could taint validator participation simply by *excluding* some alive benign validators (up to f) and progressing without them. For example, a malicious leader could deliberately avoid sending leader proposals to them, while the f malicious validators work together with the remaining $f+1$ benign ones to make sure all requests are committed successfully on these $2f+1$ valida-

tors. We refer to such excluded, non-faulty validators as being placed *in-dark*. In-dark validators could further be excluded in other protocol phases, in addition to leader proposals, by f malicious validators. Since no state transition is ever triggered on in-dark validators, they remain in the initial state and are thus absent from participation. Although they will timeout and complain, since fewer than $f+1$ validators complain, view-change is not triggered to replace the malicious leader and they are in-dark continuously.

All protocols tolerate the absence of up to f validators by design, but the performance of different protocols is impacted differently. As illustrated in Section 2, dual-path protocols (i.e., Zyzzyva, SBFT) are adversely impacted since the more expensive slow paths are initiated, while single-path protocols (i.e., PBFT, CheapBFT, Prime, HotStuff-2) could be positively impacted due to less resource consumption.

The learning agents in BFTBrain featurize absence by utilizing information that is already collected locally during protocol execution. First, *fast path ratio* captures the percentage of slots committed in the fast path over the total number of committed slots. For single-path protocols, all slots are committed in the slow path. Second, for each slot, the agent sums the number of (valid) distinct messages from each sender, deriving the *number of received messages per slot*. Note that this feature does not incur more messages to be sent or received; it simply counts messages as they arrive and pass preliminary processing (de-serializing and sender verification) before they can be excluded from protocol steps like voting. In fact, these two features could capture a sufficiently big subset of abnormal behaviors, encompassing not only omission failures but also leader equivocation and network partitions.

F2: Slowness of proposal. In leader-based BFT protocols, every slot is initiated by a leader proposal, which significantly affects the system's end-to-end performance. In the case of a faulty leader, validators use a timer to trigger view-change, which will replace the leader, hence guaranteeing liveness. However, a malicious leader can deliberately slow down its proposals without being replaced, resulting in poor latency and throughput. Slowness may not necessarily be a deliberate act by a malicious leader, it could result simply from a weak or overloaded leader, albeit to a lighter extent.

Section 2 illustrates the effect of this factor. Protocols with routine or proactive leader replacement (i.e., HotStuff-2, Prime) maintain good performance under such slowness, but perform sub-optimally in other normal cases. To featurize this factor, each node in BFTBrain timestamps every leader proposal received, and measures the average time interval between receiving two consecutive proposals.

State 3: Hardware and system configurations. The last category comprises hardware and system configurations. Hardware-level factors include network settings that affect latency and bandwidth, and also machine configurations such as CPU frequency and the number of cores. We assume the network latency and bandwidth follow certain non-shifting distributions that capture noises in the network. System-level configurations include the number of nodes in the system and the geo-distribution of the nodes. Compared to State 1 and 2, both hardware and system configurations are fairly static and do not change rapidly at the timescale of a consensus deployment. Thus, BFTBrain does not explicitly featurize these factors because (1) the impact of these factors is implicitly encoded in the predictive model trained online, and (2) CMABs will converge even without any explicit features [12], the purpose of which is to accelerate convergence so that the optimal action is reached before the world changes.

Actions. BFTBrain's action space consists of the same set of leader-based protocols that are studied in Section 2, namely, PBFT, Zyzzyva, CheapBFT, Prime, SBFT, and HotStuff-2. As we will show later, since BFTBrain builds a separate model for each candidate protocol, features of the protocol design are encoded in the model itself. Thus, BFTBrain does not require protocol-specific feature engineering for encoding the action space, making it easy to incorporate new protocols into the BFTBrain framework. Although BFTBrain focuses on choosing the best-performing protocol, configuring protocol internal parameters (e.g., values of different timers and the interval for rotating leaders) intelligently at run-time can be an interesting future extension.

4.3 Predictive Model

Each learning agent hosts some predictive models, which follow the *value based* RL approach: given the featurized current state, predict the performance (i.e., reward) of each action (i.e., protocol). The simplest implementation would be to build a single predictive model for all protocols, but this has a major drawback. While features *W1-W4* in the workloads category are completely independent from the previous action, the featurized absence-from-participation $F1$ and slowness-of-proposal $F2$ have a "one-step dependency": the current observed $state^{t+1}_{F1,F2}$ is dependent on the previous $protocol^t$. When the workload and fault scenario shift, such one-step dependency might prevent convergence to the new optimal protocol. For instance, if BFTBrain has converged to protocols whose leader has lower parallelism (e.g., Prime due to message aggregation in global ordering), the measured slowness of proposals will be higher than other protocols, regardless of whether a fault is actually happening or not. In other words, the interpretation of the slowness-of-proposal feature changes based on the previous action. If the model learns that a high slowness-of-proposal is bad for Zyzzyva, then once Prime is chosen, slowness-of-proposal will always seem high, and Zyzzyva may not ever be selected again.

Luckily, unlike in the general case of Markov decision processes, the dependency observed here is limited to a single time step. That is, the prediction of the next best action is independent *given the immediately prior action*. To solve this issue rooted in one-step dependency, the learning agent trains a separate model for each possible (previous protocol,

protocol) pair, and divides the experience buffer into several smaller *buckets* according to the (previous protocol, protocol) pair as well. In terms of bandit theory, assuming there are K protocols in our action space, BFTBrain's approach is equivalent to playing K bandit games where each game has K arms. In each game, the current observed $state^{t+1}_{F1,F2}$ is independent from the previous action $protocol^t$.

It is worth mentioning that this transformation does not completely remove the one-step dependency. The action made at epoch t will determine which of the K bandit games is being played at epoch $t+1$. A multi-armed bandit algorithm will not be able to take advantage of the fact that some of the K bandits may have significantly better reward distributions than others. Thus, the convergence bound on regret of bandit algorithms will not apply to our scenario. However, since each of the K bandits will be played an unbounded number of times eventually (assuming the probability of any action never fully reaches 0), regret is still bounded in the limit.

Specifically, for each possible $(protocol^t, protocol^{t+1})$ pair, BFTBrain uses a lightweight random forest [15] as the predictive model, which is trained exclusively on the corresponding experience bucket. The model takes the featurized state as input, and outputs the predicted performance for the corresponding candidate action $protocol^{t+1}$. Thus, at inference time, given a known previous protocol and the current state, the learning agent enumerates K models to get the predicted performance for each candidate protocol, and then chooses the candidate with the best predicted performance to be carried out. Once there is a tie on the best predicted performance, we break the tie randomly to avoid local maxima. When an experience bucket is empty, BFTBrain prioritizes exploring this bucket by choosing the corresponding candidate protocol to be carried out.

Integration with Thompson sampling. Integrating a predictive model with Thompson sampling requires the ability to sample model parameters from $P(\theta \mid E)$ — the distribution of model parameters given the current experience. The simplest technique (which has been shown to work well in practice [55]) is to train the model as usual, but only on a bootstrap [14] of the training data. In other words, the predictive model is trained using $|E|$ random samples drawn with replacement from experience E, inducing the desired sampling properties. BFTBrain uses this bootstrapping technique on each experience bucket and predictive model for its simplicity.

