Message from the OSDI '25 Program Co-Chairs

Welcome to the 18th USENIX Symposium on Operating Systems Design and Implementation (OSDI '25).

We're pleased to once again co-locate OSDI with the 2025 USENIX Annual Technical Conference (USENIX ATC '25). Together, these conferences present a broad and exciting collection of research papers, showcasing some of the most innovative work in the systems community. We hope you leave with new ideas, new collaborators, and new friends.

This year, OSDI received 339 submissions, of which 48 were accepted with shepherding. In addition, 5 papers from Revise-and-Resubmit track were later accepted, bringing the total to 53 papers included in the OSDI '25 proceedings — an overall acceptance rate of 16%. Three additional revise-and-resubmit papers are still under review and, if accepted, will appear in next year's OSDI '26 proceedings.

OSDI remains a single-track conference, allowing attendees to engage fully with every paper presented. We've organized a three-day program where all presentations are held in a single room, encouraging shared discussion and broad exposure to the entire program.

To fairly and thoroughly evaluate submissions across the wide range of topics OSDI covers, we assembled a program committee of 92 expert reviewers (not including the two of us as co-chairs). Reviewing such a large volume of high-quality research is no small task. Each paper received at least three reviews in the first round. A select group of papers advanced to a second round and received two or three additional reviews. We then held an intensive online discussion period followed by a two-day program committee meeting.

In total, the committee produced more than 1,500 reviews and thousands of discussion comments. We deeply appreciate the thoughtful and constructive feedback provided by the program committee. Reviewers also need to conduct additional reviews for revise-and-resubmit papers. Their careful assessments helped ensure that the selected papers reflect the best of what the systems community has to offer. Each accepted paper was assigned a shepherd from the committee to help the authors refine their work based on reviewer feedback, and we're proud of the clarity and quality of the final versions. We also extend our sincere thanks to the small group of external reviewers who generously contributed their expertise when additional perspectives were needed.

We also want to recognize the contributions of the Artifact Evaluation Committee, which was shared between OSDI and USENIX ATC. Co-chaired by Ryan Huang and Tianyin Xu—both of whom also served as OSDI '25 program committee members—this team assessed the supporting artifacts submitted with papers. Their work plays a key role in promoting reproducibility and encouraging rigorous experimental methods. One paper this year was recognized with a Distinguished Artifact Award.

The poster session at OSDI '25 was organized by Patrick P. C. Lee and Chen Li, who also served on the program committee. They coordinated the submission and selection process for this session, which includes posters from both accepted papers and additional research contributions. The poster session offers another opportunity for attendees to exchange ideas and connect with the broader systems community.

Once the accepted papers were decided, we began the process of deciding on the Jay Lepreau Best Paper Awards. A small committee of non-conflicted Program Committee members—excluding both program co-chairs— read all of the top-ranked and PC-nominated papers and made the final decision on the award papers. We sincerely thank the best paper selection committee for their thoughtful evaluations and dedication to recognizing outstanding contributions to the community—especially within a tight timeframe.

We are incredibly grateful to the many people who contributed to this conference. To the authors: thank you for submitting your work and for your dedication to pushing systems research forward. To the program committee and external reviewers: thank you for your time, expertise, and thoughtful evaluations. Special thanks to Eric Mugnier from UCSD and Carol Zhang from Microsoft Research for their behind-the-scenes help in the PC meeting, including conflict tracking and note-taking.

We also thank the USENIX staff for their exceptional support and professionalism. Their experience and coordination behind the scenes made the organizational process smoother at every step—from paper submissions to final conference.

Finally, thank you to all attendees. Conferences like OSDI thrive because of your participation, your questions, and your collaboration. We hope you enjoy the program, reconnect with colleagues, and discover new ideas and directions in systems research.

It has been an honor to serve as the Program Co-Chairs for OSDI '25. Thank you for trusting us with this role, and we hope the conference is rewarding and inspiring for you.

Warm regards,
Lidong Zhou

Abstract

Distributed protocols are challenging to design correctly. One promising approach to improve their reliability is to use formal verification to prove that a protocol satisfies a desired safety property. These proofs require finding an inductive invariant that holds in the initial states of the system, implies safety, and is inductive over state transitions. Devising an inductive invariant is a difficult task that prior work has either required the developer to find manually by a painful search process, or automated by constraining the protocol to a decidable but restrictive fragment of logic.

In this work, we aim to automatically find inductive invariants without restricting the logic. We achieve this with two key insights. First, many of the complex inter-host properties that prior work required the developer to provide can instead be expressed using *Provenance Invariants*, a class of invariants that relate a local variable in a host to its provenance, i.e., the protocol step that caused it to take on its current value. By tracing the provenance of one host variable back to another host's actions, we can derive an invariant relating the two hosts' states. Second, we develop an algorithm called atomic sharding to derive Provenance Invariants automatically by statically analyzing the protocol's steps.

We implement these ideas in a tool called Basilisk and apply it to 16 distributed protocols, including complex ones like Multi-Paxos. Basilisk automatically finds inductive invariants and proves their inductiveness, with little or no developer assistance. In all cases, these generated inductive invariants are sufficient for us to prove safety without needing to identify any new invariants.

1 Introduction

Distributed protocols are notoriously difficult to design and implement correctly. After decades of relying on testing to develop robust protocols, in the last ten years many researchers and developers have turned to formal verification as an attractive alternative [2, 16, 24, 30, 31, 33, 36]. In this approach, the developer typically proves that some desirable safety property (e.g., no two nodes hold a lock at the same time) is maintained throughout all executions of the protocol.

Unfortunately, a safety property is, on its own, often too weak to support an inductive argument. Instead, one typically proves safety by finding a stronger property, called an *inductive invariant*, that satisfies the following three conditions: (1) it implies the safety property, (2) it holds in the initial states of the system, and (3) it is maintained by all steps. The developer must find such an inductive invariant and prove it meets these conditions in order to complete their proof.

In recent years, researchers have proposed a series of algorithms and tools that derive and prove these invariants automatically, with little to no input from the developer [7, 9, 13–15, 21, 28, 37, 38]. However, such approaches share a major obstacle to their practicality: they require the target protocols to be written within a decidable logic, such as *effectively propositional reasoning* (EPR [29]). Expressing a protocol in EPR is itself a challenging endeavor [26]. As an example of its restrictiveness, EPR prohibits common programming patterns such as the use of arithmetic (e.g., $i := i + 1$).

Rejecting the restrictions of EPR allows the developer to write their protocols naturally, but such freedom comes at a cost. Working in an undecidable logic means that the developer must manually derive and prove an inductive invariant for each protocol. As many have observed [9, 21, 37, 38], this requires significant effort. A key difficulty stems from the iterative and creative nature of finding a correct inductive invariant. It is hard to know *a priori* what the clauses in an inductive invariant should be. Rather, the developer starts with their best guess, then repeatedly attempts to prove the inductiveness of their current guess, gradually narrowing in on a correct inductive invariant. Developing an invariant this way is labor intensive. For instance, the authors of IronFleet [10, 11] report spending months to identify and prove an inductive invariant for the Multi-Paxos protocol [18, 19].

Recently, Kondo [40] showed how to automatically find small portions of the inductive invariant. Unfortunately, much

of the remaining portions, particularly the conceptually difficult ones—those expressing inter-host properties that span multiple hosts and protocol steps—were left to the developer's intuition. For example, Kondo's proof of Paxos [19] required 20 such properties, which anecdotally took experts two person-weeks to derive.

In this work, we set our sights on a more ambitious goal of *automatically finding inductive invariants in an undecidable setting*. Of course, by the very nature of undecidability, this is an impossible task to achieve for all protocols. And yet, with the right insights, we believe this problem can be solved for many practical, complex protocols, much like how modern SAT solvers can solve large practical instances in reasonable time, despite SAT being an NP-hard problem.

We achieve this ambition based on two insights, which together drastically increase the amount of automation that we can achieve in finding inductive invariants.

Our first insight is that inter-host properties, which prior work delegated to the developer's intuition [11, 40], can be proven as a consequence of multiple simpler invariants that relate host states to network messages. For example, if host R's current state is $x = 5$, that can be traced back to the protocol step that most recently updated x based on some received message M, usually based on some field of M. Message M can in turn be traced back to the state of the message's sender, S, creating a causal chain between the hosts R and S that is invariant. We introduce *Provenance Invariants* as a way to keep track of this lineage. Provenance Invariants are always derived by statically inspecting the steps of single hosts in isolation, which makes them much more intuitive and frees the developer from deriving complex, inter-host properties.

The use of Provenance Invariants, however, creates a new challenge, as we now have a much larger number of simple invariants to generate. Recent prior work [40] automatically generates only one of the three categories of such invariants: those related to steps that send network messages. The other two categories, namely, invariants related to receiving messages and local steps, were either only partially automated or not supported at all.

Our second insight allows us to significantly automate the tracking of provenance through the system's execution. We observe that if a part of a host's state, which we call a *shard*, is always updated atomically—no steps modify only some variables in the shard but not others—then we can automatically track the provenance of this shard to one of the steps that modify it. Concretely, if a shard is in a non-initial state, it means that one of the steps that modify it must have occurred. We propose an *atomic sharding algorithm* to determine such shards and generate Provenance Invariants from them.

Using these insights, we developed Basilisk, a tool that uses Provenance Invariants and atomic sharding to automatically derive inductive invariants and prove their inductiveness for a wide variety of distributed protocols, with the help of minor hints from the developer. In doing so, Basilisk relieves developers from manually formulating an invariant and proving its inductiveness. This allows the developer to focus their efforts on the final task, using the Basilisk-generated inductive invariant to prove the desired safety property. This remaining proof is conceptually *significantly easier*, as it does not involve identifying an inductive invariant.

We evaluate Basilisk's utility by applying it to 16 protocols, including notoriously complex ones like Multi-Paxos [19]. Our evaluation shows that in all cases, the inductive invariants of these protocols can be expressed using simple Provenance Invariants that can be derived from a single host's steps. We further show that Basilisk can find all the inductive invariants for all 16 protocols almost fully automatically.

In summary, this paper makes the following contributions.

- It advances the state-of-the-art in automatic invariant inference by structuring inductive invariants as a collection of simple invariants that can be derived from the protocol steps of individual hosts.
- It introduces *atomic sharding*, a technique that allows us to automatically track the provenance of host states through the protocol's execution.
- It introduces Basilisk, a tool that uses the above techniques to automatically derive the inductive invariants of a wide range of distributed protocols, with only occasional minor hints from the developer.

2 The Burden of Inductive Invariants

Proving that a distributed protocol is safe entails defining a desirable safety property φ (e.g., that all nodes reaching a decision agree on the outcome) and then showing that φ is an *invariant* (i.e., that φ holds in all reachable states of the protocol's execution).

In all but the most trivial protocols, however, φ is not an *inductive* property, even if it is indeed an invariant. This means that there exist (unreachable) states satisfying φ that can transition to an unsafe state. Because it is not possible to decide whether a given state is reachable, proving φ's invariance requires identifying a stronger property representing an over-approximation of the set of reachable states—an *inductive invariant* I—that (1) implies φ, (2) holds in the initial state, and (3) is *inductive*, meaning that if I holds in some state, it holds after the protocol takes one step from that state. Typically, I is expressed as the conjunction of a series of smaller invariants, $I = I_1 \wedge \cdots \wedge I_m$.

According to conventional wisdom, if we reject the onerous restrictions of decidable logics (§1), then finding an inductive invariant is a creative and laborious endeavor. Even after designing the protocol, the developer typically does not know all of the clauses needed to construct an inductive invariant. Instead, the developer begins with an educated guess of a candidate invariant, and then follows an iterative *invariant-proof*

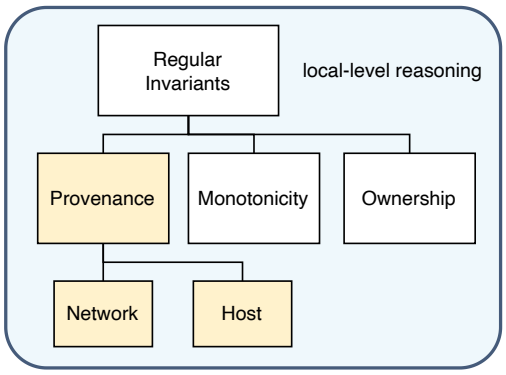

Figure 1: Our invariant taxonomy. We introduce the concept of Provenance Invariants, while Monotonicity Invariants and Ownership Invariants are originally introduced in Kondo [40].

loop: they attempt to prove that the candidate invariant is inductive, fail to complete the proof, and then refine the candidate based on feedback gained from the proof attempt. Each iteration involves writing proof code and creatively devising changes to the candidate invariant. Unfortunately, it might take many iterations before the developer arrives at a correct inductive invariant and proof. Indeed, in frameworks such as IronFleet [10] that require the developer to manually devise and prove inductive invariants, such a process reportedly took months for complex protocols like Multi-Paxos.

Recently, Kondo [40] took a first step towards automating this burdensome invariant-proof loop. It proposes an invariant taxonomy that carves out a category of invariants that can be systematically derived, so that only the remainder need to be hand-written by the user. Kondo observes that these manually written invariants often talk only about host state and not the network, but this simplification does not spare the user from going through the invariant-proof loop. Coming up with the required properties often requires a deep understanding of why the protocol works, since the properties span multiple hosts and steps, and cannot be easily derived from the protocol description. This understanding can be difficult to translate to an invariant even for the protocol's designer, let alone a verification engineer working with an existing protocol.

3 Expressing Inductive Invariants with Only Regular Invariants

We present how we use only simple, mechanically derivable invariants—called Regular Invariants—to craft inductive invariants that prove the safety of distributed protocols.

Regular Invariants (Figure 1) are a class of invariants introduced in Kondo's invariant taxonomy [40]. The defining feature of Regular Invariants is that they capture localized properties, which can be easily derived by examining steps of individual hosts in the protocol, without concern for how hosts interact. As a result, they are both easy for developers

```
1:  datatype Preference = Yes | No
2:  datatype Decision = Abort | Commit
3:  datatype Message =
4:      VOTE(v: Preference, src: nat) | DECIDE(d: Decision)
5:  datatype Option⟨T⟩ = None | Some(v: T)
6:  datatype Coordinator = Variables(
7:      numParticipants: nat,                    // some constant N
8:      decision: MonotonicOption⟨Decision⟩,     // initially None
9:      yesVotes: MonotonicSet⟨nat⟩,             // initially empty
10:     noVotes: MonotonicSet⟨nat⟩               // initially empty
11: )
12: datatype Participant = Variables(
13:     hostId: nat,                             // unique identifier ∈ [0,N)
14:     preference: Preference,                  // non-deterministic constant
15:     decision: MonotonicOption⟨Decision⟩      // initially None
16: )
```

Figure 2: Hosts and message states of the Two-Phase Commit protocol. Since there is only one coordinator, the coordinator's identifier is implicit. Moreover, since VOTE messages are destined for the coordinator, and DECIDE is broadcast to every participant, we omit their destination fields. MonotonicSets are add-only, while MonotonicOptions are write-once.

to derive manually and well-suited to automation. As a subclass of Regular Invariants, Monotonicity Invariants capture the "add-only" nature of data types such as monotonic counters, grow-only sets, and append-only lists, by asserting how their values may evolve during an execution. Another subclass is Ownership Invariants, which describe the ownership of unique resources in the system. We use these subclasses unchanged from Kondo's invariant taxonomy.

Our key insight is that a new class of Regular Invariants, which we call *Provenance Invariants* (§3.2), can be used to express both *inter-host* (§3.3) and *intra-host* (§3.4) properties in distributed protocols. These properties were previously beyond the scope of Regular Invariants and automation tools [40], leaving developers to manually derive and prove them. With the introduction of Provenance Invariants, we can express these properties, and in turn entire inductive invariants of distributed protocols, using only Regular Invariants. We present our algorithm to automatically derive Provenance Invariants in §4.

To ground our discussion, we use the classic Two-Phase Commit protocol as a running example in the rest of the paper.

3.1 Running Example: Two-Phase Commit

In this protocol, a group of participants work with a single coordinator to decide whether to abort or commit a transaction. Figure 2 specifies the states of hosts in the system.

The protocol runs as follows, with Figure 3 formally defining some of these steps:

```
1:  // Local computation that doesn't receive or send messages
2:  step CoordinatorMakeDecision(
3:      v: Coordinator, v′: Coordinator)
4:      ∧  v.decision = None
5:      ∧  if |v.yesVotes| = v.numParticipants then
6:             v′ = v.(decision := Some(Commit))
7:         else if |v.noVotes| > 0 then
8:             v′ = v.(decision := Some(Abort))
9:         else
10:            v′ = v
11:
12: step CoordinatorSendDecide(
13:     v: Coordinator, v′: Coordinator, send: Message)
14:     ∧  v.decision.Some?
15:     ∧  send = DECIDE(v.decision.value)
16:
17: step ParticipantReceiveDecision(
18:     v: Participant, v′: Participant, recv: Message)
19:     ∧  recv.DECIDE?
20:     ∧  v.decision = None
21:     ∧  v′ = v.(decision := Some(recv.d))
22:
```

Figure 3: Some examples of the hosts' steps in the Two-Phase Commit protocol. Each step defines a relation between a host's current state v and its new state v' after taking the step. Expressions of the form $v' = v.(X := Z)$ indicates that v' is identical to v except for the field $v'.X$, which has the value Z. Note that we use the conjunction operator $\wedge$ to denote a bulleted list of conjuncts, and the '?' syntax is used to assert if a value is of a particular type or variant.

*a*1. A single coordinator and N participants are initialized.

*a*2. Participants send their preferences to the coordinator through VOTE messages.

*a*3. Upon receiving a VOTE message, the coordinator updates its *yesVotes* or *noVotes* appropriately.

*a*4. If the coordinator has obtained Yes votes from every participant, it decides Commit. Otherwise, if it received a No vote, it decides Abort (*CoordinatorMakeDecision* step in Figure 3).

*a*5. Once the coordinator makes a decision, it broadcasts it as a DECIDE message (*CoordinatorSendDecide*).

*a*6. A participant, on receiving a DECIDE message, sets its local *decision* to match (*ParticipantReceiveDecision*).

The safety property we want to prove is that if any participant decides Commit, then every participant's local *preference* must be Yes.

3.2 Provenance Invariants and Execution Histories

Provenance Invariants are expressed using the notion of *history-preservation* [40]. A history-preserving protocol model augments a host's current state with an append-only log of previous states, referred to as its *history*. This history captures a snapshot of every state a host transitions through, from its initial state to its current state.

Formally, a Provenance Invariant connects a property of the current state of the system to how an adjacent pair of states in a host's history must be related by the host taking some step, where this step is one that made the property true. We define two categories of Provenance Invariants.

First, a *Network-Provenance Invariant* relates a message m in the network to the execution of one of a few host steps $T_1, \ldots, T_j$ that must have sent it. Formally:

$$\begin{aligned} m \in network \implies \exists\, i : & \; T_1(hist[i], hist[i+1], m) \\ & \vee \ \ldots \\ & \vee \ T_j(hist[i], hist[i+1], m) \end{aligned}$$

where *hist* is the history sequence of m's sender. This disjunction of steps is necessary because it is not always possible to attribute the provenance of a message to a unique step, such as when multiple steps send the same message.

In our Two-Phase Commit example, the following statement is a Network-Provenance Invariant:

> "For every DECIDE message m in the network, there must be adjacent states v, v' in the coordinator's history such that $CoordinatorSendDecide(v, v', m)$."
> (*Decide-Msg-Provenance*)

Second, a *Host-Provenance Invariant* relates a local property q of a host's current state h_{cur}—which we call a *provenance witness*—to one of a few steps the host must have taken in order for the local property to be satisfied. This witness q must be a property that is not true in any initial states of the host. Formally, with *hist* as the history sequence of the host in question:

$$\begin{aligned} q(h_{cur}) \wedge \big(\forall\, h : \neg\,(HostInit(h) \wedge q(h))\big) \implies \exists\, i : & \\ \neg\, q(hist[i]) \wedge q(hist[i+1]) & \\ \wedge\ (T_1(hist[i], hist[i+1]) & \\ \vee \ \ldots & \\ \vee \ T_j(hist[i], hist[i+1])) & \end{aligned}$$

Again, we have a disjunction of steps because it is possible that there is more than one step that makes q true.

For example, the following is a Host-Provenance Invariant in Two-Phase Commit, with its antecedent serving as the

provenance witness:

> "If a participant's *decision* is Commit, there must be adjacent states v, v' in its history, together with a received message m, such that *ParticipantReceiveDecision*(v, v', m)."
> (*Participant-Decision-Provenance*)

Crucially, every individual Provenance Invariant is inductive, due to the immutable nature of execution histories. For instance, consider the property *Decide-Msg-Provenance* above. It is trivially inductive because for any message in the network, the fact that the sender performed a step that sent it is forever recorded into the history, so there is no subsequent transition that ever can make this invariant false. We leverage this feature to automatically generate inductive invariants of distributed protocols (§5.3).

3.3 Expressing Inter-Host Relationships Using Provenance Invariants

We demonstrate that global relationships between remote hosts—which prior work [10, 40] asked the developer to creatively supply and manually prove—can actually be expressed as conjunctions of well-chosen Host-Provenance Invariants and Network-Provenance Invariants.

To illustrate, consider the inter-host property:

> "If some participant decided Commit, then the coordinator also decided Commit."
> (*Participant-Agreement*)

This property is a clause in the inductive invariant of Two-Phase Commit that Kondo [40] required developers to craft manually.

Using Provenance Invariants, we can imply *Participant-Agreement* by the conjunction of *Participant-Decision-Provenance* and *Decide-Msg-Provenance*. In particular, suppose that a participant host h decided Commit. Then by *Participant-Decision-Provenance*, h must have executed step *ParticipantReceiveDecision*. By the body of this step (Figure 3), we know that h received a message $m = \text{DECIDE}(\text{Commit})$ from the network. Next, we infer from *Decide-Msg-Provenance* that m's sender (namely, the coordinator), must have sent m via step *CoordinatorSendDecide*. This step itself says the coordinator's decision agrees with the message at the time of sending. Given that the coordinator does not equivocate on its decision, we arrive at our conclusion that the coordinator's current decision is also Commit.

More formally, when a host r updates its state upon receiving a message m, we can trace this update to the execution of some step T_r via a Host-Provenance Invariant. This induces a relationship $\beta(r, m)$ between the updated host state and m, given directly by T_r's specification. In addition, the receipt of m implies, via a Network-Provenance Invariant, that m's sender s executed a step T_s that sent m. This creates another relationship $\alpha(s, m)$ relating the host s and the message m, given by T_s's specification. When taken together, α and β imply some inter-host relationship between s and r, namely, $\exists m : \alpha(s, m) \wedge \beta(m, r)$. By transitively chaining such arguments, we can derive relationships between the head and tail hosts of a causal chain of messages.

The above argument establishes how inter-host properties, which logically connect the state of recipient hosts to the state of sender hosts, may be implied using Provenance Invariants. With this technique, inductive invariants do not need to explicitly describe inter-host properties, which prior work like IronFleet and Kondo required users to creatively and laboriously produce. Instead, they are replaced with simpler, localized Provenance Invariants.

3.4 Expressing Local Properties Using Provenance Invariants

Beyond inter-host properties, an inductive invariant may also describe local properties of individual hosts. One example is:

> "If the coordinator decided Commit, then its *yesVotes* set is of size *numParticipants*."
> (*Coordinator-Decision-Provenance*)

Prior work [10, 40] required the user to manually derive such properties. We capture them with ease using Host-Provenance Invariants, which lend themselves to automation (§4).

Our observation is that local properties such as *Coordinator-Decision-Provenance* can be attributed to local computation steps, i.e., steps that do not receive a message. Examples of such steps include those that are triggered by a timeout or local conditions.

Just as a Host-Provenance Invariant may trace the provenance of a state update at a host to a step that receives a message, it may likewise trace it to a local computation step. For instance, to derive *Coordinator-Decision-Provenance*, the Host-Provenance Invariant:

> "If the coordinator decided Commit, then it must have executed step *CoordinatorMakeDecision*."

attributes the coordinator's Commit decision to step *CoordinatorMakeDecision*. This step itself says that for the coordinator to decide Commit, it must have satisfied in a previous state the enabling condition that it has gathered Yes votes from every participant. Then, given the monotonic add-only nature of the *yesVotes* set, we conclude that *yesVotes* set is of the threshold size.

The next section presents our technique for automatically deriving the Provenance Invariants that underpin our proofs.

4 Automating Provenance Invariants With Atomic Sharding

To get the most out of expressing inductive invariants using only Regular Invariants, we aim to derive the required Provenance Invariants automatically given a distributed protocol. We first explain a new *atomic shard principle* to describe a category of mechanically derivable Host-Provenance Invariants (§4.1). We then present an *atomic sharding algorithm* to automatically derive invariants based on this principle (§4.2). Finally, we explain how we derive Network-Provenance Invariants (§4.3).

4.1 Automating Host-Provenance with the Atomic Shard Principle

To automatically derive Host-Provenance Invariants, we first identify a set of useful provenance witnesses. For each witness q, we then determine the set of candidate steps that could affect its provenance. Whenever q holds, we know that at least one of these steps must have been executed.

We propose the atomic shard principle to meet this goal. First, we define a *shard* to be a subset of a host's local variables. A shard σ is *atomic* if all variables in the shard are always updated "atomically"—there are no protocol steps that only modify some variables within σ but not others. Each atomic shard σ is then associated with the set of steps A_σ that modify its variables.

The *atomic shard principle* states that when the current value of some variable in an atomic shard σ differs from its initial value, then every variable in this shard must have attained their current values through an atomic step in A_σ.

From this principle, we obtain one Host-Provenance Invariant per atomic shard. Formally, let $\sigma := \{x_1, \ldots, x_k\}$ be an atomic shard of a host, and suppose $A_\sigma := \{T_1, \ldots, T_j\}$ are the protocol steps that modify this shard. Then, given that h_{cur} is the host's current state, we first define a provenance witness as the predicate:

$$q(h) := (h.x_1 = h_{\text{cur}}.x_1) \wedge \ldots \wedge (h.x_k = h_{\text{cur}}.x_k)$$

The atomic shard principle tells us that if the host's current state satisfies q, and if q is not true in any initial states of the host, then variables x_1 through x_k must have attained their current values when the host executed one of the steps in A_σ at some point in its history. This is the Host-Provenance Invariant:

$$\begin{aligned} & q(h_{cur}) \wedge \big(\forall\, h : \neg(\mathit{HostInit}(h) \wedge q(h))\big) \implies \exists\, i : \\ & \quad \neg\, q(\mathit{hist}[i]) \wedge q(\mathit{hist}[i+1]) \\ & \quad \wedge\ (T_1(\mathit{hist}[i], \mathit{hist}[i+1]) \\ & \qquad \vee \ldots \\ & \qquad \vee\ T_j(\mathit{hist}[i], \mathit{hist}[i+1])) \end{aligned}$$

where *hist* is the history sequence of the host.

As a concrete example, consider the Host-Provenance Invariant *Participant-Decision-Provenance* from §3.2. We observe that $\{decision\}$ is an atomic shard at the participant host, and *ParticipantReceiveDecision* is the only step that modifies this shard. From this, we infer *Participant-Decision-Provenance*:

$$\begin{aligned} & h_{cur}.\text{decision} = \text{Some}(\text{Commit}) \implies \exists\, i : \\ & \quad \mathit{hist}[i].\text{decision} \neq \text{Some}(\text{Commit}) \\ & \quad \wedge\ \mathit{hist}[i+1].\text{decision} = \text{Some}(\text{Commit}) \\ & \quad \wedge\ \mathit{ParticipantReceiveDecision}(\mathit{hist}[i], \mathit{hist}[i+1]) \end{aligned}$$

4.2 Atomic Sharding Algorithm

We present an *atomic sharding algorithm* to automatically identify atomic shards σ and their associated steps A_σ. This occurs in three phases. First, we estimate the *footprint* of each host step. Second, we analyze how footprints intersect to identify atomic shards. Finally, we further refine each shard to more effectively handle collection-type variables such as sets and maps.

Estimating footprints. We define a host step's *footprint* to be a set of local variables that the step may modify. For each step, we estimate its footprint via a static analysis of the host's description. §5.3 describes how we implement this analysis in practice.

Importantly, it is safe to overestimate a step's footprint, which our syntax-based approach inevitably does—a footprint may contain variables that the step never modifies, or variables that may only be conditionally updated. Too much overestimation, however, leads to weaker and less useful invariants. On the other hand, our algorithm never underestimates footprints, which would result in incorrect invariants.

Our algorithm (and hence the Basilisk tool—§5) currently rejects a protocol if it contains a footprint with two variables that are conditionally updated via different conditions. For example, it prohibits a step that either updates x or y with the expression "if c then $x := 5$ else $y := 6$". This restriction does not sacrifice generality, as any such step may be equivalently written as two steps, with the enabling condition c for a step that updates x and $\neg c$ for another that updates y, respectively. We currently rely on the developer to perform such transformations wherever they are needed.

Computing maximal atomic shards. Next, we identify atomic shards by analyzing footprint intersections to find subsets of host variables that are always updated atomically.

This extraction process is best visualized using a Venn diagram. Let steps S_1, S_2 and S_3 be the three steps that a hypothetical host takes. The ovals F_1, F_2 and F_3 in Figure 4 represent the respective footprints of these steps. By definition, each partition in the Venn diagram is an atomic shard:

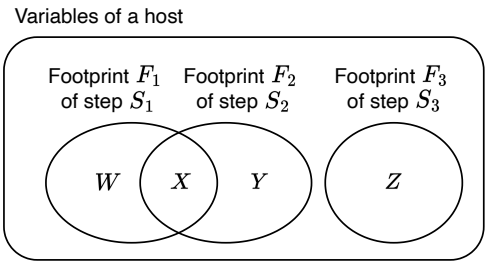

Figure 4: The footprints of three steps of a hypothetical host. Regions W through Z represent maximal atomic shards.

- region $W \coloneqq F_1 \setminus F_2$, with associated steps $A_W \coloneqq \{S_1\}$,
- region $X \coloneqq F_1 \cap F_2$, with $A_X \coloneqq \{S_1, S_2\}$,
- region $Y \coloneqq F_2 \setminus F_1$, with $A_Y \coloneqq \{S_2\}$, and
- region $Z \coloneqq F_3$, with $A_Z \coloneqq \{S_3\}$.

This process extracts *maximal* atomic shards, which are ones where adding an additional variable to it would violate its atomicity. In most cases, maximal atomic shards provide greater utility over ones that are non-maximal. To illustrate, consider a host with two local variables x and y, and $\{x, y\}$ is a maximal atomic shard modified by a single step T. Suppose T receives a message m and sets $x \coloneqq m.x$ and $y \coloneqq m.y$. The atomic shard principle yields the Host-Provenance Invariant:

> "If x or y do not hold their initial values, then they must have obtained their current values through a message m, where $m.x = x$ and $m.y = y$."

However, if we split $\{x, y\}$ into non-maximal atomic shards $\{x\}$ and $\{y\}$, we obtain two invariants:

- If x does not hold its initial value, it must have obtained its current value through a message m_1, where $m_1.x = x$; and,
- if y does not hold its initial value, it must have obtained its current value through a message m_2, where $m_2.y = y$.

This is strictly weaker than the single invariant we draw from the maximal shard. For instance, we can no longer prove the existence of a singular message m that satisfies both $m.x = x$ and $m.y = y$.

Additional refined atomic shards. In the special case when shards contain collection-type variables (e.g., sets and maps), however, maximal atomic shards yield limited benefit. This is because these collection types "collapse" provenance, making it difficult to relate them to other fields.

To demonstrate, consider a host with two local variables x: int and s: set⟨int⟩, where the latter is initially empty, and suppose $\{x, s\}$ is a maximal atomic shard that is modified by a single step T. Further suppose that T receives a message m and sets $x \coloneqq m.x$ and adds $m.y$ to s. Using the $\{x, s\}$ shard, we infer the Host-Provenance Invariant:

> "If x or s do not hold their initial values, then they must have obtained their current values through T."

However, this is not strong enough for us to trace the provenance of the host's current state to the message that led to that state, which is the primary benefit of a Host-Provenance Invariant. In particular, we cannot say:

> "For all items e in s, if e is not initially in s or x does not hold its initial value, then there must be a message m with $m.x = x$ and $m.y = e$."

This property is false because e may have arrived in a message $\hat{m}$ with $\hat{m}.x = \hat{x} \neq x$, and x was subsequently updated to its current value by a completely different message.

Hence, to trace the provenance of specific items in collections such as s, we further identify *refined* atomic shards that package every collection-type variable in its dedicated (non-maximal) shard.

With refined shard $\{s\}$, we can reason about the step that introduced each individual item in s:

> "For all items e in s, if e is not initially in s, then e must have been added to s through T."

which establishes the additional fact that the host received a message m where $m.y = e$ for every e in s.

Finally, note that while atomic sharding always generates correct invariants, it does not cover the space of all Host-Provenance Invariants. There are instances where it may fail to capture necessary properties, and hence the developer must supply an additional hint. We describe these hints in §5.4 and characterize the scenarios requiring them in §6.4. However, our evaluation shows that such cases are rare in practice.

4.3 Automating Network-Provenance

The procedure for generating Network-Provenance Invariants is much simpler. For each message variant M defined in the protocol, we identify a set of steps $\{T_1, \ldots, T_j\}$ that send messages of variant M. We then infer the following Network-Provenance Invariant:

$$\begin{aligned} \forall\, m :\ & \text{variant}(m) = M \ \wedge\ m \in S.\text{network} \\ \implies & \exists\, i : \big(T_1(hist[i], hist[i+1], m) \\ & \qquad \vee\ \ldots \\ & \qquad \vee\ T_j(hist[i], hist[i+1], m)\big) \end{aligned}$$

where *hist* is the history sequence of m's sender.

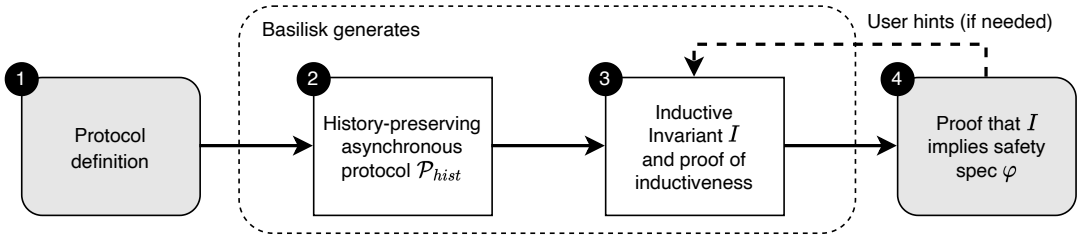

Figure 5: Basilisk workflow. Shaded bubbles represent artifacts that the user writes, while white boxes represent artifacts that Basilisk generates. In a few cases, the user may discover while writing the proof in step ❹ that the inductive invariant I generated in ❸ is too weak. In such cases, the user provides hints (the dashed arrow) that enable Basilisk to generate a stronger invariant.

5 Proving Protocols With Basilisk

Armed with the power and simplicity of Provenance Invariants, we design and implement Basilisk, a tool that finds the inductive invariants of distributed protocols with minimal guidance from the user.

Basilisk is designed for protocol models written in general verification frameworks such as Dafny [20], where determining the inductiveness of an invariant is an undecidable problem. It targets asynchronous message passing systems in which hosts communicate over an unreliable network that may arbitrarily delay, drop, duplicate, or re-order messages. We choose this network model for its generality and prevalence in real systems. While we do not explore stronger models in this work, we expect that their stronger guarantees would enable us to generate stronger invariants.

We implement the Basilisk prototype by modifying the Kondo codebase [39], which itself extends the Dafny version 4.2 verifier [1]. Overall, Basilisk's implementation adds about 2,000 lines of C# code to the Dafny verifier.

Figure 5 illustrates the Basilisk developer workflow. Step ❶: The developer starts by defining the hosts in the protocol, including their initialization conditions and local state transitions. Step ❷: Basilisk automatically generates a history-preserving asynchronous protocol $\mathcal{P}_h$. It models an asynchronous network and maintains the execution history of hosts. Step ❸: Basilisk generates an inductive invariant of $\mathcal{P}_h$, along with a proof of its inductiveness. Step ❹: The user proves that this inductive invariant implies the protocol's safety property. In rare instances, to complete this proof, the user may need to provide hints so that Basilisk will produce a stronger inductive invariant.

5.1 Step ❶: Protocol Definition

The user defines the state and protocol steps of each type of host in the system (e.g., Figures 2 and 3). Each step may send a message (including broadcast), receive a message, perform both send and receive, or do neither. This is a more permissive model than Kondo, which prohibits steps that both send and receive. Basilisk extends easily to steps that send or broadcast more than one message; we did not implement that as none of the protocols in our evaluation required such a feature.

The user then defines a Hosts record representing the state of all hosts in the system. Each field in the record is a list of hosts of a particular type. For example, in Two-Phase Commit:

$$\textbf{datatype}\ \text{Hosts} = \text{Hosts}(\textit{coordinators}\text{: seq}\langle\text{Coordinator}\rangle,\ \textit{participants}\text{: seq}\langle\text{Participant}\rangle)$$

The user then describes the initial states of Hosts using a *HostsInit* predicate. Typically, this specifies that each host satisfies its own local initial conditions, together with some global state constraints. For instance, in Two-Phase Commit:

$$\begin{aligned}&\textbf{predicate}\ \text{HostsInit}(s\text{: Hosts})\\ &\quad\wedge\ |s.\text{coordinators}| = 1\\ &\quad\wedge\ \textit{CoordinatorInit}(s.\text{coordinators}[0],\ |s.\text{participants}|)\\ &\quad\wedge\ \forall\, id :\ \big(0 \le id < |s.\text{participants}| \implies \textit{ParticipantInit}(s.\text{participants}[id], id)\big)\end{aligned}$$

where *CoordinatorInit* and *ParticipantInit* circumscribe the initial states of the coordinator and participant hosts.

Finally, the user defines a state transition relation for each host in the system. This is a disjunction of the possible steps that the host can take. For example, the coordinator in Two-Phase Commit has the transition relation:

$$\begin{aligned}&\textbf{predicate}\ \text{CoordinatorNext}(h\text{: Coordinator},\ h'\text{: Coordinator},\ \textit{send}\text{: Message},\ \textit{recv}\text{: Message})\\ &\quad\vee\ \ldots\\ &\quad\vee\ \textit{CoordinatorSendDecide}(h, h', \textit{send})\\ &\quad\vee\ \textit{CoordinatorMakeDecision}(h, h')\end{aligned}$$

where *CoordinatorSendDecide* and *CoordinatorMakeDecision* are defined in Figure 3.

Monotonicity hints. Like in Kondo [40, §3.1], the user labels monotonic variables, such as grow-only sets, when specifying hosts. These types implement a *less-than-or-equal-to (lteq)* partial order relation that captures their monotonic properties, which Basilisk uses to express Monotonicity Invariants in step ❸.

5.2 Step ❷: Asynchronous Protocol Model

With the above inputs, Basilisk generates a *history-preserving* asynchronous protocol $\mathcal{P}_h$. This model includes a sequence *history* where each entry is a snapshot of all hosts in the system, with the latest entry representing their current state. The global state of the protocol contains this history, together with an asynchronous network that is modeled as a monotonically increasing set of sent messages:

datatype GlobalState = GS(*history*: seq⟨Hosts⟩,
network: set⟨Message⟩)

Similar to prior work [10, 40], the protocol's behavior is expressed using the temporal logic of actions (TLA [17]) as a state machine that can perform a non-deterministic series of atomic steps. At first, *history* holds only the initial state of the system, and the network has no messages:

predicate Init(S: GlobalState)
$\wedge$ $|S.\text{history}| = 1$
$\wedge$ HostsInit(S.history[0])
$\wedge$ $S.\text{network} = \emptyset$

In each transition of the system, a non-deterministically chosen host performs a non-deterministically chosen local step. If this step involves the host receiving a message, then the message must be from the *network* set and addressed to the receiver host. If the step involves sending a message, the message is added to the *network* set, with the sender host marked as its source. Moreover, the new Hosts snapshot is appended to the *history* sequence:

step Next(S: GlobalState, S': GlobalState)
$\wedge$ $|S.\text{history}| \geq 1$
$\wedge$ $S.\text{history} = \mathit{trunc}(S'.\text{history})$
$\wedge$ SystemNext($\mathit{last}(S.\text{history})$, $S.\text{network}$,
$\mathit{last}(S'.\text{history})$, $S'.\text{network}$)

Here, given a sequence s, $\mathit{trunc}(s)$ yields s with the last item removed, while $\mathit{last}(s)$ returns the last item. *SystemNext* describes how the current state of hosts and the network changes as the result of the step, calling upon the host transition relations the user defined in step ❶.

5.3 Step ❸: Generating Regular Invariants

From $\mathcal{P}_h$, Basilisk automatically generates an inductive invariant I. This I is expressed as the conjunction of a series of Regular Invariants. This includes Provenance Invariants and Monotonicity Invariants. There is a final category, Ownership Invariants, which we inherit from Kondo [40, §3.1], but omit from this discussion as it is not the focus of this work.

Basilisk automatically generates Provenance Invariants using the atomicity principle described in §4. To compute footprints, Basilisk relies on parsing Dafny's state update syntax.

There are two formats with which a host step may modify local state. The first uses Dafny's state update syntax $v' = v.(Z_1 := X_1, \ldots, Z_k := X_k)$. This expression means that host state v' is identical to current state v except for the fields Z_1 through Z_k, which are assigned the values X_1 through X_k, respectively. The second format expresses some relation $r(v'.Z, v, m)$ between an updated field $v'.Z$, the current host state v, and any incoming message m. For simplicity, the Basilisk prototype permits only the former update syntax.

Meanwhile, Basilisk inherits Kondo's technique for generating Monotonicity Invariants. For each monotonic variable specified in step ❶, Basilisk generates an invariant stating that the variable satisfies its *lteq* relation as its value evolves over history. Such invariants assert the monotonic nature of their data types (e.g., the coordinator host's non-equivocation of its decision when proving *Participant-Agreement* in §3.3), and are crucial in stating how some properties that are true of a host's past state are also true in its present state.

Finally, Basilisk also produces a mechanically checked proof of I's correctness. Namely, given a pair of global states S and S', the proof shows that Init(S) implies $I(S)$ and that Next(S, S') $\wedge$ $I(S)$ implies $I(S')$. Given the mechanical and local nature of Regular Invariants, and the fact that each individual Provenance Invariant is inductive (§3.2), these proofs follow a systematic structure and are easy to formulate.

5.4 Step ❹: Proving Safety

Finally, let $\varphi(h\text{: Hosts})$ be the protocol's safety property. The user employs the inductive invariant I generated in the previous step to prove that $\varphi_h(S) := \varphi(\mathit{last}(S.\text{history}))$ is an invariant in $\mathcal{P}_h$. This involves two proof obligations proven as lemmas in Dafny, to show that $I(S) \wedge \varphi_h(S)$ is an inductive invariant. They are:

*Ob*1. Init(S) implies $I(S) \wedge \varphi_h(S)$; and,

*Ob*2. $I(S) \wedge \varphi_h(S) \wedge \text{Next}(S, S')$ implies $I(S') \wedge \varphi_h(S')$.

This procedure requires some creativity from the user, to show how a collection of simple Regular Invariants imply that, say, all hosts agree on the decision value in a consensus protocol. It is, however, a much more straightforward and well-defined task compared to IronFleet or Kondo. Here, the user concentrates only on proving safety using I, which is already inductive, and avoids going through the invariant-proof loop (§2) to discover an inductive invariant.

Possible failure modes. When trying to prove the above obligations, the user may fail in two ways. First, although Basilisk only generates correct inductive invariants, they may not be strong enough to establish safety. Our evaluation (§6.4) shows that this is usually because the atomic sharding algorithm cannot generate every correct Host-Provenance Invariant. As a remedy, the user manually supplies the provenance

witness for a desired Provenance Invariant as a hint to Basilisk, explaining how some particular host transitions affect local state (represented by the dashed arrow in Figure 5). Such hints are usually quite straightforward to provide, requiring far less effort than global, inter-host invariants.

Second, the protocol definition written in step ❶ may be incorrect, meaning it contains a step that violates safety.

Basilisk handles both failure modes gracefully. With Basilisk, the user proves safety in a modular fashion by showing that it holds across each protocol transition. As a result, when verification fails, the verifier advises the user on the exact host step where the proof breaks down. This helps the user identify which invariants may need to be strengthened or where a potential protocol bug might reside.

6 Evaluation

To assess the Basilisk methodology, we apply it to a diverse set of distributed protocols, listed in Table 1. This list is informed by our experience in designing and implementing distributed protocols, and seeks to cover the space of common protocols. We used the protocols in the first block in Table 1, namely Echo Server, Ring Leader Election, Simple Leader Election, Paxos, Paxos-Combined and Paxos-Dynamic, to develop and refine the concepts of Provenance Invariants and atomic sharding, before applying it to the remaining protocols in the second block. Notably, every protocol and its inductive invariant is outside of the EPR decidable fragment of logic [29].

We specify each protocol as a state machine in Dafny following the IronFleet style [10], together with a safety property (Appendix A contains a description of each protocol and its safety property). Using this state machine definition, Basilisk generates a provably correct inductive invariant I, expressed as a conjunction of Regular Invariants. Using I, we prove that the safety property is an invariant in the protocol, by manually proving the obligations $Ob1$ and $Ob2$ defined in §5.4.

We also compare Basilisk's results to the previous state-of-the-art, Kondo [40]. Note that because Kondo prohibits protocol steps that both receive and send messages, the protocol descriptions used by Kondo are modified from the Basilisk versions to accommodate this restriction. Because of the effort required to accommodate this restriction and prove these protocols using Kondo, we did not apply Kondo to every protocol.

Our evaluation determines whether Basilisk is effective in helping developers prove the safety of their distributed protocols. To do so, we address the following questions.

1. How effective is Basilisk in finding the inductive invariants of various distributed protocols? (§6.1)
2. How burdensome is expressing and proving protocols using Basilisk? (§6.2)
3. How efficiently can a verifier like Dafny verify the invariants and proofs produced using Basilisk? (§6.3)
4. What are the cases where the Basilisk methodology requires developer assistance? (§6.4)

6.1 Effectiveness of Basilisk in Finding Inductive Invariants

The *'User invs'* columns in Table 1 show the number of manually derived invariant clauses the user supplies to prove the safety of each protocol using Basilisk and Kondo, respectively. Basilisk succeeds in finding inductive invariants for all 16 distributed protocols on which it was evaluated. This is a significant improvement over Kondo, which required user-supplied invariants for most protocols.

Note that three ownership-based protocols (Distributed Lock, ShardedKV, and ShardedKV-Batched), each of which has a safety property that asserts the exclusive ownership of resources, can already be proven completely automatically using Kondo. Unsurprisingly, Basilisk achieves the same on these protocols, as Basilisk inherits the ownership reasoning of Kondo.

These results highlights the effectiveness of Basilisk along two fronts. First, it supports our hypothesis that many deep protocol properties can be implied by only simple Regular Invariants in our generalized invariant taxonomy. This includes properties of protocols that are widely regarded as very challenging for human developers, such as Multi-Paxos.

Second, it demonstrates the feasibility of finding the inductive invariants of distributed protocols automatically, even in general verification frameworks such as Dafny.

Altogether, Basilisk simplifies the developer's workflow, as manually finding inductive invariants demands a large amount of creativity and expertise. With Basilisk, users avoid the invariant-proof loop process of IronFleet and Kondo, where a developer must meticulously craft a candidate inductive invariant, only to realize that it is wrong after spending time to prove it correct.

6.2 Ease of Expressing and Proving Protocols

While Basilisk reduces the user's burden in finding inductive invariants, one might worry that it simply shifts this effort elsewhere rather than eliminates it, requiring the user to compensate with more labor in other aspects, such as writing more proof annotations. However, our evaluation demonstrates that Basilisk avoids this pitfall and materially improves the user's proof experience.

Protocol expressiveness. Given a conceptual protocol, expressing it in Basilisk is significantly easier than in Kondo, as evidenced by the fewer lines of code required to define the protocol (*'Size'* in Table 1). This is due to two reasons.

	Basilisk							Kondo						
	Size	User invs	Mono annots	Prov hints	Lines of proof *Safety*	Lines of proof *Total*	Time (sec)	Size	User invs	Mono annots	Recv hints	Lines of proof *Safety*	Lines of proof *Total*	Time (sec)
Echo Server [40]	157	0	1	0	8	49	5.1	260	1	1	0	0	40	7.9
Ring Leader Election [3]	99	0	0	0	80	115	5.3	179	1	0	0	30	63	8.0
Simple Leader Election [34]	149	0	1	0	45	87	7.3	255	3	1	0	33	94	13.6
Paxos [19]	418	0	5	0	444	486	24.6	631	20	5	2	558	777	42.9
Paxos-Combined	319	0	5	0	445	497	57.5	-	-	-	-	-	-	-
Paxos-Dynamic	414	0	4	2	479	522	42.4	-	-	-	-	-	-	-
Flexible Paxos [12]	418	0	5	0	441	483	22.8	633	20	5	2	559	780	49.4
Distributed Lock [10]	134	0	0	0	0	39	5.0	194	0	0	0	0	31	4.7
ShardedKV	152	0	0	0	0	39	5.9	213	0	0	0	35	68	5.0
ShardedKV-Batched	164	0	0	0	0	38	5.6	225	0	0	0	0	31	5.1
Lock Server [21]	212	0	0	0	0	38	7.3	287	1	0	0	20	59	6.3
Two-Phase Commit	278	0	3	0	95	139	7.4	385	4	3	0	119	186	8.9
Three-Phase Commit [32]	323	0	5	0	108	152	8.3	-	-	-	-	-	-	-
Reduce	135	0	0	0	30	69	24.4	-	-	-	-	-	-	-
Raft Leader Election [25]	172	0	1	2	52	93	6.3	-	-	-	-	-	-	-
Multi-Paxos [19]	447	0	4	2	522	565	61.5	-	-	-	-	-	-	-

Table 1: User experience metrics of Basilisk compared to Kondo. A lower number is better for every column, and the shaded cells under Kondo highlight areas where it is outperformed by Basilisk. *'Size'* counts the lines of code the user writes to express the protocol. *'User invs'* is the number of invariant clauses that the user manually supplies. *'Mono annots'* is the number of monotonic type annotations the user writes—these numbers are identical between Basilisk and Kondo. *'Lines of proof'* is the amount of proof code the user writes to complete the safety proof. In both Basilisk and Kondo, '*Safety*' is the size of the Dafny lemmas used to prove safety, while '*Total*' includes additional definitions of proof obligations. In Kondo, '*Total*' also includes the definitions of manually-written invariants, which Basilisk does not require. Finally, *'Time'* is the time Dafny takes to verify the final proof of the history-preserving asynchronous protocol.

First, in event-driven message passing systems, a common mode of operation for hosts is to receive a message, perform some computation based on the content of the message, and then send out messages in response. In Basilisk, such behavior is more naturally modeled as a single, atomic state machine step that receives the message, performs the computations, and sends the response (as is also the case in IronFleet [10]).

In contrast, because Kondo does not permit host steps that both receive and send messages, such host behavior must be modeled as two distinct steps—one that receives the message and performs the computation, and another that sends the responses. This leads to awkward protocol descriptions, as steps must be broken down into multiple smaller steps. For example, in Echo Server, the server host forwards a copy of every request it receives. In Kondo, this extremely simple step must be modeled as separate steps that a) receive and store the request locally, and b) send a response based on the locally stored request. Basilisk does not suffer from this restriction, and hence lets users specify their protocols more naturally.

Second, defining a protocol in Basilisk only requires the user to specify the initialization condition and state transition relation for hosts (§5.1). In contrast, Kondo additionally needs the user to define a synchronous version of the protocol [40, §4.2], resulting in more code and effort.

Proof annotation effort. To prove the correctness of a distributed protocol, both Basilisk and Kondo require the user to write additional proof code to prove that the desired safety property is indeed an invariant. We quantify this effort using the lines of code in the final proof (*'Lines of proof'* in Table 1).

For Basilisk, this effort involves writing a lemma to convince the Dafny verifier that Basilisk's generated inductive invariant implies the protocol's safety specification. Proving this lemma is the only step that demands user creativity when using Basilisk, and the size of this lemma is listed under the *'Safety'* sub-heading. Meanwhile, the *'Total'* sub-heading shows the total number of lines in the proof file, which includes the aforementioned lemma, and "standard lines" such as the definitions of the proof obligations *Ob*1 and *Ob*2, and import statements for other Dafny modules.

For Kondo, the *'Safety'* sub-heading counts lines of code in lemmas proving that the user-derived invariants, in conjunction with the safety property, is an inductive invariant in a synchronous version of the protocol [40, §4.2]. It also includes modifications that the user must then make to these

lemmas in order to prove the final asynchronous protocol. The *'Total'* count for Kondo includes the aforementioned lemmas and modifications, "standard lines" as described above, and also the definition of the user-supplied inductive invariant.

We observe that Basilisk is competitive with Kondo in terms of proof effort. For simple protocols such as Echo Server and Ring Leader Election, Kondo requires fewer proof annotations than Basilisk. However, Basilisk requires significantly less effort when handling complex protocols. In the case of Flexible Paxos, for example, Basilisk's safety lemma is 21% smaller than Kondo's (441 lines vs. 559 lines). Also, the user avoids defining their own inductive invariant, which comprises over 200 lines in Flexible Paxos. Importantly, this metric also hides the additional effort of the invariant-proof loop process demanded by Kondo, as it only shows the size of the final artifact, not the amount of proofs and invariants written and deleted while deriving the final product.

User guidance. Both Basilisk and Kondo rely on user guidance to automatically derive and prove invariants. Basilisk uses three types of hints: provenance witnesses, monotonicity labels and ownership labels.

Of these categories, the most interesting is Basilisk's use of provenance witnesses (listed under *'Prov hints'* in Table 1), which is a generalization of Kondo's receive witness conditions [40, §5.1] (listed under the *'Recv hints'*). Kondo required the user to provide one receive witness for every generated Receive Invariant, and it used Receive Invariants sparingly—two each for Paxos and Flexible Paxos (§7 explains the relationship between Host-Provenance Invariants and Kondo's Receive Invariants).

In comparison, Basilisk relies heavily on Host-Provenance Invariants, yet can generate most of them fully automatically through atomic sharding (§4). A hint is only required when the generated provenance invariants are not strong enough. For instance, only 6 out of 64 Host-Provenance Invariants used by the protocols in our evaluation required the user to provide provenance witnesses as hints. We characterize the conditions under which the user may need to manually provide provenance witnesses in §6.4.

Meanwhile, Basilisk requires the user to annotate monotonic data types and resource ownership semantics [40]. In these respects, Basilisk inherits the behavior of Kondo, resulting in an identical user experience. The *'Mono annots'* columns in Table 1 list the number of annotations used to prove each protocol; protocols that are available in Kondo share the same numbers as Basilisk. As for ownership labels, only Distributed Lock, ShardedKV, ShardedKV-Batched and Lock Server use them. We omit ownership from Table 1 because the user experience is identical to Kondo.

6.3 Verification Latency of Basilisk Invariants and Proofs

Verifier latency plays a crucial role in ensuring a positive developer experience, as it enables a fast feedback loop that helps users quickly complete or correct incomplete or erroneous proofs. The *'Time'* columns in Table 1 report the time taken by the Dafny verifier to check the final proof of each history-preserving asynchronous protocol. These times include checking the invariants and lemmas generated by the Basilisk and Kondo tools, as well as any user-supplied ones. Notably, they exclude the verification time of the synchronous protocol required by Kondo. The time required for both Basilisk and Kondo to produce their auto-generated invariants and lemmas is less than 2 seconds in all cases, and does not contribute significantly to overall verification latency.

Our results show that Basilisk achieves good verification performance that scales reasonably with protocol complexity. Even for challenging protocols like Multi-Paxos, verification completes in a minute, providing an efficient turnaround that supports interactive development.

Interestingly, although not a design goal, we observe that Basilisk outperforms Kondo in verification speed, particularly on complex protocols. For example, the Flexible Paxos proof verifies in less than half the time with Basilisk compared to Kondo. We hypothesize that this improvement stems from two reasons.

First, as explained in §6.2, the improved expressivity of Basilisk allows a protocol to be expressed with fewer host steps compared to Kondo. This reduces the complexity of the host state machines, resulting in a smaller burden on the verifier.

Second, Basilisk and Kondo differ in how proofs are authored and optimized. Dafny's verification time is sensitive to proof structure, and Basilisk users write the final asynchronous proof directly, allowing them to iteratively optimize it for fast verification. In contrast, Kondo users focus on writing a synchronous proof, and the asynchronous proof is generated from it without optimization for verifier performance.

6.4 Limitations

Atomic sharding algorithm. First, our atomic sharding algorithm does not identify every Provenance Invariant of a given protocol. In particular, it cannot derive relationships between variables when their relationships are only *implicitly* established across multiple steps.

As an example, consider a host that keeps track of all events occurring during the current calendar year. This set of events is emptied when the year changes. The host keeps the local variables *currentYear*: int and *events*: set⟨string⟩ that is initially empty. The host has two steps: T_1 receives a message m and adds $m.event$ to *events* only if $m.year = currentYear$; T_2 increments *currentYear* and resets $events := \emptyset$. In this case,

Basilisk generates the following invariant from observing T_1:

> "For all e in $h.events$, there is a message m and an h_{hist} in the host's history such that $m.event = e$, and $m.year = h_{hist}.currentYear$."

where h is the current state of the host. This invariant fails to imply the stronger property that for any such m, $m.year = h.currentYear = h_{hist}.currentYear$, which is only established because another step T_2 empties *events* whenever *year* is incremented, thereby establishing an implicit relation between entries in *events* and the current value of *currentYear*. If this stronger property is required for the proof, then the user must provide a provenance witness to inform Basilisk of this stronger relationship between *events* and *currentYear*.

While it is certainly possible to design protocols that pathologically attack this weakness, we did not observe many implicit relationships in our real-world examples. In particular, the only implicit relationship that we observed in real protocols is when hosts reset certain collections (e.g., a set of votes) when they enter a new epoch, as is the case with all three protocols that required Provenance hints in Table 1.

Second, the strength of Provenance Invariants generated by the atomic sharding algorithm corresponds to the accuracy of the estimated footprints. Overestimation of footprints may lead to steps being spuriously associated to atomic shards. These steps are then added to the disjunction expression in the generated Provenance Invariants, weakening these invariants. The user may then manually strengthen the generated invariants using provenance witnesses. In our experience, however, we did not face this issue with any of the protocols to which we applied Basilisk.

General limitations. Basilisk is not guaranteed to be complete. There may be instances of protocols and safety properties for which Basilisk cannot generate an inductive invariant strong enough to complete the proof, even with the help of user-supplied provenance witnesses. We did not come across such cases. If they arise, however, the user may augment Basilisk's generated invariant with manually-written clauses.

In addition, the protocol's safety specification is trusted, i.e., assumed to be correct. Also, while the protocol description is verified, a developer must trust that the description accurately models their actual system, or employ prior techniques [10,36] to provably connect it to their implementation.

We also assume the correctness of Dafny and all its underlying dependencies and hardware. A successful proof is only as trustworthy as these components.

Finally, Basilisk is designed to prove the safety of crash fault tolerant distributed protocols. Liveness proofs and weaker fault models are beyond its scope.

7 Related Work

Many techniques to verify distributed systems have been proposed in recent years. Historically, these techniques either allow arbitrary protocol descriptions at the cost of developer effort to manually find and prove inductive invariants, or provide significant automation by forcing the developer to fit their protocol description into a decidable logic.

7.1 Using Undecidable Logic

Early frameworks for verifying protocols written in undecidable logics entirely relied on the developer to devise and prove inductive invariants [10, 36]. Similarly, recent frameworks like Aneris [16] and Grove [31] support verification of distributed systems using separation logic. They combine reasoning about implementations and protocols, but require the developer to write and prove all of the invariants by hand.

Some approaches partially automate the proof process, but they do so by restricting the allowed protocols. Examples include Pretend Synchrony [35], PSync [6], the $\mathbb{CL}$ logic [5] Model [4], and *ConsL* [22].

The Message Chains work [23] proposes a structure for invariants that focuses on messages, and they use specification mining over randomly generated executions to infer some of these invariants in their benchmarks. Our Provenance Invariants connect host state to protocol steps, and can be derived statically from the protocol description instead of using specification mining. Our static analysis approach works for all of our benchmarks. Message chains are potentially complementary if a protocol cannot be verified with Basilisk's automatically generated invariants and a message chain invariant would help.

The most recent and related work to Basilisk is Kondo [40]. Both Basilisk and Kondo help the developer identify invariants when verifying distributed protocols in a Dafny-based setting. Kondo's invariant taxonomy introduces two top-level classes of invariants: Protocol Invariants and Regular Invariants. Protocol Invariants are inter-host or intra-host properties that do not talk about the network. Crucially, Kondo requires the developer to manually derive and prove Protocol Invariants, which remains a creative and laborious task. In contrast, Basilisk automatically proves such properties via Regular Invariants (§3). We leave the theoretical exploration of the logical relationship between Protocol Invariants and Basilisk's generated Regular Invariants to future work.

Basilisk also inherits Kondo's automation for two subclasses of Regular Invariants, Monotonicity Invariants and Ownership Invariants. However, this paper proposes Provenance Invariants, which replace and generalize Message Invariants in Kondo's taxonomy. Network-Provenance Invariant correspond to Kondo Send Invariants. Host-Provenance Invariants subsume Kondo's Receive Invariants, and we also generalize them to properties whose provenance is a local tran-

sition rather than a message receive. Finally, Kondo does not fully automate deriving Receive Invariants, whereas Basilisk does via the atomic sharding algorithm (§4).

7.2 Using Decidable Logic

Many frameworks and algorithms rely on protocols and invariants expressed in EPR, a decidable fragment of first-order logic [8, 14, 15, 21, 27, 28, 33, 37, 38]. These all share a critical limitation, in that they require the developer to write their protocol within a restrictive language, which disallows quantification of the form $\forall\exists$, as well as theories like arithmetic. Translating protocols into EPR requires expertise and is not always possible [26].

8 Conclusion

This paper presents a general class of Provenance Invariants that can be systematically derived from a distributed protocol and can be used to prove interesting inter-host properties by, for example, chaining a Host-Provenance Invariant that shows a message was received, with a Network-Provenance Invariant that connects the message to the sender's state. We develop an atomic sharding algorithm to find Provenance Invariants given only a protocol description. We implemented atomic sharding in a tool called Basilisk, which is able to generate inductive invariants sufficient to prove the safety of 16 distributed protocols without any user-defined invariants.

A Artifact Appendix

Abstract

The artifact represents the source code of the Basilisk prototype. It also contains the descriptions of the protocols used in the evaluation (§6) of Basilisk, together with the scripts and proof annotations required to verify each protocol.

Scope

The artifact lets readers validate how Basilisk relieves developer effort in verifying distributed systems. This is measured by the following criteria:

1. The user only needs to provide a few simple hints for Basilisk to automatically generate an inductive invariant for each protocol.

2. The user should be responsible for writing fewer lines of proof code, compared to Basilisk's predecessor Kondo.

Contents

This artifact has two main directories.

local-dafny. The directory local-dafny/ contains the source code and executable for the Basilisk tool. It is developed on top of the Kondo artifact [39], which itself is a fork of Dafny 4.2.0 [1]. The core Basilisk functionality is implemented in the local-dafny/Source/DafnyCore/Basilisk/ sub-directory.

basilisk. The directory basilisk/ contains the descriptions of protocols on which Basilisk is evaluated (§6). Each protocol is also associated with an example user-written safety proof (step ❹ of Figure 5) and a script to run the verification commands.

Hosting

The artifact is hosted on GitHub: https://github.com/GLaDOS-Michigan/Basilisk (commit version fd0bc04). A copy of the repository is also hosted on Zenodo: https://zenodo.org/records/15392830.

Requirements

The artifact was developed and tested on an M3 MacBook Pro running MacOS Sequoia.

List of Protocols Evaluated

In this section, we describe each protocol listed in Table 1, and their associated safety property.

Echo Server. A server host receives messages from clients and responds to each message with an identical message.

Safety property: The set of responses a client has received from the server is always a subset of the messages it has sent.

Ring Leader Election. The classic Ring Leader Election protocol [3].

Safety property: At most one host is elected as the leader.

Simple Leader Election. Hosts request votes from peers and votes for a single peer [34]. A host declares themselves leader if they receive a majority of votes.

Safety property: At most one host is elected as the leader.

Paxos. The classic Paxos protocol [19].

Safety property: No two hosts can learn different values.

Paxos-Combined. Variation of Paxos where each host process assumes all three of leader, acceptor, and learner roles.

Safety property: No two hosts can learn different values.

Paxos-Dynamic. Variation of Paxos-Combined where leaders can dynamically increase their ballot number to retry their proposal.

Safety property: No two hosts can learn different values.

Flexible Paxos. The standard Flexible Paxos protocol [12].

Safety property: No two hosts can learn different values.

Distributed Lock. Hosts pass around a single lock in a ring configuration [10].

Safety property: At most one host holds the lock at any instant.

ShardedKV. A sharded key-value store where a shard may transfer a key to another shard.

Safety property: Every key is owned by at most one host.

ShardedKV-Batched. Same as the ShardedKV, except keys may be transferred in arbitrary-sized batches.

Safety property: Every key is owned by at most one host.

Lock Server. A single server host may grant a lock to one of many client hosts, and clients may return a lock it holds back to the server [21].

Safety property: At most one client holds the lock at any instant.

Two-Phase Commit. The classic Two-Phase Commit protocol.

Safety property: The conjunction of

1. All processes that reach a decision reach the same decision as the coordinator,
2. The Commit decision can only be reached if all processes prefer Yes, and
3. if all processes prefer Yes, then the decision must be Commit.

Three-Phase Commit. The classic Three-Phase Commit protocol [32].

Safety property: Same as Two-Phase Commit.

Reduce. A distributed protocol for a sum computation. Each host starts with a partial array segment, then computes the sum of the elements in their respective segment before sending it to a distinguished host. The distinguished host adds up all the values it receives from other hosts and returns the value.

Safety property: The value returned by the distinguished host is the sum of elements in the array formed by the concatenating all the hosts' array segments.

Raft Leader Election. The leader election phase of the Raft protocol [25].

Safety property: Each term has at most one leader.

Multi-Paxos. The classic Multi-Paxos protocol [19] where hosts reach consensus for a log of values rather than a singular value. Like Paxos-Dynamic, each host assumes leader, acceptor, and learner roles, and may increase its ballot number to retry proposals.

Safety property: For all entries in the log, no two hosts can learn different values.

Deriving Semantic Checkers from Tests to Detect Silent Failures in Production Distributed Systems

Abstract

Production distributed systems provide rich features, but various defects can cause a system to silently violate its semantics without explicit errors. Such failures cause serious consequences. Yet, they are extremely challenging to detect, as it requires deep domain knowledge and substantial manual efforts to write good checkers.

In this paper, we explore a novel approach that directly derives semantic checkers from system *test code*. We first present a large-scale study on existing system test cases. Guided by the study findings, we develop T2C, a framework that uses static and dynamic analysis to transform and generalize a test into a runtime checker. We apply T2C on four large, popular distributed systems and successfully derive tens to hundreds of checkers. These checkers detect 15 out of 20 *real-world* silent failures we reproduce and incur small runtime overhead.

1 Introduction

Distributed systems today provide rich features through hundreds to thousands of APIs, parameters, commands, *etc.* However, various faults can cause a system to *silently* violate its semantics without explicit errors. For instance, a distributed message service that provides a publish API promising at-most-once semantics may deliver some message twice.

Despite the silent symptoms, such failures lead to severe consequences including data loss, wrong results, inconsistency, and vulnerabilities. The failure impact is further propagated to applications that rely on the affected semantics. The lack of explicit error signals allows these failures escape existing failure detectors [57, 67, 76]. Moreover, with few error messages, developers are clueless in debugging failures.

Ideally, bugs causing silent failures should be eliminated in testing. However, it is elusive to eliminate all bugs in production distributed systems. Indeed, a recent study shows that silent failures are prevalent in mature, extensively-tested distributed systems [68]. They take up *39% of all studied failures*. Recent studies from multiple cloud companies suggest that silent violations can come from not only software bugs but also mercurial CPU cores [37, 55, 84].

Therefore, there is a pressing need for *runtime verification* [53], a safeguard mechanism to continuously monitor a deployed distributed system and quickly detect silent failures at the scene. Central to this mechanism are a set of checkers that validate system semantics, *e.g.*, at-most-once delivery. We call them *semantic checkers* and distinguish them from generic checks (*e.g.*, for CPU usage, timeouts, and exceptions).

Since semantic checkers require system-specific knowledge, the conventional wisdom is that they have to be written *manually*. For large distributed systems, this is a daunting task. Unlike prior runtime checking works [32, 49, 65, 66] that focus on checking small programs or a handful of well-defined properties for protocols, the systems we target have abundant *loosely-defined* semantics. Even for semantics described in simple text informally, mapping them to a concrete, correct checker is not easy. One needs to deeply understand both the system code and behavior to decide what needs to be checked, what is expected, when should the check be triggered, *etc.*

The thesis of this paper is that it is feasible to automatically construct semantic checkers that are expressive and accurate for large distributed systems without significant manual efforts.

We observe that a distributed system's test cases often contain valuable information about the system semantics, which we can leverage to synthesize semantic checkers. There are solutions [41, 47, 52] that use statistical methods to automatically infer likely invariants from software execution traces (often obtained from running a test suite). Those inferred invariants only express program variable relations, which are too low-level to check system semantics. Many of the inferred invariants are false due to inaccuracies in statistical inference. A recent work [68] leverages regression tests for past failures to infer event relationship, but it has the same limitations.

Our key insight is that the *test code* encodes rich information, including semantics-specific oracles—*assertions*, and carefully-designed workloads (*e.g.*, Figure 1). This rich information is not leveraged in existing solutions. But if existing tests contain expressive checks, why do they still fail to prevent silent failures? This is because they are written in a way that is tied with specific input in a fixed setup, while the relevant semantics can be violated in production due to different bugs triggered by other inputs and dynamic conditions.

Based on the above observation and insight, we propose a novel approach that leverages the existing test codes developers already wrote and *directly transforms* them into semantic checkers. Our basic idea is to reuse the code skeleton of a

test case, but we relax its strict constraints to generalize the test into a *parameterized checker function*. The generated checkers can then be deployed with the system to production and activate under workloads different from the original tests to detect *new semantic violations*.

We design an end-to-end framework, T2C, that realizes this idea. T2C reduces manual efforts and generates checkers that are expressive and accurate to cover various system semantics.

Achieving the above objectives is extremely challenging. First, test code contains a mixture of instructions and many instructions are not applicable to a semantic checker. Second, test code is inherently written to check specific instances, while a useful checker needs to apply in other instances. Third, a test only applies in certain scenarios. We need to determine the precondition for the derived checker, which is not clearly specified in the test. The practices of writing tests also vary, even for tests from the same system.

It is important to recognize that, without domain knowledge, automatically generalizing all test cases into checkers is impossible. T2C aims to synthesize a significant number of checkers from existing tests to provide comprehensive coverage of semantics.

To understand the feasibility of our approach, we conducted a large-scale study on 210 test cases from six distributed systems. The study found that interestingly many test codes in practice have clear patterns to leverage for transformation and generalization, *e.g.*, the use of test utility function, simple relations between assertions and the workloads.

Guided by our study, T2C leverages a combination of static and dynamic analyses to transform existing test code into reusable semantic checkers. At a high level, T2C statically identifies the key checking logic embedded in test cases—typically assertions tied to important system behaviors—and repackages them into standalone *checker functions*. To ensure these checkers are meaningful beyond the original test context, T2C then dynamically analyzes the system and test code to trace relevant data and control flows. This enables T2C to extract the necessary *preconditions* under which the behavior should hold. By combining preconditions with checker functions, T2C produces semantic checkers that are both precise and generalizable. Finally, T2C performs multi-level validation on the synthesized checkers to ensure they are valid.

We have applied T2C on four widely-used distributed systems, ZooKeeper, Cassandra, HDFS and HBase. T2C successfully transforms 672 test cases in these systems into verified semantic checkers. We sample and reproduce 20 user-reported production silent failures, and the synthesized checkers detect 15 of them in a median of 0.188 seconds. Interestingly, most test cases from which the checkers are derived were added by developers long before the failures.

The main contributions of this work are as follows:

- We proposed a novel approach to synthesize semantic checkers from test code and presented a large-scale study on existing tests to validate the feasibility of this approach.

```
1  public void testSessionTimeout() {
2    DisconnectableZooKeeper zk = createClient(TIMEOUT);
3    zk.create("/stest", new byte[0], OPEN_ACL, EPHEMERAL);
4    zk.close();
5    zk.disconnect();
6    zk = createClient(TIMEOUT);
7    Assert.assertTrue(zk.exists("/stest",false) != null);
8    Thread.sleep(TIMEOUT*2);
9    Assert.assertTrue(zk.exists("/stest",false) == null);
10   zk.close();
11 }
```

Figure 1: A test from ZooKeeper that validates the semantics of ephemeral znodes. The test creates an ephemeral znode (/stest), disconnects the client, and checks whether the znode is correctly removed after the session timeout.

- We designed T2C, an end-to-end framework that uses a hybrid of static and dynamic analysis techniques to realize the proposed approach for large distributed systems.
- We evaluated T2C on widely-used distributed systems, and showed its effectiveness on synthesizing expressive checkers that can detect production silent failures.

T2C is open-sourced at https://github.com/OrderLab/T2C.

2 Background and Motivation

In this section, we first use a real example to elaborate on our insight and proposed approach. We then present a feasibility study on existing test cases in popular distributed systems.

2.1 Example

ZooKeeper is a distributed coordination service that exposes hierarchical namespace of data called znodes. One feature it provides is ephemeral znode, the semantics of which guarantees that (i) an ephemeral znode exists for as long as the creating client's session, and (ii) it is deleted once the associated session ends. In a real-world silent failure [22], users observed that some ephemeral znodes were not removed even after the client session was long gone. This failure occurred *not* because the ephemeral znode semantics was not tested. Like other popular distributed systems, ZooKeeper has test cases for all major features including ephemeral znode. Figure 1 shows a test that exists prior to this failure.

However, the test cases are written to check only a few specific examples, *e.g.*, `/stest` in Figure 1, in a controlled setup. Passing the test cases does not imply that the system can obey the tested semantics once deployed. The production system in this case encountered a rare concurrency bug. This buggy condition does not appear in the test setup.

Nevertheless, the test does explicitly check the semantics. It includes two assertions (line 7 and 9) that describe the two guarantees of ephemeral znode. It also includes workloads that exercise the semantics (line 3–5).

To leverage this test for detecting failures in production, we may attempt to directly reuse it (with some changes so the `zk` client checks against the production instance instead of the testing instance). This would work if the ephemeral znode that violated the semantics happened to be exactly `/stest`, or if

Software	Language	Category	Version	Tests	
				Total	Sampled
ZooKeeper	Java	Coordination	3.4.11	434	35
Cassandra	Java	Database	3.11.5	4118	35
HDFS	Java	File Sys.	3.2.2	3265	35
MongoDB	C++	Database	7.1.0	1276	35
CephFS	C++	File Sys.	1.11.0	506	35
Mesos	C++	Cluster Mgr.	18.2.0	233	35

Table 1: Sampled test datasets from six studied systems.

the bug affected all ephemeral znodes. Neither was the case: only some znodes were affected in the production failure and they did not have the tested example path `/stest`.

The problem here is that the checking logic in the test is too restrictive. If we relax it, it is possible to retrofit the test into a more general checker. For example, by symbolizing the concrete arguments in it (`/stest`, *etc.*), we can transform the assertions and related statements into a parameterized checker function, which can be invoked with other arguments.

2.2 Feasibility Study

The example above is promising. However, not all tests are like it. Some tests may not have assertions for system semantics, or their assertions may be too specific to convert into a more general checker. To understand the feasibility of our approach, we conduct a study on existing test cases in six popular distributed systems shown in Table 1. We randomly sample 210 test cases to analyze, with 35 cases for each system.

For each case, we seek to answer the following main questions: (1) do tests contain useful semantic checks? (2) how is the checking done? (3) can the checking logic be generalized from tests to production settings?

The majority (87%) of the studied tests use standard assertions, such as `assertTrue` and `assertEquals`, as the checking mechanisms. The remaining tests do not have any explicit assertions. They are either performance benchmarks or checking by throwing an exception. These tests are typically not designed to expose semantic violations.

Finding 1: *Most sampled tests contain explicit assertions to check the system semantics.*

Hereinafter, we focus on the 183 tests that use assertions (which percentages presented will be based on). We summarize their checking approaches into several patterns (Figure 2):

- Check if the result of one operation matches the input to preceding operations, *e.g.*, the test writes something to a file, and checks by reading from the same file and comparing if the result matches the argument in the write operation.
- Check the consistency of a workload. For example, one HDFS test case selects several target nodes for storing a file; it then uses an assertion to verify whether these target nodes reside in different racks.
- Check whether the return result matches the impact of some operation or expected status of the system. For example,

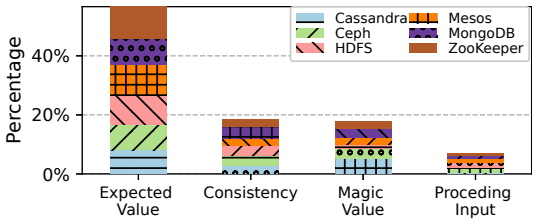

Figure 2: Assertion type distribution (Finding 1).

`testAbortNewFileAfterFlush` writes a file but shortly aborts it; it then verifies that the destination directory is empty: `assertEquals(0, testDir.list().length)`

- Comparing the result of an operation with a "magic value", which is a constant predefined by developers. For example, `ASSERT_EQ(url_unescape("foo%20bar"), "foo bar")` checks the `url_unescape` operation correctly decodes the input string. The constant `"foo bar"` is a magic value.

In the first three patterns, the checking is based on contexts within the tests. For the last pattern, the magic value is hard-coded, so deducing why it is expected can be difficult. Among the 183 tests, 37 (20%) tests have the last pattern.

Finding 2: *Checking is typically based on contexts within a test, but 20% tests check by comparing with magic values.*

Since the assertion checking involves comparing with an expected value, we examine the constraints between the expected values in assertions and other values in the test to figure out how to get the expected value in a semantic checker.

Interestingly, in many tests, the expected values in assertions do *not* need to be changed even if the workload varies, such as `true`, `0`, or system configuration. Figure 1 is an example: even if the path changes, the expected value `null` holds.

When the expected values do vary, it is common for them to have simple *equality* relation with other values in the test. For example, a Cassandra test uses an assertion `assertEquals("CREATE ROLE role1",obfuscate("CREATE ROLE role1"))`. The expected value can be simply inferred from the argument to the `obfuscate`. In other cases, the assertions use a defined variable from the workload as the expected value. Thus, we can directly find the source of the expected value.

The constraints in 117 (64%) tests fall into the above three categories (constant, equality, same variable). In another 26 (14%) tests, the constraints are simple arithmetic relations, such as greater than, or smaller than.

Finding 3: *In the majority of the tests, the constraints of the expected values are simple, because they do not need to change, or equal some other values, or directly use variables defined in the workload, or are basic arithmetic relations.*

In the remaining 40 (22%) tests, the constraints cannot be inferred without domain knowledge. They use magic values that do not have simple relations with other values in the test. For example, in ZooKeeper test case `testValues`, to get the expected values in `assertEquals(14L, values.get("sum_key2_test")`, we need to guess the operation from the string, and then calculate

the result. These steps cannot be automated without further knowledge. The assertion for `url_unescape` is another example.

Finding 4: *In a non-negligible number of tests, the expected values cannot be easily inferred from other values in a test.*

Besides using assertions directly in the test function, 40 (22%) tests invoke some utility functions that perform the checking. These functions are written to ease setup or result checking and are modular. They contain rich domain-specific logic. One function is often used by multiple test cases.

Finding 5: *Using utility functions is a common practice in tests, which can be leveraged in creating semantic checkers.*

We explore if the checking logic can be generalized from tests to production by replacing specific instances. Some tests use magic values, making them hard to generalize. Even if expected values are replaceable, assertions may not apply in production due to special configurations. For example, in the Cassandra test `createSuccess`, the assertion `assertFalse(tmd.params.compression.isEnabled())` only works if compression is disabled.

Interestingly, we find the tests to be more general than we anticipated. Of the 183 tests with explicit assertions, 65% satisfy both requirements of generalization: (1) the constraints of expected values are easy to infer; (2) the checked semantics are not limited to just special configurations or corner cases.

Finding 6: *Almost two thirds of the tests have checking logic that can be generalized to production.*

Finally, we examine if the assertions in the tests involve disruptive actions, such as deleting files or restarting the cluster. If so, invoking the checkers in production may pose risks. While many test cases involve such dangerous operations, they are part of the workload. When we retrofit a test into a semantic checker, the checker does *not* exercise the workload. It waits for the clients or users to execute these operations in production, and activates the assertions afterward.

Finding 7: *Although a test workload may contain disruptive operations, the assertions do not perform such operations.*

2.3 Implications

While transforming tests into runtime checkers is an ambitious goal, our study shows that it is promising. Existing tests contain valuable semantic information. Since most tests use assertions as the checking mechanisms (Finding 1), we can recognize their checks from standard interfaces. Findings 3 and 6 imply that deriving a checker function more general than the test is feasible, as the expected values can adapt to different instances. Moreover, the values used in assertions often have simple relations with other values in the workload, thus inferring the constraints to avoid over generalization is possible. The modularity from utility functions commonly used in test cases (Finding 5) also eases the transformation.

Nevertheless, we identify two primary challenges with this approach. First, a test contains code that both exercises a system and checks if the system behaves properly, while a checker is only responsible for the latter. Thus, our solution needs to decouple the two and make the checks standalone. Second, identifying the checker precondition is not easy. The checker should only be invoked when the production system exercises the semantics relevant to the test. In addition, the original test only uses a few example inputs, but the checker should also apply on inputs from production.

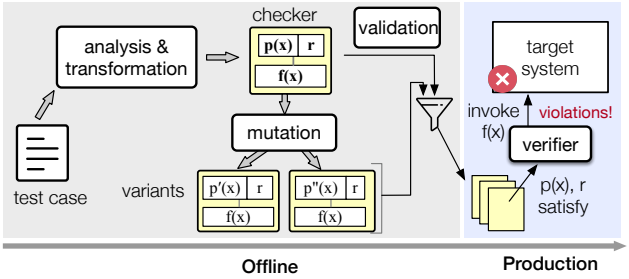

Figure 3: Workflow of T2C.

In the general case, both challenges are too hard to address automatically without domain knowledge. Some restrictive tests are also unnecessary or not applicable to run in production. We thus do not target transforming all tests but instead aim to transform a decent number of promising tests to fill the void of semantic checkers in large distributed systems.

3 Overview of T2C

Informed by our study, we design T2C, an end-to-end framework that transforms existing test cases into semantic checkers to detect silent failures in production distributed systems. Our framework assumes that checkers derived from specific test inputs or setups generalize reasonably well to broader scenarios encountered in production. This assumption is supported by our empirical study (Section 2.2).

Different from existing solutions, T2C directly leverages the test code and takes a *transformation* approach. It preserves the code structure of a test while extracting and generalizing the essential checking logic. T2C does not require a large number of traces for statistical inference. Moreover, unlike the state-of-the-art solution that relies on regression tests of past failures [68], T2C targets any unit tests or integration tests. T2C aims to not only reduce the manual effort but also generate checkers that are accurate and expressive enough to capture a wide variety of system semantics.

T2C is designed to be a monitoring system, where checkers only provide failure alerts and diagnosis clues to operators; they do not automatically mitigate failures (by crashing or restarting the system). This scope is the same as existing monitoring tools. T2C enhances existing solutions with stronger checks to reliably detect silent failures with low false alarms.

Problem Statement. Given a test case T, T2C aims to derive a runtime checker C that verifies the system semantics tested by T. The checker C consists of three components: (1) C_f, the

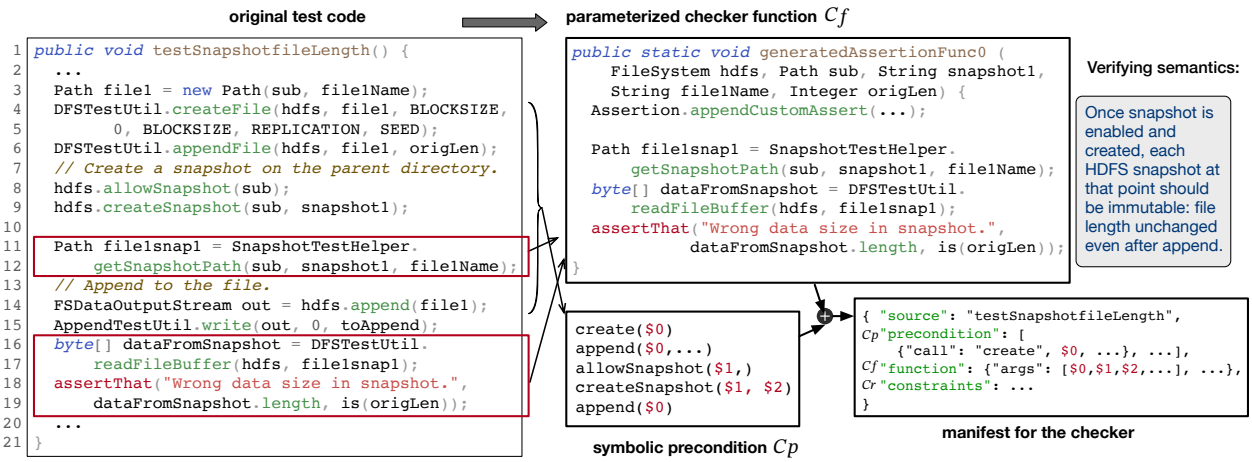

Figure 4: Example of checker T2C generated for a test in HDFS.

parameterized checker function; (2) C_p, the symbolic checker precondition; (3) C_r, the constraints that include relations between parameters, constant values for specific parameters, and system configurations.

Input and Output. To apply T2C on a new system, developers need to provide a configuration file that describes the code structure information (*e.g.*, path to system packages and test packages) and the compilation instructions. T2C will use these information to automatically analyze and execute tests. In addition, developers need to specify a few core system classes for instrumentation.

T2C outputs a list of checker functions as well as one manifest file (in JSON format) for each checker function. The manifest file records metadata for the checker, such as the source test name, the precondition, and the constraints.

Workflow. Figure 3 shows the high-level workflow of T2C, which consists of two phases: *offline* and *production*.

In the offline phase, T2C performs static analysis and dynamic analysis on the given test case T. Figure 4 shows an example of the semantic checker that T2C automatically derives from a non-trivial HDFS test case. It identifies the checking related instructions in the test, and transforms them into a standalone checker function C_f. It also derives the symbolic precondition C_p as well as the constraints C_r. During this process, a key goal is to relax the constraints in T, so that the checker can apply on more general scenarios. However, if T is written too restrictively, the derived C may not be general enough. To address this problem, T2C further introduces a mutation step that aims to produce variant checkers by applying some changes to C_p and C_f. After generating a set of candidate checkers from existing tests, T2C performs a validation step to filter invalid checkers. Developers can then further inspect and select from the validated checkers to deploy together with the target system.

In the production phase, the system runs with the selected checkers and the T2C verifier. The verifier monitors the system workload, and evaluates whether any checker's precondition C_p and constraints C_r satisfy. If so, it activates the checker function C_f and passes the concrete arguments accordingly. When some checker fails, the verifier generates an alert and a debugging report about the semantic violation.

4 Checker Generation and Validation

This section describes the T2C designs for its *offline stage* (Figure 3): checker generation and validation. Checker generation contains several steps as Figure 5 shows.

4.1 Encapsulate Checker Function

A test case contains many instructions such as preparing input and invoking system APIs. To construct a semantic checker, T2C is most interested in extracting the essence—the test oracle instructions, which contain the correctness criteria for certain system semantics. As our study shows, most test oracles are written as assertion instructions.

However, a test oracle instruction alone cannot be directly used as a runtime checker. The checking logic in the test code typically contains a series of instructions, so only including the oracle instruction would be incomplete and not even executable. For example, in Figure 4, the test oracle is in line 18 (`assertThat`), but it depends on several other instructions including calling a helper function to get the snapshot file path, and defining variable `dataFromSnapshot`.

T2C uses static analysis to encapsulate the test oracle along with its related instructions into a *standalone checker function*. T2C identifies test oracle in the form of assertions. If a test does not contain any assertions, T2C will not generate checkers.

Algorithm 1 shows the core algorithm for the checker function construction. For a given test T, T2C first constructs a control-flow graph (CFG). It then runs *backward* data-flow analysis on the CFG. The analysis' goal is to construct a parameterized checker function C_f, and derive three things: (1) the set of parameters, S_a, for C_f's definition, (2) the set of intermediate variables, S_i, to declare locally in C_f, and (3) the list of instructions in T, S_s, to copy to the C_f function body. Other concepts in the algorithm align with classic dataflow

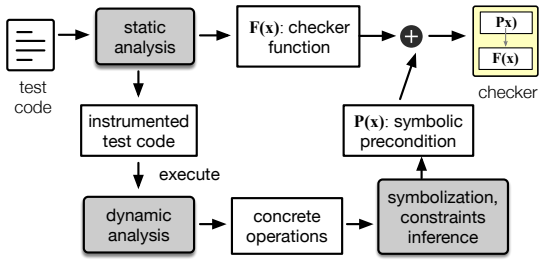

Figure 5: Checker generation workflow in T2C.

Algorithm 1: Checker function encapsulation.

Input: the target test `T`

Output: constructed checker functions, each C_f consists of: Set S_a of parameters in the generated function, Set S_i of intermediate variables, Set S_s of instructions to copy to the generated function

foreach $T_o \in findTestOracles(T)$ **do**
  $S_a \leftarrow \emptyset$; $S_i \leftarrow \emptyset$; $S_s \leftarrow \emptyset$; $W \leftarrow \{T_o\}$;
  do
    Take s from W; **if** $shouldExclude(s)$ **then**
      continue;
    $Out[s] \leftarrow \bigcup_{s' \in succ(s)} In[s']$;
    $In[s] \leftarrow Gen(s) \cup (Out[s] \setminus Kill(s))$;
    $S_i \leftarrow S_i \cup In[s]$; $S_s \leftarrow S_s \cup s$; $W \leftarrow W \cup pred(s)$;
    $S_a \leftarrow In[s]$;
  while $W \neq \emptyset$
  $S_i \leftarrow S_i \setminus S_a$; $C_f \leftarrow output(S_i, S_s, S_a)$

analysis: `shouldExclude` determines whether a statement should be omitted from the checker. It is used to filter out operations that are dangerous for runtime checking, such as system restarts. `In[s]` and `Out[s]` represent the input and output dependencies of a statement s, capturing the relevant variables when s is reached (`In[s]`) and when s is exited (`Out[s]`). `Kill(s)` is a helper function that returns old variables removed by statement s. `Gen(s)` is a helper function that returns new variables introduced by statement s.

The analysis starts by identifying the test oracle (assertion) T_o. To compute S_s, we use the program slicing algorithm [86] which includes the T_o and its dependent instructions. The main dependencies are calculated based on S_i.

To compute S_a and S_i, the analysis identifies all the values used in each expression in T_o. Those values are to be defined in C_f. We need to distinguish whether they should be local variables or function arguments.

Our basic idea is that a value by default is in S_a (an argument), but if it is derived from other values, we move it to S_i and add its source values to S_a. To do so, the analysis recursively follows the use-def chains until it reaches values that are "out-of-scope"—either constants or variables defined outside the test case function. Those values are put in S_a, while the values along the chains are in S_i. The rationale for this analysis is that arguments naturally come from external sources, while local variables are to assist checker execution.

Take Figure 4 as an example. The algorithm will start from the assertion statement in line 18, which is simple to locate. This assertion includes two workloads with variables `dataFromSnapshot` and `origLen`. The algorithm's goal is to identify how to construct these workloads for runtime checking. Thus, it traverses backwards, analyzing each preceding statement. For example, when analyzing line 16, the algorithm finds out `dataFromSnapshot` is generated by a function call `readFileBuffer`. Thus the algorithm marks this statement to include in the checker function, and add the parameters of `hdfs` and `file1snap1` to the tracking set instead of `dataFromSnapshot`. This process continues until the start of the test is reached. Eventually the algorithm marks all related statements (lines 11, 16, 18) to include, as well as a list of parameters (`hdfs`, `sub`, `snapshot1`, `file1Name`, `origLen`) for this checker function.

T2C also includes relevant branch instructions to S_s and variables used in the branch conditions in computing S_a and S_i. Thus, the derived C_f preserves T's control-flow structure.

At the end, T2C defines C_f with S_a and construct the checker body with S_s and S_i. T2C automatically fills in the missing parts including variable initialization and type conversion. It also handles name aliases—any statements that introduce aliases are included through data-flow propagation, since the algorithm constructs slices based directly on explicit data and control dependencies.

Side Effects. Our slicing algorithm does not provide soundness guarantee. It may include operations with side effects, *e.g.*, `write`. Some test instructions could be even dangerous to apply in production, such as `delete`. Those instructions are part of the original test workload but should not be included in C_f, because a checker should mainly observe production system state and not exercise workload. It should wait for some client or user to invoke such operations.

Our above algorithm is able to naturally exclude many of these instructions in computing backward slices for the assertions. The HDFS test in Figure 4 is an example. Although it includes instructions for creating snapshots, appending files, *etc.*, the checker function T2C derives only reads the file.

However, some instructions may still be included. For example, if an assertion directly checks the return value of a `write` call, the slice will include the `write` instruction based on the dependency. To avoid this situation, we refine the slicing algorithm to stop if it reaches a method that may introduce side effects to the system. We use purity analysis [80, 88] to construct a list of side-effecting operations. At the start of the static analysis phase, T2C analyzes the system call graph and outputs the side-effecting operation list, which is used in the encapsulation phase. We also add additional operations for each system. For example, we add three operations for HBase: "compact", "truncate" and "clean". Even if the list mistakenly misses some side-effecting operations, these operations will be exposed in the validation phase (Section 4.4).

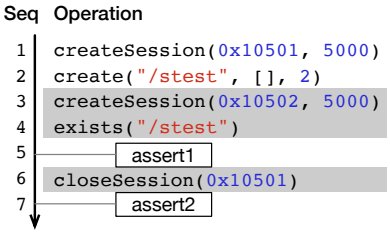

Figure 6: Concrete system operations from running test in Figure 1.

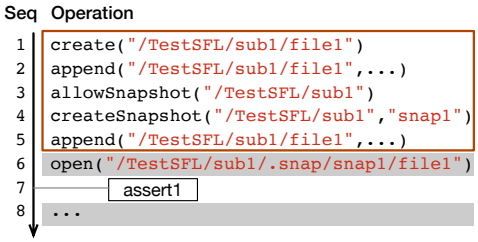

Figure 7: Concrete system operations from running test in Figure 4.

Multiple Assertions. One test may contain multiple assertions. T2C tries to derive one checker for each assertion separately. Although it can be appealing to combine multiple assertions in one checker function for efficiency reasons, it can introduce complexities. For example, if we encapsulate the two assertions in Figure 1 into one checker function, we need to decide whether to include the `Thread.sleep` instruction (line 8) in between them. By the slicing algorithm, we will not. But the second assertion will produce false alarms when the client session is not gone yet. Including this instruction is not perfect either, because the sleep timeout does not guarantee that the session is gone. The true operation to wait for before invoking the second assertion should be the system operation `closeSession` (seq. 6 in Figure 6), which is initiated by the system rather than the checker. By separating the two assertions into two checkers, we avoid the complexities. The second checker uses `closeSession` as its precondition.

Differences with Traditional Program Slicing. Our algorithm has a few key differences from traditional program slicing [86]. Program slicing includes all instructions that influence an assertion, even if they modify the system. T2C refines slicing by stopping at side-effecting operations using a combination of static purity analysis and a manually curated list of known unsafe operations, ensuring that the checker remains observational. Program slicing may include all control-flow branches affecting an assertion. Besides extracting relevant instructions S_s, T2C also identifies (1) the set of parameters, S_a and (2) the set of intermediate variables, S_i for checker construction. Program slicing merges all assertion-dependent statements into a single slice. T2C separates each assertion into its own checker to avoid unintended interactions.

4.2 Identify Checker Precondition

The checker function generated in the above step will be standalone. However, it should only be invoked when the production system exercises the semantics underlying the original test. For example, in Figure 4, it will check the HDFS snapshot's file immutability semantics, but it is only applicable if some client in production has requested HDFS to take a snapshot using relevant APIs. Essentially, each C_f has a *precondition* C_p (our usage of the term slightly differs from Hoare logic), which T2C will derive.

Approach. Our basic idea is to extract code before the assertion that does not directly impact assertion values, treating it as preconditions. However, setup code like cluster startup is irrelevant to runtime checking and should be excluded. Therefore, T2C focuses on relevant operations after system runs, targeting *system APIs* used during tests. Since static analysis struggles with identifying target APIs and their arguments due to wrappers and polymorphism, T2C uses *dynamic analysis* on test code to derive preconditions.

4.2.1 Obtain Concrete Precondition

T2C includes an instrumentation library. It adds hooks to the system interfaces to record information including the operation type as well as the concrete arguments used. We focus on entry interfaces on the *server code*. For example, in HDFS, T2C instruments public methods in the `NameNodeRpcServer` class, such as *create* and *createSnapshot*. T2C then executes the test code and records the instrumented information.

After the test execution, T2C obtains an ordered sequence of system operation invocations, each with concrete arguments. The next question is *how to determine the concrete precondition from this sequence?* T2C treats the subsequence that occurs before the execution of T_o as the candidate precondition. To identify this subsequence, the instrumentation library adds hooks to T_o in the test code as well, which emits a record of T_o's execution in the sequence. However, this subsequence likely also contains operations that are exercised to provide arguments to T_o. These operations should be *excluded* from the precondition, because they are initiated by the checking. In other words, they belong to the checker function C_f constructed in Section 4.1.

Take Figure 6 as an example, which is the sequence of operations T2C obtains when running the test in Figure 1. The 5th operation is the marker T2C emits for the assertion in line 7 of Figure 1, so that candidate precondition is the first four operations. However, the 3rd and 4th operations provide arguments to the assertion, so T2C excludes them. Similarly, for the sequence T2C obtains from the test in Figure 4, the precondition includes only the first five operations (Figure 7).

Figures 6 and 7 also show that the operations T2C obtains in the dynamic analysis are at the system side, which can have differences with the static names appearing in the test code, because the test uses many wrappers. Focusing on system-side operations provides a clean way for T2C to deduce the precondition despite many test-specific methods. It also allows the precondition to apply in the production system.

While our heuristic excludes computations that do not directly affect assertion parameters, these computations may

still affect indirectly, *e.g.,* sorting an array. Such operation will be either captured during dynamic analysis as precondition (if sorting is instrumented) or during encapsulation as part of the checker (if sorting is a library call used in the assertion).

4.2.2 Symbolize Concrete Precondition

The precondition determined from Section 4.2.1 is tied with the specific workloads in the test. Such precondition is not very helpful for the in-production checker, because it cannot apply to scenarios beyond the original test. For example, the concrete precondition T2C extracts for Figure 1 (also Figure 4) is tied with one fixed path and does not apply to other paths.

To address this problem, T2C uses a novel idea to symbolize the concrete values and turn C_p into a symbolic precondition. However, we cannot simply turn each concrete value into a separate symbolic value. We need to identify the constraints among them, which is challenging in the general case.