Overhead of learning. First, BFTBrain's training overhead is not larger than the strawman of building a single predictive model, since in every epoch, only one model which corresponds to the updated bucket needs to be retrained. For such a bucket, the time complexity for training a single random forest is $O(n \log n)$, where n is the number of data points. Thus, given the same total population of data, it even incurs less training overhead than the strawman solution, since the bucket contains fewer data points than the single unified experience buffer. Second, BFTBrain's inference overhead is $O(K)$, where K is the number of candidate protocols. Lastly, BFTBrain has the same memory overhead as the strawman for storing training data. However, it incurs $O(K^2)$ memory overhead for storing the models. Since random forest is a very lightweight model as compared to deep neural networks, such model storage overhead is negligible.

5 Learning Coordination

The goal of the *learning-coordination* mechanism is to form an agreement at each epoch on a *report quorum* that includes local metrics collected from $2f+1$ nodes.

Specifically, learning coordination is performed in every epoch t. After executing w requests (a hyper-parameter) in epoch t, each node i gathers local performance indicators p_i^{t-1} measured during epoch $t-1$, featurizes the next state f_i^{t+1}, and broadcasts both metrics inside a report message. To ensure that at least $f+1$ metrics in the report quorum are honest measurements, it is important that the metrics reported by honest nodes are measured by **themselves**. That is, if a node j has been placed in-dark (defined in Section 4.2) or temporarily slows down during epoch t, it may not have executed w requests by itself. Rather, node j will have recovered the consensus state through a *state-transfer* from other nodes. In this case, j should avoid reporting the state features it has copied from others, and likewise, avoid reporting performance indicators collected from partial or no execution. Therefore, node j will not report any metrics for epoch t. Note that in addition to the f benign nodes being placed in-dark, in the meantime, the f Byzantine nodes that contributed to committing requests can refuse to report their metrics. Hence, there may not be enough $2f+1$ nodes reporting for the epoch.

In order for nodes to agree on a quorum of (valid) reports to be used as input for the learning engine, any "blackbox" validated Byzantine consensus primitive (VBC) seeded with a leader collecting reports from $2f+1$ nodes can be utilized. Specifically, for each epoch t, the leader of VBC initiates VBC-PROPOSE($(t, reportQC^t)$, P) once it receives valid report messages (p_i^{t-1}, f_i^{t+1}) where both fields are non-null from $2f+1$ nodes, or when a timer expires. Here, P is an external validity predicate that checks if $reportQC^t$ includes at least $f+1$ distinct reports.

Each node participating in VBC gates voting for a leader proposal it receives by applying the validity predicate P to it. Once a quorum of reports $reportQC^t$ is decided by VBC, if it includes sufficient $2f+1$ reports, each node takes the median value of each field in order to obtain a robust global performance measurement p^{t-1} and state feature f^{t+1}, thereby triggering the retraining and inference process. Taking the median value from an aggregated set of metrics guarantees that despite f arbitrarily manipulated values from Byzantine nodes, the global value taken is between two honest measurement values. Otherwise, if $reportQC^t$ does not include sufficient reports, each node retains the decision from the

previous epoch instead of deriving any new learning decision, and complains about the leader in VBC as well as the leader in the current protocol used by the node for committing client requests. Note that since VBC is a separate consensus instance, the leader of VBC can be different from the leader of the current protocol in BFTBrain. Either of them acting maliciously can result in insufficient reports being collected.

For completeness, Appendix C.1 presents in Algorithm 1 a detailed learning coordination protocol where VBC is implemented using PBFT. Due to space limitations, the safety, liveness, and robustness guarantees of BFTBrain's learning agents are discussed and proved in Appendix C.2.

6 Implementation

We implemented BFTBrain in Java using Bedrock [5], a unified platform for BFT protocol implementation and experimentation. The Bedrock platform consists of four main components: the core unit, the state machine manager, the plugin manager, and the coordination unit. The core unit defines entities (e.g., clients and validators), maintains the application logic, enables users to specify different workloads and benchmarks, and track the execution of requests via sequence numbers and views. The state machine manager parses Bedrock's domain-specific language (DSL) for rapidly prototyping BFT protocols, and defines the states and transitions of the specific BFT protocol for each entity. The plugin manager enables implementing protocol-specific behaviors that cannot be captured by Bedrock's DSL, while the coordination unit manages the run-time execution of Bedrock.

All protocol candidates in BFTBrain's action space utilize Bedrock. On top of it, we implemented a workload and fault generator, which allows users to specify time-varying dynamics inside a `YAML` configuration file, enabling parameterized random sampling and scheduling of predefined sequences of events. To enable switching among BFT protocols, we implemented a new state machine manager which loads all plugins required by BFTBrain when the system boots, and uniquely tags each protocol state and transition such that different protocols do not interfere. This approach has negligible overhead since such loading and tagging only happens when the system boots, and lookup for states and transitions at run-time takes a (small) constant time. We implemented the learning agent separately in Python using `scikit-learn`, which communicates with the companion validator process in Bedrock via gRPC. Our implementation is publicly available[2].

7 Evaluation

Our evaluation aims to answer the following questions:

1. How fast can BFTBrain converge to the best-performing protocol under static conditions without pre-training?
2. How does BFTBrain compare to fixed protocols and existing learning-based approaches in dynamic environments?
3. How does the hardware setup affect the performance of fixed protocols? How does BFTBrain compare to existing learning approaches under different hardware setups?
4. How robust is BFTBrain and how does it compare to existing learning approaches under adversarial data pollution?
5. What learning overhead does BFTBrain introduce?

In the rest of this section, we present the experimental setup and then answer each of the above questions.

7.1 Experimental Setup

Testbed. Unless otherwise specified, our testbed consists of several bare-metal xl170 machines on CloudLab, each with a 10-core Intel E5-2640v4 processor at 2.4 GHz, 64GB ECC Memory, and two dual-port Mellanox ConnectX-4 25 GB NIC. Each server is connected via a 10Gbps control link and a 25Gbps experimental link to Mellanox 2410 switches in groups of 40 servers. Our experiments are conducted using the experimental link.

System configuration. Our experiments are carried over networks of two sizes: $n = 4$ and $n = 13$. In all experiments, we run multiple client threads on a separate xl170 server, where each client follows the standard closed-loop buffer design, i.e., allows at most 100 outstanding unacknowledged requests before issuing new ones. The number of clients is a parameter in our workload space. We use batch sizes of 10 requests throughout the experiments. Every experiment of BFTBrain starts with PBFT as its initial protocol. We use throughput as the reward function for BFTBrain to optimize.

7.2 Convergence under Static Conditions

Our first set of experiments evaluates how quickly can BFTBrain converge to the best-performing protocol under static conditions. We picked three representative settings from Table 1 where the size of the network is small: row 1, a variant of row 4 where $f = 1$, and row 8. Under each setting, we ran all six fixed protocols and BFTBrain for 10 minutes on a LAN. We note that the other rows in Table 1 yielded similar conclusions and are omitted for brevity.

Table 2 summarizes our results, listing for each static condition the average throughput (tps) of each protocol in the last 20 epochs. The last column reports the convergence time of BFTBrain, defined as the time BFTBrain spent to reach the stable peak throughput. Although each setting has a different best-performing protocol, BFTBrain always learns to select it within 0.81-5.39 minutes[3]. As we will show soon, the convergence is significantly accelerated the second time BFTBrain encounters the same conditions.