Fortunately, our study (Section 2.2) shows that many values in tests simply have an *equality* constraint, which is easy to infer. When encountering a concrete value in a clause that is equal to an earlier value, T2C assigns the same symbol rather than a new symbol. Besides *equality*, T2C also supports simple constraints such as *less than* and *contains*, which our study shows is also common. For such constraints, T2C will add them to the checker manifest file, which will be evaluated as part of the precondition at runtime.

Our constraint inference is not perfect. Two concrete values that are equal may be a coincidental choice by developers, which can over-constrain the C_p during symbolization. For example, we may symbolize `foo("/stest","/stest")` into `foo($1,$1)`, but the second argument can be arbitrary. It is possible to leverage more information in the test code to improve the accuracy and support more complex constraints. We leave this improvement as future work.

Our tool by default does not symbolize enum type parameters as workloads, based on the observation that enum type parameters are usually part of interface semantics.

4.2.3 Mutate Precondition

The above symbolization step generalizes the precondition. However, the symbolic precondition can be unnecessarily restrictive. This happens because the original test only uses one specific sequence of operations, while the tested semantics still applies when the sequence changes (slightly). Thus, the production system can violate the semantics under a similar triggering condition. For example, instead of calling `append` *once* after `createSnapshot` as the test in Figure 4 does, a client in production invokes `append` multiple times. In this case, the immutability semantics still applies. Concurrency may also affect the checker generation process. If the test execution is nondeterministic, the generated checker results may have different preconditions corresponding to different execution sequences. If we use the symbolic precondition exactly the same as the test, the derived checker will not be triggered when it can detect the violation.

To address this problem, T2C further relaxes the constraints of the precondition by *mutating* it. T2C currently supports four types of mutation: *reduce* (remove an operation), *insert* (add a wildcard that matches with any operation), *duplicate*, and *reorder* (swap the order of two adjacent operations). For the above example, we can apply the *duplicate* mutation to the `append` operation in the concrete sequence. T2C takes a simple enumerative (bounded) approach to try different mutations in different positions of the precondition sequence. Each mutation produces a *variant* precondition $C_{p'}$. It then relies on the validation step (Section 4.4) to evaluate whether the variant preconditions are necessary and valid.

4.3 Additional Handling

Control Flow Assertion. We observe that control-flow assertions are also common in tests. Unlike other assertions, control-flow assertions are designed to be not executed, *e.g.*, an `Assert.fail`. Thus, we can not simply instrument the assertion itself. To support this type of assertion, T2C flags the method call before such an assertion. When that statement is executed, T2C emits a special marker in the operation sequence to indicate that the next operation should fail.

String Queries. Some systems may not have clear operation interfaces. For example, Cassandra takes input queries as strings and uses ANTLR to generate parsers. The processing logic is complex and tightly coupled with other internals, making it difficult to find instrumentation points. We added a simple parser that interprets string queries to different system operations and extracts the operations' parameters.

System Constraints. We observe that some tests are indented for only specific system configuration and do not apply when the system configuration is different. For example, write operations should not be allowed in "read-only" mode. Thus, we also need to extract such system configuration constraints. We find that most configurations are defined in the setup phase of tests, such as `System.setProperty("readonlymode.enabled", "true")`. Before the checker building phase, T2C will search in test class bytecodes with dynamic analysis libraries, identify such system property and record in the generated checkers.

4.4 Validate Checkers

Like manually written checkers, the checkers T2C generates may not always be correct. For example, the encapsulated checker function may miss some instructions due to the inaccuracies in static analysis; a complex constraint existing in the test may not be inferred, so the precondition is too loose.

T2C uses four levels of validations to prune invalid checkers. The first level is to ensure the derived checker function passes compilation, *i.e.*, syntactic correctness. The second level is to ensure the checker function is runnable by leveraging JVM verifier, which performs various sanity checks.

The third level is a more interesting "self-validation" approach. T2C first replaces the original assertion statements

in the test with the generated checker function. It then runs the modified test. The checker function is supposed to pass because a specific workload should apply in a generalized version. If the checker function cannot pass its own test, it is problematic, so T2C marks it as invalid.

Self-validation alone is not enough, so T2C includes a cross-validation step that simulates a pre-production environment to assess checker quality. The cross-validation step aims to remove "over-generalized" checkers, meaning they incorrectly generalize test-specific invariants to broader runtime contexts. Specifically, during cross-validation, we run each checker against workloads from other passing tests (different from the test from which the checker originated). If a checker incorrectly triggers alarms during these unrelated but correct workloads, it indicates that the checker is overly general and thus producing false positives. Such problematic checkers are subsequently filtered before deployment. This cross-validation is particularly effective at filtering out checkers that over-generalize semantic-specific workloads (*e.g.,* creating a list of size 0 to check if it is empty, where 0 should remain a constant). Such checkers are triggered excessively and are invalidated during cross-validation.

We apply several performance optimizations for the validation phase. Running all tests with all derived checkers can be time-consuming. T2C runs tests that cover most system functionalities first, so a bad checker can be invalidated quickly. It discards a checker that is already invalidated by some test to avoid repeated invalidation. We also implement a parallel mode that distributes the tests to run on multiple nodes, which significantly speeds up the checker generation and validation.

5 Deployment of Checkers and Verifier

T2C deploys checkers that pass the validation together with the target system to production. Developers can also inspect and select a subset of validated checkers for deployment. T2C provides a verifier to manage the checkers in production. Its key components include an evaluator thread, a trace buffer and a precondition index, which are optimized with circular buffer and trie. For each checker, the evaluator uses the checker's manifest file to evaluate the symbolic precondition C_p and the constraints C_r against production workload. If both satisfy, the evaluator gets the concrete value for each symbol, and use them to invoke the parameterized checker function C_f.

The precondition evaluation requires information about the system state. This information is obtained by the instrumentation library described in Section 4.2.1. T2C links this library with the target system, which performs dynamic instrumentation to emit system trace in production. To evaluate the system constraints, the T2C runtime reads the related system configurations at startup time (*e.g.*, calling `System.getProperty("readonlymode.enabled")`) as part of the checker matching process. It then disables a checker if its required system constraint does not satisfy.

If C_f fails, T2C alerts operators about the possible failure

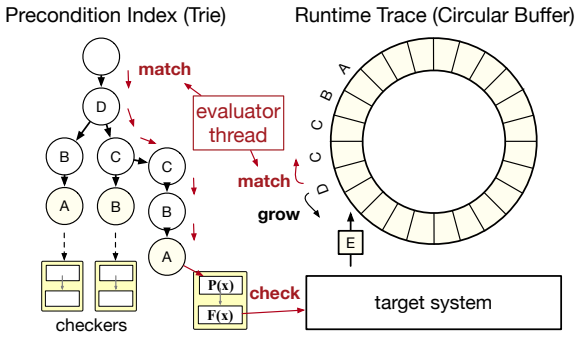

Figure 8: T2C runtime architecture.

along with debugging information such as the failed assertion and concrete arguments to help developers localize the bug.

T2C implements optimized runtime data structures (Figure 8) to reduce runtime storage and computation costs. The storage overhead mainly comes from bookkeeping system traces. T2C uses a circular buffer to manage maximum memory usage to avoid excessive GCs and automatically discard expired traces. The circular buffer design also avoids races between worker threads and the verifier. The computation overhead mainly comes from matching checker preconditions with runtime traces, which can be costly if implemented poorly (*e.g.,* loop through checkers) and generate backlogs. T2C implements a precondition index with a trie to accelerate matching. It reverses and inserts all checker preconditions (operation list) to the trie after loading checkers at the initialization stage. For example, to index three checkers, whose preconditions are `{opA, opB, opD}`, `{opB, opC, opD}`, `{opA, opB, opC, opC, opD}`, the tool constructs a trie as shown in Figure 8. The evaluator thread continuously matches patterns with the current trace suffix. This design effectively prunes unnecessary searches without traversing checkers one-by-one.

Dealing with Concurrency. Multiple clients may submit requests to the system simultaneously. As long as the preconditions satisfy, concurrency only affects the frequency of runtime checking since T2C checkers are activated based on the associated preconditions. For example, even if a checker is derived from a test that uses only a single client, if two clients issue requests to the same znode, they may also trigger the checker. Assume a checker's precondition is `s1, s2, s3`. This checker will still be triggered even if client1 sends requests that produce events `s1,s2` while `s3` is produced by client2's requests. Our evaluation benchmarks (Section 7) all use multiple clients and they do not prevent checkers from getting triggered. For concurrency in checker generation, T2C uses mutation to address this issue as described in Section 4.2.3.

Many system runtime properties, especially related to concurrency models, require special efforts to carefully design corresponding runtime checkers. T2C does not aim to check all system semantics—it automates the checker construction process by leveraging existing test assertions, significantly reducing developer effort. Although not every test assertion

can be safely transformed into a runtime checker, our approach has shown that many practical semantic checks can be safely extracted and deployed.

Checking Distributed Semantics. Some semantics involve operations across multiple nodes, which requires aggregating operations from different nodes. T2C follows two principles: assertions should run on their respective nodes; if an assertion involves workloads from multiple nodes, it should rely on RPCs, using return values from these calls to avoid introducing new issues. T2C provides a cluster mode to manage related requests across nodes in distributed environments. It aggregates traces from various nodes and, if a checker matches, sends messages to trigger assertions across nodes. This is achieved through an additional message layer, utilizing a distributed log library to forward event traces to the appropriate nodes.

Supporting System Setup Workloads. Some workloads used in the tests do not originate from normal client requests but rather from internal system setup. We refer to these as system setup workloads. We still need to capture such workloads for the checkers. For example, HDFS developers commonly use "MiniDFSCluster", a testing utility class that provides APIs for accessing internal system instances, state, configurations (*e.g.*, replication factor), or queries. To support these in production, we implement adapter classes that mimic the same interfaces but redirect the logic to interact with the actual production system. These adapters reside in the testing package and are invoked via reflection at runtime.

6 Implementation

We implement T2C mainly in Java with around 8,000 SLOC. The analysis and transformation component is implemented with Soot [83] program analysis framework. The dynamic instrumentation is implemented based on Javassist [34] bytecode editing library. The core designs of T2C, *e.g.,* the encapsulation algorithm, symbolizing arguments, are general and do not rely on Java-specific features. We believe porting T2C to support other languages, while requiring non-trivial engineering effort, will be relatively straightforward (*e.g.,* using LLVM for C/C++). T2C includes tests for its static analysis and runtime matching algorithms, as well as scripts to automate the library installation and test execution.

7 Evaluation

We conduct a comprehensive evaluation of our proposed approach. Our evaluation addresses several questions: (1) can T2C transform test cases in large distributed systems? (2) are the generated checkers useful in detecting silent failures? (3) do T2C checkers incur high false positives? (4) how fast is the T2C checker construction workflow? (5) what is the runtime overhead? The experiments are done in servers with 20-core 2.2 GHz CPUs, 64 GB memory, running Ubuntu 18.04.

7.1 Manual Effort of Using T2C

To use T2C, developers mainly need to provide information about the code structure (*e.g.*, paths to system and test packages) and compilation instructions. T2C uses this to automatically analyze and execute tests. Additionally, a few core system classes must be specified for instrumentation. This setup is minimal and a one-time effort. As a system adds new tests, T2C can generate more checkers without extra manual input. T2C also simplifies checker validation by automatically filtering out incorrect checkers, so developers only need to review noisy checkers flagged during pre-production testing.

Supporting a new system is straightforward. Our initial development of T2C uses ZooKeeper as the target system. Since then, T2C has evolved to be more general. Beyond the configuration file, developers supply a few side-effecting operations (around six per system) and testing utility adapters (about three classes per system). For example, integrating HBase took one person-week, mostly for testing and debugging.

7.2 T2C Checker Generation

To evaluate the effectiveness of T2C approach on real-world software, we apply the tool on four large systems: ZooKeeper (ZK), Cassandra (CS), HDFS (HF), and HBase (HB). We choose these systems because they are representative, widely used and have many user-reported silent failures [68]. These systems provide large test cases for T2C to analyze and generate checkers from. Each system is configured using a property file that contains 42 lines of codes on average.

T2C generates checkers for all four systems (Table 2). Each evaluated system has extensive tests (①) but not all tests are suitable for checker conversions. T2C targets a subset of the tests (②) that check system-level semantics and contain useful assertions. The excluded tests are either unit tests for data structures, or performance/stress tests tests with no assertions. We use package names to identify groups of the system tests instead of hand-picking individual tests. For example, most system tests in Cassandra are under `org.apache.cassandra.db` and `org.apache.cassandra.cql3`.

T2C succeeds in constructing checker functions for the majority of the target tests (③). It fails to convert about 7% target tests due to analysis errors in dealing with complex control flows for excluding side-effecting instructions. T2C runs the successful tests to obtain the preconditions. Upon finish generating the checkers, T2C performs sanity checks, *e.g.,* the checker structure must be complete, so only healthy checkers (④) remain. T2C then validates those checkers (Section 4.4), and retains only valid checkers (⑤). In the end, T2C generates 672 verified checkers in total. These checkers have 4.3 assertions on average. Note that this set *does not* include any tests that can reproduce failures in Table 5.

We manually inspect the generated checkers. They cover various system semantics, including request processing, storage, replication, compaction, *etc.* We observe that the completeness of the generated checkers depends on the coverage of the

System	Version	Classes	Tests			Checkers	
			①	②	③	④	⑤
ZK	3.4.11	123	428	109	100	90	46
CS	3.11.5	604	3283	257	242	232	100
HF	3.2.2	803	4304	816	729	707	230
HB	2.4	980	4287	990	948	904	296

Table 2: T2C checker generation overview.

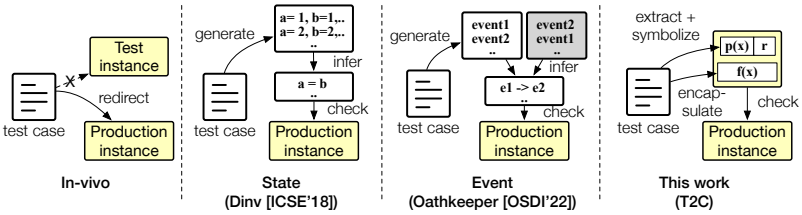

Figure 9: Comparison with the state-of-the-art semantic checkers (baseline).

system tests. With developers' continuous efforts of adding new tests, the checkers' completeness will further improve.

7.3 Detecting Silent Failures

T2C is designed to be a failure detection tool, which focuses on identifying abnormal symptoms at runtime. The key metric for a failure detection tool is once a bug is triggered in a running system and causing a failure, whether and how quickly can the tool detect the failure. This is different from bug-detection tools (*e.g.,* fuzzing), which focuses on creating the conditions, such as inputs and thread interleaving, to trigger a bug.

Failure Benchmark To evaluate generated checker effectiveness, we collect and reproduce 20 real-world silent failures from four systems. These failures are collected using the following methodology. We first query the evaluated systems' issue trackers with keywords "*silent*", "*corrupt*", "*inconsistent*", "*unexpected*", and "*incorrect*". This yields 6,190 issues (ZooKeeper: 410, Cassandra: 2054, HDFS: 1754, HBase: 1972). Then we randomly select 56 of them to inspect more closely. We read their descriptions to confirm whether the failures are indeed silent semantic violations. We exclude issues that are crashes, aborts, out-of-memory errors, or failures with explicit error signals (*e.g.,* an exception). This leads to a total of 24 cases. We attempt to reproduce each case and succeed for 20 cases (the four remaining cases lack the necessary information to reproduce). They become our evaluation failure dataset. Table 5 shows the list of evaluated cases. All of these failures lead to severe consequences. Each case takes one week on average to reproduce.

Baseline Detectors We evaluate each failure and compare T2C with three baselines (Figure 9): two state-of-the-art research solutions—Dinv [48] and Oathkeeper [68]—and one new semantic detector we develop.

- We design *in-vivo* checkers, a new checking method that continuously executes test cases (*e.g.,* create znodes) in the background. We implement such checkers by modifying the test case setup codes, and redirecting test workloads and assertions from simulated test instances to production server instances, so that tests can expose production issues.
- We implement *state* checkers based on Dinv [48], which infers key system state relations based on traces collected from test suite execution, *e.g.,* $lockSet_{t1} \cap lockSet_{t2} = \emptyset$. Dinv only supports systems written in Go language. We add support for Java programs.

		ZooKeeper	Cassandra	HDFS	HBase
In-vivo	Tests (total)	428	3283	4304	4287
	Tests (in-vivo)	391	56	1497	278
	Checkers (tests*)	94	46	73	78
State	States	131	470	1,244	691
	Data points	91,423	76,865	143,069	327,344
	Checkers (state invs.)	47,466	11,083	23,159	35,144
Event	Inferred failures	8	10	10	9
	Checkers (event invs.)	285	129	1209	1641

Table 3: Baseline checker metrics. *tests are sampled.

- We evaluate *event* checkers proposed by Oathkeeper [68], which infers semantic rules (*e.g.,* $lock \rightarrow unlock$) from past failures and uses the inferred rules to detect new failures. Oathkeeper supports ZooKeeper and HDFS. We port it to Cassandra and HBase.

We show the baseline checker metrics in Table 3. Similar to T2C, our methodology of converting in-vivo checkers targets tests that are applicable to intercept requests in client setup codes to redirect. This approach aligns better with test style in ZooKeeper and HDFS, which results in a higher applicable percentage in these two systems. We then sample a subset (291) of in-vivo checkers to deploy in production to shorten the time for checking a full round. For state checkers, their quantity is determined not by the number of test cases, but by the number of system states the tool monitors. More test cases yield additional traces of these states and enhance the inference accuracy. We generate 116,852 state checkers, most of which perform a simple arithmetic operation. For event checkers, their number is related to the number of past failures input into the tool. We generate a total of 3,264 event checkers.

Results Table 4 shows the detection results by different checkers. T2C detects most failures, in total 15 cases, compared to the baseline checkers. Tests we use to generate useful checkers were added long time ago by developers before the failures (3.9 years on average). In comparison, event checkers (based on Oathkeeper [68]) and state checkers (based on Dinv [48]) only detect five and three cases, respectively. Even the combination of all baseline checkers only detect eight cases. In general, T2C is particularly effective in detecting cases that require fine-grained assertions. While event and state checkers can expose some failures, they are limited to relatively simple relations. The in-vivo checkers are derived directly from unit tests without generalization—they reuse the exact concrete inputs and workloads originally used in

tests, rather than generalizing to variable runtime conditions as T2C does. As a result, in-vivo checkers only detect issues when the production workload exactly matches the specific scenario encoded in the original test.

T2C misses five failures. This is unsurprising since T2C cannot guarantee detecting all silent failures. It aims to extract semantics developers have implicitly encoded in the existing test code and generalize the checks for detecting a class of failures. For the missed failures, we find either the system lacks tests that cover the violated semantics, or there is some related test but contains no useful assertions or the test workloads are written in a spaghetti style (usually a result of several ad-hoc patches) that are hard to generalize. For such cases, if developers improve the test coverage and quality, the failures can still be likely detected. To demonstrate this, we add a test (Figure 10) for the missing detected case HB2. T2C successfully detects the case with the newly generated checker.

Case Studies **HF1** [10]: This is a running example in this paper. The constructed checker is shown in Figure 4. Developers observe that snapshots were modified after appending original files (Figure 11) due to a buggy implementation under certain configurations, which violates the immutable snapshot semantics. T2C detects the issue by comparing the returned snapshot size with the written size. State checkers cannot detect this issue since there is no corrupt state (the bug is in the read function implementation). Event checkers cannot detect the issue since normal and buggy traces are identical.

CS1 [4]: During an upgrade of Cassandra from 2.1.17 to 3.11.4, developers observe incomplete results from range queries due to a bug in the mixed mode implementation, which violates the semantics of range queries. T2C successfully detects and alerts on the incomplete result. State checkers cannot detect this failure since the bug lies in the query logic. Event checkers report no violations due to event traces.

ZK1 [23]: A transient network issue causes a delete proposal packet from the ZooKeeper leader to the follower to be dropped. A logic bug then prevents ephemeral nodes from being removed on the follower, even though the owner session has already expired. This violates the semantics that ephemeral nodes should exist as long as the session that creates the znode is active. T2C detects the ephemeral node still exists after the session expiration. State checkers detects this issue using ownership relations between ephemeral nodes and owner sessions. Event checkers cannot detect the issue since the deletion still happens, but the node is put back due to buggy synchronization.

ZK-new [24]: T2C is intended as a monitoring service for failures instead of bug finding, which is a complementary direction that focuses on crafting inputs and triggering conditions to test a system. Our evaluation thus focuses on evaluating T2C's ability to detect known, real-world failures from widely-used distributed systems. Nevertheless, during our evaluation, T2C successfully exposes a new bug in the latest ZooKeeper release (3.9.2). During our fault injection testing, T2C reports violations. With a close inspection, we observed that the ZooKeeper cluster was experiencing data inconsistency among different nodes (some ephemeral nodes never expire on certain followers). It is caused by `loadDatabase` loading a snapshot with a higher transaction id than the truncated log, causing the transaction replay to fail. T2C provided traces to help locate the root cause. We reported this bug to developers. This new bug is marked as "critical" (P1), which leads to data corruption and inconsistency, a severe consequence.

7.4 False Alarms and Side Effects

We evaluate the false alarm ratios of different checkers. To expose the corner cases that over time could occur in a real deployment, we run the system on Jepsen [14], a widely used testing framework for distributed systems. We implement clients in Clojure for all evaluated systems and define common APIs. Jepsen then generates random workloads and automatically injects network faults every 10 seconds. We cal-

```
1 public void testModifyTableSize() {
2   TableName tableName = TableName.valueOf("/test");
3   TableDescriptor desc = TestUtils.setupDesc();
4   admin.createTable(desc);
5   TableDescriptor newDesc =
    TableDescriptorBuilder.newBuilder(desc)
6       .setMaxFileSize(MAX_FILE_SIZE).build();
7   admin.modifyTable(newDesc);
8   assertEquals(MAX_FILE_SIZE,
    admin.getDescriptor(tableName).getMaxFileSize());
9 }
```

Figure 10: The test added for HB2.

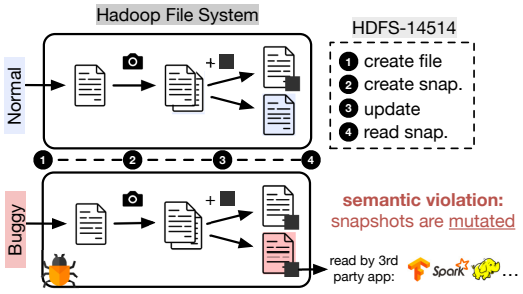

Figure 11: HDFS Snapshot Violation (HF1).

culate the false alarm rate as the ratio of total alarms reported in failure-free scenarios to the total times the checkers are triggered in a 30-minute duration.

The results are shown in Table 6. Overall, in-vivo checkers incur the highest false alarm rates (on average 47.4%) due to their inflexibility in adapting to differences between test and production environments. Meanwhile, with two filtering policies, static (exclude tests using specific APIs or configurations), and dynamic (exclude checkers report violations in dry runs), their false alarms can be reduced. State checkers also produce a high ratio of false alarms, which include false rules from test environments, such as `REQUEST_PREPROCESS_SAMPLE_RATE=0.1`. Some state rules are statistically probable but lack semantic soundness, *e.g.,* the value of `readRespCache.cacheSize` is not equal to `cnxnExpiryQueue.expirationInterval`, which involves two totally unrelated variables. Event checkers and T2C have a lower false alarm rate compared to the previous two types of checkers, thanks to the validation mechanism. The absolute numbers of failed T2C checks are: ZooKeeper (403), Cassandra (100), HDFS (24), and HBase (258). It is unnecessary for developers to analyze individual checking results, as most false alarms originate from a few noisy checkers. For ZooKeeper, nearly all false alarms come from two tests. Developers can address these by running a profiling test before deployment or adding a dynamic ban list.

On average, 56% of checkers generated by T2C are activated. The checkers T2C generates usually have more expressive and more complex preconditions, thus most of them will not be triggered at a high frequency. Thus, T2C does not need to incorporate probabilistic detection unlike other works such as Dinv. The absolute numbers of T2C checking are: ZooKeeper (31997), Cassandra (9905), HDFS (752), and HBase (41547).

	In-vivo Orig.	In-vivo +Sta.	In-vivo +Dyn.	State	Event	T2C
ZooKeeper	2.6	1.7	0	14.2	3.9	1.3
Cassandra	55.3	11.5	0.5	4.7	9.6	1.0
HDFS	68.9	35.4	0.1	6.2	9.3	3.2
HBase	62.6	44.0	1.9	22.8	17.9	0.6

Table 6: False alarms (%).

False negatives require a systematic approach to trigger silent semantic failures (which is a major research challenge) and an oracle to tell if a silent failure has happened. Our result in Table 4 provides some insights on what types of failures cannot be detected by T2C (*e.g.,* if the system does not have a test checking the violated semantics, or the test is of poor quality). Systems installed with T2C checkers do not experience noticeable anomalies, *e.g.*, file corruption, thanks to the filtering of unsafe APIs during checker construction.

7.5 Performance and Overhead

Offline Performance We measure the performance of each step in T2C 's workflow. Table 7 shows the results. The retrofitting phase usually finishes within minutes, which shows our static analysis algorithm is efficient even for large systems. The building and validation phase are more time-consuming as they require executing all test cases with intense instrumentation and logging.

Online Setup We next measure the runtime overhead of different detectors. We use popular benchmarks configured as follows: for ZooKeeper, we use an open-source benchmark with 15 clients sending 15 K requests (40% read); for Cassandra and HBase, we use YCSB with 40 clients sending 100 K requests (50% read); for HDFS, we use built-in benchmark NNBenchWithoutMR which creates and writes 100 files, each file has 160 blocks and each block is 1 MB.

Online Results As shown in Table 8, state checkers incur the highest overhead on system throughput, more than 50% on average. Its overhead does not come from the large number of invariants (most checker executions are arithmetic) but rather recordings for all tracked states. In-vivo checkers incur a 2.4% overhead, which comes from test workloads and checking in the background. Event checkers show a 1.8% overhead on throughput, since they only los event types and their the instrumentation is selective. In comparison, T2C generates a 4.0% overhead on average. The main contributing factor is low frequency of checker activation. As discussed in the previous experiment, T2C-generated checkers typically have precise and complex preconditions and the preconditions of many checkers are only infrequently satisfied at runtime. As a result, these checkers only run infrequently and this significantly reduces the overhead. Another key factor is from the efficient searches through our data structure optimizations.

We measure the CPU and memory usage under the baseline and T2C. The results show a moderate CPU usage increase: ZK (637.9% to 705.5%), CS (305.3% to 336.0%), HDFS (42.3%

	Retrofit	Build	Validate
ZK	25	4487	3837
CS	121	6774	6054
HF	78	23551	25170
HB	149	14401	13331

Table 7: Processing time in each step (s).

	In-vivo	State	Event	T2C
ZK	0.1	24.8	1.9	1.4
CS	3.0	59.0	1.8	9.1
HF	4.4	61.6	2.7	3.8
HB	1.9	93.3	0.7	1.5

Table 8: Throughput overhead (%).

to 46.7%), and HBase (232.6% to 253.1%). The memory usage increase is within 6%, with ZK from 1156.3 MB to 1219.3 MB, CS from 1209.7 MB to 1276.2 MB, HDFS from 684.8 MB to 722.7 MB, and HBase from 777.9 MB to 794.5 MB.

8 Limitations and Future Work

While T2C can generate expressive checkers from tests, our methodology relies on certain assumptions on test quality. T2C is less effective when the test: (1) does not target checking system semantics, *e.g.,* low-level data structure correctness; (2) does not include useful assertions; (3) requires complex preconditions which cannot be easily expressed or generalized. Additionally, automatically generating accurate and flexible checkers remains challenging due to limitations in existing program analysis techniques. Our precondition mutation process and the heuristics used for inferring the generalized relation constraints in checkers can also introduce inaccuracies. We plan to explore new solutions such as large language models (LLMs) to address these limitations.

T2C minimizes the safety risks of side effects by using static analysis to exclude dangerous system operations and dynamic cross-validation mechanism to filter poorly generalized checkers. However, these measures do not fully guarantee generated checkers side-effect free. To use runtime checkers in real deployment, operators could employ additional safeguards through integrating stronger isolation mechanisms (*e.g.,* sandboxing) or formal verifying generated checkers—a direction we plan to explore in future work. We also consider initially deploying T2C in testing or pre-production environments (*e.g.,* staging deployment) to be a practical way of gaining confidence before production deployment.

9 Related Work

Understanding failures in distributed systems have been a classic topic. Recent efforts pay increasing attention to complex failure patterns [25, 28, 45, 58, 69, 74, 77, 95, 96], such as fail-slow faults [50, 70, 94], metastable failures [56], and silent data corruption [85]. Lou *et al.* conduct a study on characteristics of silent semantic failures [68], which provides evidence about the prevalence and severity of such failures. Researchers have explored various testing [38, 44, 46, 64, 71, 87, 97] and verifying [31, 43, 51, 54, 59, 60, 75, 82, 91–93] techniques in software systems. Nevertheless, bugs can still occur in production due to complexity, limited resources, and scalability challenges. T2C complements existing approaches by offering a practical and low-effort approach to expose failures that escape testing.

Several solutions have been proposed to detect non-crash failures [62, 63, 76]. Panorama [57] converts components to external observers. OmegaGen [67] generates mimic checkers to detect faults within component internals. They rely on error indicators (exceptions/timeouts) to detect failures. T2C identifies silent semantic failures without explicit errors.

Many works [26, 29, 33, 66, 73, 79] provide models for developers to write runtime checks. D3S [65] allows developers to write functions that check distributed predicates as relations between states. SQCK [49] uses a declarative query language to check and repair a file system image. This manual approach is time-consuming and error-prone. These checks typically focus on well-known properties. T2C does not require excessive manual efforts. It scales to large systems and keeps the checkers up-to-date. The derived checkers capture loosely-defined semantics in modern distributed systems.

A line of work [27, 30, 35, 36, 42, 52, 61, 90] automatically mines likely invariants from software execution traces. Daikon [40] and Dinv [48] infer key state relations from test suite execution. Oathkeeper [68] infers relations between semantic-related events from test runs on buggy and patched code versions. These systems suffer from high inaccuracies due to the statistical approach. The inferred invariants have limited expressiveness to capture the diverse system semantics. T2C provides more expressive and accurate runtime checks.

PCheck [89] extracts configuration usage codes in a program as configuration checks. Ctests [81] connects the existing tests with configurations from production. ZebraConf [72] runs tests to find heterogeneous-unsafe configuration parameters. Zodiac [78] mines semantic checks from online resources for infrastructure deployment configurations. They target at detecting misconfigurations, thus address fundamentally different challenges. While Ctests also transforms a test, it focuses on configuration parameters. In contrast, T2C targets system semantics and performs more complex transformation. T2C also determines the checker precondition.

10 Conclusion

This paper explores an ambitious approach to automatically construct expressive semantic checkers for large distributed systems from existing test code. We present a study to provide insights on the feasibility. The study guides us to design and implement a practical framework T2C using static and dynamic analyses. Our evaluation of T2C on large distributed systems and real-world silent failures demonstrates its efficacy.

University of California, Berkeley; [†] *University of Oregon;* [*] *University of Michigan*

Abstract

Replicated state machines (RSMs) cannot communicate effectively today as there is no formal framework or efficient protocol to do so. To address this issue, we introduce a new primitive, Cross-Cluster Consistent Broadcast (C3B) and present PICSOU, a practical implementation of the C3B primitive. PICSOU draws inspiration from networking and TCP to allow two RSMs to communicate with constant metadata overhead in the failure-free case and a minimal number of message resends in the case of failures. PICSOU is flexible and allows both crash fault tolerant and Byzantine fault tolerant consensus protocols to communicate. At the heart of PICSOU's good performance and generality is the concept of QUACKs (quorum acknowledgments). QUACKs allow nodes in each RSM to precisely determine when messages have definitely been received, or likely lost. Our results are promising: we obtain up to 24× better performance than prior solutions on microbenchmarks and applications, ranging from disaster recovery to data reconciliation.

1 Introduction

Many organizations today use replicated state machines (RSM) underpinned by consensus protocols to provide reliability, fault isolation, and disaster recovery. This includes key-value stores [37, 50, 79], cluster managers [25], and microservices [21, 66, 70]. These RSMs frequently need to communicate with each other in an efficient and timely manner. Etcd [37] to Etcd mirroring over Kafka, for instance, is a popular approach for disaster recovery across clusters [33]. Similarly, autonomous organizations often run their replicated key-value store locally for ease of management, but share access with other entities. For example, conversations with government agencies reveal that, for operational sovereignty, services cannot be managed across agency borders. Instead, any shared information must be communicated across RSMs and explicitly reconciled [75]. Furthermore, in the blockchain ecosystem, there is a growing push towards interoperability, which requires distinct RSMs (blockchains) to communicate [20, 90].

These examples speak of a common need: RSMs must support the ability to efficiently and reliably exchange messages with other RSMs that may or may not implement the same consensus protocol internally.

Unfortunately, existing solutions are either ad-hoc, offer vague or evolving guarantees [20], rely on a trusted third-party [92]), or require an expensive all-to-all broadcast [9, 34]. For instance, Apache Kafka, the most popular approach for exchanging data across organizations, internally relies on a third RSM for safely sharing state.

All-to-all broadcast is even more problematic: while RSMs usually run within the same datacenter, there exist many RSMs which are geographically distributed. In these cases, cross-RSM communication will take place over WAN, which offers significantly reduced bandwidth at a much higher dollar cost. This frequently causes communication to become a bottleneck.

Any system that allows RSMs to communicate should satisfy four requirements: 1) *strong guarantees*: there should be a precise and formal way to discuss RSM-RSM communication 2) *robustness under failures*: actively malicious or crashed nodes should neither affect correctness nor cause system throughput to drop [32] 3) *low-overhead in the common-case*: for efficiency, an RSM to RSM communication protocol should send a single message with constant metadata in the failure-free case 4) *generality*: arbitrary RSMs with heterogeneous sizes, communication, and fault models should be able to communicate. It should, for instance, be possible to link a Byzantine Fault Tolerant (BFT) consensus protocol with a Crash Fault Tolerant (CFT) consensus algorithm

To this effect, we first propose a new primitive, Cross-Cluster Consistent Broadcast (C3B), which can be used by two arbitrary RSMs to communicate. C3B generalizes Reliable Broadcast to guarantee that if RSM A sends m, at least one correct replica in RSM B should receive m.

We then introduce PICSOU, a practical C3B protocol that allows arbitrary RSMs with heterogeneous communication and failure models to communicate efficiently. Designing a C3B protocol that provides good performance in the failure-free case is fairly simple as a simple leader-to-leader broadcast suffices. The challenges instead arise from designing an efficient protocol that *remains robust to failures* [32]. The key to PICSOU's good and robust performance lies in observing that the C3B problem shares similar goals to TCP [80]. TCP seeks to offer reliable, ordered delivery between two hosts in a way that dynamically reacts to congestion and

anomalies in the network. To do so at low cost, TCP leverages full-duplex communication and cumulative acknowledgments (ACKs) to asynchronously detect when messages have been received. In contrast, repeated ACKs of the same message reveal message loss. PICSOU takes inspiration from these techniques and modifies them to account for the differences between C3B and TCP: 1) unlike TCP, which is exclusively designed for point-to-point messaging, PICSOU must handle many-to-many communication and disseminate knowledge of failed/successful message deliveries across many nodes, 2) PICSOU must ensure that no Byzantine participant will violate correctness or cause excessive retransmissions. In contrast, TCP does not consider malicious failures.

To address these challenges, PICSOU introduces the notion of QUACKs. A QUACK is a cumulative quorum acknowledgment for a message m. It concisely communicates the fact that all messages up to m have been reliably received by at least one correct node; *repeated* QUACKs for m indicate that the next message in the sequence was not received at the receiving RSM.

Using QUACKs in PICSOU yields multiple benefits. First, it ensures *generality*. It allows for PICSOU to seamlessly work for crash fault tolerant systems as well as for both traditional and stake-based Byzantine fault tolerant protocols. PICSOU makes no synchrony or partial synchrony assumption. Second, PICSOU's QUACK-driven implementation has low overhead. In the failure-free case, PICSOU sends each message only once, and requires only two additional counters per message. When failures do arise, PICSOU remains *robust* as its resend strategy minimizes the number of messages resent: no Byzantine node can unilaterally cause spurious message retransmissions.

Our results confirm PICSOU's strong guarantees. PICSOU allows disparate protocols such as PBFT [28], Raft [69] and Algorand [40] to communicate. On two real-world applications, Etcd Disaster Recovery [33] and a data reconciliation application [75], PICSOU achieves 2× better performance than Kafka. In our microbenchmarks, when consensus is not the bottleneck, PICSOU achieves 3.2× better performance than a traditional All-to-All broadcast for small networks (4 nodes), and up to 24× for large networks (19 nodes). In summary, this paper makes the following contributions:

1. We introduce Cross-Cluster Consistent Broadcast primitive, which allows for two RSMs to communicate robustly and efficiently.
2. We present PICSOU, a practical C3B protocol. Key to PICSOU's good performance is the use of QUACKs (cumulative quorum acknowledgments), which precisely determines when messages have definitely been received, or likely lost.
3. We evaluate PICSOU on realistic workloads, showing that it can successfully allow disparate RSMs to communicate more effectively that prior solutions.

2 Formalising the C3B primitive

We first introduce and formalize the C3B primitive. C3B is the blueprint for any communication protocol between RSMs and should be sufficiently general to support various communication and failure models.

2.1 System Model

We first discuss the necessary formalism. Consider a pair of communicating RSMS. For the sake of exposition, we denote the sending RSM as $\mathcal{R}_s$ and the receiving RSM as $\mathcal{R}_r$. In practice, communication between these RSMs is full-duplex: both RSMs can send and receive messages.

Most modern RSMs are either *crash fault tolerant* (they guarantee consensus when up to $\mathbf{f}$ nodes crash) or *Byzantine fault tolerant* (they guarantee consensus when up to $\mathbf{f}$ nodes behave arbitrarily). In line with PICSOU's stated generality and efficiency goals, we adopt the *UpRight* failure model [31]. It allows us to consider Byzantine nodes and crashed nodes in a unified model, letting us design a system that optimizes for each type of failure. In the UpRight failure model, Byzantine nodes may exhibit *commission failures*; they may deviate from the protocol. All other faulty nodes may suffer from *omission failures* only: they follow the protocol but may fail to send/receive messages. Crashed nodes, for instance, suffer from permanent omission failures once crashed. Correct nodes, by definition, never fail[1]. In this setup, each RSM consists of $\mathbf{n}$ replicas. We denote the j-th replica at the i-th RSM as R_{ij} (where i is either the sender or the receiver RSM). Each RSM interacts with a set of clients, of which arbitrarily many can be faulty.

We say that an RSM is safe despite up to $\mathbf{r}$ commission failures and live despite up to $\mathbf{u}$ failures of any kind. For example, using the UpRight model, we can describe traditional BFT and CFT RSMs using just one equation: $2\mathbf{u}+\mathbf{r}+1$; Setting $\mathbf{u}=\mathbf{r}=\mathbf{f}$ yields a $3\mathbf{f}+1$ BFT RSM and setting $\mathbf{r}=0$ yields a $2\mathbf{f}+1$ CFT RSM. Safety and liveness of any RSM are defined as follows:

Safety. If two correct replicas R_{i1} and R_{i2} in RSM $\mathcal{R}_i$ commit transactions T and T' at sequence number k, then $T=T'$.

Liveness. If a client sends a transaction T to RSM $\mathcal{R}_i$, correct replicas in $\mathcal{R}_i$ will eventually commit T.

Note that we make no assumptions about the communication model of the underlying RSM. We only assume messages are eventually delivered and that the receiving RSM $\mathcal{R}_r$ can verify whether a transaction was in fact committed by the sender RSM $\mathcal{R}_s$ (more details in Section 3).

[1] This is of course a simplification, necessary to say anything about an RSM. All practical systems assume that this $\mathbf{f}$ stays true at any given point in time, and that the set of failed nodes only changes. It allows making statements such as "$\mathbf{f}+1$ votes ensure that at least one correct node participated".

We generalize our system model to support *shares*. The notion of share is used in stake-based BFT consensus protocols where the value of a share determines the *decision-making power of a replica* [42]. For a replica R_{ij} in RSM $\mathcal{R}_i$, we write δ_{ij} to represent the replica's stake; the total amount of share in RSM $\mathcal{R}_i$ is then $\sum_{l=1}^{|\mathbf{n}_i|} \delta_{il}$. A stake-based consensus algorithm is safe as long as replicas totaling no more than $\mathbf{r}_i$ shares deviate from the protocol. The system is live as long as no more than $\mathbf{u}_i$ shares fail to send/receive messages Traditional CFT and BFT algorithms simply set all shares equal to one.

Adversary Model. We assume the existence of a standard adversary which can corrupt arbitrary nodes, delay and reorder messages but cannot break cryptographic primitives. As is standard, we assume that reconfigurations are possible [7, 38] and that there exists a mechanism for an RSM to reliably learn of the new configuration and/or share assignments. We provide more detail on how such a mechanism can be implemented in Section 4.4

2.2 Cross-Cluster Consistent Broadcast

The C3B primitive enables efficient and reliable communication between a sender RSM and a receiver RSM.

To formalize C3B, we first need to define two new communication primitives that express exchanging messages between RSMs. These operations are at a coarser granularity than the traditional *send* and *receive* operations, which define the operations performed by a specific node or replica.

Transmit. If a correct replica in $\mathcal{R}_s$ invokes C3B on message m, we say that RSM $\mathcal{R}_s$ *transmits* message m to RSM $\mathcal{R}_r$.

Deliver. If a correct replica from $\mathcal{R}_r$ outputs message m, we say that RSM $\mathcal{R}_r$ *delivers* message m from $\mathcal{R}_s$.

We can then define the two correctness properties that all C3B implementations must satisfy:

Eventual Delivery. If RSM $\mathcal{R}_s$ transmits message m to RSM $\mathcal{R}_r$, then $\mathcal{R}_r$ will eventually deliver m.

Integrity. For every message m, an RSM $\mathcal{R}_r$ delivers m from $\mathcal{R}_s$ if and only if $\mathcal{R}_s$ transmitted m to $\mathcal{R}_r$.

Note that the deliver operation requires only that one correct node receives the message, not that all correct nodes receive it. This is by design: our goal is to make the C3B condition as flexible as possible to suit application needs. In practice, it is easy to strengthen this condition to either guarantee delivery to all nodes or to establish ordering between RSMs, as correct nodes in the receiving RSM can simply broadcast or invoke consensus on delivered messages. In the name of generality, the C3B primitive talks about a single message only, and does not worry about ordering across messages. PICSOU, nonetheless, uses knowledge of ordering for efficiency, as we describe next.

3 Design Overview

PICSOU *efficiently* implements the C3B primitive while remaining *general* and *robust* under failures. The design of PICSOU is centered around three pillars:

(P1) **Efficiency.** In the (common) failure-free case, where messages are received in a timely fashion, PICSOU should only send a single copy of each message across RSMs, and no more than $O(n)$ copies within a cluster. Any additional metadata sent as part of PICSOU should have constant size.

(P2) **Generality.** PICSOU should support RSMs of arbitrary sizes, with diverse failure models and communication models, including crash and Byzantine faults as well as synchronous and asynchronous networks. The protocol logic must also work well for both traditional BFT systems and newer Proof-of-Stake protocols, where a replica's share determines the weight that its vote carries.

(P3) **Robustness.** PICSOU should remain robust to failures. Crashed or malicious replicas should have minimal impact on performance [32]. There is a tension here: while the protocol should aggressively resend dropped messages to minimize latency, Byzantine nodes should not cause correct nodes to resend messages, which can spuriously hurt throughput.

Much like TCP flows, communication between RSMs is *streaming*, *long-running* and often *full-duplex*. PICSOU thus draws inspiration from TCP's approach to congestion control and message loss to guarantee efficiency and robustness.

Two ideas are central to TCP's good performance: 1) leveraging full-duplex communication and 2) cumulative ACKing. In TCP, nodes simultaneously exchange messages, and TCP leverages this bidirectional communication to piggyback acknowledgments onto messages and minimize bandwidth requirements. Cumulative ACKing then keeps these acknowledgments small: with a single counter k, a receiver informs a sender that it has received all packets with sequence number up to k. Receiving a repeated counter with value k instead informs the sender that the packet with sequence number $k+1$ is either lost or delayed.

For *efficiency*, PICSOU also leverages full-duplex communication and cumulative ACKing. However, PICSOU must also handle many-to-many communication as each RSM consists of multiple replicas. For *generality*, PICSOU must support crashed nodes, Byzantine nodes, as well as Byzantine nodes whose stake determines their voting power; PICSOU makes use of the *UpRight* fault model to simultaneously handle crash and Byzantine nodes, and leverages the mathematics of *apportionment* to work seamlessly with staked-based systems. For *robustness*, PICSOU must ensure that replicas cannot trigger spurious message retransmissions. PICSOU uses QUACKs to determine when a message has definitely been received or is likely lost.

Overview. PICSOU's protocol logic can be divided into the following logical components.

(1) *Consensus*: On either side of PICSOU lies a replicated state machine. Each RSM receives requests from clients and runs a consensus protocol that commit these requests on each RSM replica. PICSOU assumes two properties of consensus to guarantee correctness: first, all replicas eventually receive all messages, and second, all replicas agree on the content of each slot in the log.

(2) *Invoking* PICSOU: If an RSM wants to transmit a request, each replica forwards the committed request to the co-located PICSOU library. RSMs are not required to forward every committed message to PICSOU. This step is application-specific. For example, if two organizations only share a subset of their data, the RSM will only transmit messages that touch these particular objects.

(3) *Transmitting a message*: PICSOU sends the message on behalf of the sending RSM. In line with our stated efficiency goals, PICSOU ensures that, in the absence of failures and during periods of synchrony, a *single sender* forwards each request to a *single replica* in the receiving RSM. To minimize the risk of repeated failures caused by a faulty sender or receiver, PICSOU carefully rotates sender-receiver pairs. In doing so, it ensures that every sender will eventually communicate with a correct receiver and vice-versa.

(4) *Detecting successful or failed sends:* PICSOU must quickly determine whether a message has definitely been received (and thus can be garbage collected) or has definitely been dropped or delayed (distinguishing between message drops and delays is not possible in an asynchronous system). Failure detection must be accurate to prevent Byzantine nodes from causing spurious re-transmissions; it must be efficient and should not require additional communication between nodes. PICSOU adapts TCP's cumulative acknowledgment approach to detect when messages have been received or dropped, even when malicious replicas can lie. These acknowledgments are piggybacked on incoming messages, thus minimizing overhead.

(5) *Retransmissions*: When the protocol detects that a message has been dropped (with high confidence), PICSOU intelligently chooses the node responsible for resending the message. Unfortunately, concurrent node failures can cause multiple messages to be dropped simultaneously. To address this issue, PICSOU includes (constant size) information about which messages have been lost, allowing the protocol to recover multiple dropped messages in parallel. Traditional TCP can eschew this constraint as it assumes failures are rare and considers point-to-point communication only.

Correctness We defer a full description of correctness and proofs to Appendix A.1 and A.2 [1].

4 Protocol Design

We now describe each component of the protocol: transmitting a message, detecting successful/failed sends, and retransmissions. For clarity of exposition, we describe the protocol as consisting of a sender RSM $\mathcal{R}_s$ and a receiver RSM $\mathcal{R}_r$ proceeding in synchronous timesteps. In practice, nodes operate independently and act as both the sender and the receiver. We start by describing PICSOU's behavior in the common case (§4.1) before considering failures (§4.2). We add support for stake in §5. We include protocol pseudocode in Appendix A.3 [1].

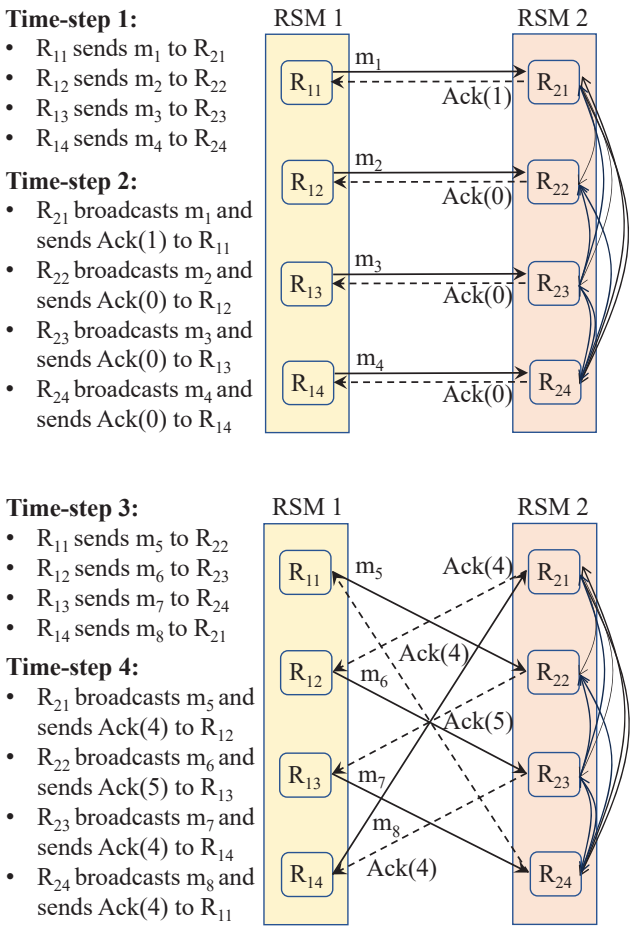

Figure 1: Example failure-free run in PICSOU

4.1 Failure-free behavior

Sending a message. PICSOU's send logic has three goals: 1) minimize the number of nodes sending the same message 2) maximize the chances that a message will be received quickly 3) asynchronously disseminate knowledge of received messages to other nodes. PICSOU achieves these goals by round-robin partitioning the set of requests across all sending RSM replicas and rotating receiver nodes every round.