Obviously, in this experiment, BFTBrain is not able to surpass the best-performing protocol in any given setting. Additionally, as shown in the table, it experiences a marginal increase in switching overhead when compared to the leading protocol in each specific setting. Nevertheless, owing to its adaptability, BFTBrain does deliver the best average and best

[2] https://github.com/JeffersonQin/BFTBrain

[3] Most RL systems quantify convergence time in minutes.

Table 2: Throughput of protocols and the convergence time of BFTBrain under various static conditions. The highest throughput in each row is highlighted in **blue**.

Condition	Average Throughput (tps)							Conv. Time (minutes)
	PBFT	Zyzzyva	CheapBFT	Prime	SBFT	HotStuff-2	BFTBrain	
Row 1 (LAN)	9133	**13664**	11822	4601	11067	6882	13100	0.81
Row 4 (LAN)*	10303	1025	**12297**	3749	2920	5156	11803	2.08
Row 8 (LAN)	989	988	989	**4527**	989	2640	4329	5.39
Row 1 (WAN)	5325	9503	**12201**	1639	8261	2882	11101	1.58
Average	6438	6295	9327	3629	5809	4390	**10083**	2.47
Worst	989	988	989	1639	989	2640	**4329**	5.39

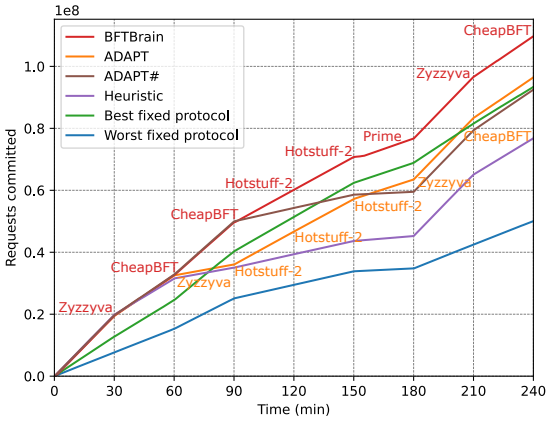

Figure 2: Adaptivity of BFTBrain under changing conditions. The vertical dashed lines indicate when conditions change. Labels indicate the dominant protocol that BFTBrain and ADAPT choose under each condition.

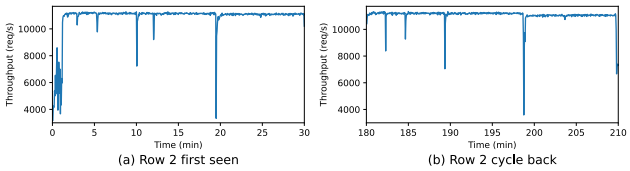

Figure 3: BFTBrain's throughput (a) during minutes 0-30, and (b) during minutes 180-210. In both periods, it encounters the system conditions captured in row 2 of Table 1.

worst-case performance across all settings in the table. In contrast, fixed protocols exhibit subpar average and worst-case throughput, underscoring our initial premise that no single fixed protocol excels under all circumstances.

7.3 Adaptivity under Changing Conditions

Our next set of experiments evaluate BFTBrain under dynamic conditions, demonstrating clear performance benefits.

Cycle back conditions. In the initial series of experiments, we selected rows 2-7 from Table 1, each characterized by an identical network size ($f = 4$). We ran the settings of each row for 30 minutes each, employing a round-robin approach to switch to the next row and repeating the cycle from the beginning after reaching row 7. We compared BFTBrain against five baselines: the fixed protocols with the best and worst performance (based on the number of committed requests throughout the entire experiment), ADAPT, ADAPT#, and an expert heuristic. Details on the last three are explained below.

To be faithful to ADAPT's design [10], we excluded all features capturing faults (i.e., State 2 in Section 4.2), and pre-trained ADAPT with complete data that we collected in these changing conditions when running BFTBrain for hours spanning multiple protocols. To study the effect of *unseen conditions* in supervised learning, we implemented another baseline named ADAPT#. In ADAPT#, we used the same set of complete features as BFTBrain, but pre-trained it on partial data that we collected in these changing conditions, i.e., excluding data corresponding to the settings of rows 5-7. In both ADAPT and ADAPT#, for fair comparison, we used the same set of BFT protocols as BFTBrain in their action space. The expert heuristic we used is designed based on insights gleaned from Table 1, namely: if proposal slowness is greater than 20ms, use Prime; otherwise, use Zyzzyva.

Figure 2 shows the cumulative number of committed requests over time, where the slope of each line indicates its current throughput. Throughout the 4-hour experiment, BFTBrain successfully converges to the best-performing protocols whenever the conditions change. In terms of the number of requests committed, BFTBrain demonstrates 18% improvement over the best fixed protocol (i.e., HotStuff-2), 119% over the worst fixed protocol (i.e., PBFT), 14% over ADAPT, 19% over ADAPT#, and 43% over heuristic.

As expected, both ADAPT and ADAPT# exhibit similar performance to BFTBrain for the first 60 minutes, as the system is operating without faults and their features and training data encompass these conditions. However, both methods encounter challenges when the conditions shift to rows 4-7. ADAPT struggles since it fails to recognize the changes in conditions, as faults are not captured in its feature space. While ADAPT# does detect the changes due to its expanded feature set, these conditions were absent during its pre-training phase.

Two things are worthy of noting. First, BFTBrain not only outperforms both supervised learning based approaches, but also completely removes the cumbersome data collection and pre-training process prior to deployment. Second, in common stable conditions corresponding to row 2, BFTBrain

outperforms HotStuff-2 by 57% while being able to switch to HotStuff-2 when conditions become advantageous for it.

Figure 3 further demonstrates how BFTBrain's throughput changes over time: (a) during minutes 0-30, and (b) during minutes 180-210. In both periods, it encounters the conditions captured in row 2 of Table 1. Obviously, when the system condition cycles back to what it has seen before, BFTBrain converges to the best-performing protocol much faster than the first time (2s vs. 70s). The blips in both throughput plots indicate that certain sub-optimal protocols have been chosen for a few epochs. These are the explorations made by the Thompson sampling algorithm when it samples the less likely model parameters. When conditions are dynamic, such sampling is crucial to avoid being stuck at a local sub-optimal decision, since the predictive model can gain insights on the performance of unexplored protocols in the current condition.

Randomized sampling. Our next experiment evaluates BFTBrain's adaptivity when there are *more variations* in the state space and when the variations are *more frequent*. Specifically, each dimension in the state space follows a certain normal distribution. We varied each dimension every 1s by randomly sampling from its distribution, and shifted the mean and variance of such distribution every 20 minutes. Appendix D.2 presents the detailed experiment setup and results. In a nutshell, during the entire 2-hour deployment, BFTBrain commits 44% more requests than ADAPT. This is a much larger improvement than the 14% improvement demonstrated in the cycle back experiment and can be explained as follows. Certain input factors in the cycle back experiment are correlated, e.g., a request size near zero is correlated with high proposal slowness. Thus, although ADAPT suffers from incomplete features, it indirectly learns the best-performing protocol under high proposal slowness using other features, as shown in Figure 2 between 90-150 minutes. However, randomized sampling breaks such correlations, and as a result, ADAPT does not have enough information to know how the surrounding environment changes which leads to poor performance.