By definition, each replica in an RSM contains a log of committed requests, a subset of which should be transmitted to the other RSM. PICSOU assumes that each request transmitted through PICSOU is of the form $\langle m,k,k' \rangle_{Q_s}$, where m is a request committed at sequence number k by a quorum of replicas in RSM $\mathcal{R}_s$. Each protocol sets a specific threshold t above which the request has acquired sufficiently many

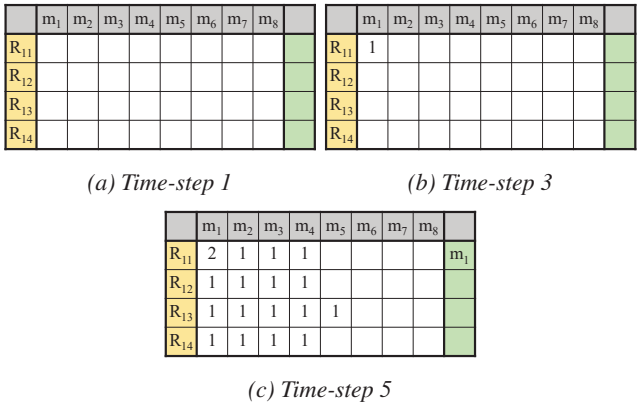
signatures Q_s to be deemed committed. k' is an optional sequence number that denotes the position of the message in the stream of messages that will be transmitted through PICSOU. k' must be sequentially increasing; $k' = \perp$ indicates that the message should not be transmitted. Including both k and k' allows $\mathcal{R}_s$ to filter which messages will be transmitted to $\mathcal{R}_r$.

PICSOU evenly partitions the task of transmitting committed messages across all replicas such that each message is sent by a single node: replica R_{sl} sends messages with sequence number $(k' \bmod \mathbf{n}_s \equiv l)$. Additionally, each sender rotates receivers on every send: if RSM $\mathcal{R}_r$ has size $\mathbf{n}_r$ and replica R_{sl} last sent to replica R_{rj}, then R_{sl} will next send to R_{rJ}, where $J \equiv j+1 \bmod \mathbf{n}_r$. Node IDs themselves are assigned by PICSOU using a verifiable source of randomness [40] such that malicious nodes cannot choose specific positions in the rotation. Note that, as is standard in TCP, we allow senders to transmit a window of messages in parallel.

Receiving a message Upon receiving a message, the j-th replica R_{rj} checks that the message $\langle m, k, k' \rangle_{Q_s}$ is valid (the message has provably been committed by the sender RSM) and if so, broadcasts it to the other nodes in its RSM. Importantly, the receiving node does not need to recommit the message. It can simply apply it to its local state as mandated by the application logic.

Rotating sender-receiver pairs in this way guarantees that every pair of replicas will eventually exchange messages and ensures that (1) information about the state of each node is propagated to every other node in the system, and (2) no sender is continuously sending to a faulty replica (or vice-versa). This process is also essential to bounding the number of retransmissions needed with failures (§4.2).

We illustrate PICSOU's logic in Figure 1. For clarity of exposition, we assume that 1) in each time-step, each replica completes all relevant tasks in parallel, 2) all sent messages are received in the next time-step, and 3) only one RSM sends, the other only acks. In our implementation, acks are piggybacked on messages. Consider a system with $\mathbf{n}_s = \mathbf{n}_r = 4$ replicas ($\mathbf{u} = \mathbf{r} = 1$). In time-step 1, replicas R_{11}, R_{12}, R_{13}, and R_{14} of RSM_1 send messages m_1, m_2, m_3, and m_4 to receivers R_{21}, R_{22}, R_{23}, and R_{24}, respectively. In time-step 2, these receivers internally broadcast these messages to the other nodes in their RSM. Concurrently, R_{21}, R_{22}, R_{23}, and R_{24} acknowledge receipt of these messages and send $\text{ACK}(1)$, $\text{ACK}(0)$, $\text{ACK}(0)$, and $\text{ACK}(0)$ to senders R_{11}, R_{12}, R_{13}, and R_{14}. We discuss acknowledgments later in the section. In time-step 3, R_{11}, R_{12}, R_{13}, and R_{14} rotate receivers and send messages m_5, m_6, m_7, and m_8 to R_{22}, R_{23}, R_{24}, and R_{21}. In time-step 4, receivers once again broadcast the received messages in their RSM. Simultaneously, R_{21}, R_{22}, R_{23}, and R_{24} rotate receivers for their acknowledgements, and send $\text{ACK}(4)$, $\text{ACK}(5)$, $\text{ACK}(4)$, and $\text{ACK}(4)$ to senders R_{12}, R_{13}, R_{14}, and R_{11}.



(a) Time-step 1 *(b) Time-step 3*

(c) Time-step 5

Figure 3: Sender's view of events in Figure 1 in time-steps.

Detecting successful sends. To guarantee correctness, committed messages must eventually be received by a correct node in the receiving RSM. Every node in the sending RSM (not just the sender) must thus learn whether a message has *definitely* been received by a correct node. This is necessary to preclude correct nodes from unnecessarily resending messages. There are three primary challenges: (1) malicious nodes may lie about the set of messages received, (2) for efficiency, PICSOU should not require nodes within an RSM to exchange information beyond the necessary message broadcast, and (3) any additional metadata should be small. PICSOU realizes these goals through *cumulative quorum acknowledgments* (or QUACKs). A cumulative quorum acknowledgment with value k proves to the sending RSM that all messages with sequence number up to k have been received by at least one correct replica. More specifically, each replica, upon receiving a message with sequence number k, inserts it into a sorted list containing all previously received messages. The replica then identifies the highest message m_p in the list for which all messages with a smaller sequence number have been received. It then crafts an acknowledgment $\text{ACK}(p)$ that cumulatively acknowledges receipt of messages 1 to p. PICSOU takes advantage of the full-duplex nature of

the protocol to piggyback these acknowledgments onto the messages that the receiving RSM is itself sending to the sending RSM. If no such message exists, the RSM sends a no-op.

On the sender side, each replica eventually receives messages and acknowledgments from all $\mathbf{n}_r$ receiving replicas, thanks to PICSOU's round-robin strategy. Each replica maintains an $\mathbf{n}_r$ sized array that summarizes the highest acknowledgment received from each replica of receiving RSM. A message m_p is QUACKed if at least $\mathbf{u}_r + 1$ replicas have acknowledged receipt of all messages up to p. As there are only $\mathbf{u}_r$ failed replicas, one of these replicas must be correct. We thus have the guarantee that this correct replica will broadcast the message to all other remaining correct replicas. Note that PICSOU additionally uses MACs to safely transmit ACKs when configured to handle Byzantine failures ($\mathbf{r} > 0$).

Example. Continuing with our example in Figure 1, we highlight the protocol logic for both the receiver RSM (Figure 2) and the sender RSM (Figure 3). Each row in Figure 2 describes a sorted list of messages received at each replica, with the last column denoting the highest cumulative acknowledgment for this node. At time-step 1, all lists are empty and cumulative acknowledgment values are all set to 0 (2a). At time-step 2, receivers R_{21}, R_{22}, and R_{23} (2b) store messages m_1, m_2 and m_3. R_{21}'s cumulative acknowledgment counter thus increases to 1, while others stay at 0 as they are still missing m_1. R_{21}, R_{22}, and R_{23} thus send $\text{ACK}(1)$, $\text{ACK}(0)$ and $\text{ACK}(0)$ to the sender RSM. At time-step 3, each receiver, thanks to the internal broadcast mechanism, receives all four messages. All cumulative acknowledgment counters thus go to 4 (2c). By time-step 4, receivers R_{21}, R_{22}, and R_{23} have all received m_8, m_5 and m_6. R_{22} has received messages m_1 to m_5, and thus updates its cumulative acknowledgment to 5. In contrast, R_{21} and R_{23} have received messages m_8 and m_6 respectively, they are missing m_5 and thus cannot yet update their cumulative acknowledgment counter. R_{21}, R_{22}, and R_{23} send $\text{ACK}(4)$, $\text{ACK}(5)$ and $\text{ACK}(4)$ back to the sending RSM. Finally, at time-step 5, the internal broadcast mechanism disseminates all these messages; each replica can update its cumulative acknowledgment to 8.

Now consider the sender-side logic (Figure 3), which processes these cumulative acknowledgments and determines when a QUACK has formed. Recall that a message is QUACKed at a replica if this replica receives $\mathbf{u} + 1 = 2$ acknowledgments for m. Initially, all QUACK counters are empty (3a). At time-step 3 (3b), R_{11} records that it has received an acknowledgment for m_1 ($\text{ACK}(1)$) from R_{21}. At time-step 5, (3c), R_{11} receives $\text{ACK}(4)$ from R_{24}. It updates its local array, indicating that it has received acknowledgments for m_1 by two unique nodes, and marks m_1 as QUACKed. It also records the received acks for m_2, m_3, and m_4. Similarly, all other replicas indicate that they have received an ack for m_1, m_2, m_3, and m_4. Additionally, R_{13} indicates it received an ack for m_5 as it received $\text{ACK}(5)$.

Summary The joint techniques of full-duplex communication, cumulative acking, and rotation of sender/receiver pairs allow PICSOU to ensure that all RSM replicas eventually learn which committed requests have been delivered. The protocol achieves this with only two additional counters and with no additional communication between replicas of an RSM beyond the necessary broadcast.

4.2 Handling Failures

Faulty replicas can: 1) fail to send or broadcast messages sends and broadcasts, 2) send invalid messages to DDoS the network, 3) collude to repeatedly drop messages, and 4) send incorrect acknowledgments to break correctness or trigger spurious retransmissions. PICSOU must effectively handle these failures without sacrificing correctness or performance. To this effect, PICSOU must quickly and reliably detect *when* a message has *definitely* been dropped or delayed and quickly retransmit it. The system must do so without any additional communication beyond resending the message itself.

Detecting failed sends. The protocol once again leverages QUACKs to detect failed sends. Recall that all sender replicas eventually obtain a QUACK for every message that has *definitely* been delivered. One can instead leverage duplicate QUACKs to learn when a correct replica has *not* received a specific message. In more detail, let us assume that a QUACK for message m_k has formed at R_{sl}. This QUACK indicates that at least $\mathbf{u}+1$ (at least one correct) replicas have received every message up to message m with sequence number k. A duplicate acknowledgment $\text{ACK}(k)$ from one of these replicas implies that this replica claims not to have received the message at sequence number $k+1$. Once a duplicate QUACK forms for the k-th message at replica R_{sl}, R_{sl} learns that a correct replica is complaining about missing message $(k+1)$, and thus that the message has legitimately been lost or delayed. All other replicas of the sending RSM $\mathcal{R}_s$ will eventually receive a duplicate QUACK and thus detect the failed exchange. The use of the UpRight failure model, which distinguishes actively malicious failures $\mathbf{r}$ from all other failures, allows us to reduce the size of the duplicate QUACK: while the initial QUACK is of size $\mathbf{u}+1$, duplicate QUACKs must be of size $\mathbf{r}+1$ as they must be large enough to preclude actively malicious nodes from triggering spurious resends. In a system with only crash failures (when $\mathbf{r}=0$), a single duplicate ACK() is sufficient to trigger a message resend: nodes may crash but do not lie.

Retransmitting the dropped message. Upon detecting a failed send, the message must be quickly retransmitted. Just as a single replica was responsible for sending the initial message, PICSOU ensures that a single replica is "elected" as the re-transmitter. It does so *without* requiring additional communication between replicas. The protocol logic hinges on three observations: 1) all correct replicas know about all the messages that must be transmitted (by definition of an RSM) and know who initially sent the message, 2) all

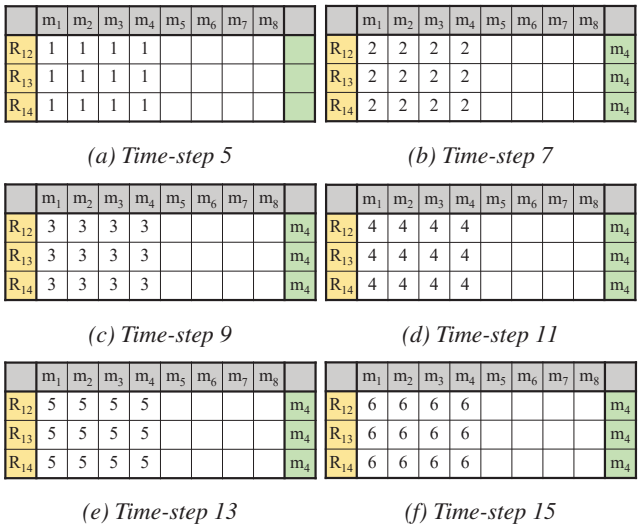


Figure 4: Sender's view of events. R_{11} *fails after TS 2 in Figure 1.*

correct replicas eventually learn about which messages have been QUACKed, and 3) the number of repeated QUACKs indicates the number of failed retransmissions. PICSOU uses this information to compute the ID of the re-transmitter as: $sender_{new} = (sender_{original} + \#_{retransmit}) \bmod \mathbf{n}_s$. Each correct replica computes this function and retransmits the message if its ID matches $sender_{new}$. Each retransmission round thus has a single sender.

To illustrate, consider once again our initial example (Figure 1), but this time, let us assume that sender replica R_{11} fails in time-step 2, after sending message m_1 but before sending messages m_5 and m_9. As a result, no receiver receives these messages. In Figure 4, we time-step through this failure scenario. For simplicity, we assume that the receiving RSM sends periodic acks every time-step. As before, all non-failed replicas of RSM_1 receive their first ACK(4) in time-step 5 (Figure 1); In time-step 7, all replicas receive a second ACK(4) message, from a different node, allowing them to mark messages m_1 to m_4 as QUACKed. They continue receiving ACK(4) from *distinct* replicas in time-step 9 and 11. Receivers cannot acknowledge any message greater than m_4 as they are yet to receive m_5. In time-step 13, the senders receive their first duplicate ACK(4) message. By the end of time-step 15, the senders have received at least $\mathbf{r}_r + 1 = 2$ duplicate ACK(4) messages, confirming that m_5 is missing. R_{12} proceeds to resend m_5.

The pitfalls of sequential recovery. Unlike traditional TCP in which message drops are not adversarial, faulty replicas can carefully select which messages to drop. For instance, in a $\mathbf{n} = 2\mathbf{u} + \mathbf{r} + 1$ setup with $\mathbf{u} = \mathbf{r} = 1$, if a node omits all received messages, every fourth message will need to be resent. In this setup, PICSOU can hit a throughput bottleneck. A QUACK conveys information about the *lowest* message that has been dropped by the system, but says nothing about later messages. This approach is optimal metadata-wise but serializes recovery: if messages m_i, m_{i+4}, m_{i+8}, etc. have all been dropped, resending m_{i+8} first requires detecting the failed send of message m_i, retransmitting m_i, QUACK m_i, before repeating the same process for m_{i+4}. Only then can the failed send of m_{i+8} be handled.

Parallel Cumulative Acknowledgments. To address this issue, we must augment our cumulative acknowledgments with a limited form of selective repeat [93]. Each receiver sends both a cumulative acknowledgment and a list summarizing the delivery status of up to ϕ messages past the sent cumulative acknowledgment. The cumulative acknowledgment counter concisely summarizes the set of contiguous messages received so far. The ϕ-list instead captures any "in-flight" missing messages. Sending ϕ-lists over the network is efficient as the delivery status of each message takes at most one bit to encode. This list can further be reduced with techniques such as compression or bloom filters.

Sender replicas can now, concurrently, form QUACKs for ϕ concurrent messages and thus retransmit ϕ messages in parallel. This reduces latency without resorting to eager message resends. The maximum size of ϕ-lists is an experiment-specific parameter. The actual number of elements in a ϕ-list depends on the number of in-flight messages at the time of sending a cumulative acknowledgment.

Analysis During periods of synchrony (when messages are not dropped or delayed by the network), PICSOU retransmits messages at most $\mathbf{u}_s + \mathbf{u}_r + 1$ times. This limitation is fundamental to all C3B protocols (Lemma 1 in Appendix [1]). The number of resends can become a concern for latency if the number of failures is large. In practice, however, the probability of actually hitting this bound is small. Intuitively, in a CFT or BFT system, each node is more likely than not to be correct. As such, the probability of continually selecting incorrect nodes in every sender-receiver pair decreases exponentially every retry. One can use this reasoning to provide strong bounds on the maximum number of retries when the network is well-behaved. We prove, for instance (in Appendix A.2 [1]) that PICSOU needs to resend a message at most eight times to ensure that a message be delivered with 99% probability, and at most 72 times to ensure a $100 - 10^{-9}$% success probability.

4.3 Garbage Collection

At first glance, garbage collecting messages in PICSOU appears straightforward. The sending RSM, upon receiving a QUACK for m, can garbage collect m as the message has been received by a correct replica. Unfortunately, this approach can lead to scenarios in which PICSOU stalls. Consider, for instance, an execution in which sender R_{sl} sends a message m_k (at sequence number k) to replica R_{rj} of RSM $\mathcal{R}_r$. Now, consider the case in which R_{rj} is faulty and broadcasts m_k to precisely $\mathbf{u}_r + 1$ replicas, $\mathbf{u}_r$ of which are faulty. These replicas reply to the sender RSM that m has been successfully received, allowing for a QUACK to form at the sender, and for message m to be garbage collected. Unfortunately, if these

$\mathbf{u}_r$ replicas then stop participating in the protocol, no QUACK will ever form for any message with sequence number greater than k (only one correct replica has seen m). Instead, the sending RSM will receive repeated duplicate acknowledgments for m, a message which it has already garbage collected!

We must consequently modify the garbage collection algorithm slightly. If a sending replica ever receives a duplicate QUACK for message $m_{k'}$ where $k' < k$ *after* having quacked and garbage collected message m_k, it includes, as additional metadata, the sequence number k of its highest quacked message. This information conveys to the receiving RSM that all messages up until k (included) have been received by *some* correct node in the receiving RSM, but not necessarily the same one. Replicas in the receiving RSM, after having received $\mathbf{r}_s + 1$ such messages (ensuring that at least one correct node is in the set), can then either (1) advance their cumulative acknowledgment counter to k and mark message m as received, or (2) obtain m from other replicas in the RSM. Only then can m be garbage collected. We offer both strategies in PICSOU.

4.4 Reconfiguration

PICSOU assumes that reconfigurations are possible but rare. It assumes that there exists a service indicating the set of nodes associated with each configuration. This is standard practice in the literature [7, 37, 38]. Knowledge of membership is either maintained internally in the RSM [87] or using an external configuration service [37, 87]. Most existing state-of-the-art blockchain systems [3, 10, 40, 51, 59, 67, 75, 83, 94] also require known node membership. To deal with churn and scale, these systems work in epochs where it is assumed both node membership and relative stake are both publicly known and fixed. PICSOU piggybacks on this assumption. PICSOU then only needs to ensure that the set of ACKs received for a particular message all match the same view and that the relevant $(\mathbf{u}+1/\mathbf{r}+1)$ threshold has been reached (for that view).

Messages acknowledged as delivered before a reconfiguration occurs do not need to be resent. Reconfiguration in an RSM, by definition, preserves any state across configurations. Messages not acknowledged as delivered before the reconfiguration begins must be resent as they may or may not have persisted. After reconfiguration completes, PICSOU simply resends messages for which it did not receive a quorum of acknowledgments in the prior configuration.

5 Weighted RSMs – Stake

The current description of the protocol assumes that replicas have equal weight in the system. When considering proof-of-stake systems like Algorand, each replica can instead hold differing amounts of *stake* or *shares* in the system. We write δ_{ij} for the share of R_{ij}; the total amount of stake in RSM $\mathcal{R}_i$ is then $\mathbf{\Delta_i} = \sum_{l=1}^{\mathbf{n}_i} \delta_{il}$. The RSM is safe as long as replicas totalling no more than $\mathbf{r}_i$ shares deviate from the protocol; the RSM is live as long as replicas totalling no more than $\mathbf{u}_i$ shares omit messages. The existence of stakes changes: (1) when a replica can establish a QUACK, and (2) to whom a particular message must be sent.

5.1 Weighted QUACK

It is straightforward to modify QUACKs to deal with stake. Each cumulative acknowledgment message simply becomes weighted. The acknowledgment message from replica R_{il} with share δ_{il} has a weight δ_{il} and a QUACK forms for message m when the total weight of the cumulative QUACK for m from RSM $\mathcal{R}_i$ is equal to $\mathbf{u}_i + 1$.

5.2 Sending a message

Identifying the appropriate sender-receiver pair for sending a message requires more care. Traditional BFT systems couple voting power, physical node and computation power. This is no longer the case with stake: different nodes can have arbitrarily different stakes. This problem is compounded by the fact that stake is unbounded and often in the billions [40]. A single physical node can effectively carry both arbitrarily large or arbitrarily small stake.

We want to ensure that we maintain the same correctness and performance guarantees as in non-staked systems. Unfortunately, the round-robin approach we described in §4.1 no longer works well. Consider for instance a system with $\mathbf{n}_i = 1000$ total stake, spread over two machines. R_{i1} is Byzantine and has $\delta_1 = \mathbf{u}_i = 333$, while R_{i2} has $\delta_2 = 667$. Using round-robin across these replicas disproportionately favors R_{i1} which represents only 33.3% of the shares in the system, yet is tasked with sending/receiving half the total messages. We must thus skew choosing sender-receiver pairs towards nodes with higher stake. To highlight the challenges involved, we first sketch two strawmen designs:

- *Version 1: Skewed Round-Robin.* The most straightforward approach is to have replica R_{il} with stake δ_{il} use round-robin scheduling to send δ_{il} messages on its turn. This is, eventually, completely fair since all nodes send precisely as many messages as they have stake in the system. Unfortunately, this solution suffers from very poor performance under failure as it has *no parallelism*: if stake is in the order of billions in the system, a single faulty node may fail to send large contiguous portions of the message stream, triggering long message delivery delays. Rounding stake is unfortunately not an option: as stake is unbounded, each physical node can, in effect, have infinitely small (or arbitrarily large) stake in the system. One physical node can have $\delta_l = 1$ while another has $\delta_l = 1 \times 10^9$. Rounding errors weaken liveness as more retransmissions may be needed to identify a correct sender-receiver pair.
- *Version 2: Lottery Scheduling.* For our next attempt, we consider lottery scheduling, a probabilistic scheduling algorithm [89]. Each node is allocated a number of tickets according to its stake; the scheduler then draws two random tickets to

choose the next sender and the next receiver. Lottery scheduling addresses the parallelism concern mentioned above. Over long periods of time, the protocol is completely fair, and each sender-receiver sends/receives according to its stake. Unfortunately, due to the randomized nature of the protocol, over short periods of time, the proportion of sender and receiver pairs chosen may skew significantly from their shares in the system.

Dynamic Sharewise Scheduler. Our solution must (1) offer good parallelism; trustworthy replicas should be able to send messages in a bounded unit of time, (2) ensure fairness over both short and long periods; each node should send messages proportional to its shares, and (3) tolerate arbitrary stake values. These properties are exactly those that the Linux Completely Fair Scheduler (CFS) seeks to enforce. CFS defines a configurable time quantum during which each process is guaranteed to be scheduled; each process then gets CPU time proportional to its priority.

Our *dynamic sharewise scheduler* (DSS) adopts a similar strategy with one key modification. As stake is unbounded, DSS cannot guarantee as easily as CFS that all nodes will send a message within a fixed time period t. Instead, DSS maximizes the following objective: given a fixed time period t, how can PICSOU schedule sender-receiver pairs such that each node sends/receive messages *proportionally* to its shares. While this may appear straightforward, the ability for nodes to have arbitrarily large (or small) stake makes reasoning about proportionality challenging. DSS turns to the mathematics of *apportionment* to handle this issue [19, 81]. Note that PICSOU uses DSS to identify both senders and receivers in the same way. For simplicity, we thus discuss apportionment from the perspective of senders only.

Apportionment is used to fairly divide a finite resource between parties with different entitlements or weights[2]. Formally, an apportionment method M defines a multivalued function $M(\vec{t},q)$. Here, $\vec{t}$ represents the entitlement of node R_{il}, that is the amount of messages that it should send or receive. In our case, this corresponds to its stake $\vec{t}_{il} = \delta_{il}$. q denotes the total number of messages that can be sent in the specified time quantum t. DSS makes use of Hamilton's method of apportionment [19, 81], which proceeds in four steps:

- First, DSS finds the standard divisor (SD_i), the ratio of the total amount of stake over the number of messages in a quantum, $SD_i = \frac{\Delta_i}{q}$. Intuitively, this defines how much stake must "back" each message.
- Next, DSS computes the standard quota (SQ_{il}) for each node R_{il}, $SQ_{il} = \frac{\delta_{il}}{SD_i}$, which indicates how many messages each replica should send. As this number may not be a whole number, DSS also computes the matching *lower quota* (LQ_{il}), which takes the floor of the standard quota. The difference between the standard quota and the lower quota is called the penalty ratio PR_{il}.

[2]It is, for instance, used to assign the number of seats per state in the US House of Representatives.

DSS	Stake	q	δ_0	δ_1	δ_2	δ_3	c_0	c_1	c_2	c_3
d_1	100	100	25	25	25	25	25	25	25	25
d_2	1000	100	250	250	250	250	25	25	25	25
d_3	1000	100	214	262	262	262	22	26	26	26
d_4	100	10	97	1	1	1	10	0	0	0

Figure 5: Apportionment Example. c_0,...c_3 refers to the number of messages that must be sent (or received) by each node per quanta

- DSS adds up these lower quotas to find the number of messages that will be sent $q_{whole} = \sum_l^{\mathbf{n}_i} LQ_{il}$, without worrying about any unfairness introduced by rounding.
- If $q_{whole} < q$, that is if there is still space to send additional messages, DSS decides to increment the allocation of each R_{il}, in decreasing order of penalty ratio PR_{il}.

Worked Example. Intuitively, the algorithm described above splits messages fairly across nodes while minimizing the degree of imbalance introduced by the need to round stake up or down. Consider for instance the stake distribution and message quanta in Figure 5. The first two scenarios are straightforward as each replica has equal amounts of stake. In both settings, running Hamilton methods, with a SD of 1 in d_1 and of 10 in d_2 reveals that each node should send 25 messages. d_3 highlights where apportionment shines. In this example, stake is not distributed equally among replicas. The SD is 10 as before. Replicas obtain LQs respectively of 21 for R_{i0} ($PR_{i0} = 0.4$) and 26 for the other three replicas ($PR_{i1} = PR_{i2} = PR_{i3} = 0.2$). The sum of all LQ yields only 99. As such, there is one message left to assign after considering the "easily partitionable" work. R_{i0} has the highest PR and is thus furthest away from a fair assignment. Hence, we increase its message assignment by 1, from 21 to 22.

5.3 Retransmissions

Two issues remain to ensure eventual delivery with stake: (1) the process of apportionment may select so few senders and receivers ($q < \mathbf{u}_s + \mathbf{u}_r + 1$) that reliable delivery is not guaranteed. (2) if the total stake across both RSMs is large, then all safe $q > \mathbf{u}_s + \mathbf{u}_r + 1$ may be too large to achieve parallelism. For example, if the total stake of RSM $\mathcal{R}_s$ is $\mathbf{\Delta}_s = 4$ and RSM $\mathcal{R}_r$ is $\mathbf{\Delta}_r = 4,000,000$ then $q > \mathbf{u}_s + \mathbf{u}_r + 1 = 1{,}333{,}335$ which is an unrealistic number of messages to generate in a time quantum.

The core issue present is that for reliable delivery, every message m_k, across all resends, must be sent and received by nodes whose stake, together, exceeds $\mathbf{u}_s + \mathbf{u}_r + 1$. This couples the number of resends needed to the (effectively unbounded) amount of stake in a network, and forces us to use increasingly large time quanta. Consider two networks with identical large stake values. If $\mathcal{R}_s$ and $\mathcal{R}_r$ both have $\mathbf{\Delta}_s = \mathbf{\Delta}_r = 4,000,000$, with each node having $1,000,000$ stake, each message send would pair replicas with 1,000,000 stake and we would reach $\mathbf{u}_s + \mathbf{u}_r + 1 = 2,666,667$ stake after 3 message sends even without apportionment. This contrasts with our original example ($\mathbf{\Delta}_s = 4$,$\mathbf{\Delta}_r = 4{,}000{,}000$). Each replica in $\mathcal{R}_s$ and $\mathcal{R}_r$ is equally trusted, but we require

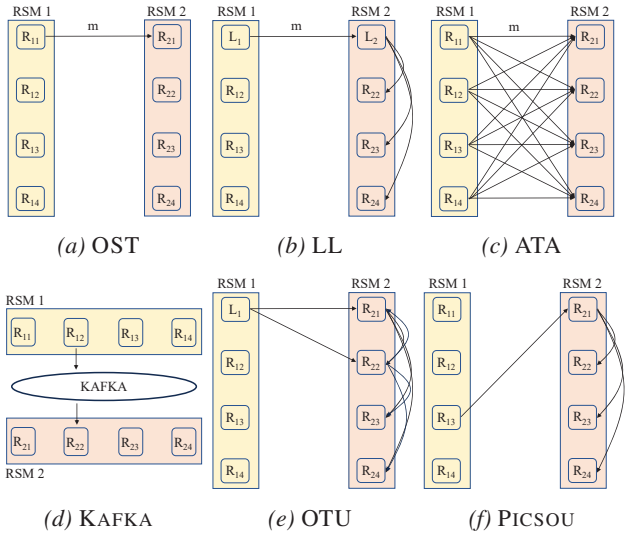

Figure 6: C3B *baseline summary.*

$\mathbf{u}_s + \mathbf{u}_r + 1 = 1{,}333{,}335$ resends solely because the *relative* value of stake in the two RSMs has changed.

Thankfully, this is not fundamental. To sidestep this issue, PICSOU proportionally scales up the weights of the two communicating RSMs to their Least Common Multiple (*LCM*), and handles failures with the scaled stake values independent of apportionment. For instance, assume that the total stake of RSM $\mathcal{R}_s$ is $\mathbf{\Delta}_s$, RSM $\mathcal{R}_r$ is $\mathbf{\Delta}_r$ and the $LCM = \text{lcm}(\mathbf{\Delta}_s, \mathbf{\Delta}_r)$. PICSOU scales the two RSMs as follows:

1. Compute the multiplicative factor ψ for each RSM: $\psi_s = \frac{LCM}{\mathbf{\Delta}_s}$ and $\psi_r = \frac{LCM}{\mathbf{\Delta}_r}$.
2. Multiply the stake of each replica with the multiplicative factor of its RSM.

Scaling up RSMs is only necessary during message failures, allowing to keep message quanta small in the common-case. A replica thus uses the scaled up RSM weights upon receiving its first duplicate quack for a message m.

6 Evaluation

PICSOU aims to offer good performance in the common-case, while remaining robust to faults when failures do arise. We aim to answer the following three questions.

1. How does PICSOU perform in the common case (§6.1)?
2. How does PICSOU remain robust to failures (§6.2)?
3. How does PICSOU perform in real applications (§6.3)?

Implementation We implemented PICSOU in $\approx$ 4500 lines of C++20 code with Google Protobuf v3.10.0 for serialization and NNG v1.5.2 for networking [2]. PICSOU is designed to be a plug-and-play library that can be easily integrated with existing RSMs. We evaluate PICSOU against five other comparable protocols (Figure 6).

1. **One-Shot (OST)**: In OST, a message is sent by a single sender to a single receiver. OST is *only* meant as a performance upper-bound. It does not satisfy C3B as message delivery cannot be guaranteed.
2. **All-To-All (ATA)**: In ATA, every replica in the sending RSM sends all messages to all receiving replicas ($O(\mathbf{n}_s \times \mathbf{n}_r)$ message complexity). Every correct receiver is guaranteed to eventually receive the message.
3. **Leader-To-Leader (LL)**: The leader of the sending RSM sends a message to the leader of the receiving RSM, who then internally broadcasts the message. This protocol does not guarantee eventual delivery when leaders are faulty.
4. **KAFKA**: Apache KAFKA is the de-facto industry-standard for exchanging data between services [56]. Producers write data to a Kafka cluster, while consumers read data from it. Kafka, internally, uses Raft [69] to reliably disseminate messages to consumers. We use Kafka 2.13-3.7.0.
5. **OTU**: GeoBFT [42, 44] breaks down an RSM into a set of sub-RSMs. Much like LL, GeoBFT's cross-RSM communication protocol, OTU, has the leader of the sender RSM send its messages to at least $\mathbf{u}_r + 1$ receiver RSM replicas. Each receiver then internally broadcast these messages. When the leader is faulty, replicas timeout and request a resend. OTU thus guarantees eventual delivery after at most $\mathbf{u}_s + 1$ resends in the worst-case (for $O(\mathbf{u}_r * \mathbf{u}_s)$ total messages).

RSMs. We consider four representative RSMs.

1. **File**: An in-memory file from which a replica can generate committed messages infinitely fast. This is a baseline to artificially saturate the C3B protocols.
2. **Raft [37]**: A widely used CFT RSM, used in services like Kubernetes Cluster. We run Etcd's Raft version v3.0.
3. **ResilientDB [45]**: A high performance implementation of *PBFT* [28], a well-known representative BFT protocol.
4. **Algorand [40]**: A popular PoS blockchain protocol [40].

Experimental Setup. We deploy up to 45 GCP c2-standard-8 nodes (Intel Cascade Lake, 8vCPU, 32 GiB RAM, 15 GBits/s). Each experiment runs for 180 seconds (30 second warmup/cool down). All experiments run PICSOU with a ϕ-list of 200k and 256 bits for 0.1kB and 1MB messages, respectively (best results for our specific network setup). We further assume that RSMs forward all messages to the other RSM, as this represents a worst-case scenario for PICSOU. As is standard [43, 68, 78, 84, 97], unless stated otherwise, replicated operations in our experiments are no-ops , which ensures that the bottleneck is not execution.

Metrics. RSM *throughput* is the number of consensus invocations completed at an RSM per second; C3B *throughput* is the number of completed C3B invocations per second. When baselines, like OST, do not acknowledge received messages, we calculate C3B throughput as the number of unique messages sent from sender RSM to receiver RSM.

6.1 File RSM Common Case Performance

Our first set of experiments aim to stress test the six C3B protocols (PICSOU, OST, ATA, LL, OTU, and Kafka) *without* failures. We use the "infinitely fast" File RSM to saturate

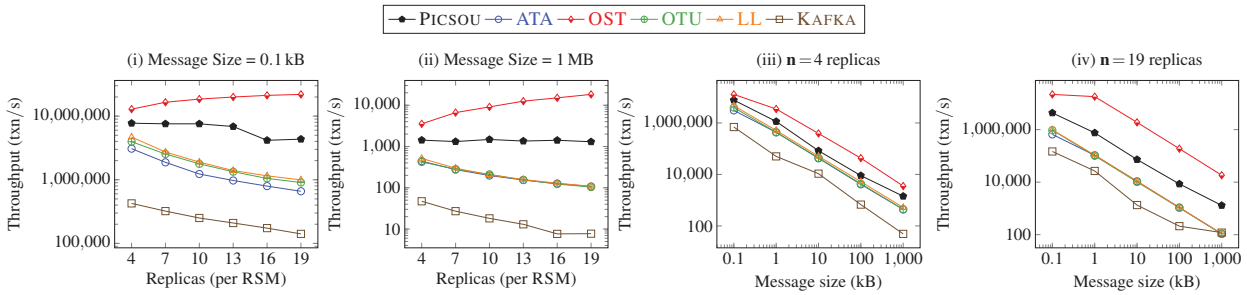

Figure 7: Throughput of C3B *protocols as a function of network size and message size*

all C3B implementations. In all cases, we include the OST line as the upper-bound of our networking implementation.

Varying number of replicas in each RSM. We first consider the relative performance of PICSOU as a function of the network size. We fix the message size to 0.1 kB and 1 MB and increase the number of replicas in each RSM from 4 to 19 (Figure 7 (i)-(ii)). For small network sizes, PICSOU outperforms ATA by a factor of 2.5× (small messages) and 3.2× (large messages) and in larger networks it increases to 6.6× and 12.1×. PICSOU sends only a linear number of messages, while ATA must send a quadratic number of messages. Like PICSOU, LL and OTU send a linear number of messages, but quickly bottleneck at the leader since it needs to send every message. OST's performance, as expected, increases with network size as increasing the number of replicas increases the number of parallel messages. Kafka performs significantly worse in all cases, as it internally runs consensus.

Varying Message Size. In Figure 7 (iii)-(iv), we fix the size of each RSM to $n=4$ (small) and $n=19$ replicas (large) and increase the message size from 0.1 kB to 1 MB. As expected, the performance of each C3B implementation drops as a linear function of the message size. Note that PICSOU performs relatively better than other protocols for large message sizes as they hide the moderate compute overheads introduced by the system. For instance, on a large network PICSOU performs over 12× better than ATA, LL, and OTU for large messages. Instead, for small messages, PICSOU only performs 6.6×, 4.4×, and 4.9× better (respectively).

Impact of Stake Next, in Figure 8 (i), we study how well PICSOU performs for weighted RSMs when stake distribution becomes unequal. We fix the message size to 100 B.

Consider 1) two RSMs where the throughput is *throttled* and one replica in each RSM gets increasingly more stake; 2) two RSMs where throughput is not throttled, but one replica still gets a larger share of stake over time. Our aim is to demonstrate that PICSOU does not lose any performance under unequal stake distributions.

We run two experiments. First, we artificially throttle the File RSM such that PICSOU cannot transmit over 1M txns/s, regardless of the stake distribution (flat 1M lines on the graph). Next, we allow each node to have access to an unmodified File RSM. In these experiments PICSOU i refers to the setting where the high-stake node has $i\times$ more stake

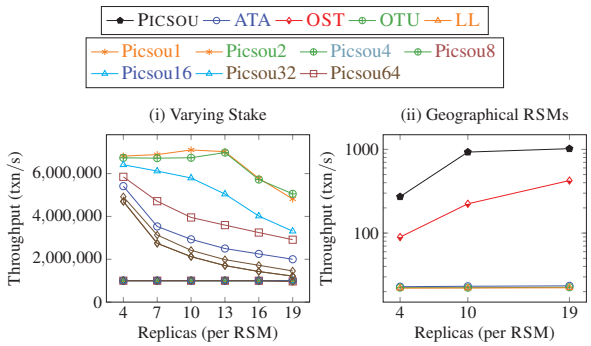

Figure 8: Impact of Stake and Geo-replication.

than other nodes. Initially, shifting the stake distribution to one node does not affect performance as the high stake node can handle the additional load. Eventually, however, this node becomes a bottleneck, thus causing throughput to decrease.

Geo-replication In Figure 8(ii), we run geo-replicated experiments by deploying one RSM in US-West and the other RSM in Hong Kong (cross-region bandwidth, pair-wise is 170 Mbits/sec, RTT 133 ms). We fix the message size to 1 MB and vary RSM size from 4 to 19. The lower bandwidth across pairs of machines disproportionally affects ATA, LL, and OTU. PICSOU outperforms ATA, by 12× (for network size 4) and 44×, (for network size 19). Somewhat counter-intuitively, the performance of both PICSOU and OST increase as a function of network size; increasing the number of receivers gives senders access to more bandwidth in Google Cloud. PICSOU intentionally has its senders send to multiple receivers and thus (artificially) outperforms OST, which fixes unique sender-receiver pairs.

6.2 Impact of failures

We now consider performance under failures.

Crash Failures. In this experiment, we crash 33% of the replicas in each RSM (Figure 9 (i)); message size set to 1 MB and ϕ-list size as 256. PICSOU's performance drops by a factor of 22.8% − 30.5%. This is expected: PICSOU, by default, fully maxes out links with "useful" information. Removing a third of the links thus removes a third of the available bandwidth. Nonetheless, PICSOU continues to outperform ATA, OTU, and LL by at least 2× on small networks, and up to 8.9× on larger networks.

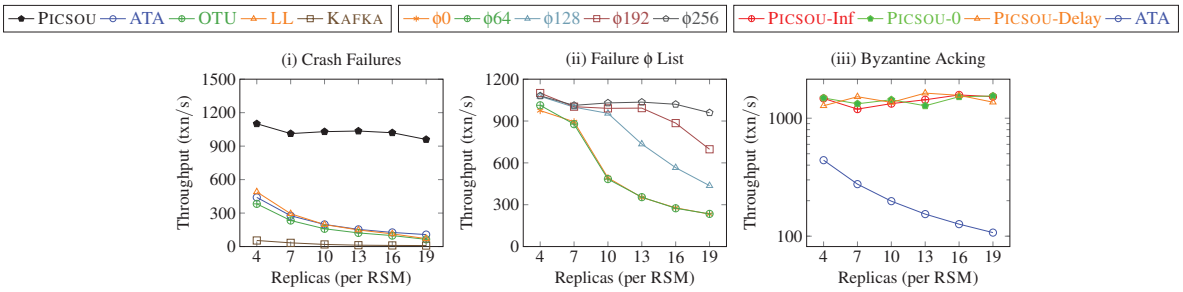

Figure 9: Effects of Failures on PICSOU.

Byzantine Failures. Next, we consider the impact of Byzantine failures in the system. While it is impossible to model all arbitrary failures, we consider four main classes of attacks. Malicious nodes can (1) send invalid, uncommitted messages, (2) collude to drop long sequences of messages $\mathbf{u}_s + \mathbf{u}_r$ times, (3) selectively drop messages, and (4) send incorrect acknowledgments. The first attack amounts to a DDOS attack (as correct replicas will discard invalid messages) and is thus out of scope. PICSOU defends against the second attack by assigning node IDs using a verified source of randomness (the probability that all byzantine nodes get assigned contiguous node IDs is negligible). We focus on the last two scenarios.

1. **Impact of ϕ-list scaling on Byzantine failures.** ϕ-lists bound the possible performance drop from malicious nodes selectively dropping messages. We again assume 33% of replicas are faulty in both RSMs (Figure 9 (ii)), this time Byzantine. We consider a message size of 1 MB. Our results illustrate that the larger ϕ-list size helps PICSOU quickly recover from Byzantine failures, despite the larger ϕ-list increasing metadata sizes. We observe that a ϕ-list size of 256 is optimal for recovering from the 33% Byzantine attacks. As the network gets larger, the time it takes to complete a full broadcast gets longer, which increases the latency to confirm a delivery. Thus, more messages can be dropped before we can detect that they are dropped, hence the larger ϕ-list.
2. **Sending incorrect acks.** Malicious nodes can choose to lie in their acknowledgments. We simulate this behavior in Figure 9 (iii) by having malicious nodes send acks for overly high sequence numbers (Picsou-Inf), overly low ones (Picsou-0) or offset by ϕ (Picsou-Delay). We find that this behavior is much less harmful than simply crashing. Correct nodes wait for a quorum of $\mathbf{u}_r + 1$ matching acks in order to consider the message delivered, and thus already assume that $\mathbf{u}$ of those acks will be lies. Lying about an ack thus only temporarily delays the formation of a quorum.

6.3 Application Case Study

We now study impact on real-world applications (Section 1).

Disaster Recovery. Disaster recovery (DR) ensures continued fault-tolerance in the presence of full datacenter outages, and is a popular feature of modern cloud environments [14, 16, 33, 41]. DR deployments often implement cross-datacenter RSM mirroring over Kafka, where the Kafka cluster is located in the receiving datacenter. We run Etcd DR [33] by deploying two Etcd RSMs in two distinct datacenters, one in GCP region us-west-4 and the other in us-east-5. Communication is unidirectional for DR, since only a single sending RSM is sending data to the mirrored RSM and the mirrored RSM does not have any information to send back (other than acks).

Etcd DR invokes PICSOU on all *put* transactions and assigns them a new, sequential, internal sequence number. This new sequence number is necessary as DR only applies to a subset of Etcd transactions (just puts, not gets or reconfiguration). The receiving RSM thus simply applies all put transactions in sequence number order.

In Figure 10 (i), we plot the throughput of Etcd DR (in MB/s) with various C3B protocols for different message sizes; each RSM has 5 replicas. OST achieves maximum theoretical throughput for an Etcd cluster running a C3B protocol; ETCD is the baseline for maximum throughput from a single Etcd RSM without any communication; one can only transmit messages as fast as Etcd commits them. There are two primary resource bottlenecks in the system: the cross-region network bandwidth and Etcd's disk goodput (since it synchronously writes each transaction it commits to disk). ATA broadcasts every message to all machines, so its throughput is bottlenecked by the cross-region network bandwidth (50 MB/s). Similarly, OTU and LL are bottlenecked because they limit the number of nodes sending unique messages over the network in parallel. In contrast, PICSOU shards the set of messages across all sending nodes, so each node uses 50 MB/s bandwidth to send $1/5$-th of the messages (5 nodes per RSM). Thus, PICSOU has an effective 250 MB/s of bandwidth available, resulting in saturating Raft's disk goodput of 70 MB/s. In case of KAFKA, we can only deploy 3 nodes, at most 3 shards, so it can achieve at most 150 MB/s. KAFKA can still can achieve potentially the same goodput as PICSOU. However, in our testing, KAFKA was still unable to achieve optimal performance given its sensitivity to high network latency.

Data Sharing and Reconciliation As described in §1 (Figure 10(ii)), there are operational and sovereignty concerns associated with managing a single RSM across trust domains. We implement the data reconciliation application described in [75]. In this setup, two distinct entities, Agency A and Agency B, run their own Etcd RSM but exchange data to ensure that any shared state remains consistent. Specifically,

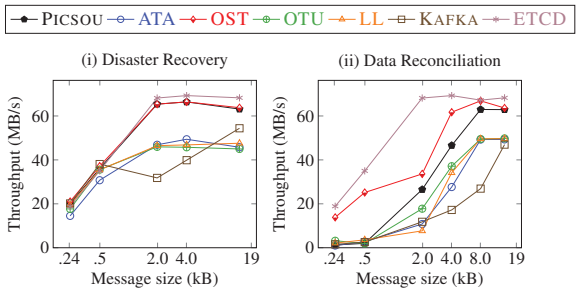

Figure 10: Disaster Recovery and Data Reconciliation.

each RSM sends *key-value updates* for shared data. The receiver then checks whether the values match and takes remedial action if not. Communication between RSMs is bidirectional. ATA, LL, OTU, and PICSOU all behave similarly to the performance discussed in the disaster recovery experiment, albeit with a lower starting goodput since there is extra processing time needed for looking up keys and comparing their values. KAFKA had unusually low performance since we were running into a known issue with high latency KAFKA consumers which are not addressed in these result. We are in the process of addressing this.

Decentralized Finance. Our final application implements a blockchain bridge, designed to foster interoperability between chains [29], for instance for asset transfer. We implement an asset transfer application across three types of wallets: (1) two POS Algorand chains, (2) two traditional permissioned PBFT ResilientDB [44, 45] chains, and (3) interoperability between ResilientDB to Algorand chains. Algorand's base throughput with another Algorand instance is 120 blocks/second. ResilientDB's base throughput when communicating with another ResilientDB cluster is ≈6000 batches/second (of size 5kB). The cross-chain throughput when Algorand sends to ResilientDB is 135 blocks/second. PICSOU has minimal impact on the throughput of any of the RSMs, with less than 15% decrease in throughput in the worst case. This decrease in throughput is independent of node stake. Latency will instead increase proportionally to network size – this property is fundamental to PICSOU's high throughput, but may be unacceptable in some large scale blockchain or RSM deployments. (2) PICSOU successfully handles throughput differences between RSMs; the slow Algorand RSM efficiently communicates with the much faster ResilientDB RSM.

7 Related Work

The problem of reliably sending messages within groups of participants through *reliable broadcast* or *group communication* is well-studied [22, 24, 26, 39, 47, 48, 62, 76], in both the CFT and BFT setting [4, 5, 23, 24, 26, 86]. These works consider communication among groups but do not consider communication between groups. PICSOU leverages the internal guarantees provided by these communication primitives to build a group-to-group communication primitive, C3B.

Logging Systems. Shared logs are a popular way for reliably exchanging messages [18, 27, 36, 52, 53, 56, 61, 88, 91]. Systems such as Kafka [56], RedPanda [73], Delos [17] have become industry standards [17]. While these systems work well in the CFT setting, they are not directly applicable to the BFT setting: this log becomes a central point of attack. Moreover, most of these systems use relatively heavyweight fault tolerance: Kafka, for instance, internally makes use of Raft.

Communication between RSMs. Two lines of work have considered communication between RSMs, but in different contexts. First, Aegean [6] makes a similar observation as this paper: it highlights that replicated services rarely operate in a vacuum and must instead frequently communicate. However, Aegan solves a strictly orthogonal problem. It focuses on how to correctly replicate services that can issue nested requests to other (possibly replicated) services. Aegean presents the design of a shim layer that exists between replicated service and backend service and manages all the communication/data storage. Second, Byzantine fault tolerant communication between RSMs has been a topic of interest in the context of *sharded* BFT systems that view each shard as an independent RSM. These shards periodically need to communicate with each other to process cross-shard transactions [9, 35, 42, 58, 71, 74, 78, 98, 100]. Most of these systems simply adopt the all-to-all communication pattern between the shards that we evaluate in §6. GeoBFT [44] and Steward [8] are two exceptions. Steward uses a hierarchical consensus architecture; all communication between the clusters is managed by a designated primary cluster, which internally replicates requests via Paxos. GeoBFT uses OTU.

Blockchain bridges. With the rise of blockchain technology and cryptocurrencies [11, 12, 13, 46, 54, 60, 64, 65, 77, 85] there is a new found interest in blockchain interoperability [20, 29, 30, 49, 55, 90, 92, 99]. These works focus on the *correct* conversion of assets from one blockchain to the other. They can be broadly clustered into two groups (1) *blockchain bridges*, and (2) *trusted operators*. A blockchain bridge requires a replica of the sending RSM to send a committed contract to a replica of the receiving RSM. Recently, several such blockchain bridges have popped up [15, 72, 82]. Unfortunately, they provide few formal guarantees, which has led to massive financial attacks and hacks [92, 96, 99]. Moreover, these bridges continue to be impractical because of their high cost [96]. Trusted operator systems are, in contrast, much more practical [57, 90, 95], but as the name suggests, they require centralized management. Works like Thema [63] instead use BFT RSMs to communicate between two non-replicated services.

8 Conclusion

This paper introduces the C3B primitive and proposes PICSOU, an efficient implementation of C3B. We show that, by borrowing techniques from TCP and adapting these to the crash and BFT context, we can develop a solution that allows RSMs to efficiently exchange messages.

Abstract

RDMA-enabled memory disaggregation has emerged as an attractive approach to reducing memory costs in modern data centers. While RDMA enables efficient remote read/write operations, it presents challenges in remote memory (de)allocation. Consequently, existing systems adopt coarse-grained allocations (in GBs), leading to memory waste.

We introduce FineMem, an RDMA-connected remote memory management system that enables high-performance, fine-grained memory allocation. FineMem addresses latency and scalability challenges related to fine-grained allocations. It removes RDMA memory region (MR) registration costs from allocation paths through per-compute node MR pre-registration, while ensuring remote memory isolation using RDMA memory windows and a trusted allocation service on each compute node. It employs a lock-free, one-sided RDMA-based protocol to allocate memory chunks (e.g., 4KB, 2MB) without involving the memory node's CPU and maintains metadata consistency during compute node failures via logging. We show that FineMem reduces remote memory allocation latency by as much as 95% compared to state-of-the-art remote memory management systems. It enables memory malloc systems, key-value stores systems, and swap systems running on FineMem to achieve low memory waste with minimal overhead.

1 Introduction

The growing need for hyperscalers to reduce memory costs [18, 38, 43] has made memory disaggregation an attractive architectural approach in system design. Unlike traditional architectures that tightly couple memory with compute resources – often leading to memory underutilization [38], disaggregated memory (DM) decouples memory (memory nodes) from compute (compute nodes), and enables dynamic allocation of memory across multiple compute nodes. Over the past decade, memory disaggregation has emerged as a pivotal area of systems research [8, 22, 34, 38, 61, 62, 64, 73].

Advancements in high-speed interconnect technologies, particularly Remote Direct Memory Access (RDMA) [51], have made it feasible to implement DM systems effectively. RDMA, facilitated by RDMA-capable network interfaces (RNICs [26, 46]), allows compute nodes to perform direct memory read/write operations on remote memory nodes using one-sided operations, bypassing the memory node's CPU entirely. Minimizing CPU involvement on memory nodes is critical for achieving low latency and high throughput, especially given their limited processing power [41, 58, 65, 73].

Despite RDMA's strengths in data access, it presents significant challenges in efficient memory allocation and deallocation. Allocating memory from a memory node involves several operations: the OS in memory node needs to pre-fault physical memory pages using mmap(), registers and copies page table entries to the memory transaction table (MTT) in the RNIC, and generates on-device memory management units with capabilities, named memory regions (MRs [4]) with rkey [53]. These operations are notably time-consuming and must run on memory node CPUs — for instance, registering a 4MB memory region can take more than 480 µs.

To work around RDMA's inefficiencies in memory (de)allocation, existing disaggregated memory applications/systems (e.g., memory malloc systems [15, 59, 70], key-value store systems [41, 58, 73], and swap systems [3, 22, 48]) resort to coarse allocation strategies, often grabbing chunks of 1GB or more at a time. While this approach amortizes the overhead of allocations, it comes at a steep cost. Large memory chunks lead to significant memory underutilization because unused portions of these coarse-grained chunks cannot be reclaimed or shared safely across multiple DM systems in the disaggregated memory pool. This leaves RDMA-based DM systems facing a difficult dilemma: either suffer from crippling allocation overheads or tolerate memory waste.

In this paper, we introduce FineMem, a fine-grained remote memory management system. It delivers fine-grained memory allocation and deallocation (e.g., 4KB, 2MB, ...)

*Yongkun Li is the corresponding author.

with minimal memory waste and high performance, employing one-sided RDMA. FineMem supports flexible allocation granularities across diverse DM systems within a shared disaggregated memory pool. By using one-sided RDMA, FineMem bypasses the memory node's CPU during allocations, ensuring that it does not suffer from a scalability bottleneck [41, 58, 65, 73]. FineMem tackles three key challenges: 1) removing MR registration latency from the DM system's allocation path, 2) enabling efficient and highly concurrent allocations of free remote memory chunks, and 3) ensuring metadata consistency when facing compute node failures.

To remove MR registration overheads during allocation, FineMem builds upon a strawman approach while addressing critical isolation challenges. The strawman method pre-registers the entire remote memory space as a single MR when a memory node boots. When a DM system starts on the compute node, the memory node shares the MR rkey with the system, allowing it to allocate or access chunks from the pre-registered MR. While this strawman approach removes MR registration overhead from systems, it introduces significant isolation issues. A DM application/system can potentially access any remote memory belonging to other applications/systems. Additionally, coordinating (de)allocation across DM systems requires sharing the memory management metadata region (which contains information on free/used memory chunks), allowing any DM system to read/modify this metadata. This lack of protection poses significant security risks to the entire memory pool.

FineMem first uses the memory window (MW [14]) feature in RDMA to ensure memory access isolation across DM systems. The memory node pre-binds a MW to each chunk with a specific rkey. When (de)allocating fine-grained chunks, FineMem uses one-sided operations to acquire/invalidate rkeys, thus removing bind-related RPC at the allocation critical path. Secondly, FineMem employs compute node allocation services to protect remote memory management metadata (e.g., index, redo-log, and rkey). DM Systems use inter-process communication (IPC) to interact with the allocation service for (de)allocation, and only the allocation service holds the rkey necessary to read or modify the metadata region.

To enable efficient, highly concurrent allocations of remote memory chunks across compute nodes, FineMem employs a carefully designed two-layer bitmap tree to accelerate allocation. It effectively limits the number of RDMA round-trips to locate a free chunk. Additionally, FineMem embeds contention control information into the bitmap, thereby avoiding further contention and reducing the number of retries for allocation's RDMA Compare-and-Swap (CAS) update, which results in more predictable latency.

Finally, to ensure metadata crash consistency in the event of compute node failures, FineMem executes allocation in two steps: 1) a commit point to confirm allocation success, combined with temporary redo-log information, and 2) flushing logs and updating related bitmap while detecting inconsistencies using timestamps and commit point metadata. This mechanism ensures metadata consistency for the search index and redo-log, thereby enabling reliable failure recovery.

We have implemented FineMem on Linux and demonstrate its portability across various systems, including memory malloc systems (such as jemalloc [19], mimalloc [36]), key-value store systems [41, 58, 73], and kernel swap systems [2, 3, 22, 64]. Based on mimalloc [36], we built FineMem-User, a user-space DM object malloc system that uses FineMem's DM allocation APIs. We also ported a popular swap system, FastSwap [3], and a DM-native key-value store [58] to integrate with FineMem (Sec. 5). Our evaluations show that FineMem reduces the latency for remote memory allocation by up to 95% compared to state-of-the-art designs. For memory systems, FineMem improves memory utilization by 2.25× to 2.8× compared to coarse-grained memory management, while introducing minimal overheads of only 2.5%-4.1%.

In the rest of this paper, we demonstrate existing memory management designs for DM and their limitations (Sec. 2); discuss FineMem's design (Sec. 3, 4, 5); characterize FineMem's performance through allocator benchmarks and end-to-end applications on memory systems (Sec. 6); discuss the limitations and potential extensions of FineMem (Sec. 7); review related work (Sec. 8); and conclude (Sec. 9). The implementation of FineMem is available at https://github.com/ADSLMemoryDisaggregation/FineMem.

2 Background and Motivation

2.1 Remote Memory Management and RDMA

Memory disaggregation introduces a remote memory pool shared by compute nodes. In this work, we focus on RDMA-connected DM, where compute nodes access shared memory nodes via RDMA primitives.

RDMA supports two communication patterns: Remote Procedure Call (RPC) using send/receive operations, and direct remote memory access through one-sided read/write operations that bypass the receiver cores. One-sided operations require external memory authorities on RDMA NICs. Before clients can perform one-sided operations, a memory region (MR) must be registered [4] with the RNIC. During registration, the driver pins the physical memory pages and maintains page mappings in an on-chip page table [15]. The registration process returns a region key (rkey) that allows clients to directly access the MR. Clients within the same Protected Domain (PD) and possessing the appropriate rkey can freely read/write the contents of the MR. Consequently, malicious clients possessing the correct rkey could launch attacks by modifying the MR contents. Similar to MR, the RDMA specification defines memory windows (MWs) as an external memory protection mechanism built on top of MRs, providing rkeys that grant fine-grained access capabilities to contiguous ranges of memory.

State-of-the-art DM usage typically relies on disaggregated memory systems, which can be categorized into two types: DM-transparent and DM-native systems. DM-transparent systems leverage the kernel's swap mechanism, enabling unmodified applications to run on a disaggregated memory pool, thereby transparently extending local memory [3, 10, 22, 23, 57, 64]. In contrast, DM-native systems introduce new programming models [15, 54, 59, 62, 70] (e.g., memory malloc systems that allow applications to operate on a memory pool through APIs for remote memory allocation and access) or algorithmic redesigns [41, 58, 73] (e.g., kv-store systems) to fully exploit the performance of DM. Recent researches [10, 23, 55] have also explored hybrid solutions that combine elements of both approaches. For instance, FDP-DC [55] supports both DM-transparent and DM-native applications/systems within a single memory pool. Consequently, DM pools now support a variety of DM applications and systems running concurrently, as discussed in [10, 15, 23, 55, 59, 62, 70]. To accommodate such diversity, the DM pool must support sharing among multiple types of DM applications/systems.

For all these DM systems, DM pools require memory managers to allocate and free memory based on runtime demands. Similar to memory management in single-node operating systems, DM systems interact with the DM memory manager to allocate and deallocate memory chunks (e.g., 4KB, 2MB). However, unlike memory management in single-node OSes, RDMA-based memory (de)allocation is expensive.

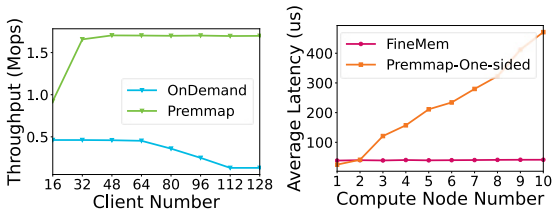
2.2 Remote Memory Allocation Challenges with RDMA

Memory allocation over RDMA differs from local memory allocation in two significant ways: the need for MR registration and the (unsurprising) fact that allocations occur over the network. In this section, we quantitatively evaluate how these two factors affect application performance.

Memory Region Registration is Costly. The overhead associated with RDMA MR registration is a well-documented problem [15, 24, 34, 45, 56, 62]. MR registration, which involves pinning physical memory pages and updating the RNIC's page tables, incurs significant overhead (e.g., a 4MB remote memory registration takes 480 µs).

In Fig. 1(a), we illustrate the impact of MR registration costs on end-to-end application performance using a DM kv-store system, FUSEE [58]. We compare on-demand MR registration for each 4KB chunk allocation with a baseline using a pre-registered large memory region (Premmap, no MR registration during runtime). In a YCSB-A workload with a 50:50 search-to-update ratio, the on-demand approach achieves only 26.7% of the throughput of Premmap (64 clients), highlighting that frequent MR registration during runtime is impractical for remote memory allocations.

Frequent Remote Allocations Over Network are Costly.



(a) MR registration impact to kv-store.

(b) Chunks allocation latency of one-sided approach.

Figure 1: Remote Memory Allocation Challenges with RDMA: (a) MR registration overheads. (b) Scalability issues in existing one-sided RDMA-based approach (due to metadata design).

Beyond MR registration, handling remote allocations presents challenges because the operations occur over the network, introducing additional latency and potential bottlenecks.

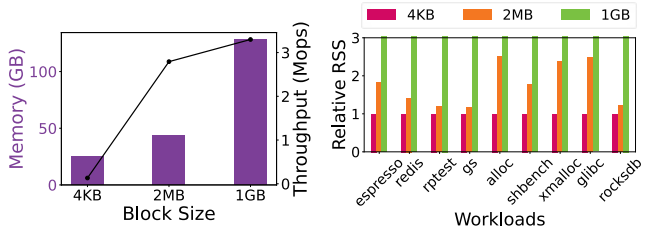
Systems that delegate memory allocation to memory nodes via RPC (e.g., FUSEE [58]) face scalability issues, as memory nodes often have limited processing power. Memory allocation involves traversing metadata, and frequent (de)allocations impose significant processing demands. Similar to prior works [41, 65, 73], we found that the RPC-based approach becomes bottlenecked by the memory node's compute power as more clients are added. For example, in Fig. 1(a), FUSEE's throughput (even with Premmap) plateaus after 32 clients. FUSEE OnDemand encounters additional scalability issues when the number of clients exceeds 64. This highlights the need for a one-sided RDMA-based allocation approach, as used by systems like CXL-SHM [70] and our proposed FineMem.

While avoiding bottlenecks at memory nodes, existing systems using one-sided access for allocations still experience unpredictable network round-trips due to their metadata designs. In Fig. 1(b), we evaluated a general allocation benchmark from ThreadTest [6], where multiple threads repeatedly allocate and free chunks from the memory node. To isolate the effects of MR registration costs, we pre-registered sufficient memory. As shown, the latency of existing one-sided approaches (e.g., Premmap-One-sided built on CXL-SHM [70]) deteriorates significantly as the number of clients (32 threads each) increases. This degradation is caused by a high number of one-sided RDMA Compare-and-Swap (CAS) retries over the network for each allocation, which occur when there are many concurrent allocations (details in Sec. 3.1).

In summary, remote memory allocation and deallocation over RDMA face both the MR registration cost challenge and scalability issues due to network overheads and the limited processing power of memory nodes.

2.3 The Allocation Overhead vs. Memory Waste Dilemma in Existing Works

Due to the challenges with MR registration and other operations, existing systems either rely on statically pre-mmapped



(a) Trade-off on block sizes, using OnDemand DM allocation.

(b) Applications' Resident Set Size (RSS) using mimalloc with huegpages.

Figure 2: Dilemma in KV-Store and General Workloads: (a) Kv-store reaches better performance with memory wastes. (b) Memory fragmentation with hugepage granularities (1GB's RSS is collapsed to no more than 3).

regions [27, 54, 54, 58, 70, 73] or allocate memory from the remote memory pool at a coarse granularity (e.g., GBs) [2, 3, 8, 15, 22, 48, 59, 64, 68]. However, these approaches can introduce significant memory waste. Next, we characterize the tradeoff between allocation overhead and memory waste using kv-store and general workloads.

KV-Store. Using the YCSB-A workload with all key-value pairs reside in remote memory, we evaluated FUSEE's performance and remote memory usage on different block sizes (4KB, 2MB, and 1GB), as shown in Fig. 2(a). In FUSEE, updates are performed out-of-place, triggering memory allocation and deallocation, as well as memory fragmentation.

The results demonstrate a clear tradeoff between allocation overhead and memory waste. For instance, 2MB allocation granularity significantly reduces memory fragmentation (hence memory usage) compared to 1GB, which is a key optimization employed by FUSEE. However, even with FUSEE's optimizations, reducing the granularity from 1GB to 2MB results in a nearly 17% drop in kv-store throughput. This performance decline is attributed to the increased frequency of allocations, each incurring significant overhead and impacting end-to-end performance. Similarly, 4KB allocation granularity further reduces memory fragmentation but exacerbates the tradeoff due to even higher allocation overhead.

General Workloads. Fragmentation caused by different allocation granularities is a well-studied issue for general workloads, too. For instance, numerous single-node memory allocator studies have shown that larger page sizes (e.g., 2MB or 1GB) typically result in higher memory fragmentation and waste [36, 47, 52, 59, 60, 72].

In Fig. 2 (b), we used mimalloc to evaluate several benchmarks and applications, illustrating this behavior. The results show that fine-grained allocations (e.g., 2MB) significantly reduce memory fragmentation compared to larger granularities like 1GB. For specific workloads, such as shbench, extremely fine-grained allocations like 4KB are particularly effective in minimizing memory waste.

Summary. Existing RDMA-based DM systems face a tough choice: either endure significant allocation overheads or accept substantial memory waste.

In this paper, we tackle the question: Can fine-grained memory allocation be achieved with minimal overheads? Successfully addressing this challenge would reduce memory waste in disaggregated memory pools, leading to lower memory costs in modern data centers. It would also allow systems under high load to run more tasks concurrently, thereby improving overall throughput, as we will demonstrate in swap system evaluations (Sec. 6.3). Additionally, fine-grained memory allocation simplifies porting emerging applications to disaggregated memory setups. For instance, applications' local memory allocators (e.g., jemalloc, tcmalloc) could seamlessly integrate into disaggregated memory systems by replacing local mmap() calls (typically allocating memory in KB/MB units) with remote memory allocations (Sec. 6.3).

Finally, we focus on scenarios where a growing class of DM systems share a common pool of remote memory [55], as discussed in Sec. 2.1. These systems span a variety of applications, such as key-value stores (e.g., FUSEE [58]), indexing services (e.g., SMART [41]), AI inference workloads (e.g., Mooncake [49]), memory malloc systems with modified applications (e.g., CXL-SHM [70]), and swap systems with unmodified applications (e.g., Fastswap [3]). This diversity creates significant challenges in maintaining proper isolation across heterogeneous systems, particularly when third-party frameworks are involved. Additionally, conducting exhaustive tests across all possible system combinations to prevent erroneous memory access is impractical. Therefore, our approach also aims to provide low-level, fine-grained memory management that ensures coordination and isolation among DM applications/systems.

Some DM memory management works have explored on-chip authorization mechanisms for fine-grained memory allocation. For example, MIND [34] offloads memory management to on-path programmable switches [7] and introduces a VMA-based capability model for different processes. In contrast, our goal is to develop a flexible, software-based memory management solution.

3 FineMem Overview

3.1 Design Elements

FineMem is a distributed remote memory management system designed to support fine-grained, high-performance memory (de)allocation in RDMA-connected DM. Its design is driven by three key elements: 1) removing MR registration latency from the allocation path; 2) enabling efficient, scalable remote memory chunk allocation; and 3) ensuring metadata consistency during compute node failures.

Removing MR Registration While Overcoming Critical Isolation Challenges. A straightforward approach to mitigate the overhead of MR registration is to pre-register the entire remote memory as a single accessible MR for

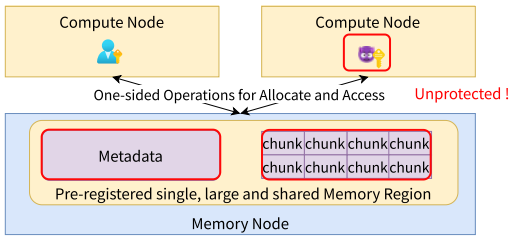


Figure 3: Isolation/Protection Challenges without MR: attacker can easily access other users' chunk and metadata.

each compute node. In this configuration, each DM system on a compute node can (de)allocate fine-grained memory chunks (subsections of the MR) by directly modifying shared allocation metadata (e.g., which chunks are free or allocated). This approach eliminates the need for runtime MR registration.

However, unsurprisingly, sharing a single MR introduces significant isolation challenges. Since the MR is associated with a single rkey, any system holding this rkey can access the entire MR, as shown in Fig. 3. This means that any entity can potentially read/write to any other user's memory chunks, leading to *privacy and security risks among systems*. Additionally, *the metadata used for memory allocation is unprotected*; each system must modify it to allocate memory, and malicious or faulty systems could corrupt or interfere with the metadata, affecting other systems.

FineMem addresses the privacy challenges by using the hardware feature of RDMA—Memory Windows (MWs) [14]. Memory windows (MWs) allow for the rapid generation and invalidation of fine-grained rkeys at a rate of one MW per microsecond. The memory node pre-binds a MW to each chunk with a specific rkey and asynchronously regenerates a new rkey with a background thread. When (de)allocating fine-grained chunks, FineMem uses one-sided operations to acquire and invalidate rkeys, thus removing MW-bind-related RPCs from the critical allocation path. This approach provides isolation between systems, as each system can only access the MWs for which it holds the corresponding rkeys. Unlike previous work that binds MWs at runtime with RPC in a single application, such as Patronus [68], FineMem focuses on one-sided MW usage for isolating multiple DM systems.

To protect the memory allocation metadata from misuse, FineMem introduces a per-compute-node runtime service (inspired by software virtualization techniques [16, 30]). This trusted service delegates remote memory allocation requests on behalf of processes, ensuring that the memory metadata is protected from DM systems' direct access.

Enabling Efficient, Highly Scalable Free Remote Chunk Allocation. As discussed in Sec. 2.2, FineMem uses one-sided RDMA access for remote allocations to prevent the memory node CPUs from becoming bottlenecks. However, this one-sided approach requires a carefully designed metadata structure to minimize network round-trips when allocating chunks.

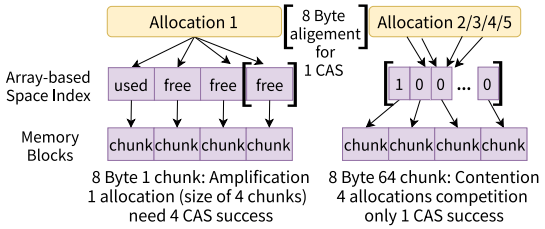

Figure 4: One-sided RDMA Based Chunk Allocation Challenge. Left: a simple chunk array may result in network amplification. Right: using bitmaps, retry time arises when multiple processes contend for the same 8B bitmap entry.

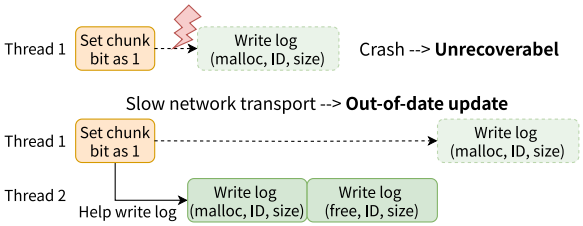

Figure 5: Two Examples of Crash Inconsistency: log lost during crash failure, and outdated update in a fail-slow failure.

Linked lists with pointer-chasing overhead. Traditional memory allocators, such as Mimalloc, XMalloc, and SFMalloc, often rely on linked-list-based free lists. However, pointer chasing—traversing pointers to locate memory blocks—introduces significant overhead when applied to remote memory, a well-known issue highlighted by prior works [41, 65, 73]. To avoid this, disaggregated memory systems often adopt array-based metadata structures, which, however, present their own challenges.

Array-based structures with search overhead. To give an example, managing free chunks using an uncompacted free-chunk array—such as in CXL-SHM [70], shown in Fig. 4 (left)—may require checking every chunk in the address space, with each check involving a round trip. This results in unpredictable and inefficient allocation times, particularly for large allocations that span multiple chunks. Alternatively, compact bitmaps (e.g., representing 64 chunks per 8 bytes) can reduce the number of round trips by enabling simultaneous search of more chunks. However, this approach still suffers from frequent Compare-and-Swap (CAS) retries, as multiple allocators may concurrently target the same 8-byte bitmap for allocation. In such cases, each allocator performs lock-free operations like CAS to allocate chunks. Yet, only one allocator can succeed, while the others must retry—each retry requiring an additional round trip (Fig. 4, right).

To address this, FineMem employs a two-layer bitmap tree structure, as shown in Fig. 7, combining the efficiency of compact bitmaps with an additional first layer to accelerate large size allocations and reduce retry attempts. Allocators read the first-layer bitmaps to allocate large memory sizes ($\geq$128KB, aligned to a power of 2) with a single CAS, or identify which *chunk groups* are empty, full, or experiencing contention (in-

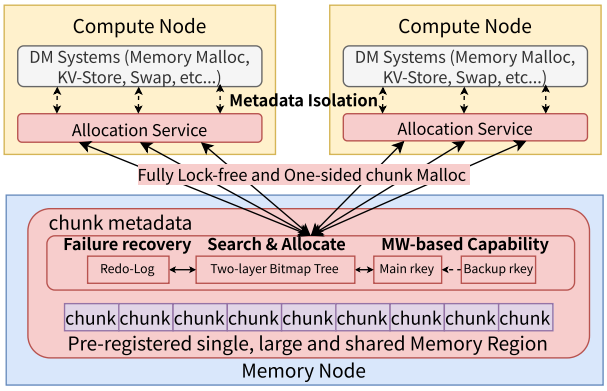

Figure 6: Remote Memory Management with FineMem.

dicating multiple concurrent allocation attempts) by a 2-bit-status in the first-layer bitmap. They then retrieve the second-layer bitmap for the selected chunk group—typically one that is neither full nor contended—to allocate small memory sizes (4KB - 64KB) with free chunks. If an allocator detects high contention on a bitmap, it can redirect its allocations to a less-contended group (Sec. 4.1).

Maintaining Metadata Consistency During Compute Node Failures. Similar to coarse-grained allocation systems, FineMem must track which memory chunks are allocated to which users to prevent memory leaks on compute node failures. To accomplish this, FineMem uses redo logging on memory nodes, written by compute nodes via one-sided RDMA, ensuring that allocations are correctly recorded. However, achieving crash consistency in a shared, bitmap-based allocation system poses unique challenges. A crash occurring before writing the redo-log can cause confusion between crash-induced and normal allocation bits. For example, as shown in Fig. 5, an inconsistency during a crash failure might cause a chunk to become unrecoverable (because it has just been marked as allocated in the bitmap but lost the detailed allocation information). Even in scenarios where other threads can assist the failed thread in writing the log, fail-slow failures can still occur, where the failed thread ultimately writes an outdated log that other threads have already written.

To address this, FineMem carefully integrates a compact temporary log into the limited 64-bit bitmap, allowing each allocation success to be temporarily logged. Each successful allocation is marked with the user's ID in the temporary log, ensuring that, in the event of a crash, the chunk can be distinguish between transient and committed states. Any thread can update (flush) this temporary log into a persistent, full log. FineMem defines a timestamp in the temporary log to prevent consistency issues due to outdated entries (Sec. 4.2). Additionally, FineMem resolves consistency issues between the two-layer bitmaps by checking both the status and temporary log consistency based on the second-layer bitmap, which acts as the commit point, ensuring the correctness of the allocation.

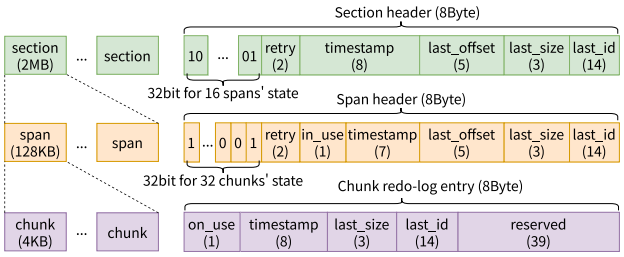

Figure 7: FineMem's Two-layer Bitmap Tree Structure with fine-grained allocation and contention control.

3.2 System Architecture

As shown in Fig. 6, FineMem integrates components from both memory nodes and compute nodes.

On the memory node, FineMem builds on core data structures that track available memory, support scalable allocations (the two-layer bitmap), manage capabilities (the MW-based capability table), and log allocations (the temporary log and full log). On the compute node, FineMem runs an allocation service on each node. It pre-mmaps the entire remote memory pool at boot time, and handles (de)allocation requests from DM systems for remote memory chunks. Once a DM system allocates a remote memory chunk, it can use the chunk for swap pages, fine-grained objects, key-value pairs, etc.

FineMem provides simple APIs, including malloc(size) and free(addr). When a DM system invokes these APIs, per-core allocation service worker threads are woken up to handle the protected remote allocations. Upon completion, the allocation service worker thread returns a DM address with an rkey to the caller. FineMem can be ported to systems like memory malloc systems [36, 63], kernel swap systems [3], key-value stores [58], etc. FineMem supports flexible allocation granularities, starting from 4KB, and ensures memory is aligned to 4KB. Systems sharing the same FineMem-managed DM pool can use different allocation granularities (4KB blocks with number of power of 2).

4 FineMem Design

In this section, we detail FineMem's design for its metadata structures for concurrent, scalable allocation, logging for crash consistency, and per-compute node allocation service.

4.1 Two-Layer Bitmaps For Concurrent, Scalable Chunk Allocation

FineMem addresses two primary remote chunk allocation challenges: 1) minimizing network round-trips during chunk searches, and 2) reducing allocation retries due to contention.

1) Two-Layer Bitmap Tree for Efficient Chunk Allocation. FineMem uses a bitmap-based free chunk index and manages the remote memory address space in two layers: sections and spans. As shown in Fig. 7, FineMem maintains

bitmaps (and metadata) for both layers. It uses a 64-bit header for each of these metadata items to align with the RDMA Compare-and-Swap (CAS) operation's work size requirement [5].

A section consists of 16 contiguous spans, with each span representing 128KB. The 32-bit bitmap for each section tracks fullness and contention (i.e., the level of concurrent allocations) of its spans, based on the most recent span allocation's CAS retry times and bitmap status, and using two bits per span to indicate its status. Span statuses 00 and 11 represent where the span is entirely free or full. Span statuses 01 and 10 represent "in-use" states, where the span is partially allocated as smaller chunks. Furthermore, 01 indicates that the span is in normal use, while 10 denotes that the span is contended.

Each span comprises 32 contiguous chunks, and a 32-bit free map to track the allocation status of these chunks. In addition to a 32-bit free map of section/span headers, FineMem reserves the remaining 32 bits for contention control and logging. FineMem uses 2 bits to track the retry count relative to two thresholds (low and high), enabling contention detection. The span header also includes an 1-bit in_use flag, which indicates whether a span is partially used or completely freed. The rest bits for logging will be discussed later.

For different allocation sizes, FineMem accesses search metadata in (up to) three steps. It first searches the section headers to identify available spans. If the requested allocation size exceeds 128KB, FineMem directly modifies the set spans to 11 using a single CAS operation. Next, it reads the span header, marks the bits corresponding to the free chunks, and updates the span header with another CAS operation. Deallocation follows a similar process with one CAS to update the related bitmap. Allocations larger than one section require multiple CAS operations to modify contiguous sections.

To optimize performance, FineMem caches section and span metadata on each compute node to reduce access latency, and batches multiple bitmap reads to amortize round-trip costs. Specifically, FineMem employs a metadata cache on each compute node, storing information for up to 64 sections and spans (a total of 512 bytes). This caching mechanism accelerates allocation requests by minimizing the need for repeated remote metadata access. When a CAS operation fails, the cache is updated accordingly. Furthermore, when cached bitmaps are exhausted or high contention is detected, the system proactively fetches new metadata blocks.

2) Contention Control to Reduce Retries. FineMem implements a simple yet effective back-pressure policy to limit contention across allocations. Each allocation header tracks the number of consecutive allocation failures. If the failure count exceeds the higher threshold (e.g., 10), the section/span is marked as contended in the header's retry bits (and also section header bitmap's span states).

Contention is detected by the allocations themselves. After a successful allocation, if the allocation process finds that the CAS failure count exceeds the threshold, it marks the section/span as 'contended (10)' to signal contention. The process will then select non-contended sections/spans, in the priority of normal (01) > empty (00) > contended (10), for future allocations.

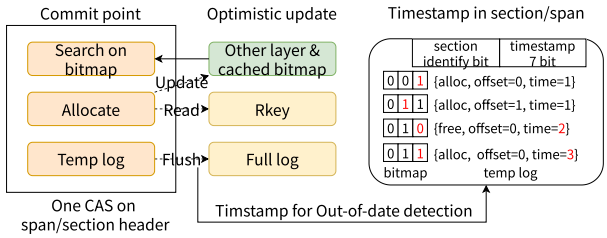

Figure 8: FineMem's Crash Consistency Design.

If a process using a contended (10) section/span detects that the failure count drops below the lower threshold (e.g., 3), it resets the status to normal (01).

In addition to the bitmap tree, FineMem maintains a per-chunk capability table and a per-chunk redo-log. Both are 8-bit aligned items in preserved linear arrays. One chunk's redo-log records information about its last allocation/free, including the allocation ID and timestamp, to facilitate recovery in case of compute node failures. The capability table stores per-chunk RDMA rkeys for access isolation.

4.2 Compute-Node-Failure Crash Consistency

FineMem implements a lock-free crash consistency mechanism by marking the CAS success to the bitmap as the commit point, complemented by a temporary log to ensure correct crash recovery. After the commit point, the system optimistically flushes the temporary log to a persistent full log with timestamp validation, and updates the other layer bitmaps, all while avoiding CAS retries and additional consistency checks to minimize overhead in maintaining consistency (Fig. 8).

1) A Compacted Commit Point. FineMem defines the commit point as the moment when an allocation successfully updates the allocation status of spans/chunks in the bitmaps (from free to used, or vice versa) through a CAS operation. This commit point, along with a temporary redo-log and timestamp, is compacted into a single CAS operation on the 64-bit section/span header.

Given the limited space available in the 64-bit section/span header, FineMem splits the redo-log into two parts: a temporary redo-log stored inline with the header's CAS requests, and a full redo-log. The temporary redo-log contains minimal information about the most recent (de)allocation of any chunks within the span/section. Specifically, it includes the last allocated chunk offset (5 bits, which allows determining whether the last request was a malloc or free by checking the bitmap), size (3 bits, sufficient given the power-of-2 size alignment), timestamp (7 bits), and user ID (14 bits).

To manage the sequence of allocations and detect out-of-date log flushing, FineMem includes a timestamp in the redo log. With a 7-bit timestamp, the value overflows after reach-

ing 127. As a result, FineMem can only determine the relative ordering of two log entries within a window of 64 timestamp updates, which corresponds to approximately 1 ms, assuming a 20 µs allocation interval. To support longer out-of-date detection, FineMem slows down the timestamp increment process. Since different chunks update their own redo-log entries, back-to-back allocations within a single section/span can share the same timestamp. Thus, FineMem's timestamp only increments when the previous operation was an allocation and the current operation is a deallocation (or vice versa), as shown in Fig .8.

2) Metadata Inconsistency Detection and Recovery. After a successful commit point, the allocation thread—or any other thread attempting to access the same section or span—is required to flush its temporary redo-log into the chunk's full redo-log before proceeding with the next operation. The system compares the timestamp of the temporary redo-log with that of the full log: if the temporary log is newer, it is flushed; otherwise, it is discarded. If the thread detects that the temporary and full logs belong to different layers (i.e., span vs. section), it further verifies the span's in_use bit to determine the most recent state and avoid acting on stale metadata.

FineMem employs lightweight, optimistic one-sided RDMA writes—instead of relying on CAS success—to update the section header's bitmap following a span commit point. During allocation, a process retrieves span headers as the commit points and checks for inconsistencies between the span and section layers. In particular, the span header's in_use bit can be used to correct an inaccurate section-layer bitmap, ensuring metadata consistency across layers.

FineMem leverages the consistency of its redo-log to enable non-blocking crash recovery for rebuilding memory allocation status. The recovery process starts by scanning the section and span metadata to flush the temporary redo-log. It then reclaims allocated chunks from the crashed node by scanning the full redo-log and regenerates rkeys for the freed chunks. To detect crashes, FineMem employs a user-space monitor on the memory node, which sends heartbeat signals every second to check the availability of each compute node.

To summarize, FineMem is designed to handle allocation/deallocation in a way that ensures crash consistency, using lock-free, one-sided RDMA verbs.

4.3 Allocation Service For Isolation/Protection

FineMem leverages memory window-based capabilities to isolate memory accesses and utilizes a per-compute node service layer to protect allocation metadata. FineMem tackles three key challenges: 1) eliminating CPU involvement on the memory node during memory window binding for allocations, 2) enabling efficient communication between user systems and the allocation service layer on the compute node, and 3) ensuring robust enforcement of isolation and protection mechanisms, even in adversarial conditions.

Table 1: MW and MR Registration Overhead Comparison.

Average Latency per 4MB (µs)	MW	MR
1*100GB Generation	1.33	456.1
25K*4MB Generation	1.34	485.5
25K*4MB Invalidation	1.33	21.9
25K*4MB Regeneration	2.37	46.5

1) Memory Node Component for Chunk Protection. FineMem utilizes Memory Windows (MWs) [14, 53] in RDMA for generating and regenerating rkeys. Unlike Memory Region (MR) registration, which incurs high latency during rkey creation and consumes significant on-chip resources [62], MWs operate on pre-registered MRs, focusing solely on access control through rkey generation. We found this approach to be resource-efficient. In our evaluation using a ConnectX-6 RDMA NICs, MWs support up to 16 million entries (64GB for 4KB chunks), and generating a MW rkey for a 4MB chunk takes only 1 microsecond—compared to hundreds of microseconds for MR registration, as shown in Table 1. FineMem overcomes the single-NIC 64GB limitation by generating multiple virtual functions (up to 128 VFs on a single ConnectX-6 NIC), with each VF assigned 16M memory windows.

MWs are pre-generated for each chunk/span/section once the MR is initialized, with the corresponding rkeys (main rkeys) stored in the capability table. To reduce the overhead of rkey regeneration during deallocation, the memory node pre-generates backup rkeys for each chunk/span/section. A pair of main rkey and backup rkey requires only 8 bytes, enabling the deallocation process to use an one-sided CAS operation to replace the main rkey with the backup rkey as part of the critical-path regeneration. This design ensures there is no critical path dependency on the memory node CPUs. The memory node then asynchronously scans the capability table, invalidates old rkeys, and generates new ones.

2) Compute Node Service Layer for Metadata Protection. FineMem introduces an allocation service on compute nodes to manage privileged operations related to metadata. On compute nodes, only the pre-initialized service has the authority to (de)allocate remote memory. All (de)allocation requests are handled and executed by this service.

Like many software virtualization techniques, FineMem's service process faces the challenge of API interception performance costs. To address concurrency, FineMem assigns a worker thread to each CPU core, with synchronization handled via shared semaphores. Callers write allocation requests to shared memory, wake up the allocation worker thread, and then wait for the allocation to complete. In our evaluation, this inter-process communication (IPC) introduces an overhead of approximately 2-10 µs—a reasonable trade-off compared to the significantly higher latency (10× to 100×) of performing fine-grained memory allocation directly on the memory node.

3) Protection Against Subversion. Finally, FineMem is de-

signed to resist subversion attempts across two key areas: API protection and binary protection.

API Protection. The service API exposes strictly controlled interfaces: malloc and free. To defend against malicious API calls, malloc operations are limited by per-system allocation size quotas, and free operations verify rkey correctness to prevent unauthorized memory releases.

Binary Protection. The allocation service enforces external private key authorization, managed by DM pool administrators, to prevent service forgery. Consequently, memory nodes establish memory management connections only with trusted allocation services through this authorization. In multi-tenant environments (e.g., public clouds), where malicious tenants might attempt to compromise allocation service keys, FineMem can leverage additional security mechanisms provided by the cloud provider. For example, deploying the allocation service at the hypervisor layer (e.g., FreeFlow [30]) ensures it remains trusted and isolated from tenants.

5 Porting Systems to FineMem

We have integrated FineMem with three types of DM systems: a user space memory malloc system that can allocate/free objects from remote memory (FineMem-User), a DM-based distributed key-value store (FineMem-KV), and a DM swap system (FineMem-Swap). These systems use FineMem's malloc(size) and free(addr) functions to allocate/free remote memory (flexible sizes, starting from 4KB chunk).

1) FineMem-User. FineMem-User is a memory malloc system that allows applications to allocate objects (e.g., bytes) from remote memory. FineMem-User bases on mimalloc [36] but manages space in DM (using FineMem). For object-size allocations, FineMem-User handles them entirely on the compute node. On slow-path when there are no local reserved chunks, it requests/frees chunks from FineMem and subdivides them into smaller slabs, similar to how (local) allocators operate (like tcmalloc/jemalloc/mimalloc [19, 36, 60]).

2) FineMem-KV. Key-value systems are popular systems for DM, and their remote memory management can be replaced with FineMem's allocation system. We re-implemented the slow path of FUSEE's block allocation [58] using FineMem, while keeping other components unchanged. This modification required only 300 LOC. Furthermore, unlike FUSEE, which requires memory node block servers, FineMem-KV becomes a completely one-sided kv-store system.

3) FineMem-Swap. FineMem can also be used to optimize DM memory utilization in swap-based [3] systems. FineMem-Swap includes three major components: i) an allocator in the kernel that provides APIs for allocating/deallocating remote pages (*page manager*) based on FineMem's chunks; ii) a mapping between local swap offsets and DM memory addresses (*remapper*), enabling on-demand binding of remote pages to swap entries; and iii) FineMem allocation on the page's swap-out path and deallocation after swap entries invalidation.

6 Evaluation

We characterize FineMem performance and overheads, and evaluate how well DM systems running with FineMem compare to state-of-the-art designs. Specifically, we answer the following questions:

- **Allocation efficiency:** How does FineMem reduce memory allocation latency compared to existing designs? What are the overheads associated with providing memory isolation and crash recovery?
- **Application-level impact:** How do memory-malloc-based applications perform when using FineMem-User for critical-path object allocation? How does FineMem-User adapt to applications with varying allocation size distributions?
- **System-level integration:** What is the end-to-end performance of representative DM systems (e.g., key-value stores and swapping systems) when backed by FineMem? How well does FineMem support memory pool sharing across multiple DM systems?

6.1 Experiment Setup

Testbed. We use a Cloudlab [17] cluster with 16 compute nodes and 1 memory node, which is a reasonable setting in datacenter memory pool [38]. Both compute and memory nodes use Intel Xeon 8360Y CPUs, the Mellanox ConnectX-6 100Gb NIC, and have 256GB of memory. Applications run on compute nodes and can use up to 32 cores, while we limit memory nodes to only use a single core. On each node, we run Ubuntu 22.04 with 5.15 Linux kernel and the Mellanox OFED 5.8 RDMA driver.

Implementations and Baselines. We implemented FineMem in C++ (8.5k LOC). We also implemented a mimalloc-based user-space allocation library, the FineMem-User (1.5k LOC for adding DM fine-grained allocation) that uses FineMem DM allocator interfaces, and ported FastSwap [32] to use FineMem interfaces with the FineMem-Swap (0.7k LOC for adding new remapper and chunk manager components in the kernel module).

We compared FineMem to three state-of-the-art baselines: Premmap-One-sided (from CXL-SHM [70], search based on free array), Premmap-RPC (from FUSEE [58] and Patronus [68], search based on memory node side allocator memkind [9]), and OnDemand-RPC (fine-grained allocation with registration). For fair comparisons, we ported these approaches within the same artifact as FineMem. For both Premmap-One-sided and Premmap-RPC, we statically pre-mapped 200GB of memory to avoid runtime MR registration. To minimize on-chip resource consumption, FineMem uses a single MR with pre-mapped hugepages [15, 45].

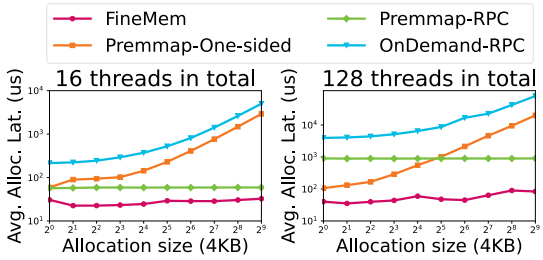

Figure 9: Allocation Performance vs. Varying Request Sizes.

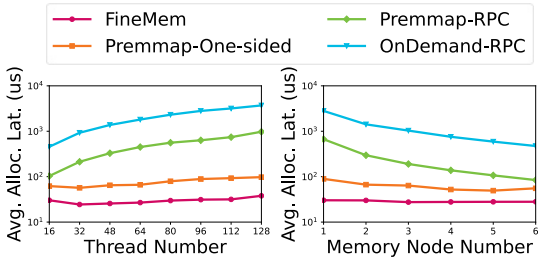

Figure 10: Allocation Performance vs. Varying Client Threads (left) and Varying Number of Memory Nodes (right). 4KB allocation granularity. Allocations distributed across multiple memory nodes using a round-robin approach.

6.2 Remote Allocation Performance

We characterize FineMem's remote allocation performance from three perspectives. First, we use allocation microbenchmarks to evaluate FineMem's performance across different allocation granularities and scalability. Second, we analyze FineMem's allocation latency, breaking it down into the various factors introduced by its design choices. Finally, we examine the memory-node-side CPU and memory overhead, as well as FineMem's crash recovery capabilities.

Microbenchmark. We utilize a Redis-based kv-store microbenchmark derived from the memory efficiency unit test in the Redis [50] test suite. This benchmark performs memory block allocations and deallocations ranging from 4KB to 2MB on remote memory. The workload initially allocates 64K blocks (totaling 256MB to 128GB) of memory, then randomly deallocates 50% and allocates another 50%, repeating this pattern. We run 500 iterations of this allocation microbench to achieve about 1 million allocations in total. Fig.9 and 10, along with Table 2, demonstrate FineMem's performance advantages over baseline approaches across various allocation granularities, levels of client parallelism, and memory node configurations. All benchmarks are executed ten times to obtain stable and converged performance results.

As shown in Fig. 10 (left), FineMem outperforms the RPC-based approaches (both OnDemand-RPC and Premmap-RPC), particularly under high client parallelism, where the RPC-based methods quickly become bottlenecked by the limited compute power of memory nodes. With a 4KB allocation granularity, we observe that the RPC-based remote allocation performance does not scale after 16 client threads. In contrast, FineMem maintains consistently low latency due to its one-sided RDMA design.

Table 2: Average/Max number of CAS retry statistics for allocation and average/P99 allocation latency. 4KB allocation granularity, 512 client threads in total.

Average / Tail	FineMem	Premmap-One-sided
Latency (µs)	43.215 / 79.347	763.01 / 16143.516
CAS Retry Times	1.333 / 142	45.108 / 20637

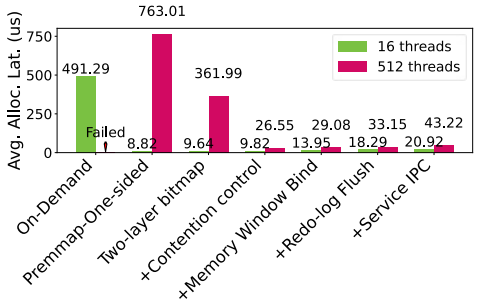

Figure 11: Factor Analysis.

FineMem outperforms existing one-sided approaches (Premmap-One-sided, without runtime MR registration) across varying allocation granularities and levels of client parallelism, as shown in Fig. 9 and 10. This performance advantage is attributed to FineMem's optimized metadata design and contention control mechanism, which significantly reduces the number of per-allocation RDMA CAS operations compared to the simple direct array design employed by existing one-sided approaches.

In the microbenchmark workloads with fragmented remote memory, the direct array metadata often requires multiple CAS operations to search for available chunks for a 4KB allocation. The performance gap becomes even more pronounced for large allocations (Fig. 9), where each chunk in a large request requires separate CAS operations.

As shown in Table 2, the Premmap-One-sided approach can require an average of 45 CAS operations per allocation, whereas FineMem requires no more than two CAS operations on average. In Fig. 11's 512-thread workload, we further drill-down the effects of FineMem's two-layer bitmap design and contention control mechanism. The two-layer bitmap reduces allocation latency by approximately 52.5% compared to the array-based approach, while the contention control mechanism contributes an additional 44% reduction by minimizing CAS retries caused by heavy contention. Combined, these two designs reduce allocation latency by approximately 95%, demonstrating the effectiveness of FineMem's design.

Factor Analysis. We evaluated the latency factors across different design components under both general cases (16-threads workload) and heavy workloads (512-threads workload), as shown in Fig. 11.

FineMem demonstrates stable latency across both general and heavy workloads. Although its chunk search mechanism involves two layers, the bitmaps are cached locally, resulting in only a slight increase in average latency compared to the

Premmap-One-sided method in 16-threads. The rkey capability introduces an additional RDMA read to retrieve the key, and the redo-log requires one RDMA CAS to flush, with each step adding approximately 5 µs. Additionally, the service layer contributes an additional 2-10 µs due to IPC overhead.

Overall, FineMem reduces allocation latency by approximately 95% compared to traditional registration-based fine-grained methods. The overhead introduced by isolation and redo-log management is minimal, accounting for only 2.5% of the registration cost.

Overhead of Pre-allocated Memory Pools. FineMem uses pre-allocated memory pools with fine-grained memory windows, which introduces initialization overhead and access latency through two primary factors. First, the pre-generation of memory windows incurs a non-trivial setup cost. Our measurements on ConnectX-5 devices indicate that creating each memory window takes approximately 166 µs. However, this overhead can be substantially reduced via parallelization: leveraging 8 threads lowers the per-window generation time to 32 µs. Second, access latency stems from on-chip cache resource contention [15, 31]. In a 32-thread experiment with randomized read to pre-generated windows (each window sequentially read in 64-byte increments), we observe that read latency increases modestly—from 4.11 µs to 4.14 µs—as the number of windows scales from 1K to 1M. Correspondingly, the impact on read/write throughput remains negligible. Importantly, recent industry efforts such as Husky [31] indicate that future hardware and software advancements have the potential to further reduce both memory window initialization overhead and contention-related access latency.

Overhead on Memory Nodes. FineMem runs two services on each memory node: the rkey regeneration thread and the recovery thread, co-running on a single core. The rkey regeneration thread scans every 100ms interval, spending 15ms for 100GB memory space (25 million 4KB chunks), and resulting in approximately 15% of one CPU usage. The regeneration speed is fast, as mentioned earlier, with 1 million memory windows regenerated per second. In our evaluation, with a backup rkey to hide the scan and regeneration time, the peak free latency remains below 1ms. The recovery detection thread wakes up every second, which has negligible overhead. Furthermore, FineMem stores external data structures at memory nodes, consuming up to 0.4% of memory (mainly caused by an 8B rkey and an 8B redo-log for each 4KB chunk), which amounts to about 400MB for every 100GB of memory.

Recovery Capability. We show FineMem's recovery ability in out-of-date detection, recovery speed, and recovery influence. 1) We ran the microbench at 1GB memory space (a narrow space with frequent malloc/free) and found that FineMem's timestamp overflow happens after about 50K memory allocation requests. As a result, updates delayed less than 1s (each allocation 20 µs) can be detected by FineMem's 7-bit timestamp, which is enough to co-work with normal RDMA timeout settings. 2) The recovery latency is highly related to memory window rebinding time, and the recovery speed is similar to memory window regeneration speed, about 1M allocation entries (chunk/span/section) per second. 3) The recovery process only has contention possibilities at span/section's bitmaps, and the influence is similar to an external thread's allocation competition, which can be handled by FineMem's concurrency design with minimal influence.