7.4 Adaptivity to Changing Hardware

The next set of experiments evaluate BFTBrain under different hardware setups from our initial protocol evaluation, and compare with the adaptivity of ADAPT to these new setups. Specifically, we reran the settings of row 1 from Table 1 on a live WAN (RTT=38.7ms, bandwidth=559Mbps) instead of on a LAN, where we placed two nodes in Cloudlab's Utah data center on xl170 machines and the other two nodes in the Wisconsin data center on c220g5 machines. We compared BFTBrain with fixed protocols and with ADAPT in this setup.

The results are summarized under "Row 1 (WAN)" in Table 2; the detailed performance plot of BFTBrain and ADAPT is provided in Appendix D.3. Interestingly, compared to "Row 1 (LAN)" where Zyzzyva is the best protocol and leads by 15.6%, running the same workload and fault conditions on WAN with different instance types renders CheapBFT the best protocol, which outperforms Zyzzyva by 28.4%. The reason is that Zyzzyva commits via the fast path and requires votes from all nodes, resulting in high end-to-end latency, given the high RTT between some nodes. CheapBFT, on the other hand, requires a smaller quorum of voters, which could be co-located inside a single data center, thus achieving lower latency. With a moderate number of clients (i.e., 50 in our workload), this results in CheapBFT also achieving higher throughput than Zyzzyva due to finite parallelism. Under this unseen hardware setup, BFTBrain converges to the best-performing protocol within 1.58 minutes. We also observe that when running in a live WAN for hours, BFTBrain remains robust to noises in the network which occasionally cause significant drops in the transient throughput of certain epochs. On the contrary, ADAPT cannot transfer the knowledge it learned on different hardware setups. As a result, when ADAPT is pre-trained with complete data we collected on "Row 1 (LAN)", it remains stuck at the sub-optimal decision Zyzzyva.

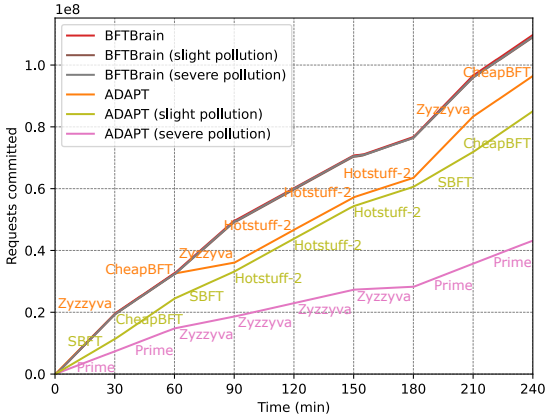

Figure 4: Robustness of BFTBrain against data pollution. The vertical dashed lines indicate when conditions change. Labels indicate the dominant protocol that ADAPT (before and after pollution) chooses under each setting.

This experiment demonstrates the operational benefits of BFTBrain when hardware configurations may differ across deployments. BFTBrain can rapidly converge to the best-performing protocol for new hardware settings without any human intervention. As discussed before, it may not be practical to recollect data and pre-train a supervised approach such as ADAPT on every new hardware setup.

7.5 Robustness of BFTBrain

In a Byzantine environment, malicious nodes might arbitrarily manipulate (i.e., pollute) their collected metrics in order to misguide the machine learning models. Our next experiment compares the resilience of BFTBrain and ADAPT under data pollution. We ran the same dynamic benchmark as the "cycle back conditions" experiment in Section 7.3, and compared BFTBrain with ADAPT's performance under two types of data pollution: slight and severe. In the slight pollution scenario, only the reward (i.e., throughput) of SBFT was increased to

2.5x of its true value. In the severe pollution, regardless of the protocol, for every single data point, both its state and reward were polluted by replacing the true values with random values. The random value was chosen uniformly between 0 and 5x the maximal true value for the polluted dimension. Note that when polluting BFTBrain, f learning agents were malicious and hence reported polluted values as their local measurements; when polluting ADAPT, the malicious centralized entity polluted training data and distributed the same data to all nodes in the system.

Figure 4 shows the number of committed requests with respect to time, under different types of pollution. Compared to non-polluted scenarios, under slight pollution, BFTBrain incurs only a 0.7% performance drop, while ADAPT suffers from a 12% drop. Thus, after such slight pollution where only less than 0.01% of the data population is polluted, BFTBrain outperforms ADAPT by 28%. Under severe pollution, although the f malicious learning agents cause a distribution shift in BFTBrain's global state and reward, BFTBrain only incurs a 0.5% performance drop. The reason is, as proved in Section C.2, the learning-coordination protocol guarantees that the global feature and reward always fall into the range between two honest local observations. On the contrary, when all features and rewards can be arbitrarily manipulated by the centralized entity in ADAPT, it performs no better than randomly choosing protocols. In the worst case, a smart pollution strategy misguides ADAPT to pick the worst protocol for each condition (as shown by the ADAPT (severe pollution) line in Figure 4), resulting in a 55% performance drop. In such a scenario, BFTBrain outperforms ADAPT by 154%.

7.6 Overhead of BFTBrain

Our last experiment evaluates the overhead incurred by BFTBrain's learning framework. We repeated the "cycle back conditions" experiment in Section 7.3, and plot BFTBrain's training and inference overhead in each epoch in Figure 15 (provided in Appendix D.4). Labels indicate the dominant protocol that BFTBrain chooses in each segment of the figure.

The training overhead increases quasi-linearly in each segment, but zigzags across different segments. The reason is that BFTBrain's training overhead increases with the number of data points in the experience bucket, and the bucket used for training (i.e., one out of K^2) depends on the previous and current protocol. Within one segment, since BFTBrain chooses the best-performing protocol dominantly after convergence, a certain bucket is selected dominantly and accumulates training data. The drops of overhead in the figure is caused by BFTBrain's exploration of other protocol, resulting in other smaller buckets being retrained. On the contrary, the inference overhead is always constant with the number of epochs.

We also measured the duration of epochs in this experiment: 0.88s in minimum and 1.31s in average. During the entire 4-hour deployment, compared to the duration of epochs, even the maximum training and inference overhead is negligible, due to the lightweight nature of random forests. More importantly, the learning agent and validator are two parallel processes. Thus, the overhead of learning does not adversely affect the node's throughput, as long as there are some spare CPU cycles devoted to the learning agent. When BFTBrain is deployed for a longer run, techniques such as periodic resampling and limiting the size of the experience bucket can be utilized [54] to control the overhead of learning.

8 Related Work

The BFT consensus problem has been studied extensively, and surveying it is beyond the scope of this work; readers may find introductory material in textbooks, various surveys, and measurement studies, e.g., [7, 17, 25, 26, 51, 56, 58, 61, 66].

BFTBrain employs a mechanism similar to *reconfiguration* which allows the system to switch the parameters of a BFT algorithm by agreement at certain positions within a sequence of decisions. The reconfiguration problem has been formalized in several works, both in the benign fault settings and the Byzantine setting, e.g., [8, 13, 16, 38, 42, 49, 50, 57].

To our knowledge, the first work to propose switching between a set of BFT protocols in real-time to adapt to dynamic conditions is Abstract [8]. It was followed by ADAPT [10], which further enhanced the approach by training a supervised learning model to govern switching. BFTBrain embraces the idea of a multi-protocol BFT engine while considerably enhancing its practicality via a decentralized reinforcement learning engine that provides significant operational benefits and by introducing deep performance metrics, capturing faults, and being hardware agnostic.

At the core of BFTBrain, learning in untrusted distributed settings is made resilient against intentional data pollution via robust aggregation and agreement. Similar techniques have been explored in robust distributed learning studies [3, 11, 32, 39, 44, 64]. More generally, harnessing learning to enhance performance has been done successfully in many systems under the umbrella of machine programming [36]: indexing [47], query optimization [54, 63, 68], database tuning [59], software analysis [41], scheduling [53], concurrency control [60], and transaction management in blockchains [62].

9 Conclusion

Existing BFT protocols lack flexibility and adaptability, leading to suboptimal performance in various scenarios. In this paper, we propose a practical reinforcement learning-based BFT system called BFTBrain, which dynamically selects the top-performing BFT protocols in real-time. Our extensive evaluation demonstrates that BFTBrain significantly outperforms existing solutions under various conditions, including dynamic environments and adversarial attacks.

A Background on Selected BFT Protocols

In this section, we provide background on BFT protocols that are experimentally studied in Section 2.

PBFT [18, 19]. PBFT (Figure 5) is a leader-based protocol that operates in a succession of configurations called *views* [30,31]. Each view is coordinated by a *stable* leader (primary). PBFT consists of pre-prepare, prepare, and commit phases. The pre-prepare phase assigns an order to the request, the prepare phase guarantees the uniqueness of the assigned order, and the commit phase guarantees that the next leader after view-change can safely assign the order.

During a normal case execution of PBFT, clients send their signed request messages to the leader. In the pre-prepare phase, the leader assigns a sequence number to the request to determine the execution order of the request and multicasts a pre-prepare message to all backups. Upon receiving a valid pre-prepare message from the leader, each backup node multicasts a prepare message to all nodes and waits for prepare messages from $2f$ different nodes (including the node itself) that match the pre-prepare message. The goal of the prepare phase is to guarantee safety within the view, i.e., $2f$ nodes received matching pre-prepare messages from the leader node and agree with the order of the request.

Each node then multicasts a commit message to all nodes. Once a node receives $2f+1$ valid commit messages from different nodes, including itself, that match the pre-prepare message, it commits the request. The goal of the commit phase is to ensure safety across views, i.e., the request has been voted on a majority of non-faulty nodes and can be recovered after (leader) failures. The second and third phases of PBFT follow the *clique* topology, i.e., have $O(n^2)$ message complexity. If the node has executed all requests with lower sequence numbers, it executes the request and sends a reply to the client. The client waits for $f+1$ matching results from different nodes.

HotStuff-2 [52]. HotStuff-2 (Figure 6) HotStuff-2 is a leader-based BFT protocol with two main properties. First, it provides linear communication complexity (rather than quadratic as in PBFT). Specifically, each all-to-all communication phase of PBFT is replaced with two linear phases in HotStuff; one from the replicas to the leader and one from the leader to the replicas. Second, HotStuff-2 uses the leader rotation technique, where the leader is replaced after every single proposal in a predetermined manner (round-robin). This is in contrast to most existing protocols that rely on a stable leader, and the leader is changed only when it is suspected to be faulty. Compared to the original HotStuff [65], HotStuff-2 reduces one phase of communication, improving the overall performance of the protocol. Chaining (also proposed in [65]) is an optimization technique that is applicable to both HotStuff and HotStuff-2. The chaining optimization involves executing some phases which are deemed identical in a pipelined manner in order to reduce the latency of request processing.

Zyzzyva [46]. Zyzzyva (Figure 7) optimistically assumes that the leader and all backups are non-faulty. Hence, upon receiving an order message from the primary node which includes the request, nodes speculatively execute requests without running any agreement and send reply messages to the client. The client waits for $3f+1$ matching replies to accept the results. If the client timer is expired and the client has received matching replies from between $2f+1$ and $3f$ nodes, as presented in Figure 8, two more linear rounds of communication are needed to ensure that at least $2f+1$ nodes

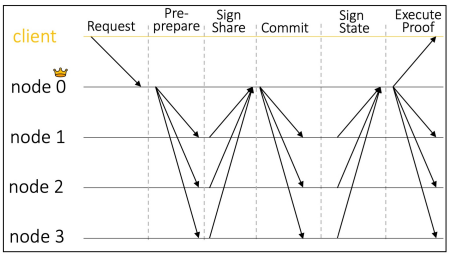

Figure 9: SBFT protocol (fast path)

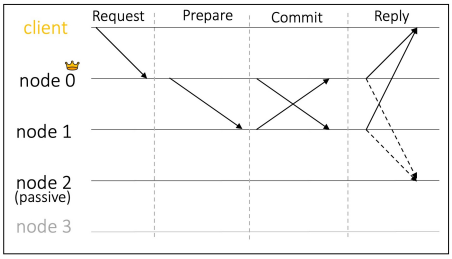

Figure 11: CheapBFT protocol

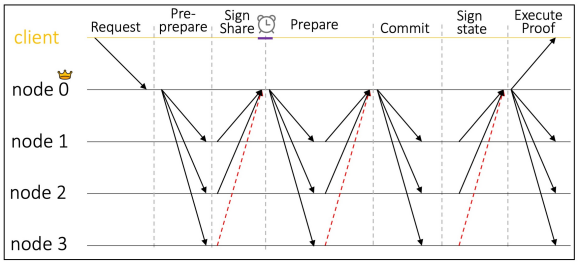

Figure 10: SBFT protocol (slow path)

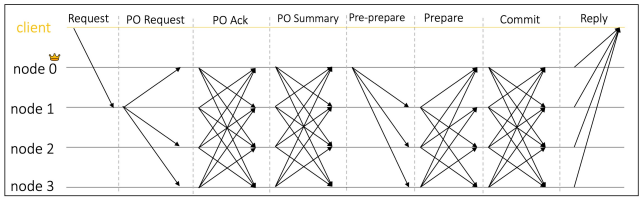

Figure 12: Prime protocol

have committed the request.

SBFT [40]. SBFT[4] presents a linear optimistic fast path (Figure 9), assuming all nodes are non-faulty. In SBFT, upon receiving a pre-prepare message from the primary node, all nodes send sign-share messages to the commit collector (i.e., the primary in our figure). If the commit collector is able to collect $3f+1$ sign-share messages, it puts them together to generate a commit message and broadcasts it to the backups. Otherwise (the commit collector does not receive messages from *all* backups in the sign-share phase and its timer is expired), SBFT switches to its slow path (Figure 10) and requires two more linear rounds of communication (prepare phase). The dual-path nature of SBFT requires nodes to sign each message with two schemes (i.e., $2f+1$ and $3f+1$). To send replies to the client, a single (execution collector) node receives replies from all nodes and sends a single (threshold) signed reply message.

CheapBFT [43]. CheapBFT (Figure 11) differs from PBFT in two major ways. First, it puts f nodes as passive nodes by optimistically assuming all nodes participating in the quorum (i.e., called *active* nodes) are honest. Second, it relies on trusted hardware to prevent equivocation. CheapBFT reduces the required quorum of active nodes to $f+1$ (the total number of nodes becomes $2f+1$) in its normal case execution, and reduces the number of phases from three to two as compared with PBFT (i.e., no pre-prepare phase). If an active node becomes faulty, it is replaced with a passive node.