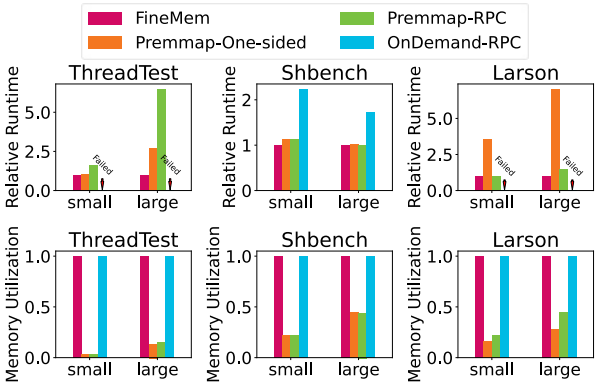

Figure 12: FineMem-User's Performance and Memory Utilization on Allocation Benchmarks.

In summary, even under heavy workloads, FineMem delivers scalable, low-latency, and predictable fine-grained memory allocation. This enables DM systems to achieve high memory utilization while maintaining strong performance.

6.3 System Case Studies

Memory Malloc System's Allocation Critical-Path. We first use the FineMem-User to demonstrate the end-to-end application performance improvement on the allocation critical path by running FineMem and other baselines with 2MB-chunk-based mimalloc on object-grained benchmarks.

1) ThreadTest [6] is a widely used allocator benchmark, creating a series of threads and repeatedly malloc/free objects. We set 256B as a small work-set (the median size of in-memory kv [69]) and 4KB (the basic OS page size) as a large work-set; 2) Shbench [44] is a stress test where some of the objects are freed in a usual LIFO order, but others are freed in reverse order. We set 8B-1KB as a small work-set, and 256B-4KB as a large work-set; 3) Larson [33] simulates a server workload using 100 separate threads which each allocates and frees objects but leaves some objects to be freed by other threads. Work-set the same as Shbench. We ran all benchmarks with 16 compute nodes, each node 32 threads.

The results, as shown in Fig. 12, highlight the performance and utilization trade-offs faced by state-of-the-art approaches:

Premmap memory waste. Premmap-One-sided and Premmap-RPC exhibit low memory utilization, even on the Shbench-large. We set 80GB memory for the premmap baselines, which is the peak memory usage of Shbench-large. Since their memory cannot be fully shared or utilized, the average memory utilization remains below 50%.

On-demand registration cost. OnDemand-RPC suffers from poor performance due to runtime memory registration. They cannot even finish some of the benchmarks (timeout).

Allocation performance issues over network. RPC baselines encounter a high concurrency bottleneck when running ThreadTest allocation benchmarks. Meanwhile, the one-sided baseline performs poorly on the Larson benchmark, where frequent thread creation and destruction in each iteration cause new threads with the Premmap-One-sided method to repeatedly start searches from the first chunk of the array.

FineMem can fully use the shared memory pool's free chunks, the same as fine-grained allocation with registration, improving memory utilization of state-of-the-art with static pre-mmap by 2.25× to 2.8×. And FineMem achieves the best performance by effectively fine-grained memory allocation in DM. It mitigates the scalability issues seen in RPC-based methods while providing fast and stable searches through its two-layer bitmap design.

Malloc System with Mixed Size Allocation Requests. To evaluate FineMem with applications that issue mixed-size allocations, we capture slow-path memory allocation system calls from various allocator and benchmark combinations.

We use the collected allocation system call sequences as requests to DM, preserving both the arrival time patterns and allocation size distributions. We selected four modern allocators: jemalloc [19], mimalloc [36], tcmalloc [60], and ptmalloc [20]. Benchmarks are chosen from the widely-used mimalloc-bench suite [13], including Shbench [44], Larson [33], Rptest [28], and Lean [1].

The size distributions of allocator and benchmark combinations, as shown in Fig. 13, vary significantly. Jemalloc and ptmalloc primarily use 4KB as the basic allocation size, tcmalloc primarily uses 2MB hugepages, and mimalloc has a median size of 64KB for small object allocation. These differences create diverse workloads with mixed allocation sizes for evaluation. To ensure trace randomness between nodes, we collect traces separately for each node and then execute them across 16 nodes, each running 8 threads.

As shown in Fig. 14, under high concurrency and mixed-size distribution, both one-sided and RPC methods experience high average latency. Besides the CPU bottleneck of RPC methods, Premmap-One-sided performs worse at jemalloc and ptmalloc. Because there are frequent 4KB chunk allocations competing with 2MB allocations, the Premmap-One-sided method finds it hard to locate an available 512 contiguous chunks in this fragmented chunk space.

In contrast, FineMem's two-layer bitmap design effectively mitigates competition between different allocation sizes and accelerates the search for power-of-2-aligned free space. It consistently maintains latency below 100 µs, with minimal impact on execution time, demonstrating FineMem's stability under high-concurrency, mixed-size allocation workloads.

Key-value System. We conducted a comparative performance analysis of FineMem-KV against different baselines

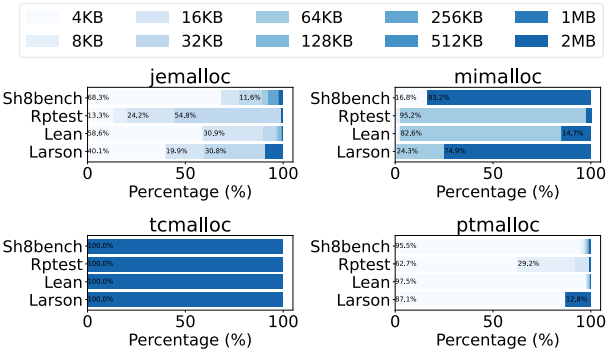

Figure 13: Mixed Size Allocation Traces' Distribution.

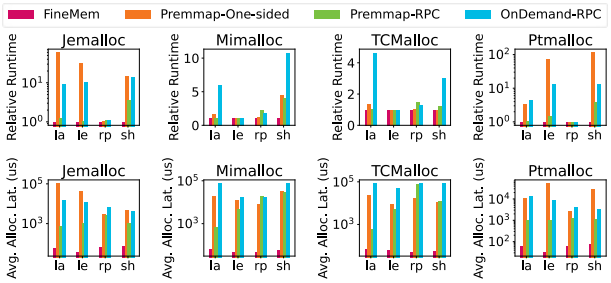

Figure 14: Performance on Mixed Size Allocation Traces.

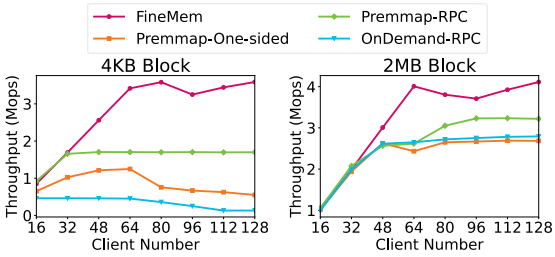

Figure 15: FineMem-KV's Throughput on YCSB-A Workload (search:update=50:50).

using standard YCSB workloads [12] (A, B, C, and D). During these tests, the client writes new key-value pairs to remote memory on each update, while allocating (or caching) multiple objects at once to reduce allocation frequency within the update transaction. For these experiments, we set the cache chunk size to 4KB (for memory efficiency) and 2MB (for better performance). Each key-value pair is 512 bytes in size.

As shown in Fig. 15, under the YCSB-A workload, which is update-intensive with approximately 50% update operations, FineMem-KV demonstrated a bandwidth improvement of around 27% to 110% over the best case of Premmap-RPC. However, in the read-intensive workloads of YCSB-B, C, and D, the performance gains were less pronounced, so we do not present those results here. FineMem's optimizations are particularly effective in enhancing FUSEE's update operations, likely due to the nature of out-of-place updates, which involve allocating new subblocks followed by freeing the old ones.

With FineMem's low latency for fine-grained allocation, using smaller block sizes like 4KB becomes more attractive. It can achieve high bandwidth similar to 2MB blocks while also

Table 3: Exclusive Fragmentation in One Compute Node.

Time(s)	1000	2000	3000	4000
Local Free Space(GB)	0	0	0	0
DM Free space(GB)	2.14	16.9	18.84	18.84
Waiting List	Snappy(33.2GB) & Redis(31GB)			

reducing internal fragmentation, resulting in a 45% reduction in memory cost compared to the 2MB block setting, as shown in the motivation section Fig. 2(a). Moreover, when testing with larger block sizes, high allocation latency still negatively impacts throughput, as shown in Fig. 15 (right), highlighting the performance advantages of FineMem.

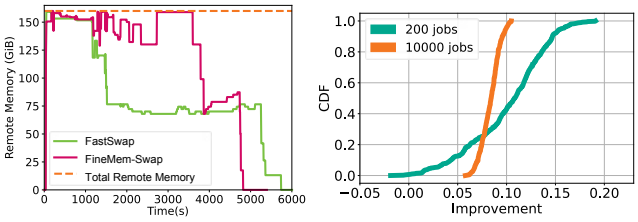
In summary, by optimizing out-of-place update operations, kv-store using FineMem resolves the dilemma between efficiency and overhead, achieving both high throughput and reduced fragmentation through fine-grained allocation.

Swap System. This evaluation focuses on comparing the memory efficiency of static pre-mapped swap systems (e.g., FastSwap) with the fine-grained dynamic swap system (FineMem-Swap). The swap systems were tested on a 7-machine testbed: 5 compute nodes with 80 GB of local memory and 2 memory nodes providing a total of 160 GB of shared DM. For FastSwap, each compute node had 32 GB exclusive memory on the DM.

Three widely deployed applications were selected for evaluation: XGBoost [11], a regularized gradient boosting framework; Snappy [21], a (de)compression library, used to compress enwiki articles [66]; and Redis [50], an in-memory database, subjected to YCSB [12] workloads. We inherited the DM-aware scheduler and simulator used by FastSwap.

We evaluated DM swap systems by placing 200 jobs with a workload ratio of XGBoost:Snappy:Redis=2:2:1 on the testbed. Compute nodes make best effort to use local memory and swap data to DM when local memory is insufficient. During system running, we collected placement data from FastSwap, and several representative states are shown in Table 3. After the 2000th second, this node had more than 50% free space in the reserved DM area, but the job queues were filled with Snappy and Redis jobs that could not be placed. As a result, FastSwap utilized only 41.39% of the total remote memory, as shown in Fig. 16 (a). In contrast, FineMem-Swap allows clients to share the DM with fine-grained allocation, resulting in an average memory utilization of 74.06%. This higher memory usage in FineMem-Swap led to a 17.71% improvement in job throughput.

To further investigate the throughput improvement in different workloads, we randomly generated 500 small workloads (each consisting of 200 jobs across 5 compute nodes sharing 160GB of DM) and 500 large workloads (each with 10,000 jobs across 40 compute nodes sharing 1280GB of DM), with varying application ratios. The CDF of FineMem-Swap's throughput improvement over FastSwap is shown in Fig. 16(b). FineMem-swap outperforms FastSwap in throughput across both small and large workloads, achieving an average throughput improvement of 8.38% to 10.69% . Therefore, FineMem improves job throughput by overcoming the static pre-mapped memory fragmentation.



(a) Remote Memory Usage. (b) Jobs Throughput Improvement

Figure 16: FineMem-Swap's Remote Memory Utilization and Job Throughput.

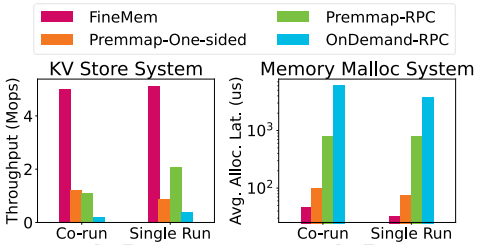


Figure 17: KV-Store System and Memory Malloc System Co-running vs. Single Running.

Overall, with support for fine-grained, on-demand allocation in the swap system, FineMem-Swap improves job throughput compared to static pre-mapped swap systems.

Memory Pool Sharing Across Systems. We conclude by evaluating the sharing of memory pools across multiple systems through a dual-workload experiment. In this setup, 8 compute nodes (16 threads each) run a kv-store system under YCSB-A workloads (in Sec. 6.3), while another 8 dedicated nodes (16 threads each) execute a memory malloc system with microbenchmarks (in Sec. 6.2) to simulate allocation-intensive scenarios and assess cross-system interference.

Fig. 17 illustrates FineMem's ability to maintain performance isolation in disaggregated memory systems. During co-execution, both kv-store throughput and allocation latency remain stable. In contrast, Premmap-RPC experiences a 46.8% reduction in bandwidth and an increase in allocation latency due to RPC core contention on memory nodes. OnDemand-RPC shows similar results with RPC contention. While Premmap-One-sided shows better tolerance for sharing, it still suffers a 75.5% reduction in bandwidth and 2.1× higher latency than FineMem, primarily due to its inherent address space search overhead. These results demonstrate that FineMem facilitates high-performance memory pool sharing in multi-system disaggregated memory environments.

7 Discussions and Limitations

While FineMem enables efficient fine-grained remote memory allocations, it does have certain limitations that we believe

are worth exploring in future work.

First, FineMem primarily focuses on scalability, isolation, and memory efficiency in DM management, along with support for compute node crash consistency. It does not address other critical issues such as cache coherence [34] or memory duplication across multiple memory nodes [35, 71]. Integrating FineMem with solutions to these aspects of DM memory management is a potential area for future research.

Secondly, FineMem pre-registers the entire remote memory, requiring DM systems to first communicate with a designated server process on the memory nodes to establish an RDMA connection. Moreover, FineMem did not optimize data-path access performance; therefore, its RDMA access performance represents a standard baseline without additional overhead or specialized optimizations.

Thirdly, FineMem focuses on RDMA-connected DM and leverages RDMA-specific mechanisms (e.g., RDMA memory windows) for isolation. FineMem's reliance on RDMA features can be technically mapped to emerging CXL-based DM. The CXL specification enables direct memory access through load/store instructions. As a fully one-sided allocator (Sec. 4.1), FineMem can seamlessly replace remote memory access with CXL memory access. Furthermore, CXL memory can be configured as globally shared memory and isolated between applications using memory protection keys (MPK), as demonstrated by Skyloft [29] and uProcess [39]. However, CXL memory presents differences in mechanisms, including memory caches [40, 70] and MPK bindings [29, 39]. Consequently, FineMem requires additional design efforts to be fully adapted to CXL, which will be addressed in future work.

Lastly, the allocation services in FineMem, which use IPC to intercept remote memory allocations, introduce overheads on the allocation path. While we believe that these overheads are justified by the security and isolation benefits provided, we are actively working on optimizing the IPC process. Future optimizations may include approaches such as kernel acceleration to further reduce these overheads.

8 Related Work

Transparent Disaggregation. To enable applications to use DM without modification, many studies leverage the swap mechanisms in kernel to utilize DM [3, 10, 22, 23, 57, 64]. For instance, Leap [2] improves the swap system's page prefetcher to better adapt to DM; Canvas [64] focuses on optimizing swap entry allocation. However, all these approaches use pre-registration strategies, leading to significant memory waste.

Native Disaggregation. Certain scenarios, such as memory malloc systems [15, 54, 59, 62, 70] and kv-store systems [41, 58, 73], allow programs to utilize DM through explicit APIs. However, many DM-native systems rely on RPC-based allocators [15, 54, 59], which do not perform well under high concurrency. Additionally, one-sided access solutions, such as CXL-SHM [70], don't provide isolation between applications.

Hybrid Usage of Transparent and Native Disaggregation. FDP-DC [55] envisions the development of a fully disaggregated and programmable data center, where applications of both transparent and native disaggregation abstractions coexist within a unified disaggregated memory pool. Furthermore, studies such as Mira [23] and Atlas [10] have explored hybrid DM data planes that combine the object-granularity of DM-native systems with the page-granularity of swap-based systems. FineMem operates under the premise that multiple applications and systems—spanning both transparent and native approaches—share a common DM memory pool.

Memory Allocator. User-space allocators [19, 25, 37, 42, 60] are widely used in software systems to enhance efficiency and performance in memory management. FineMem learns from their design philosophy and further considers the characteristics of DM architectures. LLFree [67] is a high-concurrency frame allocator in kernel, which also maintains a two-layer metadata but prioritizes exclusive entries. While FineMem adopts a sharable entry to optimize memory space efficiency.

Disaggregation Memory Isolation. For RDMA-based DM, MIND [34] uses a programmable switch, and Clio [24] uses a customized FPGA to replace the heavy MR-based isolation of RDMA NIC. To achieve both performance and easy promotion, FineMem chooses MW mechanism that comes with commercial RDMA NIC productions. Patronus [68] also uses MWs for memory protection within a single application, and it relies on RPC for memory allocation, which performed poorly in our evaluation.

9 Conclusion

We present FineMem, an efficient fine-grained remote memory management system using one-sided RDMA. FineMem removes memory region registration costs for disaggregated memory while ensuring isolation and protection through memory windows and per-compute node allocation services. FineMem features scalable and efficient metadata designs for remote chunk allocation and crash consistency mechanisms to handle compute node failures. FineMem reduces remote memory allocation latency by up to 95% compared to state-of-the-arts, enabling disaggregated memory systems to achieve low memory waste with minimal performance overhead.

Abstract

SR-IOV and I/O device passthrough enable network and storage devices to be shared among multiple tenants with high density using virtual functions (VFs), achieving near-native performance. However, passthrough does not support page faults, requiring the hypervisor to statically pin the VM-allocated memory. This approach is unacceptable for cloud service providers (CSPs) that rely on oversubscription to enhance memory utilization and reduce costs. The Page Request Interface (PRI) was designed to support device-side I/O page faults (IOPFs) through collaboration among devices, Input-Output Memory Management Units (IOMMU), and the OS. But PRI has not seen broad adoption in devices like NICs and storage.

We propose VIO, a novel dynamic I/O device passthrough approach that achieves near-native performance and is hardware-independent. By leveraging a shadow available queue, VIO can dynamically and transparently switch devices between VIO and passthrough modes based on I/O operations per second (IOPS) pressure, balancing resource utilization and performance. Each DMA request is probed via IOPA-snooping in the virtio data plane to eliminate IOPFs, while device interrupts are directly passed through to the VM guest, enabling performance close to passthrough. VIO is extensively tested and deployed by a leading global CSP across 300K VMs, supporting both legacy and new instances while reclaiming up to the equivalent of 30K VM memory daily without compromising user Service Level Objectives (SLOs). As the scale grows, the benefits continue to increase.

1 Introduction

Cloud workloads vary significantly, ranging from simple web hosting to resource-intensive applications like large language models, all of which require high-performance I/O for optimal operation. Device passthrough is commonly used in cloud environments to provide near bare-metal performance by allowing virtual machines (VMs) direct access to hardware. However, this approach has a major limitation: Direct Memory Access (DMA), which enables devices to transfer data directly to or from memory, can target any Guest Physical Address (GPA). If the address is swapped out or otherwise inaccessible, it results in an I/O page fault (IOPF). Since most devices cannot handle such faults, DMA failures may disrupt operations or even cause system crashes. To mitigate this issue, passthrough requires static pinning of the VM's virtual memory to physical memory, which precludes memory optimization techniques [31, 44, 46] like overcommitment [15] in multi-tenant cloud environments, leading to suboptimal memory utilization and resource wastage.

In 2009, PCI-SIG addressed this challenge by expanding the Address Translation Services (ATS) specification to in-

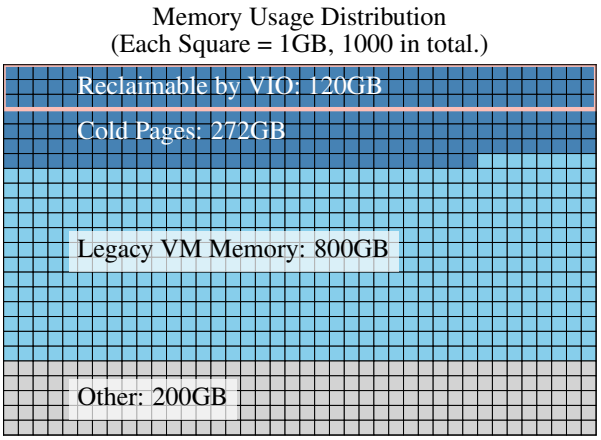

Figure 1: VMs Consumption. In a 300-node production environment, over 80% of long-running legacy (running at least one year) VMs without PRI support hold up to 800GB of memory, with $\sim$ 34% cold pages unreclaimed. With VIO enabled, approximately 120GB/day can be freed which satisfies user SLOs, translating to savings equivalent to running about 30 VMs (2C/4GB) per day.

[*]Equal contribution.

Table 1: Comparison of Memory Reclamation Methods

Method	IO-Safety	HW Compatibility	Guest modification	Reclaim type	Overhead
{v,co}IOMMU [8, 39]	✓	General	Frontend Driver	Unused + Cold	High
IOGuard [12]	✓	General	Frontend Driver	Unused + Cold	Medium
Ballooning [41]	✓	General	Frontend Driver	Unused	High
Free Page Reporting [2]	×	General	Frontend Driver	Unused	High
Hyperupcall [9]	×	General	eBPF-Tool Chain	Unused + Cold	Low
IOPF/VPRI [17]	✓	Dedicated	No	Unused + Cold	Low
VIO	✓	General	No	Unused + Cold	Low

clude the Page Request Interface (PRI) functionality [33], which enables devices to handle IOPFs. PRI relies on coordination between the Input-Output Memory Management Units (IOMMU), devices, and the operating system to manage IOPFs. Intel introduced PRI support in their IOMMUs with the 2023 Sapphire Rapids platform, significantly advancing PRI adoption despite its introduction 14 years earlier. However, delayed adoption has limited its widespread implementation, with most mainstream I/O devices—except for high-end GPUs [7, 21, 34]—currently lacking PRI support. Additionally, Linux (`v6.12`) supports PRI only in scenarios that require PASID under `IOMMU_INTEL_SVA`, further restricting its hardware compatibility [4].

Despite the potential for widespread adoption of ATS/PRI hardware and software in the future, oversubscribed cloud environments face two primary challenges. As Figure 1 depicts, in our production environment with a cluster size of 300 nodes, more than 80% of legacy VMs consume $\sim$ 800GB of memory, and this situation is expected to continue. Since the kernels of these VMs do not support PRI, hardware upgrades alone will not yield benefits. Large-scale migration to PRI-compatible devices is both technically and economically impractical. Moreover, these VMs exhibit a cold page rate exceeding 34%, suggesting an opportunity to reclaim $\sim$ 270GB of memory. Additionally, ATS/PRI introduces higher latency ($\sim 3\times$ to $\sim 80\times$) compared to CPU page fault handling due to its reliance on the PCIe bus for fault handling. This necessitates the use of an on-device buffer to store in-flight requests. The widespread adoption of SR-IOV (Single Root I/O Virtualization) technology, which virtualizes a single Physical Function (PF) of an I/O device into thousands of VFs for different guests, exacerbates scalability issues related to offline PRI and increases hardware costs [30, 40]. Therefore, PRI is not currently suitable for addressing the high-performance, high-density multi-tenant cloud scenarios.

Previous works attempt to address the challenge of statically pinning VM memory without PRI support, with solutions falling into two main categories. The first approach is software-based, including methods such as vIOMMU, coIOMMU, VProbe and IOGuard [8, 12, 39, 43]. These solutions often introduce significant performance bottlenecks, making them impractical for real-world use, and some require modifications to VM software, which is not viable in multi-tenant cloud environments. The second approach involves implementing IOPF handling at the hardware level, decoupling it from the IOMMU, as seen in solutions like On-Demand Paging and VPRI [17, 27]. However, these approaches are limited to high-end or custom hardware, restricting their broad adoption. Like PRI, these hardware solutions also introduce additional latency to I/O operations, leading to substantial performance degradation in high-performance scenarios.

In this paper, we introduce VIO (Virtual I/O), a hardware-independent, IOPF-free virtualization solution designed to deliver both high performance and low overhead in high-density, multi-tenant environments. We identify that placing page faults in the critical I/O path of complex network and storage devices is a major contributor to performance degradation. Our approach builds on the VirtIO standard, which abstracts the underlying hardware differences in VM I/O devices. VIO utilizes VirtIO's data plane to implement IOPA snooping, which detects potential page faults in advance. By eliminating IOPFs through this proactive snooping, VIO ensures high compatibility and improved performance. We implement and deploy VIO on x86 platforms, including both AMD and Intel.

As Table 1 highlights, the key differentiator of VIO is that it requires no modifications to the guest software stack—all changes reside solely in the host hypervisor. This design choice is critical for our environment, which includes hundreds of thousands of long-running VMs (running at least one year) from which memory needs to be reclaimed. The design implications and technical details are discussed further in §3.3. Prior solutions that rely on guest frontend driver or eBPF modifications are unsuitable for such deployments. Furthermore, existing approaches largely overlook the need to adapt to dynamically varying IOPS, whereas VIO addresses this gap, offering both practical engineering benefits and novel research value.

To optimize memory usage while meeting user SLOs, VIO employs dynamic device passthrough, ensuring optimal performance in high I/O operations per second (IOPS) environments. Specifically, we introduce a fine-grained, I/O pressure-based elastic passthrough strategy. Different workloads and users have varying IOPS demands, and as IOPS increase, memory requirements also tend to rise. In such cases, VIO

suspends snooping on I/O page access and directly passes the VirtIO data plane to the hardware, enabling near bare-metal performance and maximizing efficiency. When workload intensity decreases, VIO reclaims unused memory. Our experiments demonstrate that, compared to traditional passthrough, elastic device passthrough allows up to 10% daily memory reduction in production while still meeting SLO requirements.

2 Background

2.1 Trends on IO Virtualization

I/O virtualization has evolved over the years to meet the increasing demands for high performance and scalability in virtualized environments. Initially, full virtualization provided a simple and straightforward approach to I/O virtualization. In this model, devices are fully emulated through software, enabling VMs to interact with virtualized devices transparently, without requiring modifications to the guest OS. While this method offers high transparency, it incurs significant performance overhead due to frequent VM exits and data copying between the guest OS and the hypervisor.

To mitigate the performance drawbacks of full virtualization, para-virtualization [19, 24] (PV) emerged as a more efficient approach. PV reduces overhead by modifying the guest OS, allowing it to interact directly with the hypervisor through specialized drivers, rather than emulating hardware. A prominent example of PV is VirtIO, as Figure 2a illustrates, which employs a split-driver model where the guest front-end driver communicates with the host's back-end driver. This design reduces the overhead of memory-mapped I/O (MMIO) operations by avoiding unnecessary VM exits, thus improving system performance. However, as the hypervisor still manages memory and I/O operations, PV can encounter performance issues, particularly in environments with multiple concurrently running VMs.

With the introduction of technologies like VT-d, direct device assignment became feasible. This approach, particularly through SR-IOV, has gained traction due to the high-density requirements of cloud computing. As is shown in Figure 2b, SR-IOV enables physical devices to expose multiple VFs, which can be directly assigned to VMs, bypassing the hypervisor to achieve near-native I/O performance. Each VF is isolated and has its own PCI registers and interrupt handling, making SR-IOV highly effective for high-performance applications. However, SR-IOV requires vendor-specific VF drivers in the guest OS, and its lack of full compatibility across hardware vendors introduces fragmentation and device migration challenges in large-scale cloud environments.

To overcome these limitations, a hybrid approach combining SR-IOV and VirtIO has been proposed. As is shown in Figure 2c, SR-IOV provides hardware-level isolation for improved I/O performance, while VirtIO ensures compatibility and simplifies driver management. This hybrid model, known as VirtIO hardware offloading, allows VMs to access SR-IOV-enabled devices using standard VirtIO drivers, reducing vendor lock-in and facilitating seamless integration with existing software stacks. By offloading the VirtIO backend to hardware, this approach enhances both performance and scalability, offering a robust solution for modern virtualized environments.

The evolution of I/O virtualization reflects the growing demand for solutions that balance high performance with broad compatibility [29]. As virtualization technologies continue to advance, the need for efficient and scalable solutions becomes increasingly critical. VirtIO, now widely adopted as the de facto standard in virtualization environments, epitomizes this trend. As virtualization continues to evolve, the emphasis on achieving both performance and universality will intensify, with VirtIO playing a central role.

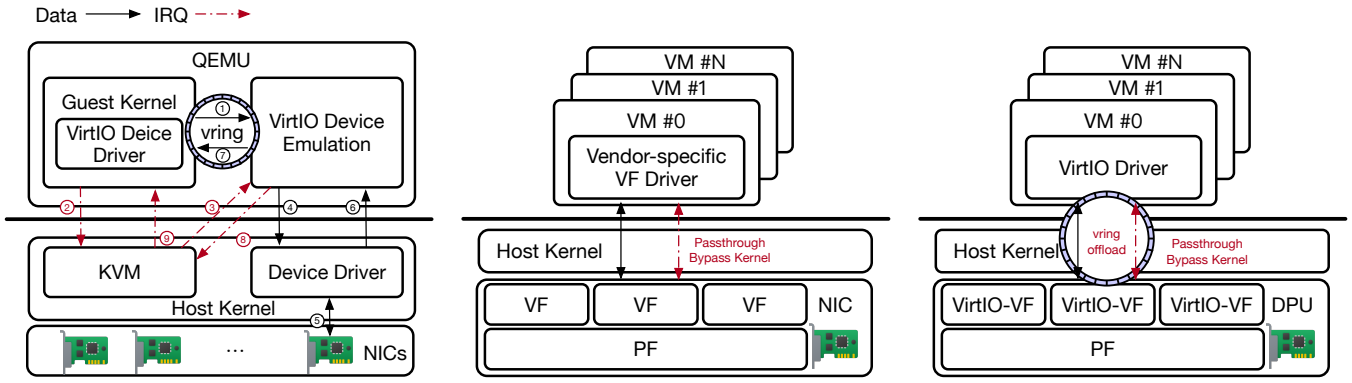
2.2 Pitfalls of IO Devices with IOPF

In traditional memory management, when the CPU encounters a page fault, i.e., when it attempts to access a virtual page not currently mapped to physical memory, an exception is triggered. The operating system's memory management unit (MMU) handles the fault by performing the necessary address translation, which often involves loading the page from disk into physical memory. Once the page is mapped, the CPU can resume its operation seamlessly.

Similarly, when an I/O device performs DMA to access a virtual memory page that has not been mapped yet, it triggers an IOPF. However, unlike the CPU, devices generally cannot handle such faults on their own. The device lacks the ability to resolve the fault [11, 28] or perform the necessary address translation. If the system fails to resolve the IOPF, it can lead to severe system instability and may even result in a system panic.

To address this issue, PCI-SIG introduced the PRI in the PCIe 4.0 specification. PRI provides a standardized interface that allows devices to request the physical address translation of virtual memory pages from the host system. With PRI, when a device encounters an IOPF, it can directly request memory translation from the operating system or hypervisor. This mechanism enables the system to resolve IOPF without CPU intervention, allowing the device to continue its memory access without causing a system crash.

Figure 3 illustrates how PRI handles IOPFs. Initially, the device's PRI function sends a page request message to the IOMMU over PCIe (①). This message is received by the PRI Server (PRS) within the IOMMU, which writes it to the PRS event queue, triggering a host interrupt (②). This interrupt asynchronously notifies the IOMMU driver, leading to significant delays. In steps ③ and ④, the memory subsystem handles the process similar to a CPU page fault: the system requests a physical page, populates it, and updates the page



(a) VirtIO (b) SR-IOV (c) VirtIO Offload

Figure 2: The evolution of I/O virtualization. (a) VirtIO illustrates the para-virtualization approach with a split-driver model to improve performance by reducing VM exits. (b) SR-IOV demonstrates hardware-level direct device assignment for near-native performance by exposing VFs to VMs. (c) VirtIO hardware offload combines the benefits of SR-IOV and VirtIO, leveraging hardware offloading to achieve both high performance and broad compatibility.

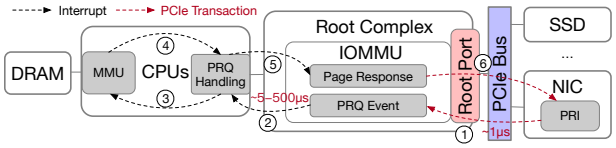


Figure 3: IOPF Handling Process. PRQ handling in step ② introduces the most significant delay, followed by memory population and response delivery.

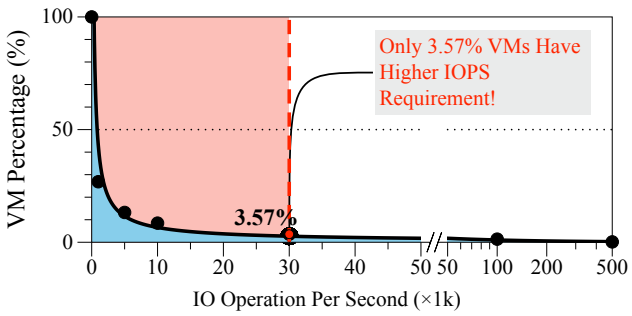

Figure 4: IOPS distribution in a CSP production environment, showing a long-tail pattern where 73.14% of workloads have IOPS below 1,000, while less than 3.57% exceed 30,000 IOPS.

tables. Finally, the IOMMU driver sends a response to the device PRI interface (⑤, ⑥).

Mellanox [20] and VPRI focus on optimizing the latency of the IOPF process, claiming that the entire IOPF handling cycle introduces a latency of a few hundred milliseconds. However, based on previous studies and our experiments, we find that because IOPF occurs in the critical path of DMA, any delays in this path can cause the device to drop the current packet. The device then relies on higher-layer protocols (such as TCP/RDMA) to handle packet loss through retransmission. This retransmission process can lead to packet damming or flooding, causing delays that are several hundred milliseconds long, $\sim$ 100 times the latency of the IOPF itself.

Moreover, another significant pitfall in the deployment of ATS/PRI arises from the need for synchronization between on-device memory and the CPU's page table information. Modern systems, especially those with large memory configurations, such as 2TB memory machines, face substantial challenges when attempting to manage this synchronization. For example, using a 4KB page size, synchronizing such a large memory footprint can lead to an enormous overhead in terms of memory storage. Specifically, the system must handle the synchronization of up to 500MB memory, which results in a considerable memory requirement just to maintain consistency across device and CPU memory page tables. This scale of memory management creates a significant burden in terms of both energy consumption and computational overhead, which, when combined with the performance penalties from DevTLB misses and the need for extensive TLB capacities, exacerbates the challenges associated with scaling ATS/PRI in production environments.

In summary, PRI-based solutions place IOPF handling in the critical I/O path, which interrupts the original flow of I/O operations, thus leading to significant performance degradation. Therefore, due to its inherent characteristics, PRI is not suitable for use in I/O-intensive environments.

2.3 IOPS Distribution in Cloud Environment

As is illustrated in Figure 4, the IOPS distribution in a CSP production environment demonstrates a distinct long-tail pattern. The vast majority of virtual machines, accounting for

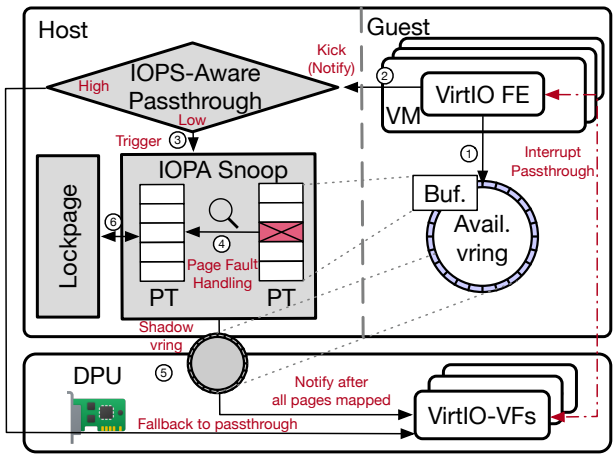

Figure 5: Overview. The figure illustrates the VIO process, where IOPF handling is offloaded to the hypervisor, transparent to both the software and hardware. This approach eliminates IOPF overhead from the critical I/O path, improving performance while maintaining full compatibility.

73.14%, have IOPS demands that do not exceed 1,000. This indicates that most workloads in the cloud operate at relatively low IOPS levels. Meanwhile, only a small fraction of virtual machines—less than 3.57%—require more than 30,000 IOPS, highlighting the rarity yet importance of high-IOPS workloads in production environments.

This distribution reflects the resource heterogeneity in cloud environments, where low-IOPS workloads dominate while high-IOPS workloads represent a smaller but critical segment. The latter are often accompanied by memory-intensive operations. In such scenarios, memory oversubscription, a common practice to optimize resource utilization, can lead to significant interference with high-IOPS workloads, disrupting performance and potentially violating SLOs.

To address these challenges, a potential solution involves an elastic passthrough strategy capable of dynamically switching between resource sharing and passthrough modes based on real-time workload demands. Under typical conditions, low-IOPS workloads efficiently share resources to maximize utilization. When workloads intensify and IOPS demands increase, the strategy shifts to direct passthrough, minimizing overhead and delivering near-native performance. By dynamically adjusting working mode based on IOPS intensity, such an approach has the potential to balance high efficiency and reliable performance across diverse and complex workloads in cloud environments.

3 Design & Implementation

3.1 Overview

Based on our analysis and observations, we propose a novel IOPF system called VIO, as is illustrated in Figure 5. VIO is a software-based, elastic device passthrough solution that adheres to the VirtIO 1.0 standard. The design of VIO enables IOPF support without relying on any specific CPU or hardware vendors, achieving this entirely through software. In contrast to the less widely adopted ATS/PRI solution, VIO is hardware-independent and transparent to the guest operating system. The key features of VIO are as follows:

1. IOPA-Snoop: VIO snoops every VirtIO command to ensure that DMA-buffered pages are handled correctly. This mechanism guarantees that page faults will not occur during device DMA operations, eliminating the need for PCIe PRI-based page requests.

2. IOPS-Aware Elastic Passthrough: As device I/O pressure increases, VIO switches to a passthrough mode. It uses a shadow available ring to enable elastic switching between device passthrough and VIO passthrough. By toggling the IOPT in the IOMMU to the shadow available ring, VIO achieves transparent passthrough mode switching for the VM. This mechanism also supports seamless upgrades to VIO for existing VMs, enabling hot upgrades without disruption.

3. Adaptive Lockpage: VIO implements device-agnostic I/O page access logging through IOPA-snoop, which collects information about IO page access pattern. Based on this information, VIO introduces an adaptive lockpage mechanism that optimizes the usage of I/O hot pages, improving memory efficiency and reducing IOPFs.

Figure 5 illustrates the VIO process as follows: **Step ①:** The VirtIO frontend in the VM prepares the buffer and places it in the available ring. **Step ②:** The VirtIO frontend then uses a kick to notify the backend that the buffer is ready for device use. **Step ③:** Depending on the current IOPS pressure, the process is divided into two paths: (a) When the VM is under heavy load, the process directly follows the passthrough fast path. (b) When the device is in VIO mode, the kick triggers an IOPA-Snoop. It is important to note that in both modes, hardware interrupts are directly passed through to the virtual machine. **Step ④:** The IOPA-Snoop thread handles any page faults in the buffer prepared in step ① by querying the Extended Page Table (EPT). **Step ⑤:** The IOPA-Snoop thread then kicks the actual hardware, initiating the I/O operation.

During hardware I/O operation, IOPA-Snoop ensures that the device can continue the operation without being interrupted by an IOPF. Compared to the PRI-based solution, this

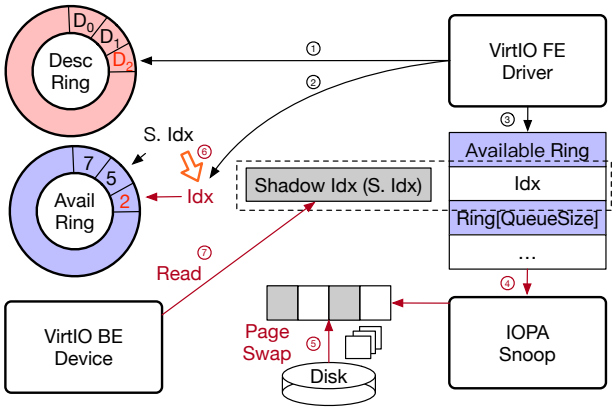

Figure 6: Overview of IOPA Snoop. This module offloads IOPF handling to the hypervisor, without device involvement. It ensures that DMA operations can continue without IOPF by guaranteeing that all pages are mapped before the device accesses them.

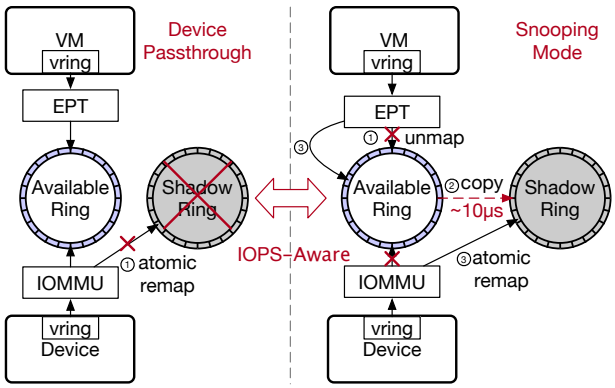

Figure 7: Elastic passthrough. It illustrates the IOPS-aware mechanism, switching between snooping and passthrough modes using shadow page tables to manage memory mappings.

approach removes the IOPF overhead from the critical path of the I/O operation.

The changes in the VIO process described above occur within the host's hypervisor, making them transparent to both the upper-level guest and the underlying hardware. Unlike PRI, the current page fault handling in VIO is no longer initiated by asynchronous interrupts. This design ensures that performance improvements in IOPF handling are achieved without requiring modifications to guest operations or additional hardware functionality. By offloading IOPF handling to the hypervisor and optimizing the I/O path, VIO enhances system performance while maintaining full compatibility between the guest and the hardware.

3.2 IOPA-Snoop Mechanism

VirtIO is a general I/O virtualization framework that allows the hypervisor to emulate a variety of virtualized devices, making them accessible within a virtual machine through API calls. It is widely used in cloud environments to enhance virtualization I/O performance and ensure compatibility across different systems. Virtqueue serves as the transport layer abstraction between the VirtIO front-end and back-end. To prevent devices from encountering page faults during DMA, VIO introduces the IOPA-Snoop module to manage the virtqueue.

Figure 10 illustrates the process by which the VirtIO front-end adds requests and notifies the back-end for consumption. **Step ①:** The front-end driver allocates a buffer and adds it to the descriptor table. **Step ②:** The front-end driver then adds a new entry with the head index of the descriptor chain, which describes the request in the available ring entries. **Step ③:** The front-end driver increments the index by the number of new entries.

In the standard VirtIO path, the back-end device eventually observes the available index and uses the buffer allocated in step ① by referring to the descriptor table based on that index. If the page in the buffer has been unmapped by the hypervisor, it triggers an IOPF, which would normally require the ATS/PRI hardware process to resolve. If the back-end device waits for the page fault to be handled before continuing, it would need to store additional information in a special buffer to manage multiple in-flight page faults. This is impractical for I/O devices due to resource limitations. As a result, most hardware implementations drop the related packets, relying on higher-layer protocols like TCP/RDMA to handle retransmission, which leads to performance degradation.

In our approach, we introduce a shadow index mechanism, where the device and driver operate on different indices. After step ③, the device sees a shadow index, which has not yet been updated and still points to the old address in the available ring. The following steps outline the process: **Step ④:** The IOPA-Snoop module detects the index update and snoops the buffer allocated in step ①. **Step ⑤:** The IOPA-Snoop module reads the unmapped data from the swap to ensure that the pages in the buffer are correctly mapped. **Step ⑥:** The shadow available index is then updated to the available index. **Step ⑦:** The back-end device observes the updated shadow available index and proceeds with the DMA operation.

In this process, IOPF handling is entirely managed on the hypervisor side, with no direct involvement from the device. Even when multiple page faults occur simultaneously, the handling process remains consistent with traditional CPU page fault handling, effectively removing IOPF handling from the critical path of the DMA operation.

3.3 Elastic Passthrough

In cloud environments, many VMs run for extended periods and may not be able to easily take advantage of new hardware features such as PRI. To ensure that both existing hardware

and software can benefit from improvements, we introduce elastic passthrough. Elastic passthrough enables VMs to seamlessly switch between device passthrough and snooping mode without requiring any changes to the VM or the underlying hardware.

To protect sensitive data from malicious VMs, the hypervisor utilizes EPT to control each VM's memory access. The VM's MMU translates Guest Virtual Addresses (GVA) into GPA, while the hypervisor maps these GPAs to Host Physical Addresses (HPA). Additionally, the IOMMU translates I/O Virtual Addresses (IOVA) to HPA, ensuring that malicious devices cannot gain unauthorized access to memory via DMA.

VIO utilizes separate page tables for the device and driver when accessing the available ring. VIO employs separate available rings: a native available ring for the device and a shadow available ring managed by the hypervisor. This design allows the hypervisor to use the shadow available ring for snooping mode, without necessitating any modifications within the VM's guest OS or applications.

Transitioning from Passthrough to Snooping: As is shown in the right side of Figure 7, when switching from passthrough mode to snooping mode, the hypervisor follows these steps: **Step ①:** Unmaps the available ring in the EPT, blocking new requests if any are in-flight. **Step ②:** Copies the contents of the available ring to the shadow available ring, which takes about 10 microseconds. **Step ③:** Atomically remaps the available ring to the shadow available ring in the IOMMU's IOPT, and then remaps the EPT back to the available ring. This sequence completes the transition to VIO mode without any noticeable changes to the VM or device.

When operating in snooping mode, each I/O request from the VM triggers an IOPA-Snoop operation. Each snooping operation introduces a small overhead (approximately 4µs according to our measurements, as detailed in the §4.1). At low IOPS, the cumulative overhead of snooping is negligible, and the benefits of preventing IOPFs outweigh this cost. However, as the IOPS increases, the cumulative overhead of these snooping operations grows proportionally, potentially becoming a significant performance bottleneck. Furthermore, we observe that VMs with high IOPS workloads tend to require most, if not all, of their allocated memory to maintain performance. In such scenarios, the benefits of memory reclamation through snooping diminish, making it more efficient to switch these heavy-load VMs back to passthrough mode.

Transitioning from Snooping to Passthrough: To mitigate the snooping overhead under heavy I/O load and to avoid unnecessary snooping for VMs that benefit little from memory reclamation, VIO incorporates an IOPS-Aware Elastic Passthrough feature. An IOPS monitor tracks the I/O activity of the VM. When the IOPS exceeds a predefined threshold (e.g., 100k IOPS in our production environment), the system automatically triggers a switch back to passthrough mode. The left side of Figure 7 illustrates this transition process. During this transition, the hypervisor remaps the shadow available ring back to the original native available ring, allowing the VM to operate in passthrough mode and bypass the snooping overhead, thereby maintaining high I/O performance. This threshold-based switching mechanism dynamically adapts to workload demands, ensuring that the system operates efficiently across varying I/O loads.

The transition from snooping mode back to passthrough mode is optimized to minimize performance disruption. Before initiating the switch, the hypervisor proactively swaps in swapped-out pages. Because snooping continuously swaps in pages, relatively few pages need to be swapped in when transitioning back to passthrough mode. This swap-in operation occurs in parallel with ongoing snooping, effectively hiding the latency of page retrieval. When the actual mode switch takes place (remapping the shadow available ring to the native available ring), all necessary pages are already resident in memory. This design choice eliminates IOPFs from the critical path of the transition, resulting in a smooth switch with no noticeable performance degradation.

To ensure that VIO can benefit existing long-running legacy VMs, we utilize a combination of Elastic Passthrough and VMM live upgrade. VMM live upgrade is a technique that has been widely adopted in both industry and academia to update the underlying hypervisor (KVM/QEMU) without requiring any reboot or reconfiguration of the VMs themselves [37]. VIO's design is implemented entirely within the hypervisor, meaning that no modifications or upgrades are necessary within the guest VMs to take advantage of its benefits.

We choose Orthus [50] to live upgrade VMM as it is widely deployed in our production. This VMM live upgrade process leverages a dual KVM approach, where a new, upgraded version of KVM can be loaded while the original KVM instance continues to run the VMs. Then, the VMs are "grafted" from the old KVM to the new KVM, and device ownership is handed over to the new VMM. This process enables a seamless upgrade of the QEMU process using a fork-exec model, where the original QEMU process forks, and the child process loads the new QEMU image. The upgraded QEMU includes VIO's Elastic Passthrough capabilities. Once the legacy VM is running under the upgraded hypervisor, its transition between passthrough mode and VIO's snooping mode operates identically to a VM that was initially started in a VIO-enabled environment.

Figure 8 illustrates the Iperf performance of a legacy VM during this upgrade process in our production environment. As the graph shows, there is some performance fluctuation during the 200ms window while QEMU is upgraded and the VM is switched to VIO mode. It's important to note that this fluctuation occurs under peak Iperf bandwidth conditions.

During a production rollout, we schedule these upgrades during periods of low workload for the legacy VMs to minimize any potential impact. Crucially, the VMs do not need to

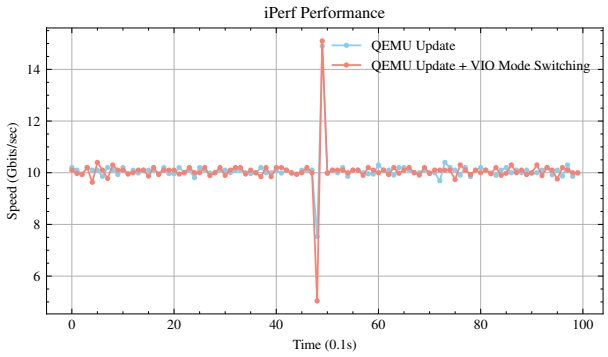

Figure 8: iPerf performance during VMM upgrade

be restarted or reconfigured, and the entire process is transparent to the guest operating system and applications. This is a significant advantage, as it avoids the complexity and potential disruption of coordinating upgrades across a large number of diverse VMs.