Prime [4]. Prime (Figure 12) is a robust protocol by incorporating a pre-ordering stage. In the pre-ordering stage, nodes exchange the requests they receive from clients and periodically share a vector of all received requests, expecting the leader to globally order requests following those vectors. In this way, nodes can also monitor the leader to order requests in a fair manner. Prime also uses timers to periodically check performance of the protocol and replace the primary node if it does not provide acceptable performance (e.g., under slowness attack) corresponding to the current network condition.

[4] SBFT tolerates both crash and Byzantine failure ($n=3f+2c+1$ where c is the number of crashed nodes). Since the focus of this paper is on Byzantine failures, we consider a variation of SBFT where $c=0$.

B Switching BFT Protocols

In this section, we describe how BFTBrain performs the actual switching from BFT protocol t to $t+1$.

Similar to Abstract, BFTBrain operates in epochs. Each epoch in BFTBrain can be considered as a *Backup* instance in Abstract, which is marked by the completion of k requests, where k is a predefined constant hyper-parameter. For each epoch, an existing BFT protocol in our action space (i.e., PBFT, Zyzzyva, CheapBFT, Prime, SBFT, and HotStuff-2) is selected by the learning agent and remains unchanged throughout the epoch.

The *Backup* instance in Abstract is a thin wrapper that can be put around an existing BFT protocol. *Backup* works as follows: it is inactive until it receives a request containing a valid init history, which is an unforgeable history generated by the preceding BFT instance. At this point, *Backup* sets its state by executing the requests in the init history it received. Then, it simply executes the first k requests committed by the underlying BFT protocol, aborts all subsequent requests, and returns the signed sequence of executed requests as the init history for the next BFT instance. A client can switch from a *Backup* instance t to instance $t+1$ as soon as it receives $f+1$ signed messages from different replicas, containing an identical init history. The client uses the init history to invoke instance $t+1$. Once instance t aborts some requests and switches to $t+1$, it cannot commit any subsequently invoked requests.

Optimizations of Abstract. Abstract also implements the following optimization for the switching procedure above: align switching from a *Backup* instance with a checkpoint in order to minimize the size of init history, which is transferred through clients. In Abstract, BFT instances t and $t+1$ might be run on two different clusters, and not every instance is a *Backup* instance whose progress condition is k committed requests. For example, an instance could be *Quorum* whose progress condition is $3f+1$ matching history, or *Chain* whose progress condition is one correct reply, both of which require an honest client to validate the progress condition and initiate the switching. On the contrary, in BFTBrain, all BFT instances are run on the same cluster of machines, and every BFT instance is a *Backup* instance. Thus, the optimization can be taken one step further inside BFTBrain. First, instead of relying on the client, each replica has enough information to decide whether to switch or not. Once executing k requests, each replica multicasts an init history (i.e., checkpoint) to all other replicas. Second, an honest replica does not need to be blocked and wait for $f+1$ signed matching init history and execute it before starting the new epoch, since the init history is already reflected in its local service state. Once k requests are committed in epoch t and the BFT protocol for $t+1$ is derived by the learning agent, epoch $t+1$ is invoked. In other words, the switching can be performed asynchronously inside BFTBrain with low overhead.

Speculative Backup instances. *Backup* can be easily implemented over an existing BFT protocol, except for speculative protocols where clients are the commit collectors, e.g., Zyzzyva. This is because such protocols rely on clients to decide if a request has been committed, while the replicas might not have enough information to tell. Specifically, in Zyzzyva, if a request commits in the slow path where the client only receives $2f+1$ replies with matching history (instead of $3f+1$ replies in its fast path) and multicasts a commit certificate to all replicas, the replicas can deterministically commit the request as well. However, if a request commits in the fast path, the client directly completes the request without notifying the replicas. Thus, the replicas can not decide whether the current epoch is finished.

To address this issue, when running speculative protocols in epoch t, BFTBrain enforces the k-th request (i.e., the last request in t) to be a special NOOP request and to be committed in the slow path. On each replica, the view-change timer for this request is only removed when it can be considered as committed. Specifically, for the k-th request, the leader acts as a dummy client and multicasts a commit certificate even if $3f+1$ replies with matching history are received. Upon receiving the commit certificate or $f+1$ signed matching init history for epoch $t+1$, replicas can safely consider the k-th request of epoch t as completed. Note that a malicious dummy client might refuse to multicast the commit certificate. In this case, view-change is triggered and a new leader will be elected, which will act as a new dummy client for this request. Then, in the NEW-VIEW message, for this k-th request, the new leader always inserts a ORDER-REQ message where the original NOOP request is replaced by the NOOP request proposed by its own dummy client. For this special request, no safety issues exist since its content is not part of the service state. The mechanisms above guarantee that each honest replica will successfully commit this request (i.e., liveness), and thus concluding the current epoch.

Correctness of switching. Below, we discuss the safety and liveness of switching between epochs.

Safety. Abstract's idempotency theorem [8] specifies that if individual BFT instances are correct, irrespectively of each other, then the system composed through switching is also correct. Since each BFT instance in BFTBrain is an existing protocol whose safety has been previously proven (instead of our newly invented protocol), the composed system is safe.

Liveness. Abstract guarantees liveness if a request is not aborted by all instances, which can be made simple by reusing an existing BFT protocol as one of the instances. Apparently, BFTBrain satisfies this requirement too.

Moreover, to ensure liveness, Abstract exponentially increases the parameter k with every new instance of *Backup* by default. This is to prevent a corner case with very slow clients: k requests committed by a single *Backup* instance i might all be invoked by the same, fast client, while a slow client can then get its requests aborted by i. The same can happen with a subsequent *Backup* instance, and so forth. By exponentially increasing k, this liveness issue is resolved since no realistic load increases faster than exponentially. Alternatively, by having the replicas across different *Backup* instances share a client input buffer, such an issue can also be prevented without exponentially increasing k. BFTBrain takes the latter approach, since all epochs run on the same cluster, so the client input buffer is naturally shared across epochs.

C Learning Coordination

In this section, we present BFTBrain's learning coordination protocol and discuss the correctness of BFTBrain.

C.1 Detailed Description of The Protocol

Algorithm 1 presents the detailed learning coordination protocol, where VBC (i.e., any "blackbox" validated Byzantine consensus primitive) is implemented using PBFT. As shown in lines 1-7, after executing w requests (a hyper-parameter) in epoch t, each node i collects local performance indicators p_i^{t-1} measured during epoch $t-1$, featurizes the next state f_i^{t+1}, and broadcasts both metrics inside a report message. Each agent i collects the received valid report messages where p_j^{t-1} and f_j^{t+1} are non-null, into a local set $reportQC_i^t$. Upon collecting $f+1$ report messages from different agents, the agent triggers the coordination protocol for epoch t and starts a view-change timer $\tau_{c,1}$ to track the progress (lines 8-11).

Each time an agent l becomes the leader, as shown in lines 12-15 (the view-change leader is omitted), it starts an addi-

Table 3: The throughput of each studied protocol under different conditions. Each row characterizes a different condition, where the best throughput is highlighted in **blue**.