Overall, Elastic Passthrough allows VMs in a virtualized environment to seamlessly switch between full device passthrough and VIO modes. This flexibility ensures that memory usage is optimized and performance goals are achieved without requiring any changes to the VM or hardware.

3.4 Lockpage

The IOPA-snoop mechanism (see §4.1) ensures the safety of I/O pages involved in DMA operations. However, the repeated reclamation and snooping of specific pages can introduce additional performance overhead. To mitigate the frequency of page faults caused by snooping, VIO employs a lockpage mechanism to pin particular I/O hotspot pages, thereby significantly reducing the occurrence of IOPF page faults.

I/O operations exhibit strong temporal locality, as the same memory pages may be accessed repeatedly within short intervals. In contrast to the more random and less predictable access patterns typical of CPU operations, I/O operations generally follow consistent and repetitive access patterns. This predictability facilitates more effective optimization strategies, such as pinning frequently accessed pages to prevent their eviction.

VIO employs two primary lockpage strategies to leverage I/O page locality. A lockpage bitmap manages these locked pages, with memory managed in 2MB chunks. Additionally, VIO maintains an internal table, enabling it to bypass the checking of Page Table Entries (PTEs) for pages listed in the lockpage bitmap, prior to the IOPA-snoop process.

Static Lockpage: This strategy locks frequently used I/O pages based on their spatial continuity. For example, the VirtIO RX queue, which is preallocated with contiguous memory regions, is entirely locked to prevent its pages from being swapped out. This approach ensures that VIO does not need to verify the presence of these pages in memory before DMA operations, thereby enhancing performance. Currently, VIO employs static lockpage exclusively for the VirtIO RX queue due to its pre-allocated and contiguous memory layout.

Algorithm 1 Adaptive Lockpage Mechanism in VIO

```
1:  Initialize Lockpage Bitmap with 2MB granularity
2:  Initialize Active List and Inactive List for each Protection Domain
3:  procedure IOPA_SNOOP(access_log)
4:      for all page ∈ access_log do
5:          MOVETOACTIVELIST(page)
6:          if ISINACTIVELIST(page) then
7:              UNPINPAGE(page)
8:          end if
9:      end for
10: end procedure
11: procedure MOVETOACTIVELIST(page)
12:     Remove page from Inactive List if present
13:     Add page to the head of Active List
14:     if ISACTIVELISTFULL then
15:         EVICTFROMACTIVELIST
16:     end if
17: end procedure
18: procedure EVICTFROMACTIVELIST
19:     evicted_page ← Remove page from tail of Active List
20:     ADDTOINACTIVELIST(evicted_page)
21:     PINPAGE(evicted_page)
22: end procedure
```

Adaptive Lockpage: The adaptive lockpage mechanism in VIO is inspired by the Dual LRU and Multi-generational LRU algorithms utilized in the Linux kernel. The primary objective is to avoid pinning pages in the youngest generation (active list) since these pages are already identified as hot by the EPT through the IOPA-snoop mechanism. Pinning these pages would unnecessarily lock those that do not require it. Instead, the focus is on pinning pages from the second young/inactive list, which represent long-term recently used pages. By pinning these pages, the kernel's page reclaim module is prevented from evicting them, thereby reducing repeated page faults and enhancing overall system performance.

The adaptive lockpage algorithm (Algorithm 1) manages memory pages using `Active` and `Inactive lists`. When IOPA-snoop detects a page access, it transfers the page to the `Active List` and unpins it if it was previously in the `Inactive List`. If the `Active List` becomes full, the least recently used page is evicted to the Inactive List and subsequently pinned to retain it in memory. This selective pinning strategy ensures that frequently accessed I/O pages remain available, reducing the number of IOPFs and enhancing the ultimate system performance.

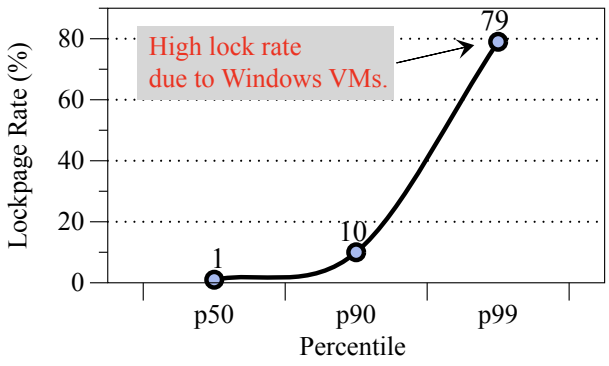

Figure 9: Lockpage rate in a production environment, showing P50 at 1%, P90 at 10%, and P99 spiking to 79% due to poor I/O locality in Windows VirtIO driver.

Lockpage Rate: We collected lockpage data from about 300K virtual machines in our production environment. As shown in Figure 9, the analysis of lockpage rates reveals significant differences in memory usage across VMs in production. The median lockpage rate is 1%, indicating strong I/O locality for most VMs. At the 90th percentile, the lockpage rate increases to 10%, reflecting the memory demands of more intensive workloads. However, at the 99th percentile, the lockpage rate jumps sharply to 79%, highlighting a subset of VMs with significantly higher memory locking requirements.

This sharp increase is largely due to approximately one-quarter of the VMs running the Windows VirtIO driver. These VMs exhibit poor I/O locality because the driver disrupts typical memory access patterns, causing a much larger portion of memory pages to be locked. This observation suggests that optimizing the Windows VirtIO driver could improve I/O locality and significantly reduce memory locking overhead. Although adaptive lockpage strategies can effectively reduce the lockpage rate, we adopt a static lockpage configuration in production for ease of maintenance.

4 Evaluation

We evaluate VIO across several dimensions through experiments. First, we examine its performance using micro-benchmarks, focusing on the end-to-end latency for handling IOPF. Next, we illustrate its performance with real-world benchmarks, comparing it to relevant hardware-based solutions. Finally, we analyze data from a production environment to verify that VIO meets the SLO requirements for users in public cloud settings.

Experimental Setup: We deployed VIO in one of the largest global CSP production environments. Due to the lack of commercially available network cards that support PRI, we chose VPRI from SOSP'24 as the baseline [17]. VPRI is a state-of-the-art hardware implementation of PRI that integrates on-device PRI functionality, enabling IOPF processing on the DPU. We have implemented VPRI ourselves, and since VIO does not rely on specific hardware conditions, we are able to support both VPRI and VIO on the same platform. Configurations are shown in Table 2.

Table 2: Environment Configuration

Type	Hardware Configuration
Host	Intel Xeon CPU Platinum 8269CY 52C/104T@2.50GHz in 2 sockets 12 * 16GB DRAM, 1TB SSD
DPU	Connection: PCIe GEN3, 8 lanes Device emulation: up to 2300 VFs Max bandwidth: 200 Gb/s
VM	4 vCPUs, 8GB RAM CentOS Linux release 7.9.2009 NIC device: dual queue virtio-net x1 10Gb/s max throughput, 190,000 PPS

Benchmarks: To demonstrate the impact of VIO, we select various I/O-intensive applications, which are highly representative of common cloud computing scenarios. The selected applications and their setups are listed as follows.

- **iperf3:** Tests network throughput using iperf3 with a single thread and a packet size of 1024 bytes. Simulates TCP-based data transfer to evaluate system bandwidth over a specified duration.[1]
- **nginx:** Measures web server performance under stress using two threads and 200 concurrent connections. Simulates heavy HTTP traffic to assess nginx's handling of simultaneous requests.[2] For Nginx benchmarks, we used 2KB static web pages.
- **Redis:** Benchmarked with redis-benchmark, using 16 threads performing GET operations on 256-byte data. Evaluates Redis's ability to handle concurrent database queries efficiently.[3] For Redis benchmarks, we used 16 connections (`-c 16`).
- **Memcached:** Tested with memaslap, using 8 threads operating on 64-byte keys (`-c 8`). Assesses Memcached's performance under concurrent GET and SET workloads.[4]

4.1 IOPA-Snooping Overhead

To evaluate the efficiency of VIO in production environments, we monitored its deployment on a sample of 10,000 VMs.

[1] iperf3, https://iperf.fr/
[2] nginx, https://nginx.org/
[3] Redis, https://redis.io/
[4] Memcached, https://memcached.org/

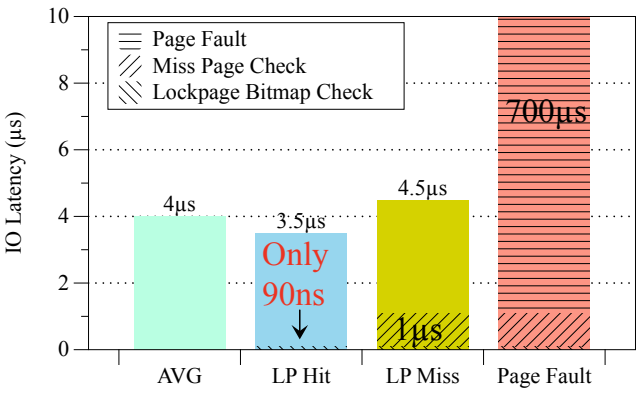

Figure 10: IOPA-Snooping Latency. The figure shows the latency distribution of the IOPA-snoop process, detailing the impact of lockpage hits (3.5µs) and misses (4.5µs) on overhead, with page faults averaging 700µs.

We sampled the IOPA-snoop process, which handles I/O page accesses in VIO. The results provide valuable insights into the latency distribution and the effectiveness of the lockpage mechanism in reducing overhead.

As is shown in Figure 10, the IOPA-snoop process incurs a average latency of 4µs, with a clear distinction based on lockpage hits and misses. When a lockpage hit occurs, the latency is reduced to approximately 3.5µs, as the system only needs to query VIO internal bitmap, which takes 90ns. For lockpage misses, the latency increases to 4.5µs, as the system must first check whether the page is present in memory, taking around 1µs. If the page is not present, a page fault is triggered, which has an average handling time of 700µs.

These findings highlight the efficiency of VIO's lockpage mechanism, which minimizes the need for costly page fault handling by ensuring that frequently accessed I/O pages are pinned in memory. Even in cases where a page fault occurs, VIO ensures robust performance with a well-contained average fault-handling latency. This efficient handling of I/O page accesses demonstrates VIO's capability to maintain low overhead and stable performance, making it suitable for large-scale cloud environments with diverse workloads.

4.2 Applications

The performance comparison between VPRI and VIO across four I/O-intensive applications, reveals differences in their ability to handle IOPF. The performance comparison between VPRI and VIO was evaluated under varying I/O pressure by injecting IOPFs at different rates (1/2/5/10 per second) and introducing diverse fault latencies. All tests were conducted under memory oversubscription conditions with Snooping mode enabled. Please note that under such high IOPS conditions, VIO would typically run in passthrough mode. However, in this case, to demonstrate the worst-case performance of VIO, we used snooping mode for comparison. These latencies are chosen to reflect the wide range of delays observed in cloud SSDs: while high-performance cloud SSDs offer read/write latencies around 4ms, others can be significantly higher. By adjusting both the IOPF frequency and latency, we simulate conditions that capture the complexity and variability of real-world cloud storage environments.

As is shown in the Figure 11, VPRI experiences significant throughput degradation as delay increases due to its reliance on retransmissions to recover from packet loss caused by IOPFs. For instance, in Redis, VPRI throughput drops by 60% under 10ms delay, while Nginx and Memcached exhibit similar degradation trends of 45% and 57%, respectively. This cascading effect of retransmissions highlights the sensitivity of VPRI to IOPF frequency, particularly in workloads with high transaction rates or network demands.

In contrast, VIO demonstrates excellent stability under the same conditions. By isolating page fault handling from the critical I/O data path, VIO avoids packet loss and retransmissions, resulting in minimal performance degradation. Across all applications, VIO's throughput reductions remain below 10%, even at higher delays. For example, in Redis, VIO achieves a modest 6% drop under a 10ms delay, while Nginx and Memcached see reductions of 9% and 6%, respectively. This consistent performance advantage underscores VIO's ability to maintain stable throughput across a range of workloads and delay conditions. Redis shows poorer performance in low IOPF situations because the frequency of snooping operations becomes a significant bottleneck due to snooping latency. When IOPS is high, total snooping overhead increases proportionally with the growth in I/O operations. This data supports the design goal of Elastic Passthrough of employing snooping in most low-IOPS scenarios and switching to passthrough in high-IOPS scenarios.

Overall, the results emphasize the effectiveness of VIO in mitigating the impact of IOPFs. While VPRI struggles with retransmission overheads that degrade performance as delays increase, VIO ensures predictable and reliable throughput by handling page faults in a non-intrusive manner. This makes VIO a robust solution for diverse cloud applications requiring stable and efficient I/O operations under varying workloads and network conditions.

4.3 I/O SLOs

In production environments, intermittent I/O jitter caused by infrastructure issues such as network congestion often results in long-tail performance degradation and packet loss. This significantly impacts I/O SLO metrics, prompting CSPs to invest substantial resources in maintaining I/O jitter within tolerable levels. However, the limitations of the current IOPF architecture exacerbate I/O jitter. Frequent IOPFs, particularly during rapid successive bursts, introduce retransmissions and delays, directly leading to I/O SLO violations.

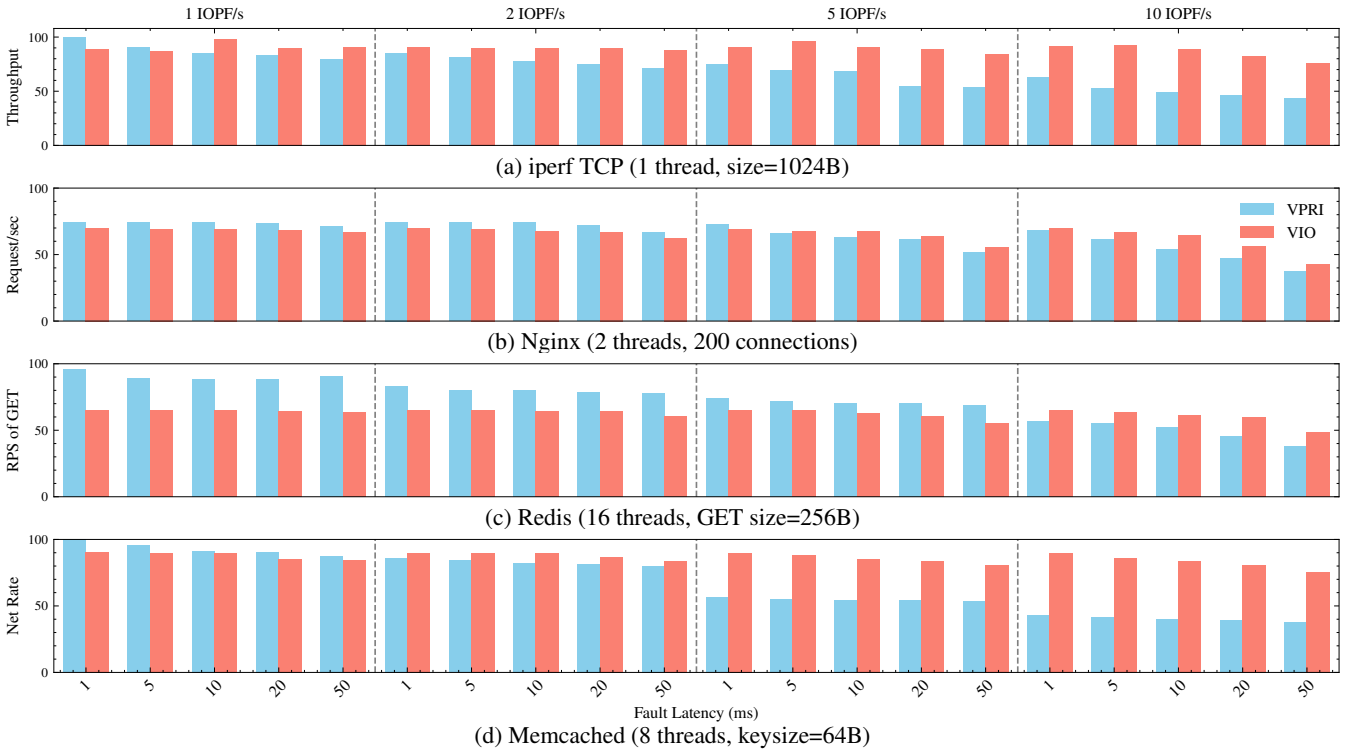

Figure 11: VPRI[SOSP'24] vs VIO Performance comparison normalized to respective passthrough mode.

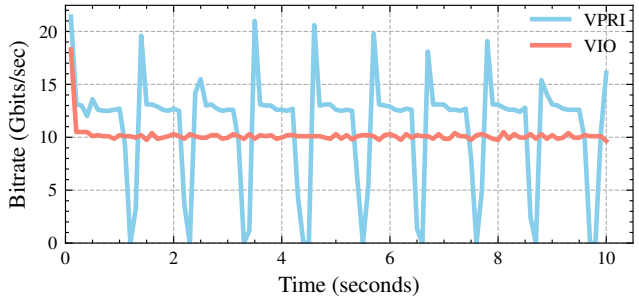

Figure 12: iperf3 performance when IOPF occurs in a fixed rate of 1s and fault latency of 5ms.

To evaluate the impact of IOPF on I/O jitter, we used iperf to measure network bandwidth, sampling throughput data every 0.1 seconds. Figure 12 reveals that VPRI suffers from significant bursts of packet loss due to its reliance on retransmissions when an IOPF occurs. This behavior leads to highly unstable throughput, frequently dropping nearly to zero during retransmission periods. These bursts not only degrade the average throughput but also amplify I/O jitter, making it difficult for VPRI to meet SLO requirements.

In contrast, VIO demonstrates remarkable stability under the same testing conditions. By decoupling IOPF handling from the critical data path, VIO avoids packet loss and retransmissions, resulting in consistent throughput that remains near 10 Gbps with minimal fluctuation. This robustness effectively mitigates I/O jitter, ensuring predictable I/O performance even under bursty or high-load conditions. Consequently, VIO enables CSPs to achieve better compliance with I/O SLOs while reducing the operational burden of jitter management, making it a reliable solution for production-scale environments.

4.4 VIO in Production

We have deployed VIO in one of the largest global CSPs for over a year. During this time, we collected extensive production data from its deployment. Throughout the upgrade and operational phases, there have been no user-reported issues related to I/O SLOs. Below, we present actual production data gathered from the deployment of VIO.

IOPF in High Oversubscription: Figure 13 illustrates the distribution of page accesses and the single IOPF observed during the trace. Under a 30% memory oversubscription rate, we analyzed a page access trace over a one-hour period using YCSB Workload on Redis.[5] During this time, the system recorded 1,464,225 unique page accesses but encountered only a single IOPF. This result highlights the effectiveness of the lockpage mechanism in maintaining low IOPF rates even under high memory pressure.

The lockpage mechanism ensures that frequently accessed I/O pages are pinned in memory, reducing the need for costly

[5]YCSB, https://github.com/brianfrankcooper/YCSB

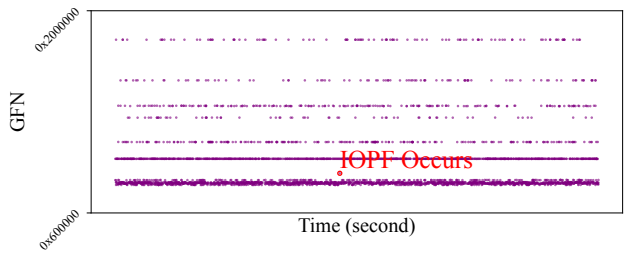

Figure 13: Page Access Trace (1:5000 Downsample). The figure shows a one-hour YCSB Workload on Redis under 30% memory oversubscription, with only one IOPF observed.

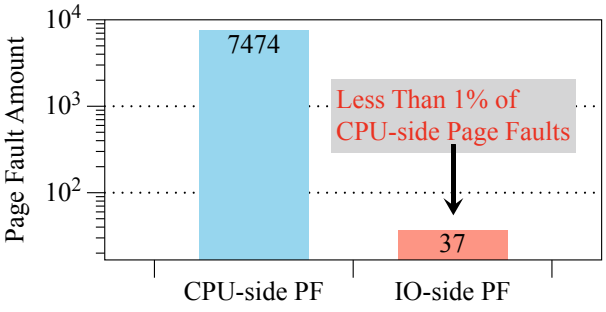

Figure 14: Daily Page Fault Comparison. The figure shows IOPFs reduced to less than 1% of CPU Page Faults, highlighting the effectiveness of the lockpage mechanism in ensuring I/O SLO requirement.

page faults. In this case, the mechanism effectively identified and locked critical pages, allowing the workload to run with minimal interruptions.

Daily Page Faults Rate: As shown in Figure 14, the lockpage mechanism in the production environment effectively reduced IOPFs to less than 1% of CPU Page Faults. By pinning frequently accessed I/O pages in memory, it minimized the occurrence of costly page faults, ensuring stable and efficient I/O operations for VMs.

This reduction in IOPFs is critical for meeting I/O SLOs. It prevents performance degradation caused by resource contention, ensuring low latency and consistent performance for critical workloads, even in high-density, multi-tenant environments.

Ablation Study: To evaluate the individual contributions of VIO's components, we conducted an ablation study using the netperf TCP_RR benchmark. [6] As shown in Figure 15, in snooping mode we observed a 3.4% performance difference between VIO without lockpage and VIO with lockpage (870,000 to 900,000 transactions per second). This improvement is attributed to the lockpage hit mechanism reducing snooping overhead by approximately 1us per operation. At

[6] netperf, https://hewlettpackard.github.io/netperf/

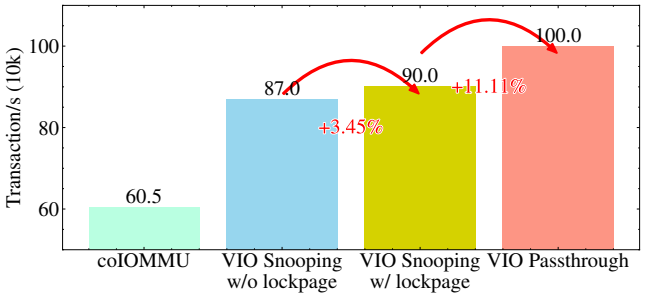

Figure 15: Ablation study of VIO under netperf TCP_RR. Lockpage improves snooping performance by 3.4%, while passthrough mode outperforms snooping by 11.1%.

high IOPS, VIO operating in snooping mode exhibits a 10% performance degradation compared to VIO in passthrough mode. This performance difference highlights the overhead of snooping under heavy I/O load and underscores the necessity for Elastic Passthrough to switch to passthrough mode in such scenarios. For comparison, we implemented colOMMU and observed that its performance at high IOPS reached only 60.5% of the native passthrough performance. This result indicates that colOMMU is less suitable for production environments with demanding I/O workloads.

5 Related Work

Static Memory Pinning Avoidance: To solve the problem of static memory pinning caused by IOPFs, PCI-SIG proposed the ATS/PRI specification [3]. However, ATS/PRI has not been widely adopted by I/O devices. Both industry and academia have explored various ways to address this issue. Previous research [17, 18, 27, 35] introduced IOPF handling into RDMA and DPU devices using methods similar to PRI from a hardware perspective. However, these PRI-like methods suffer from significant performance degradation as the number of IOPFs increases because they handle page faults in the critical path [16, 18, 49]. There have also been approaches for handling IOPF in GPUs [22, 38], but these methods are specific for GPUs, not suitable for general network and storage devices.

Many software-based solutions have also been proposed to solve the IOPF problem. coIOMMU [39] and vIOMMU [8] use para-virtualization to support IOPFs, where the guest kernel and the hypervisor work together to implement dynamic memory pinning. IOGuard [12] dedicates one CPU core to handle IOPFs in software. These software solutions either require modifications to the VM, leading to poor performance, or consume valuable CPU resources, which is unacceptable in cloud environments.

On the other hand, VIO provides a high-performance and cost-effective way to handle IOPFs without requiring changes to the guest or additional hardware features.

Memory Page Tracking: Various studies have aimed at detecting hot pages to reduce access latency by pinning or placing them in faster memory. Some approaches track memory access by utilizing page faults [23, 25, 45], while others focus on periodically checking reference bits in PTEs to monitor page hotness [26, 32, 36, 42, 48]. Modern processors provide advanced hardware features for performance monitoring, such as Intel's PEBS and AMD's IBS, which enable precise tracking of memory access events [10]. More recent works [13, 26, 47] have adopted these hardware-based techniques for enhanced memory access monitoring. However, a key challenge is balancing the trade-off between the accuracy of sampling and the overhead it incurs, especially as memory usage scales. To overcome this, a novel approach [14] combines TLB and PTE sampling, based on the observation that frequently accessed pages tend to experience a high rate of TLB misses. VIO takes advantage of its VirtIO data plane to track I/O page access in a way that is transparent to both the device and the guest OS.

6 Discussion

6.1 Compatibility

In this paper, we present a Linux-based implementation of VIO, which ensures high compatibility for several key reasons. First, VIO is built upon the VirtIO interface, a standardized virtual I/O interface that is supported across various CPU architectures and does not depend on specific hardware I/O devices or kernel versions. This makes the implementation highly portable and flexible. Second, VIO does not require any modifications to the guest OS, as it operates transparently through the VirtIO interface. This ensures that VIO maintains full compatibility with a wide range of guest OSes, including Linux, BSD, and even Windows, without enforcing any changes or additional dependencies. In theory, VIO can work with other hypervisors like Xen, Firecracker which supports VirtIO for efficient I/O virtualization. Moreover, VIO's design leverages basic virtualization features of the system, ensuring broad hardware compatibility. CPU platforms, including PowerPC, ARM, and RISC-V, can theoretically support VIO, as they widely adopt VirtIO in their virtualization ecosystems.

VIO requires guest VMs to use VirtIO and assumes the presence of a DPU that supports VirtIO offload. Major DPU vendors such as Intel and Mellanox support this functionality [5, 6], and our in-house DPU also implements it. In principle, any kernel version with VirtIO support can work with VIO. In our deployment, we have successfully migrated legacy VMs—including a 10-year-old CentOS 5 instance with kernel version 2.6.18—to VIO without modification.

6.2 Generalizability

While VIO is initially implemented and evaluated within the VirtIO framework, its underlying principles of IOPA-Snooping and Elastic Passthrough are applicable to other I/O architectures. Within the virtIO ecosystem, VIO effectively supports both network devices (virtio-net) and storage devices (virtio-blk), demonstrating its versatility. Furthermore, we have successfully extended VIO's concepts to the NVMe protocol. In NVMe, I/O submission involves writing the tail index to a doorbell register. We adapted IOPA-Snooping by intercepting this doorbell register write, enabling us to monitor I/O requests and proactively handle potential IOPFs. Additionally, we implemented Elastic Passthrough for NVMe by monitoring IOPS and dynamically switching between snooping and direct I/O, similar to the VirtIO implementation. These implementations across VirtIO-net, VirtIO-blk, and NVMe demonstrate that VIO's core ideas can be generalized beyond the VirtIO model, offering a more broadly applicable solution for managing I/O in virtualized environments.

6.3 Future Work

The VirtIO 1.1 standard draft, introduced in 2018, offers the Packed virtqueue as a more efficient alternative to the Split virtqueue [1]. Future iterations of VIO are planned to support VirtIO 1.1, further improving I/O efficiency and scalability.

7 Conclusion

This paper presents VIO, a production-level I/O virtualization framework offering hardware independence, high performance, and resource efficiency. VIO introduces: 1) an elastic passthrough mechanism adapting to IOPS demands for near-native performance; 2) an adaptive lockpage mechanism reducing IOPFs by pinning frequently accessed pages; and 3) a proactive snooping approach separating IOPF handling from the critical I/O path. Unlike PRI, which struggles with latency and limited hardware adoption, VIO provides a practical and efficient solution for large-scale cloud environments.

VIO, deployed across 300K VMs, achieves up to the equivalent of 30K VM memory daily savings while maintaining I/O SLOs with less than 1% IOPFs compared to CPU page faults, demonstrating its efficiency and scalability in production environments.

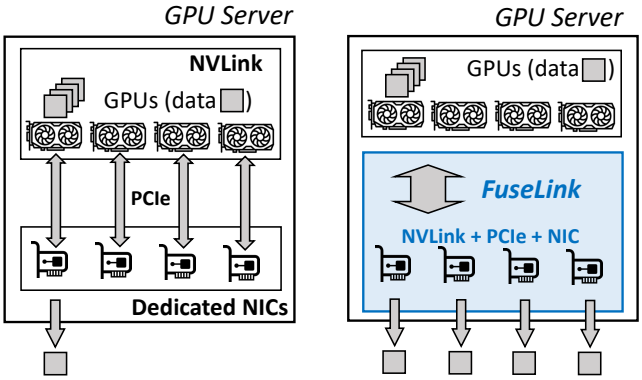
Abstract

Machine learning (ML) clusters stack multiple network interface cards (NICs) within each server to improve inter-server GPU communication bandwidth. However, existing systems fall short in fully utilizing NICs because of static GPU-NIC bindings. This leads to bottlenecks at hot-spot NICs when handling imbalanced communication in ML tasks. For example, large language model serving instances may have different communication demands across NICs; expert-parallel training tasks have imbalanced all-to-all traffic; and the embedding transmission volumes during recommendation model training vary across GPUs. To fully utilize all NICs, we propose FuseLink to enable efficient GPU communication over multiple NICs. FuseLink extends inter-server network by integrating high-speed intra-server connections, and leverages GPUs to efficiently relay traffic to idle NICs. We implement FuseLink and integrate it into NCCL, so that ML applications can benefit from FuseLink seamlessly without code modifications. Compared to NCCL, we demonstrate that FuseLink achieves up to 212GBps bandwidth between two inter-server GPUs and accelerates ML tasks with dynamic traffic patterns. Specifically, it reduces the latencies of first-token generation in LLM model servings by 1.04-2.73×, improves the training throughput of mixture-of-experts model by up to 1.3×, and accelerates deep learning recommendation model training by up to 1.2×.

1 Introduction

Efficient communication among GPUs is crucial in distributed ML tasks, especially given the expanding scale of AI infrastructure [9, 27, 32, 35, 53, 68]. Distributed ML tasks are typically bounded by GPU communication bandwidth [26, 32, 48, 54], driving the speed increase of both intra-server [1] and inter-server network. For example, NVLink [14, 39, 46, 52, 57] connects neighbouring GPUs with Tbps bandwidth; RDMA [21, 49, 66] offers inter-server connections with hundreds of Gbps bandwidth. However, RDMA NIC bandwidth grows slower compared to intra-server bandwidth [11], leaving inter-server connection a major bottleneck in distributed ML tasks.



(a) Static GPU-NIC binding (b) FuseLink

Figure 1: Current static GPU-NIC binding and FuseLink

To mitigate inter-server bottleneck, existing GPU clusters stack multiple NICs within each server to improve inter-server bandwidth [2, 23]. Currently, they bind each GPU communication to a specific PCIe-based NIC, as shown in Figure 1a. Note that the figure omits the hierarchical structure of PCIe [7] which leads to non-uniform bandwidths when a NIC access GPUs through different paths. There usually exists only one NIC that can provide full bandwidth for each GPU during inter-server communication, while other NIC bandwidths are limited by suboptimal PCIe paths.

Static binding is suitable for ML tasks with balanced traffic. For instance, 3D parallel training [42, 53] divides models into equal shards, producing identical traffic pattern across GPU workers [34]. However, for widely-deployed ML tasks that exhibit *imbalanced* inter-server traffic across NICs, stacking NICs with static traffic binding does not necessarily improve inter-server communication efficiency. Some workers may

[1]Some GPU connections, like NVLink, link GPUs within a short range between servers. However, we will still call them "intra-server connections" to differentiate them from "inter-server connections" that use NICs.

demand higher bandwidth than a single NIC (§2.1). Examples include disaggregated LLM serving [29, 40, 47, 69], mixture-of-experts (MoE) models [18, 55], and deep learning recommendation models (DLRM) [10, 25]. This traffic imbalance can lead to suboptimal performance, with some NICs being bottlenecks while other NICs remain idle. Moreover, the causes of traffic imbalance vary significantly, such as unpredictable input requests, model architectures, and parallelism methods, making it difficult to achieve optimal inter-server communication through static NIC load balancing strategies.

To fill this gap, we ponder a fundamental question: *can arbitrary ML workloads effectively leverage all available RDMA NICs for data transmission, aggregating links over multiple NICs as a "FuseLink" for inter-server communication?* If so, we could significantly improve GPU communication bandwidth, surpassing the limitations of static NIC binding, and achieve optimal NIC utilization in dynamic-traffic ML tasks, without requiring adjustments to parallelism strategies or modifications to application code.

We build FuseLink, a GPU communication framework that achieves optimal NIC utilization for distributed machine learning by enabling GPUs to flexibly transmit data through multiple NICs. Figure 1a shows a typical GPU server equipped with multiple GPUs and RDMA NICs, with each RDMA NIC statically bound to one GPU through PCIe switches (bridges). In contrast, Figure 1b illustrates FuseLink, which disaggregates the network resources of the inter-server network and enables flexible NIC utilization.

FuseLink's key idea is to integrate high-speed intra-server links as critical extensions of the inter-server network. Existing GPU communication frameworks, such as NCCL [45], leverages NVLink to improve throughput on NICs with suboptimal PCIe paths. However, these methods remains static to a specific NIC, lacking of abilities to dynamically balance NIC workloads or aggregating bandwidths. This is inherently limited by the incompatibility of intra- and inter-server networks, preventing access through NICs and NVLinks directly.

Our insight is that intra-server network can be seamlessly integrated to inter-server network by scheduling NIC workload and efficiently configure traffic relaying via intra-server connections. Additionally, we exploit characteristics of ML applications that they typically have a limited numbers of inter-server connections and send large messages in chunks [26, 32, 41, 42, 54]. These characteristics allows for efficient scheduling of traffic across NICs with runtime intra-server traffic relaying. As a result, FuseLink effectively leverages multiple NICs, aggregating multi-NIC bandwidths and significantly improving overall NIC utilization.

We build FuseLink on Nvidia platform with the following design goals:

Maximizing multi-NIC efficiency. When transmitting data from a GPU through multiple NICs, a key challenge is that multi-NIC transmission is bounded by PCIe bandwidth and PCIe topology that lacks direct connections between the GPU and NICs. We refer these NICs as *indirect NICs*. FuseLink enables efficient multi-NIC transmission by exploiting NVLink for data relaying on both sender and receiver sides.

Avoiding contention and interruption. Utilizing relay GPUs and multiple NICs should not interrupt or slow down ongoing computation and communication tasks by consuming extra memory and bandwidth resources. FuseLink avoids such interruption by employing priority-based memory management and network requests scheduling.

Readily deployable. FuseLink is designed to work with existing hardware and ML frameworks commonly found in GPU clusters, which allow benefiting from FuseLink without modifying ML applications. We implement FuseLink on top of RDMA primitives as an independent networking layer to replace the default networking system, and integrate FuseLink into NCCL [45], allowing to use FuseLink seamlessly.

We evaluate FuseLink on Nvidia GPUs with eight-lane NVLinks and eight 400Gbps NICs for inter-server communication. Our evaluation shows that FuseLink significantly improves inter-server GPU communication bandwidth, achieving 212GBps between two inter-server GPUs, surpassing the eight-lane NVLinks bandwidth. End-to-end evaluations show that FuseLink effectively accelerates ML tasks with traffic imbalance, including LLM serving task time-to-first-token (TTFT [2]) by 1.04-2.73×, MoE training by 1.3×, and DLRM training by 1.2×.

This paper makes the following key contributions:

- We design FuseLink that boosts inter-server GPU communication over multiple NICs by integrating high-speed intra-server GPU connections (e.g., NVLinks).
- We integrate FuseLink into NCCL, enabling ML applications to benefit from it seamlessly.
- FuseLink effectively improves inter-server GPU bandwidth and ML tasks efficiency under imbalanced traffic.

2 Background

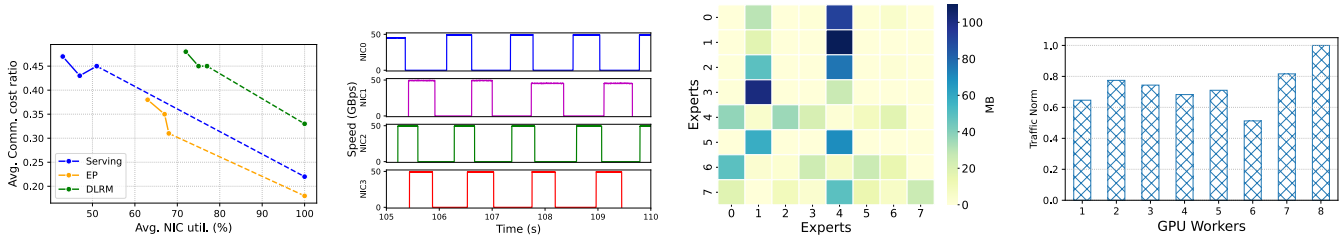
High-speed interconnect is essential to facilitate large scale machine learning. With the growing model sizes and expanding dataset volumes [16, 59, 60], real-world ML applications have been typically deployed in distributed environments [54, 56, 68], incurring large communication overhead and thus demanding high-bandwidth networks.

There have been substantial efforts on improving GPU communication bandwidth, including dedicated intra-server GPU connections and inter-server network. Industrial practices have been developing fast dedicated GPU interconnect as an integral part in ML clusters, providing Tbps network

[2] Inter-server communication impacts either time-to-the-first token (TTFT) or time-to-the-second-token (TTST), depending on when the prompt cache is transmitted to the decode phase. Here we transmit the cache before generating the first token, which affects TTFT.

ML Tasks	Communication Pattern | Cause			NIC util.	Comm. ratio
	via direct NICs	Concurrent transmission	Same traffic volume		
Distributed LLM Serving	✓	✗ | stochastic task arrival	✗ | varying requests sizes	13%-53%	11%-82%
Expert-parallel MoE	✓	✗ | async. transmission	✗ | different token batches	29%-65%	15%-42%
DLRM	✓	✓	✗ | different embeddings	59%-82%	28%-55%

Table 1: Dynamic-traffic ML tasks with communication patterns, ✓(✗) marks satisfied (unsatisfied) patterns



(a) Avg. NIC util. and comm. cost (b) Model serving (c) Expert parallelism (d) DLRM

Figure 2: Traffic imbalance and communication cost in ML tasks

between GPUs. For example, Nvidia builds NVLink and NVSwitch [46] to connect near-range GPUs; Google designs dedicated inter-chip-interconnect (ICI) for TPU groups [20]. Inter-server network [27], however, has relatively lower bandwidth on a single NIC than intra-server network. Therefore, GPU clusters typically stack multiple NICs within each server to satisfy inter-server bandwidth demand of GPUs [43]. The common configuration of NICs is to have the same number of NICs as GPUs within a server and install each NIC on the PCIe slot with direct access to the corresponding GPU slot. This ensures each GPU can get the full bandwidth of its NIC.

Despite the efforts of improving inter-server bandwidth, existing systems fail to fully utilize inter-server bandwidth for ML tasks with dynamic traffic because of the static binding of GPU traffic and NICs that causes low NIC utilization. The dynamic traffic is intrinsic to widely adopted ML tasks, including model serving [33, 37, 69], MoE models [15, 18, 55], and embedding transmission in recommendation models [10, 25]. Moreover, the NIC load imbalance is more pronounced across large GPU interconnect domains such as the NVL72 [3] system, where 72 GPUs and NICs are connected with NVLink and RDMA. We analyze the root cause by investigating ML tasks with dynamic communication patterns.

2.1 Deficiency in Dynamic-traffic ML

We test typical ML tasks with dynamic traffic shown in Table 1. Our tests are conducted on servers each with eight Hopper GPUs connected via eight-lane NVLink and eight 400Gbps NICs for inter-server network. GPU traffic is transmitted via direct NICs to maximize NIC throughput. Our metrics are NIC utilizations and the ratio of communication in ML tasks. We estimate NIC utilizations by the speed gap between static NIC binding and the ideal situation where GPUs can use all available NICs for communication. Figure 2a shows the average NIC utilizations and communication ratios in total costs, together with the estimated ideal utilization where we exploit all NICs to accelerate inter-server data transmission.

Disaggregated LLM serving. We test typical disaggregated LLM serving cases where model serving is split into prefill phase and decode phase [47, 50, 69], with processed requests sent from prefill phase to decode phase. We feed the input requests from public traces [5] randomly and record NIC utilizations when transmitting requests to decode stages. The results shows only 13%-53% of NIC utilization when transmitting data between phases, because serving traffic is stochastic, depending on task arrival times and request lengths, with traffic volumes ranging from hundreds of MBs to GBs. Even with advanced optimization tricks that overlap communication and computation [47, 50], we cannot fully utilize NICs because requests vary across GPU workers. Figure 2b depicts the recorded four NIC speeds during model serving, which shows idleness of some NICs while other NICs are busy.

MoE training. We test MoE model [18, 55] training on Mixtral 8×7B model with expert parallelism (EP) degree of eight and tensor parallel degree of four. We record NIC utilizations when GPU workers transmit tokens to peer workers with the activated experts. NIC utilization shows 29%-65%, with communication taking 28%-55% of the total cost. The root causes are asynchronized inter-server GPU communication and different token batches of experts during MoE training. Figure 2c shows the traffic map between expert models. EP training allocates expert models to GPU workers, with each worker training a subset of experts. The imbalanced traffic persists even with equal model partitions because expert layers are sparsely activated for each input token based on the output of gate layers. Since data samples are routed to different experts, GPU workers need to dispatch data to and collect

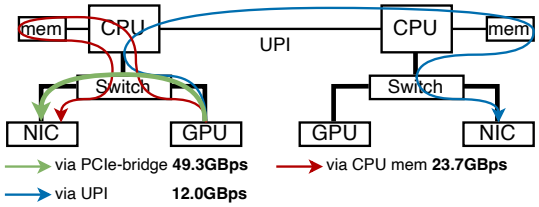


Figure 3: Conceptual intra-server PCIe topology with NIC bandwidth on different PCIe paths

data from peer workers, which leads to imbalanced all-to-all traffic across NICs. With different traffic volumes among experts, static binding of NICs and GPUs fails to fully utilize NICs bandwidth when all-to-all communication is bounded by the GPU pair with the largest traffic volume.

DLRM We test DeepFM [22], a deep learning based recommendation model with Avazu [61] dataset. DLRM [10, 25] consists of dense models and large lookup tables that store semantic embedding vectors of objects. In each training iteration, GPU workers fetch embeddings and push gradients from/to the server with the embedding table if they are not cached locally and train dense models with data parallelism. Embedding transmission volumes vary across workers, leading to different traffic volumes. Our results show that embedding transmissions achieve 59%-82% NIC utilization, and take up to 55% of the total cost. Figure 2d shows the imbalanced traffic distribution among eight GPU workers which causes performance to be bounded by the GPU worker with the largest embedding transmission.

2.2 Opportunities

Leveraging idle NICs. By analyzing dynamic-traffic ML tasks in Figure 2, we conclude that static NIC binding is not well-suited for such tasks. This is because achieving optimal NIC utilization with static NIC binding requires *transmission through direct NICs, concurrent transmission, and equal traffic volumes*. Without these conditions, communication performance is limited by tasks bound to specific NICs, while other NICs remain idle. This idle NIC capacity can instead be exploited to accelerate communication by dynamically scheduling traffic to idle NICs.

Multi-NIC communication is non-trivial because it does not improve inter-server bandwidth with only PCIe connections. On one hand, the total bandwidth is limited when all NICs access through the single PCIe interface of sender GPU. On the other hand, some NICs are indirectly connected with the sender GPU, with data traversing through PCIe root complex or even across NUMA, leading to suboptimal NIC throughput. With NVLink and imbalanced traffic in ML tasks, we can significantly improve efficiency on multi-NIC transmission.

Dynamic NVLink routing to bypass PCIe. Existing GPU communication frameworks, such as NCCL [45], leverage NVLink to bypass suboptimal PCIe paths when transmitting data through indirect NICs. However, they focus only on optimizing a single NIC, leaving other NICs restricted to suboptimal PCIe paths. This limitation prevents efficient utilization of multiple NICs for high-performance data transmission. Figure 3 presents the NIC speeds across different paths. The bandwidth of inter-server GPU communication is constrained by the PCIe interface and topology, particularly when using indirect NICs [30], which require data to traverse suboptimal paths. To address this, we enable dynamic traffic routing to peer GPUs via NVLink, allowing the efficient aggregation of multiple NICs' bandwidth for inter-server GPU communication.

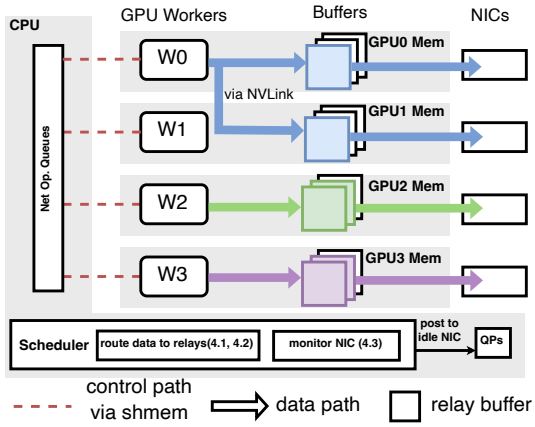

Figure 4: **FuseLink architecture in a GPU server** with four parallel GPU workers and four NICs. W0 is using both NIC 0 and NIC 1 for inter-server communication when W1 is not sending any traffic. W0 sending buffers are mapped to GPU0 and GPU1 for efficient data transmission

3 FuseLink Overview

FuseLink achieves multi-NIC communication by scheduling worker's traffic to multiple NICs dynamically with awareness of NIC load status, instead of statically binding the traffic to specific NICs. To effectively leverage indirect NICs, FuseLink routes traffic via intra-server connection to optimal GPUs for NIC access. The primary design goal of FuseLink is to achieve efficient multi-NIC transmission while minimizing contention risks, and is compatible with existing ML infrastructures. Figure 4 shows FuseLink architecture on sender side with an example workflow.

FuseLink initializes with inter-server connection setup. FuseLink explores the intra-server topology and establishes RDMA connections. During connection setup, FuseLink identifies available NICs for inter-server communication. Based on the topology, FuseLink selects the optimal data path for each NIC and GPU. If a NIC is directly connected to the GPU via a PCIe bridge or PCIe switch, it uses this direct path, as the NIC can access the GPU with full bandwidth. Otherwise,

FuseLink selects a router GPU for relaying data to the NIC. In Figure 4, GPU1 is the router when GPU0 sends via NIC1.

Inter-server GPU communication starts with receivers issuing *credits*, which are data structures containing necessary resources for initiating RDMA. These resources include receiving memory regions and requested data sizes. Crucially, the credits contain idle NICs information, derived from FuseLink actively monitoring NIC receiving load status. This allows senders to select the suitable NIC for sending data. Credits are common in RDMA-enabled applications [17, 28, 45, 62] because of its bypassing feature.

On sender side, FuseLink intercepts sending requests and waits for credits from receivers. At the same time, FuseLink monitors NIC sending load status. When credits arrive, FuseLink considers both sending NIC load status and receiving load status to select optimal NICs for data transmission. Moreover, FuseLink leverages intra-server GPU connection to route traffic efficiently to NICs. For instance, Figure 4 shows data routing through NVLink from GPU0 to GPU1 and sent through NIC1.

FuseLink gets notified when data arrives on receivers. Note that the data may be transmitted to a router GPU rather than the receiver GPU, because the sender may select a receiver NIC that has an indirect connection to receiver GPU. In this case, we stage receiving data on a router GPU first to ensure transmission efficiency. It then routes traffic via intra-server connection to receiver GPUs if needed.

Compared to existing GPU communication frameworks, FuseLink introduces several key advancements.

- **Disaggregated network resources.** Instead of operating on RDMA connections directly, FuseLink introduces an abstraction layer that unifies both intra-server and inter-server connection. This design enables efficient and flexible NIC utilization.

- **Dynamic NIC utilization.** FuseLink monitors NIC status in real-time rather than statically bind traffic to specific NICs. This approach allows to detect idle NICs and dynamically assign traffic to them, significantly improving overall bandwidth utilization.

- **Traffic routing with high-bandwidth GPU links.** Instead of statically binding traffic to NICs or intermediate GPUs [1, 44, 45], FuseLink fully leverage high-bandwidth GPU links for traffic routing, thereby bypassing PCIe constrains in traditional interconnects and enhancing communication efficiency.

3.1 Challenges

FuseLink supports multi-NIC transmission by allowing inter-server GPUs to dynamically schedule traffic to NICs. However, there presents several technical challenges:

Design	Inter-server BW(GBps)	Speedup
Baseline	49.27	1.0
Efficient relaying §4.1	78.39	1.59
Eliminate Interruption §4.2	76.37	1.55
Reduce NIC contention §4.3	178.59	3.62
Scheduling Efficiently §4.4	212.35	4.31

Table 2: Designs and achieved speedup over baseline

Relaying overhead. (§4.1) FuseLink introduces flexible intra-server traffic routing across GPUs to address the bandwidth limitations when transmitting through multiple NICs. However, GPUs are not inherently optimized for relaying data to NICs. Instead, both GPUs and intra-server connections are optimized for memory I/O between devices [24, 30], which is incompatible with PCIe-based NICs. This gap enforces frequent device synchronizations during network transmission, significantly slowing down the data path. For instance, when a GPU acts as a relay to transfer data from other GPUs to NICs, the data must be fully available on the relay GPU before NICs can access it. This results in frequent synchronizations between the relay GPU and sender GPUs. Consequently, the NIC throughput has minor improvements compared to the throughput in Figure 3. We address this challenge by actively planning relay data paths by memory remapping, thereby efficiently relaying data via GPUs for multi-NIC transmission.

Interruption and contention risks. (§4.2,§4.3) Maintaining performance isolation is challenging when utilizing NICs and GPU memory. These resources may contend for NIC bandwidth during data transmission, potentially disrupting tasks by draining GPU memory. Consequently, inter-server bandwidth is limited because of NIC contention, as listed in Table 2. The primary cause of the contention is FuseLink's strategy to schedule traffic to idle NICs when peer workers are not engaged in communication tasks. However, NIC idleness are temporal in dynamic-traffic ML tasks [10, 18, 47]. When peer workers initiate new communications, outstanding traffic may still in transmission, scheduled by FuseLink during periods idleness. We address this challenge by prioritizing ongoing tasks on relay GPUs and monitoring network resource usage with priority-based scheduling. This approach enables senders to identify idle NICs and eliminate interruption risks.