Condition Parameters					Throughput (tps)					
f	# of clients	# of absentees	request size	proposal slowness	PBFT	Zyzzyva	CheapBFT	Prime	SBFT	HotStuff-2

tional timer $\tau_{c,2}$ for collecting $2f+1$ reports. Once the size of $reportQC_l^t$ reaches $2f+1$ or $\tau_{c,2}$ expires, the leader multicasts $\langle \text{c-PROPOSE}, v_c, n_c, t, d \rangle_{\sigma_l}, reportQC_l^t \rangle$ message to all agents, where v_c is the view in the coordination protocol, n_c is the sequence number in the coordination protocol, t is the epoch id, and d is the digest of $reportQC_l^t$.

Once a coordinator agent i receives a valid c-propose with coordination sequence n_c that it has not voted for, it accepts that proposal and multicasts a c-prepare message if: (1) the size of corresponding $reportQC_l^t$ is at least $f+1$, (2) t is not committed and (3) n_c-1 is committed (lines 16-18).

Then, similar to PBFT, after the c-prepare and c-commit phases, the predicate c-committed$(v_c, n_c, t, reportQC_l^t)$ becomes true if $2f+1$ matching c-commit messages from different agents have been received. Once committed, agent i checks the size of $reportQC_l^t$. If smaller than $2f+1$, the learning algorithm (i.e., retraining and inference based on predictive models) is not invoked, and the agent utilizes the same protocol for epoch $t+1$ as in the current epoch t. It also initiates a view-change on the current BFT protocol used by its validator and multicasts a c-view-change message to all other agents. Here, s_c stands for the last stable checkpoint known to i in the coordination protocol, C_c is a set of c-checkpoint messages proving the correctness of s_c, and P_c is a set containing a set $P_{reportQC}$ for each $reportQC$ that prepared at i with a coordination sequence number higher than s_c. Each $P_{reportQC}$ contains the c-propose and c-prepare messages (lines 23-26). Otherwise, if the size is $2f+1$, for reward and each state dimension, the median value is taken as the global reward p^{t-1} and state f^{t+1}. The state-action-reward triplet for epoch $t-1$ is then added to the experience buffer, the predictive models are re-trained, and a promising BFT protocol is inferred for epoch $t+1$ based on state f^{t+1} (lines 27-31). Finally, regardless of the size of $reportQC_l^t$, a c-checkpoint message is multicast to all coordination agents.

Upon timer $\tau_{c,1}$ expires, each coordination agent multicasts a c-view-change message to all agents. Once receiving $2f+1$ c-view-change messages from different agents, the new leader l' begins the c-new-view phase similar to PBFT. At the end of this phase, l' checks all $P_{reportQC}$ of P_c components collected in the view-change quorum. If none of them includes a $reportQC$ for epoch t, l' will multicast a c-propose message to all agents which carries the $reportQC_{l'}^t$ it has collected.

We argue that the leader agent could also deliberately delay c-propose messages. However, unlike the active BFT instance in each epoch that has tens of thousands of requests to commit, this coordination protocol runs only once every epoch. Thus, the performance impact of such malicious behavior is negligible.

C.2 Proof Sketch

Below, we formalize the safety, liveness, and robustness guarantees of BFTBrain, followed by the proof sketch.

Safety. For each epoch t, each honest learning agent will agree on the same feature and the same reward if its learning algorithm is invoked.

Proof: We prove by contradiction that only one $reportQC$ can be committed for the same epoch t. First, by reduction to PBFT, c-propose, c-prepare, c-commit phases guarantee that for each coordination sequence n_c, only one $reportQC$ can be committed. Then, assume two different $reportQC$ for the same epoch t are committed at different n_c: $reportQC_j^t$ committed at $n_{c,1}$, and $reportQC_k^t$ at $n_{c,2}$, where $n_{c,1} < n_{c,2}$ and $D(reportQC_j^t) \neq D(reportQC_k^t)$. At least one honest agent i needs to accept the c-propose for both $reportQC$. Since the network is asynchronous, we consider two cases. If $n_{c,1}$ is committed before $n_{c,2}$ on i, i needs to accept c-propose with $reportQC_k^t$ when t is already committed. Otherwise if $n_{c,1}$ is committed at the same time with or after $n_{c,2}$, i needs to accept $reportQC_k^t$ whose coordination sequence is $n_{c,2}$, before $n_{c,2}-1$ is committed. Both cases contradict with line 17 of Algorithm 1. Thus, only one $reportQC$ can be committed for the same epoch t. Finally, since an honest learning agent takes the median value of the same committed $reportQC$, they agree on the same feature and reward if $reportQC$ includes $2f+1$ reports.

Following this safety property, through deterministic training (i.e., using the same random seed on each learning agent), each honest learning agent in BFTBrain derives the same action (i.e., BFT protocol) for the same epoch t.

Liveness. BFTBrain guarantees that every honest agent eventually invokes its learning algorithm in the same epoch.

Proof: If fewer than $2f+1$ reports are collected, the learning

Algorithm 1 Learning coordination

▷ On each agent i
Upon execution of w requests in epoch t
  if no state transfer happens during epoch $t-1$ **then**
    Record performance p_i^{t-1}
  if no state transfer happens during epoch t **then**
    Extract features f_i^{t+1} from executed requests in window w
  if $p_i^{t-1} \neq null \wedge f_i^{t+1} \neq null$ **then**
    Multicast $\langle \text{REPORT}, t, i, p_i^{t-1}, f_i^{t+1} \rangle_{\sigma_i}$ to all agents
Upon receiving valid REPORT message m
  Add m to $reportQC_i^t$
  if $reportQC_i^t.size = f+1$ **then**

    $f^{t+1} \leftarrow \text{median}\{m.f_j^{t+1} | m \in reportQC_l^t\}$
    Add (f^{t-1}, $protocol^{t-1}$, p^{t-1}) to experience buffer
    $protocol^{t+1} \leftarrow \text{BESTPREDICTEDPROTOCOL}(f^{t+1})$
  Multicast $\langle \text{C-CHECKPOINT}, n_c, t, i, reportQC_l^n \rangle_{\sigma_i}$ to all agents
Upon timer $\tau_{c,1}$ timeouts
  Multicast $\langle \text{C-VIEW-CHANGE}, v_c+1, s_c, C_c, P_c, i \rangle_{\sigma_i}$ to all agents
▷ On the leader agent l' of view v_c+1
if no set in the P_c components has $reportQC_l^t$ **then**
  Multicast $\langle \text{C-PROPOSE}, v_c+1, n_c, t, d \rangle_{\sigma_{l'}}, reportQC_{l'}^t \rangle$ to all agents
▷ The remaing view change routine are omitted here

algorithm will be ineffective (i.e. not invoked) for one epoch, and the BFT protocol chosen for the next epoch will be the same as the current one. We first show agents are able to commit a $reportQC$ of $2f+1$ reports within f consecutive epochs (Part 1). We then show if such $reportQC$ is committed for epoch t, every honest agent will invoke its learning algorithm in epoch t (Part 2).

Part 1: In the active BFT protocol of any certain epoch, there can be at most f honest validators placed in-dark by the malicious leader, since otherwise, $f+1$ validators will trigger a view-change to replace the leader in the epoch. The agents on these in-dark validators will not send report messages according to our protocol. In addition, at most f malicious agents can deliberately refuse to send report messages. Thus, each agent is guaranteed to receive at least $f+1$ reports for epoch t, which starts a timer $\tau_{c,2}$ on leader agent l for collecting $2f+1$ reports in $reportQC_l^t$ and a timer $\tau_{c,1}$ on each agent for tracking the progress of coordination protocol. If $reportQC_l^t$ is committed, a view-change in the active BFT protocol used by validators will be initiated if it contains less than $2f+1$ reports. Since such coordination is run once every epoch, an honest leader validator will be found within at most f consecutive epochs. Otherwise, if $reportQC_l^t$ is not committed, the leader agent will be replaced while the current epoch waits for a report quorum to be committed.

Part 2: If a $reportQC$ of size $2f+1$ is committed on an agent, it is committed on at least $2f+1$ agents, otherwise c-view-change is triggered and it will be committed in view v_c+1 or above. Thus, at least $f+1$ honest agents will multicast a c-checkpoint message containing the $reportQC$ as the service state of the coordination protocol. Every honest agent, even if it is placed in dark by the malicious leader agent, will receive this stable checkpoint and thus invoke its learning algorithm.

Robustness. If honest feature/reward values form a range $[r_l, r_h]$, the global feature/reward taken by the learning agent always falls into this range.

Proof: According to our protocol, honest nodes never report invalid (e.g., zero or null) values to others, even when they are placed in-dark and recover their service state from others.

The learning agent only takes the median value of $reportQC$ of size $2f+1$, where at most f can be arbitrary values reported by malicious replicas, and the remaining $f+1$ is guaranteed to be honest. Now we prove by contradiction: w.l.o.g., assume the median value of $reportQC$ is r_m, where $r_m > r_h$. Since there are at least $f+1$ honest values smaller than r_m, to make r_m the median, at least $f+1$ dishonest values larger than r_m need to be reported. This contradicts the fact that, at most f can be arbitrary values in $reportQC$.

D Additional Experiment Results

D.1 Comprehensive Performance Comparison

Table 3 presents the comprehensive performance comparison results, which were previously summarized by Table 1 in Section 2. Under each different condition (i.e., row), we list the throughput of each protocol in terms of transactions per second. For a fair comparison, the common internal parameters of all six protocols are configured with the same value: we set the batch size to be 10 and the view-change timer to be 100ms. The protocol-specific internal parameters (e.g., leader rotation interval of HotStuff-2, the aggregation delay for global ordering in Prime, the timer that distinguishes fast path vs. slow path in Zyzzyva) are configured with a reasonable value such that the protocol has good performance on all conditions.

D.2 Randomized Sampling

Compared to the "cycle back conditions" experiment in Section 7.3, we created a benchmark that has more variations in the state space and introduced the variations more frequently. Specifically, each dimension in category State 1 and 2 (except $F1$) follows a certain normal distribution independently. We vary each dimension every 1s by randomly sampling from its distribution, and shift the mean and variance of such distribu-

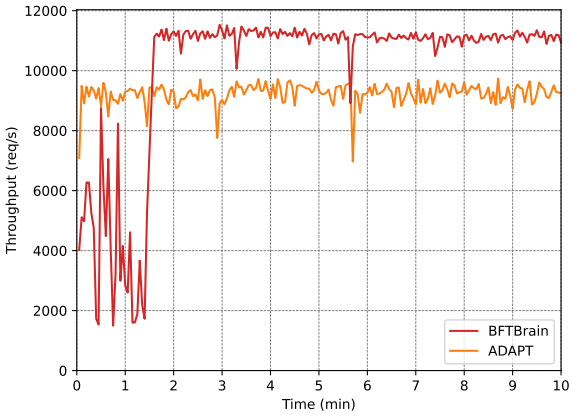

Figure 14: Adaptivity of BFTBrain compared to ADAPT under different hardware (WAN).

tion every 20 minutes. During the first hour of the experiment, all validators ($n = 13$) are responsive, whereas during the second hour, f validators are non-responsive. The entire experiment lasts 2 hours. Compared to other dimensions, we varied $F1$ at a lower frequency, since in real deployment scenarios, client workloads vary more frequently than faults in the system. The exact distribution we used and their shifting pattern can be found here[5].

We compare BFTBrain with state-of-the-art learning based approach ADAPT, which is pre-trained with complete data that we collected in this setup when running BFTBrain. Figure 13 shows the number of committed requests with respect to time. During the first 40 minutes, ADAPT performs even slightly better than BFTBrain. This is because BFTBrain incurs a few explorations (i.e., chooses sub-optimal protocols) when starting the system from scratch and the experience buckets are all empty, while ADAPT exploits its prior knowledge and thus avoids all such explorations. However, starting from 40

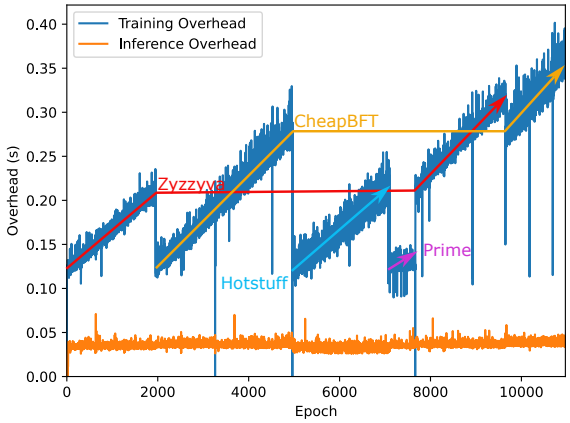

Figure 15: Learning overhead of BFTBrain in each epoch.

minutes, when the condition varies towards a more Byzantine setup (i.e., with persistent in-dark attacks and leaders that appear randomly slow), BFTBrain gradually outperforms ADAPT since the latter does not featurize faults in the system. Thus, although pre-trained with complete data, ADAPT consistently picks sub-optimal protocols since its predictive model does not have enough information to tell how the condition changed. As a result, during the entire 2-hour deployment, BFTBrain commits 44% more requests than ADAPT.

Compared to the 14% improvement in the "cycle back" experiment, BFTBrain improves ADAPT by a larger margin in this experiment. The reason is that some input factors in the cycle back experiment are correlated, e.g., a request size near zero is correlated with high proposal slowness. Thus, although ADAPT suffers from incomplete features, it indirectly learns the optimal protocol under high proposal slowness using other features, as shown in Figure 2 between 90-150 minutes. However, the randomized sampling in this experiment breaks such a correlation.

D.3 Adaptivity under WAN

Figure 14 plots BFTBrain and ADAPT's throughput with respect to time on the "Row 1 (WAN)" setup described in Section 7.4. Here, ADAPT is pre-trained with complete data we collected on "Row 1 (LAN)", while BFTBrain is started from scratch. BFTBrain converges to the optimal protocol CheapBFT after a few explorations. On the contrary, ADAPT does not perform any explorations and performs relatively well from the very beginning, but is stuck at the sub-optimal decision Zyzzyva. This is because the supervised model ADAPT trained is dependent on the hardware. Therefore, ADAPT cannot transfer what it learned on a LAN setup to a WAN setup, unless running a prolonged data re-collection process and re-training the supervised model before this new deployment.

D.4 Overhead of BFTBrain

Figure 15 plots BFTBrain's training and inference overhead in each epoch. Labels indicate the dominant protocol that BFTBrain chooses in each segment of the figure.