Scheduling overhead. (§4.4) Dynamically scheduling traffic to NICs is inherently complex, considering requirements to mitigate contention risks and to avoid traffic interference and interruption, making the reduction of control overhead a significant challenge. Existing works on communication scheduling focus mainly on task-level scheduling [51, 64, 65] to maximize network resource utilization. However, they fail to identify idle NIC resources and schedule communication efficiently. We address this issue by implementing an efficient traffic monitoring and scheduling strategy that balances monitoring accuracy with performance.

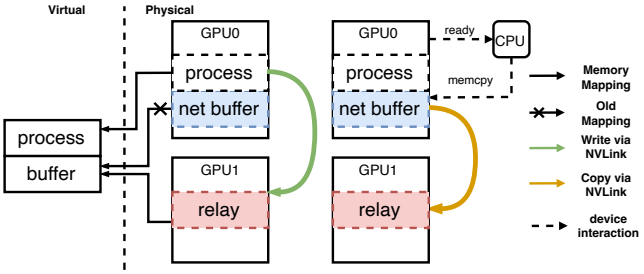

Figure 5: Candidate intra-server traffic redirection methods *D1* (left) and *D2* (right) using two GPUs as an example. The network buffer is allocated on GPU0. *D1* remaps network buffer to relay GPU and GPU threads fill relay buffer directly. *D2* initiates asynchronized memory copy between GPUs from CPU side after network buffer is ready

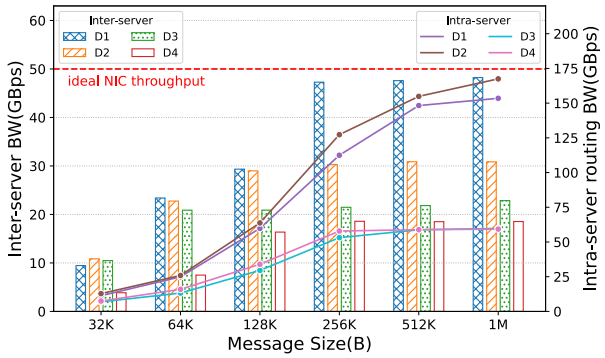

Figure 6: Intra-server relay bandwidth and indirect NIC throughput. *D1* has less intra-server bandwidth than *D2*, but has the highest indirect NIC throughput

4 FuseLink Design

We illustrate FuseLink design with a focus on solving the aforementioned challenges, achieving high NIC utilization while without interrupting peer GPUs.

4.1 Efficient Intra-server Relaying

Efficiently relaying data across GPUs to get high bandwidth on indirect NICs is difficult mainly because GPU interconnect and inter-server network are incompatible. This incompatibility enforces memory copy and device synchronizations before sending with NICs, which stalls network transmission and prolongs message latency.

To address this challenge, our insight is to exploit the existing memory I/O on network buffers during inter-server communication and redirect the traffic via memory remapping. FuseLink achieves efficient intra-server traffic relaying without modifying existing ML frameworks by taking advantages of the existing virtual address systems [6]. The system manages GPU memories in a unified virtual memory address space, which allows to map virtual memory addresses to arbitrary physical memories. With this feature, FuseLink decouples network buffers with the physical memories and remaps them to buffers on relay GPUs, so that traffic is redirected through intra-server connections via memory I/O when applications fill the network buffers.

To show the rationale of FuseLink relaying with remapping, we explore the design space by inspecting inter-server communication in two steps. ① The GPU worker fills network buffer, and ② The GPU notifies CPU to initiate RDMA transmission. To configure the data path without code modification, we have the following candidate solutions. *D1*: modify step ① so that the GPU writes data to remapped buffers on relay GPUs. *D2*: modify step ② so that the CPU copies data to relay GPUs then RDMA. *D3*: GPU threads write data to buffers mapped to host memory. *D4*: CPU initiates memory copy to host memory.

Among four candidate relaying methods, *D3* and *D4* achieve the same bandwidth as PCIe shown in Figure 3, thus limited by PCIe speed and cannot improve relaying efficiency. *D1* and *D2*, however, have pros and cons and cannot be easily compared. As shown in Figure 5. *D2* has high intra-server bandwidth when performing memory copy in a batch asynchronously, while *D1* enforces synchronized memory load and store and involves memory remapping with extra overhead. However, *D1* has only one copy step to relay GPUs, achieving higher data path efficiency and lower message latency. To this end, we set up performance benchmark to select the optimal intra-server relay method.

Benchmark indirect NIC throughput. We test GPU communication bandwidth through indirect NICs on servers with multiple GPUs, eight-lane NVLinks, and 400Gbps NICs. The theoretical bandwidth of eight-lane NVLinks is 200 GB/s. The experiment is conducted by sending messages constantly between two inter-server GPUs via indirect NICs. The traffic is routed from the sender GPU to indirect NICs with relaying methods *D1*-*D4* respectively. We record intra-server traffic relaying bandwidth and throughput on the indirect NIC under different data chunk sizes. Figure 6 shows the intra-server relaying bandwidth and indirect NIC throughput.

Among four relaying methods, *D1* achieves the highest throughput on the indirect NIC, compared to *D2*-*D4*. *D3* and *D4* route data to host memory via PCIe, thus are limited by PCIe bandwidth. In contrast, *D1* and *D2* exploit NVLink connections, achieving much higher relaying bandwidth. When comparing *D1* and *D2*, we observed that *D2* has higher intra-server relaying throughput, because CPU-initiated memory copy between devices batches memory copy, which achieves higher throughput than GPU-initiated memory copy.

However, *D1* achieves the highest NIC throughput. The reason is that *D1* has the most efficient data path between the GPU and indirect NICs through memory remapping, which brings the following benefits:

① High indirect NIC throughput: *D1* remaps network buffer to peer GPUs, so that relaying is done when GPUs fill send-

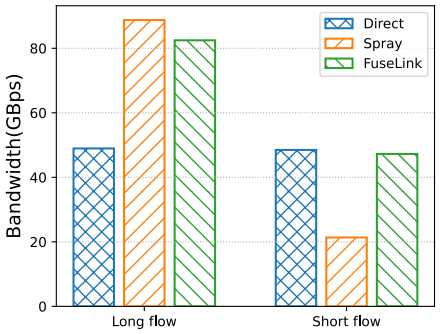

Figure 7: Performance of long flow and short flow under direct NIC communication, traffic spraying, and FuseLink interruption-free relaying

ing buffer. *D2* introduces additional data copy across GPUs, limiting the throughput over indirect NICs.

② Low message latency over indirect NICs: *D1* achieves lower message latency than *D2* over indirect NICs without additional CPU involvement. Unlike *D2* CPU-initiated relay copy, where the GPU must synchronize with CPU to signal data readiness with extra delay, *D1* eliminates such synchronization overhead. Furthermore, *D1* masks the extra intra-server relaying latency by overlapping it with pipelined intra- and inter-server communication, effectively mitigating latency penalties for small-to-medium messages.

With benchmarking, we use remapped network buffer for efficiently relaying traffic to indirect NICs because of three key performance advantages: First, it has no duplicate data copy of the traffic, compared to CPU-initiated data copy between GPUs. Second, it has less device synchronizations because GPU threads can write data directly to peer GPUs. Third, it avoids CPU involvement, which saves the latency in calling memory copy functions.

4.2 Interruption-free Relaying

While intra-server relaying brings significant benefits in NIC throughput, it brings risk of interrupting peer GPUs. Specifically, multi-NIC communication may take peer GPU bandwidth resources, and the memory consumption on relay GPUs may drain peer GPU memories, causing unexpected out-of-memory (OOM) error.

Relaying without interrupting communication. FuseLink accelerates GPU communication only during idleness of the indirect NICs. Although equally spraying traffic to all NICs within the server achieves optimal NIC utilization, it may disturb or even interrupt peer GPU communication over direct NICs. FuseLink strikes a balance between NIC utilization and fairness. This ensures that peer GPU communication tasks are not interrupted by traffic relaying.

We compare FuseLink interruption-free design against traffic spraying in Figure 7, where two GPUs send data through two NICs respectively. The first GPU has a long inter-server flow, while the second GPU is the victim, which has a relatively short flow and is constantly interrupted by the first GPU. In contrast, FuseLink exploits the indirect NIC only when the second GPU does not have inter-server traffic, preventing unfairness problem. FuseLink controls the traffic volume during intra-server relaying to avoid interference with GPUs engaged in intra-server communication. In practice, intra-server GPU communication, such as aggregation in tensor parallelism, overlaps with inter-server communication via NICs. To ensure isolation, FuseLink marks NICs as busy during TP communication and relaying, preventing contention with intra-server communication and other relaying traffic.

Relaying without interrupting memory allocation. If memory requirements of the running tasks on relay GPUs are known, FuseLink can easily eliminate OOM risks by limiting the total sizes of relay memories. Unfortunately, accurately calculating the memory footprint of a running task on GPUs remains challenging, and existing works do not have precise estimations [19], leaving risks of causing OOM due to relay buffer allocations. To mitigate this problem, FuseLink provides a best-effort solution that combines both memory usage constraints and adaptive approaches.

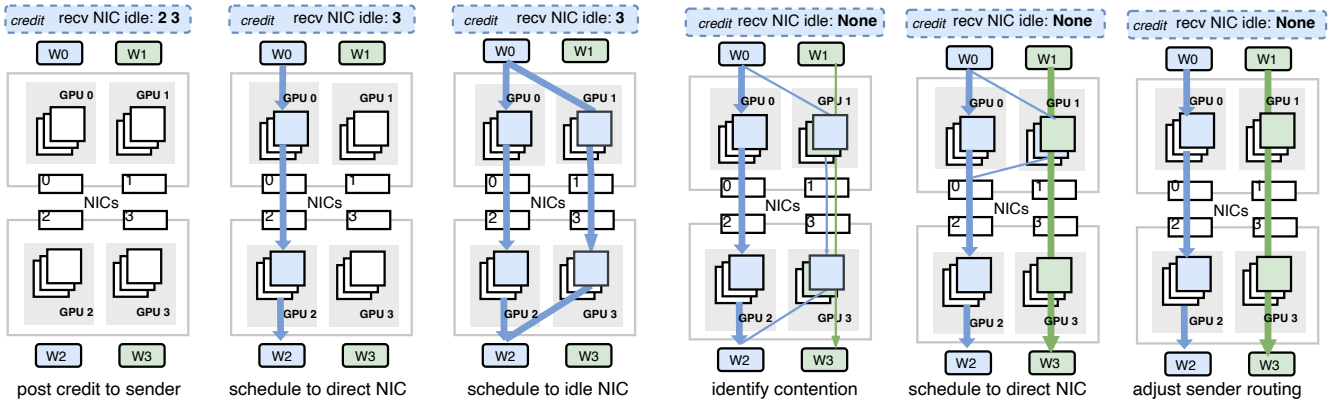
First, FuseLink sets a configurable upper limit for relay memory usage. If the relay memory on a GPU exceeds the limit, FuseLink will stop allocating more relay memories until memories from existing connections are released. Although this limitation cannot fully eliminate OOM risks, it allows FuseLink to adjust resource allocation according to user demands. For example, one may set high memory limitations to encourage FuseLink to take more multi-NIC transmissions with GPU relaying, thereby aggregating higher bandwidth with multiple NICs.

Second, FuseLink allows for prioritizing memory demands of running tasks on relay GPUs by removing relay memories when releasing can help satisfy memory allocation of the running tasks on relay GPUs. Specifically, when memory drains, FuseLink first checks whether releasing relay memories will free up enough space. If so, FuseLink releases the relay memory to give in to ongoing tasks. Otherwise, it means the task will encounter an OOM error regardless of the relay memory.

4.3 NIC Contention Mitigation

We next discuss the challenges on how to efficiently exploit idle NICs while avoiding GPU workers contending for NIC resources. Doing so is difficult mainly because of the unpredictable and imbalanced traffic in ML applications with dynamic communication patterns.

FuseLink mitigates NIC contention by assigning varying priorities to traffic from different GPUs during NIC scheduling. FuseLink monitors NIC load status and marks NIC as busy or idle, indicating whether NICs are working for high-priority GPUs. When a GPU engages in communication, it is granted the highest priority on its direct NIC, preventing peer



(a) Scheduling for exploiting idle NICs

(b) Scheduling for preventing contention

Figure 8: Traffic scheduling illustration. We emit ordinary elements in credits, such as memory regions, for simplicity

GPUs from using that NIC. Furthermore, FuseLink limits the outstanding traffic scheduled to idle NICs, thereby reducing potential contention when high-priority GPUs initiate communication. Our approach is based on the need for GPU workers to fully utilize their direct NICs in a 1:1 GPU-to-NIC configuration.

During communication, receivers encode idle NICs in credits and post to senders, who decide which NIC to transmit data based on NIC status of both sides. This design can be decomposed into two modules: 1) §4.3.1 FuseLink monitors NIC load status by inspecting completed network operations of high-priority GPUs. 2) §4.3.2 FuseLink aggregates idle NICs on both sides to guide traffic scheduling, with intra-server routing configured via memory remapping.

4.3.1 Worker-aware NIC Monitoring

FuseLink marks the status of NICs as idle or busy by monitoring the network operations posted by ML workers within the server. ML workers post network operations, such as send and receive, to FuseLink through first-in-first-out (FIFO) queues, instead of operating on RDMA connections directly. FuseLink collects network operations and post work requests to NICs. Then FuseLink polls RDMA completion queues to get finished operations.

The straightforward solution to decide whether a NIC is idle is by checking NIC TX and RX counters. However, reading counters cannot tell which worker is sending or receiving data, which hinders contention prevention when we have multiple workers transmitting data through the same NIC. Instead, FuseLink monitors NICs workload from the work requests on RDMA connections. Note that we configure NIC status to be decided by workers that have the highest priorities on the NIC. The rationale is that we aim to isolate traffic and guarantee the network performance of the high-priority worker.

FuseLink identifies idle NICs by periodically checking new completions of network operations posted by high-priority workers. If no new completion since last polling, FuseLink will mark the NIC as idle. As illustrated in Figure 8a, NIC1 is idle because W1 is not sending data to W3, and NIC0 is busy since W0 is sending to W2. Once found idle NICs, FuseLink schedules traffic from other workers to idle NICs. If a new completion is found, it means there exists new traffic since last time, and FuseLink will mark the NIC as busy. In this case, we will not schedule traffic to the busy NIC. FuseLink schedules traffic of low-priority workers to their direct NICs for performance isolation.

The rationale of marking NIC status as idle or busy is that ML applications typically have large traffic that can fully occupy NICs when they have communication tasks [34]. Therefore, we allow GPU workers to fully occupy their direct NICs. If GPU workers share direct NICs, FuseLink does not isolate traffic between these workers.

4.3.2 Load-aware Scheduling

We introduce load-aware traffic scheduling in three steps: 1) aggregating NIC load status on the sender and receiver side, 2) selecting NICs and initiating data transmission, and 3) performing intra-server traffic routing inside receivers via memory remapping.

Aggregating NIC load status. FuseLink orchestrates communication by receivers giving credits to senders and FuseLink configures credits to include NIC load status on receivers. Posting credit is necessary in RDMA communication because of the nature of RDMA that bypasses remote side processors, making senders unaware of receiver resources. RDMA communication with credits is common in existing distributed ML frameworks [1,45]. After getting credits, senders know NIC load status on both sides.

Selecting the NIC for sending. The NIC selection is based on NIC status and priorities of the worker on NICs. FuseLink selects the direct NIC of worker if it is idle. Otherwise, FuseLink selects an idle indirect NIC if exists. Note that we limit the number of outstanding operations posted to indirect NICs to reduce contention risks. Without limitation, we may post too

many requests to indirect NICs and cause severe contention when high-priority workers start communicating. If no idle NICs found, FuseLink selects the direct NIC.

Routing traffic on receivers. FuseLink writes data to receiver memory that resides on the GPU with direct PCIe connection to ensure transmission efficiency. However, the GPU could be different from the worker GPU that requests the receiving. In this case, FuseLink maps the receiving address to the memory where the received data locates. On sender side, the data may be already on relay buffers when getting credits. FuseLink remaps relay memory before the next sending operation, with the cost of one suboptimal sending.

We demonstrate the traffic scheduling with an example, as shown in Figure 8a. FuseLink first identifies NIC idleness when W1 is not posting any traffic. Then, for network operations posted by W0, FuseLink schedules them to NIC1 by allocating credits that indicate sending through NIC1. FuseLink remaps receiving memory on GPU1 to enable efficient NIC access. On sender side, FuseLink gets credits and posts sending operations to NIC1. Because the data is already on GPU0, the data is sent through suboptimal data path. After sending finished, FuseLink remaps relay buffers to GPU1 so that the subsequent sending is efficient.

When traffic contention happens on NIC1, as shown in Figure 8b, FuseLink detects contention when W1 is posting network operations to NIC1 and gets completions. In this case, FuseLink performs similar steps as exploiting idle NICs. FuseLink schedules subsequent network operations back to NIC0, together with router memory remapped to optimize data path.

4.4 Scheduling with Efficiency

FuseLink schedules communication to multiple NICs when detecting idle NICs in the server. Our design of NIC monitoring and traffic scheduling do not enforce strict idle NIC utilization or precise contention prevention, which is difficult to achieve due to control plane efficiency requirements. Instead, we have the following tradeoffs for control plane efficiency:

First, FuseLink marks NIC load status based on new completions of operations posted by GPU workers, which is later than transmission start time. The delayed marking is more efficient than detecting whether a NIC is sending traffic for a GPU worker. The delay is acceptable because existing frameworks, such as NCCL, divide large messages into chunks and send in pipeline. In NCCL, the default configuration is 512KB, which makes the delay marking about 10us under 400Gbps network.

Second, FuseLink allows bounded contention over limited number of network operations. In the worst case, FuseLink schedules a batch of operations to an idle indirect NIC and the peer worker starts communicating immediately. This ensures the scalability of FuseLink traffic scheduling in a large GPU cluster because FuseLink only needs to gather NIC utilization information of peer nodes during communication. The scheduling overhead is determined by the number of NICs and concurrent connections, which are limited by hardware configurations and ML applications.

Third, FuseLink allows bounded suboptimal transmission through indirect NICs, because the NICs selected may have suboptimal data path to the router GPUs, as illustrated in Figure 8b during receiver scheduling. We bound the suboptimal transmission by sender remapping, with the assumption that the next sending operations have optimal data path. Our design is based on the ML traffic pattern that NICs load status do not change frequently, as ML computation and communication last for long time intervals.

After optimizations, control plane overhead mainly comes from the following components:

NIC monitoring overhead. Before issuing operations, FuseLink checks NIC status and decides how to route the traffic. To reduce the monitoring overhead, FuseLink checks status of NICs after issuing a batch of network operations. For example, FuseLink checks NICs status after scheduling eight network operations. Subsequent operations are scheduled according to the NIC status after the last batch. The coarse grained NIC monitoring brings acceptable scheduling overhead because ML applications usually have large message sizes and are bounded by bandwidth.

Traffic routing overhead. When NIC encounters idleness or contention, FuseLink remaps the receiver relay buffer and switches the connection by posting credits to senders. The overhead consists of checking the NIC status, fetching new connection, and remapping relay buffers. Traffic rerouting happens when NIC status changes. In machine learning, NIC usage displays typical on-off patterns. Thus, NIC status will not change frequently, bringing limited traffic routing overhead.

5 Implementation

We implement FuseLink as an independent networking module to replace the default Infiniband networking in NCCL, a widely-used GPU communication library, so that ML applications can use FuseLink without modifying codes. We incorporate FuseLink in NCCL by intercepting networking layer functions called by NCCL proxy threads that originally post RDMA work requests to NICs. After loading the plugin, NCCL proxy threads interacts with FuseLink for GPU communication, instead of operating on NICs directly. Our implementation has about 3000 lines of code in C++.

In the default implementation, NCCL sets up worker threads as proxies to communicate with peer GPUs through inter-server network. Proxy threads build RDMA connections and post work requests to NICs. ML processes send data by writing to network buffers handled by proxy threads. When

receiving data, ML processes indicate receiving buffers and get notified from proxy threads when the data is ready.

We intercept proxy thread function calls to interact with FuseLink, including connection establishment, network buffer registration, and sending/receiving data.

Connection establishment. Instead of building raw RDMA connections, we modify proxy threads by posting connection request to FuseLink, which handles the request by setting up connections through multiple NICs within the server. After connection setup, proxy threads get connection ids that are used to post sending and receiving operations. All network operations are conducted by posting control messages to FuseLink with the connection id.

Registering buffers. By default, NCCL registers buffers on the specified device to enable RDMA NICs to access network buffers. We modify proxy threads to expose network buffers to FuseLink, which remaps buffers to relay GPUs and registers network buffers on RDMA NIC. Since each buffer only needs to be registered once in the NIC, remapping to relays brings minor overhead. Note that FuseLink maps network buffers back to original GPUs when NIC contention arises. Thus, we register network buffers on relay GPUs and original GPUs to avoid repeated registration. The registered memory regions are selected based on the current GPU to which the network buffer is mapped.

Sending & receiving. In NCCL, high-level communication tasks, such as sending a large data block and collective communication, are divided into data chunks.

On the sender side, the send function returns with an empty handler if no new credit is received. After receiving valid credits, NCCL sends with data in a ring slot and connection specified in credits. If the ring slot buffer is on a GPU that is not directly connected to the selected NIC, it means the receiver has scheduled an indirect NIC for data transmission. FuseLink marks the indirect NIC and remaps data to the buffer on a relay GPU. Send function returns with a valid handler if the data transfer to relay GPUs has started successfully. After the data is ready on the relay buffer, the sender starts data transfer to the remote side with RDMA.

On the receiver side, FuseLink collects NIC usage status to identify idle NICs and contention NICs. For each channel, FuseLink assigns one NIC to process receiving requests by giving credits to sender side specifying connections on the NIC. FuseLink schedules traffic to connections on other NICs by changing the RDMA Queue Pairs (QPs) and the memory addresses in ring slots used to receive data, which is transparent to applications.

6 Evaluation

We evaluate FuseLink capabilities in microbenchmarks and ML applications. In microbenchmark, we answer the following questions: 1) What is the maximum inter-server bandwidth for a single GPU with FuseLink compared to the default GPU-NIC binding? 2) What is the overhead of FuseLink in traffic scheduling? 3) What are the performance benefits of FuseLink on machine learning tasks with imbalanced traffic?

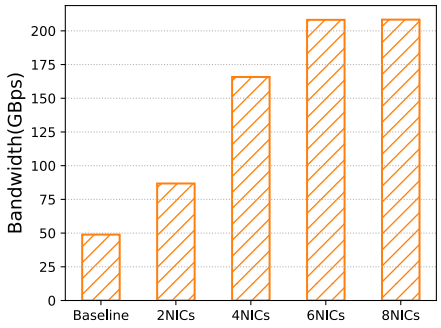


Figure 9: Average inter-server GPU bandwidth achieved by a single GPU when using different numbers of NICs

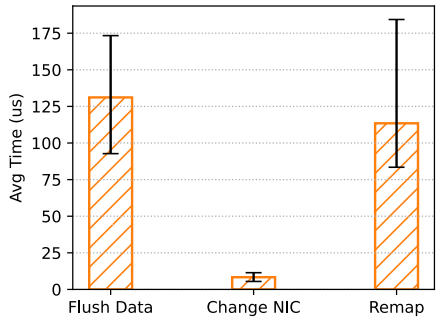

Figure 10: Average scheduling overhead decomposed into flushing data, changing NIC, and remapping

Evaluation setup. We conduct experiments on servers equipped with Intel 8480C CPU, eight Nvidia Hopper GPUs, and eight Connect-X7 400Gbps NICs for inter-server GPU communication. Intra-server GPUs are connected through eight-lane NVLinks and NVSwitches, delivering up to 200GB/s bandwidth for intra-server GPU communication. Each NIC is connected directly with one GPU through PCIe bridge, respectively. We deploy by running FuseLink scheduler as a daemon process and ML workers load FuseLink as a NCCL plugin to replace the default IB network.

Baselines. We use NCCL with PXN enabled as the baseline when performing inter-server GPU communication. NCCL with PXN automatically pick up the best path for inter-server GPU communication via both NVLink and PCIe, but is limited by statically bind traffic to paths and cannot support transmitting data through NVLink on receivers.

6.1 Microbenchmark

Bandwidth improvement. We evaluate how FuseLink can improve bandwidth when transmitting data between two inter-server GPUs. We divide the whole sending data into 512K messages, a common size for inter-server GPU communica-

Controls	Avg. cost(us)
post & pull ops	0.8-1.4
query NIC load	0.9-1.6
process send	2.8-3.5
process recv	4.9-5.6

Table 3: Network operation processing overheads in FuseLink

tion in NCCL, and post them to FuseLink controller. In the baseline experiment, the traffic is statically bound to one NIC for inter-server communication. By contrast, FuseLink sends data through direct NICs and indirect NICs with GPU relays. We change the maximum number of NICs used by FuseLink and record the average bandwidth.

As shown in Figure 9, FuseLink achieves up to 212GBps bandwidth with six NICs, compared to the default setting with about 50GBps throughput, where GPUs communicate through only one NIC. FuseLink gets higher bandwidth by utilizing more NICs during inter-server communication. The upper limitation depends on the bottleneck between GPUs and NICs. If the NVLink bandwidth is larger than the sum of bandwidths of indirect NICs, FuseLink can aggregate all NICs bandwidth at maximum. Otherwise, the maximum bandwidth is the sum of the direct NIC bandwidth and NVLink bandwidth. In this experiment, FuseLink bandwidth stops scaling because NVLink has reached the maximum throughput.

Scheduling overhead Compared to posting RDMA requests to NICs directly, FuseLink incurs scheduling overhead during monitoring NIC workload and determining the NIC to post RDMA operations (§4.3). To improve scheduling efficiency, we make tradeoff to allow bounded suboptimal scheduling and sender data path (§4.4). We show that the scheduling overhead is acceptable and the tradeoff will not harm the overall performance. Table 3 shows the overhead of FuseLink when processing RDMA operations and scheduling. NIC monitoring and NIC selection are implemented using shared memory, which brings 0.9-1.6us latency on a batch of network operations. Relay remapping is called when optimizing the data paths between NICs and GPUs, which brings around 95-193us latency in each remapping.

Figure 10 shows the scheduling overhead when FuseLink changes NIC to prevent contention. Before changing NICs, FuseLink flushes the network buffer, i.e., finish all network operations on the buffer, and finally performs buffer remapping to adjust intra-server traffic relaying. The total scheduling overhead is minor compared to the communication time in distributed machine learning.

6.2 End-to-End Evaluation

We demonstrate that FuseLink can effectively improve the NIC utilization in imbalanced traffic ML tasks and bring benefits to the overall performance.

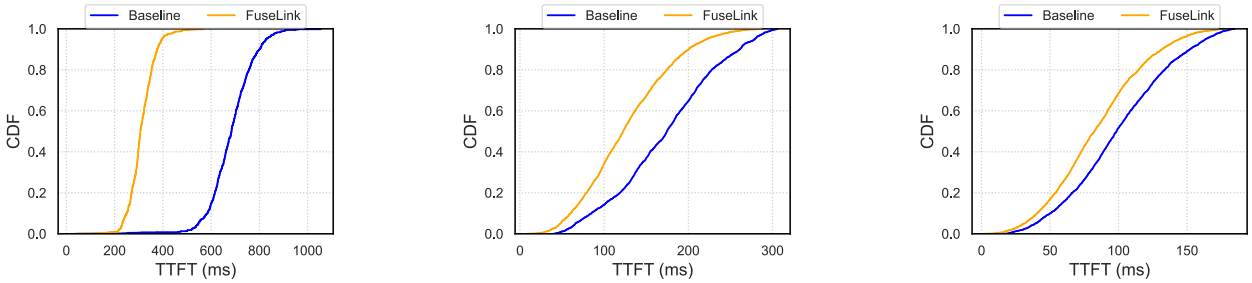
Model serving. We test FuseLink performance in model serving in disaggregated setting [47,69], where the serving process is divided into a prefill phase and a decoding phase across inter-server GPUs connected by NICs. We test OPT [67] models serving with 30B parameters under different tensor parallel degrees. We consider model serving in mixed requests, where batched user requests are fed to GPU groups for the prefill-stage computation. The processed user requests are sent to the decode-stage GPUs. The communication cost consists of sending prefix cache and user requests cache. We record the time-to-the-first-token (TTFT) as the performance metric, which includes requests computation and inter-server communication time.

#Instance	Setting	P50	P99
8	NIC Binding	684.54 ms	903.20 ms
	FuseLink	308.48 ms	464.55 ms
4	NIC Binding	174.46 ms	297.49 ms
	FuseLink	122.61 ms	259.73 ms
2	NIC Binding	98.09 ms	175.36 ms
	FuseLink	81.97 ms	160.36 ms

Table 4: Model serving TTFT comparison under different number of serving instances within a server

Figure 11a- 11c shows the CDF graph of TTFT recorded with different number of independent serving instances within a server. For every deployed serving instance, we randomly sample the serving prompt and feed to the prefill instances. We sample request lengths from public traces [5] with prefix and simulates with Poisson arrival rates. FuseLink shows 1.04-2.73× speedup over the baseline with NIC binding, where GPUs communicate only through the direct NICs. Notably, with smaller TP degrees and more instances per server, FuseLink shows greater speedup compared to scenarios with fewer instances and larger TP degrees, as the NIC exhibits more dynamic traffic pattern under more instances within a server. The performance improvement is attributed to two factors: First, FuseLink accelerates inter-stage data transmission, reducing communication overhead during first token generation; Second, FuseLink improves serving throughput and reduces the requests queueing time. Table 4 shows the TTFT of 50th percentile and 99th percentile of different numbers of serving instances within a server.

EP training. We test expert-parallel MoE training of Mixtral 8×22B model using tensor parallel degree as four and expert parallel degree as eight. In this case, each server has two experts training in parallel. We record the time spent on training iterations. Figure 12 shows the iteration times of the baseline and FuseLink. FuseLink improves the training throughput by 1.3× compared to the baseline. We notice that FuseLink brings less performance gain in later iterations, which can be explained by the design of gate layers that try to achieve load balance among experts [55], making the traffic across NICs closer to balanced NIC load compared to earlier iterations.



(a) Eight instances with TP=1 (b) Four instances with TP=2 (c) Two Instances with TP=4

Figure 11: FuseLink model serving performance under different TP degrees and number of serving instances

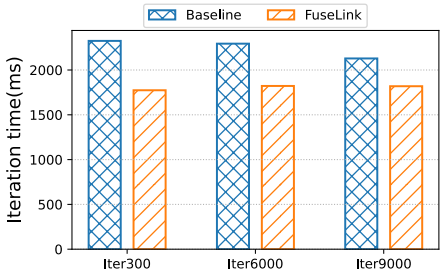


Figure 12: EP training times under NIC binding and FuseLink

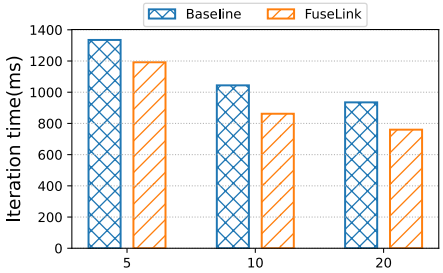

Figure 13: DLRM training iteration times under different cache sizes (GB)

DLRM training. We test FuseLink performance in DLRM training [13] model on Criteo advertisement dataset [4]. We configure 32 GPU workers to train the model in data parallelism and setup a dedicated server with large memories to maintain the embedding table. In each training iteration, the GPU workers first convert the categorical features in training samples into embedding vectors in the table. If the embedding cache does not have the required vector, the GPU workers need to fetch the embedding from the embedding server through NICs. Communication cost is mainly affected by the embedding cache sizes and training batch sizes of each worker. Limited cache sizes and large batch sizes tend to bring higher embedding cache miss and more embedding transmission. We set the training batch size as 1024 as suggested by [10]. Figure 13 shows the average iteration durations under different cache sizes when using FuseLink and static traffic binding to direct NICs. FuseLink can effectively reduce the training iteration times by accelerating embedding transmissions.

7 Discussion and Limitations

We discuss the application scope of FuseLink and limitations in existing ML infrastructures.

FuseLink in collective communication. FuseLink works the best under traffic imbalance scenarios, which are common in point-to-point communication. The point-to-point communication has become one of the major network costs in distributed machine learning, including MoE and model serving. In contrast, collective communication like ring all reduce synchronize GPUs with uniform traffic pattern across NICs [34], making them less suitable for FuseLink without extra modifications. Applying FuseLink in collective communication may require adjusting worker placements. For example, co-locating multiple data parallel groups within a server can produce imbalanced traffic across NICs in different parallel groups. However, such optimizations would require additional efforts to integrate with existing ML frameworks.

FuseLink in general GPU interconnections. FuseLink is designed and implemented on Nvidia GPU with NVLink connections, but is not limited by specific GPU devices, interconnections, or GPU-NIC ratios. In essence, FuseLink unlocks the capability of intra-server traffic routing and efficient multi-path transmission during inter-server GPU communication. FuseLink is powered by the ever-growing performance of dedicated GPU connections that have become integral in ML infrastructures. Industrial practices have deployed various of GPU interconnect [20, 46, 58] in their GPU clusters, making FuseLink widely applicable in today and future ML facilities [35, 36].

FuseLink ensures its design generality by relying on standard communication primitives. Specifically, RDMA enables NICs to access application memory from virtual address with backend physical memory mapped to any virtual memory on demand. We exploit this feature to enable RDMA NICs to access remapped location without changing the application network buffer address. We also take advantage of the GPU memory addressing that enables peer-to-peer communi-

cation between GPUs, which is essential in dedicated GPU connection to ensure efficient data transmission. The unified addressing and standard RDMA primitives do not rely on specific devices or GPU-NIC ratios. Therefore, FuseLink can be applied in general machine learning servers, including those with asymmetric GPU interconnects [8, 30] and other GPU-NIC ratios.

Corner cases of FuseLink scheduling. Since FuseLink optimizes scheduling efficiency with bounded contention, corner cases may arise where one GPU sends a small chunk of data through its direct NIC only when a peer GPU has just started using the NIC. In this scenario, FuseLink will route other GPU traffic to this idle NIC and then be preempted by the GPU with higher priority, and subsequently start using the idle NIC again in the next batch of sending. However, such cases are rare in machine learning workloads, because they feature large messages and relatively long time intervals between communication phases. This leaves sufficient time intervals for FuseLink to schedule traffic while maintaining relatively stable NIC utilization, minimizing routing frequency.

8 Related Work

PCIe $\times$ NVLink (PXN). NCCL has introduced PXN [44], an inter-server GPU communication mechanism that allows senders to use intermediate GPUs for inter-server communication. Similar to FuseLink, PXN removes the bottleneck of GPU-NIC connection that traverses through QPI/UPI, which cannot deliver full bandwidth. PXN is designed to avoid cross-rail traffic in rail-optimized GPU clusters because cross-rail traffic has to be routed through spine switches, which risks interfering with other flows in the network.

Despite the similarity of using intermediate GPUs, FuseLink has three key differences compared to PXN. First, PXN binds traffic to intermediate GPUs and statically copies data to GPUs. This can only improve one NIC throughput, yet others are in suboptimal PCIe connections. In contrast, FuseLink dynamically integrates NVLink interconnect in the network data path. Consequently, FuseLink can fully eliminate the suboptimal PCIe data path on multiple NICs during inter-server communication. Second, FuseLink identifies and leverages idle NICs, while PXN is configured statically by NCCL, given the system topology before running communication tasks. Finally, FuseLink achieves higher inter-server bandwidth for GPU communication by utilizing multiple NICs, while PXN is bounded by the single NIC bandwidth.

Multi-Path network protocols. Researchers have proposed datacenter networking protocols that aim to improve network resource utilization. For example, MP-TCP [63] and MP-RDMA [38] are multi-path transport protocols designed to utilize the rich path resources in datacenter networks; NetChannel [12], a host network stack that disaggregates the dedicated data path to improve utilization of host network resources. These protocols and network systems focus on a similar problem that network resources, such as host data paths and network paths, are not fully utilized because of dedicated resource assignments.

FuseLink differs from these works on the network resources and methods for multiplexing. On one hand, existing works try to multiplex network data paths with only host memories, while FuseLink mainly focuses on inter-server communication on GPU memories, which requires considering PCIe bandwidth and topology. On the other hand, FuseLink exploits dedicated intra-server GPU connections and integrates into inter-server networking to enhance inter-server networking, which is not explored in existing works.

Data path optimization. There have been efforts to improve network resource utilization from host side by solving the best data paths for inter-process communication. For example, SocksDirect [31] improves inter-process communication efficiency by implementing efficient communication primitives and automatically schedules the best data path to carry out data transmission, such as shared memory and RDMA. ARK [24] accelerates GPU communication by implementing an efficient DMA controller operated by GPUs, together with a GPU-driven execution model to improve computational efficiency without interfering with networking. FuseLink has similar methodologies that improve data path efficiency during GPU communication.

However, existing works on optimizing GPU communication data paths cannot be applied in dynamic ML tasks directly, because they cannot detect or leverage idle NICs timely. In contrast, FuseLink explored a new direction that exploit the underutilized NICs in dynamic-traffic ML tasks, with data path optimization in runtime.

9 Conclusion

In this paper, we present FuseLink to enable inter-server GPUs to efficiently communicate over multiple NICs. FuseLink exploits dedicated intra-server network for intra-server traffic routing to fully utilize GPU interconnects when communicating through NICs. FuseLink achieves improved inter-server bandwidth without interrupting ongoing computation and communication tasks on peer GPUs. Through our evaluation, we verify that FuseLink is effective in dynamic-traffic machine learning tasks, achieving high inter-server GPU bandwidth and accelerating machine learning tasks including LLM serving, EP MoE training, and DLRM training.

Tigon: A Distributed Database for a CXL Pod

Yibo Huang, Haowei Chen, Newton Ni, Yan Sun†, Vijay Chidambaram, Dixin Tang, Emmett Witchel
The University of Texas at Austin †*University of Illinois Urbana-Champaign*

Abstract

Building efficient distributed transactional databases remains a challenging problem despite decades of research. Existing distributed databases synchronize cross-host concurrent data accesses over a network, which requires numerous message exchanges and introduces performance overhead.

We describe Tigon, the first distributed in-memory database that synchronizes concurrent cross-host data accesses using atomic operations on CXL memory. Using CXL memory is more efficient than network-based approaches, but Tigon's design must address CXL's higher latency and lower bandwidth relative to local DRAM, as well as CXL's limited hardware support for cross-host cache coherence. For TPC-C and a variant of YCSB, Tigon achieves up to 2.5× higher throughput compared with two optimized shared-nothing databases that use CXL memory as a transport and up to 18.5× higher throughput compared with an RDMA-based distributed database.

1 Introduction

Despite decades of research, efficiently scaling a transactional database to multiple hosts remains a challenging task due to the complexities of data synchronization and concurrency control across hosts [17, 33, 48, 49, 56, 61, 66, 77, 85]. Existing distributed databases synchronize cross-host concurrent data accesses over a network, which introduces high and variable overhead due to cross-host message exchanges and high network latencies. For example, traditional shared-nothing databases partition data across hosts and let each host process all read/write operations to its partition [17, 33, 56, 66]. The performance of this architecture drops significantly when the database needs to process a large number of *multi-partition transactions*, that is, transactions that need to read or write data in multiple partitions and will be executed by multiple hosts. Multi-partition transactions are costly due to numerous message exchanges between hosts and the two-phase commit (2PC) protocol necessary to complete them [23, 48, 49, 61, 77, 85].

A recent line of research leverages RDMA to accelerate distributed transaction processing [4, 13, 20, 21, 32, 62, 71–73]. Many papers adopt an RDMA-based shared and disaggregated memory architecture to avoid multi-partition transactions [19, 44, 75, 78–80, 87]. However, the latency for memory access through RDMA networks is one to two orders of magnitude higher than local DRAM [26] and synchronizing concurrent read/write operations to database tuples through RDMA networks is still expensive, because round trips on RDMA-based networks have latencies in the microseconds range.

This paper proposes a new direction for building distributed transactional databases: *instead of synchronizing cross-host concurrent data accesses over a network, we propose synchronizing these accesses directly through memory, leveraging the capabilities of emerging CXL technology*. CXL memory is a memory module that can be physically connected and shared by a small number of hosts (e.g., 8–16 [6, 45]). The CXL protocol allows CPUs to directly access CXL memory using normal load and store instructions, and it provides much lower latency compared with RDMA-based shared memory. With CXL version 3.0 (and in 3.2 [2], which is the current version as of this writing) the specification allows CXL memory to be shared across hosts with hardware cache coherence, which provides new opportunities for cross-host data sharing and data synchronization. We call a collection of machines that share CXL memory a *CXL pod* [11, 29, 74, 86].

While CXL memory has advantages over RDMA and other networking technologies, it must be used with care. CXL memory has two major limitations: 1) it has higher latency (214-394 ns vs. 111-117 ns) and lower bandwidth (18-52 GB/s vs. 218-246 GB/s for a read-only workload) compared with local DRAM, as measured on hardware prototypes in a recent study [47]. and 2) only a small part of the physical CXL memory space, ranging from dozens to hundreds of MBs, will be kept hardware cache-coherent as reported in recent work from AMD [30]. Higher latency and lower bandwidth means a database cannot simply place all its data in CXL memory if it wants to achieve peak performance. Limited hardware cache-coherent memory means that database synchronization structures must be reorganized to minimize the use of this memory.

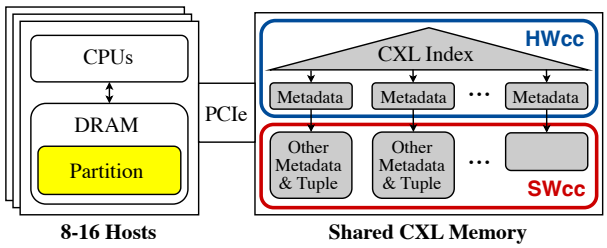

Figure 1: Tigon on a CXL pod.

In this paper, we introduce Tigon[1], the first distributed in-memory database that leverages CXL memory for efficiently synchronizing cross-host concurrent data accesses. Tigon benefits from the performance of CXL memory while avoiding CXL's weaknesses, based on a key insight about general transactional workloads: *while the size of a database could be large, the size of the set of tuples that will be concurrently read or written by running transactions from different hosts is small*. This is because each transaction typically accesses a small number of tuples (e.g., from a few to dozens) and the number of concurrently running transactions is typically equal to the number of available CPU cores for an in-memory database. For example, in TPC-C [7], a transaction accesses an average of 39 tuples, with a total data size of approximately 7 KB. Assuming 1,000 cores, each core executing one transaction, the system has at most 39K active tuples, which amount to 7 MB of data. We call such a set of tuples the *Cross-host Active Tuples* or CAT for short. We design Tigon to efficiently maintain the CAT in CXL memory, thereby increasing performance by converting multiple message exchanges into data structure operations. Because the data structure needs to contain only data that is currently shared, Tigon's performance is not limited by CXL's inferior latency and bandwidth relative to local DRAM.

Tigon initially partitions data across hosts as shown in Figure 1 and dynamically maintains the CAT in CXL memory. Cross-host concurrent accesses to the CAT can be efficiently synchronized using atomic operations, metadata (e.g., database latches), and hardware cache coherence, allowing Tigon to adopt a single-host concurrency control protocol to ensure transaction semantics without using 2PC. If one host needs to access a tuple stored in a remote host, Tigon moves the tuple to shared CXL memory. The data shared in CXL memory will be moved back to its original host based on a system policy that considers access patterns to the shared data. In addition, each host can retain the data accessed exclusively by that host in local DRAM, leveraging its low latency and high bandwidth.

Tigon addresses two broad challenges for maintaining the CAT in CXL memory. First, maintaining the CAT in the limited hardware cache-coherent region may introduce frequent data movement between local DRAM and CXL memory, increasing CXL memory bandwidth usage and the latency for processing a transaction. Tigon addresses this challenge with an efficient software cache coherence protocol that enables it to use CXL memory that is not kept coherent by hardware. Tigon uses the capacity of this large software cache-coherent region for database data, which reduces the need for data movement. Tigon also reduces data movement with common sense optimizations like only copying updated tuples from CXL memory back into local DRAM.

Indexes and certain metadata (e.g., database latches) require intensive synchronization across hosts, which is efficiently provided by atomic instructions operating on hardware cache-coherent memory. A key design principle for Tigon is to separate data by synchronization requirements: synchronization-heavy metadata (e.g., indexes and latches) is stored in the hardware cache-coherent (HWcc) region, while other data (such as tuples) is stored in the software cache-coherent (SWcc) region, as illustrated in Figure 1. Databases already have synchronization primitives to ensure the integrity of tuples under concurrent accesses, so we co-design Tigon's software cache coherence protocol with the database's mechanism for protecting the integrity of tuples to minimize synchronization overhead.

The second challenge Tigon addresses is to efficiently access data and provide transaction semantics (i.e., ACID properties) while data is moving between local DRAM and CXL memory. To do so, Tigon utilizes database latches and indexes to provide efficient access to the CAT under data movement and enhances concurrency control (i.e., two-phase locking (2PL) and next-key locking) and logging protocols to ensure transaction semantics without using 2PC. First, for a tuple moved to CXL memory, the owner host can cache a shortcut pointer to quickly find this tuple without searching the CXL index in CXL memory, reducing latency and CXL memory bandwidth usage. The challenge is to ensure its correctness under concurrent data movement. Second, we enhance 2PL to work together with a scalable logging protocol [82] such that Tigon, running on multiple hosts, does not need to use 2PC when committing transactions. Finally, we design an enhanced next-key locking protocol that maintains minimal additional metadata for each tuple to avoid the phantom problem [24]. We also design a lightweight data movement policy that keeps tuples that will most likely be exclusively accessed by a single host in local DRAM.

The novelty of Tigon lies in its use of inter-host CXL memory to accelerate transaction processing, while avoiding the performance pitfalls of using CXL memory naïvely. Tigon uses inter-host CXL memory to accelerate message passing, but it also reduces the need to pass messages by using data structures in inter-host CXL memory that are synchronized via atomic operations. The result is greater throughput for transaction processing, especially transactions that access data from multiple partitions. Experiments on TPC-C and a variant of YCSB demonstrate that Tigon achieves up to 2.5× higher throughput compared with two optimized shared-nothing databases using CXL memory as a transport and up to 18.5× higher throughput compared with an RDMA-based distributed database.

While prior research has explored improving the efficiency

[1] A Tigon is a hybrid of a male tiger and a female lion.

of databases using CXL memory [8, 10, 39, 60], none considers leveraging limited hardware cache-coherent memory for building an efficient distributed database. This work is also different from prior research on memory tiering and pooling [22, 45, 54, 59, 65], which makes CXL memory available to applications transparently, placing the burden of memory management and data migration to system software (or software and hardware [83]). Tigon, in contrast, is built to explicitly move data to and from CXL memory shared among multiple hosts and explicitly allocates CXL memory and places data structures in either the hardware or software cache-coherent regions.

This paper makes the following contributions:

- We introduce the first distributed in-memory database that synchronizes cross-host concurrent data accesses via atomic operations on CXL memory.
- We address the hardware limitations of CXL memory by maintaining the CAT in CXL memory and using a software cache coherence protocol to reduce the cost of maintaining the CAT (§3.2).
- We design new methods for efficiently accessing the CAT under data movement and enhance concurrency control and logging protocols to ensure transaction semantics without using 2PC (§3.4 and §3.5).
- We implement Tigon (https://github.com/ut-athenarc/tigon) and perform extensive experiments that show its performance advantages over shared-nothing databases and an RDMA-based distributed database (§4).

2 CXL Pod Background and Challenges

Compute Express Link (CXL) is a high-performance, open-standard interconnect for communications between CPUs, devices, and memory based on PCIe 5.0 and 6.0. CXL memory is a memory module connected to one or multiple hosts and has different characteristics depending on the CXL specification [2] version and the type of device. Type-3 CXL devices are memory expanders (that use the CXL.mem protocol), with the version 1.1 CXL specification allowing a single host to access PCIe-connected memory in a cache-coherent manner. CXL 3.0 and the most recent CXL 3.2 specify cacheline-granularity memory sharing and cache coherence across multiple hosts.

A recent study [47] shows that CXL memory has significantly higher latency (214-394 ns vs. 111-117 ns) and lower bandwidth (18-52 GB/s vs. 218-246 GB/s for a read-only workload) compared with local DRAM. Exact bandwidth depends on the specific hardware prototype and the memory access pattern. Another study [64] reports 11.7 GB/s sequential read bandwidth, but falls as low as ∼5 GB/s for other access patterns.

CXL pod. A CXL pod [11, 29, 74, 86] includes a small number of machines (e.g., 16) that connect directly to a shared CXL memory module via multiple ports (called a multi-headed device [2] (MHD)). The advantage of an MHD is that it allows multiple hosts to connect to a single memory device without a switch, which adds significant latency. This scale of configuration provides rich computing resources for transactional databases and has small latency and bandwidth penalties compared with a single host [45].

A CXL pod is an intermediate organization between a shared-memory multi-processor and a distributed system. The pod has hosts with local, hardware cache-coherent memory. Each host also connects to a single, shared CXL memory module. The inter-host CXL memory supports limited (and expensive) hardware cache coherence. There is a long debate in computer architecture as to the limits of scalability of SMP machines [36, 53], but the pod provides a new set of tradeoffs. We built Tigon to navigate this novel and complex tradeoff space.

CXL memory devices that can be used in a CXL pod exist, notably SK Hynix's Niagara 2.0 [6] and a Microsoft prototype [11]. The former is limited to 8 hosts, and the latter to 2. Neither supports hardware cache coherence, but their latency and bandwidth are broadly similar to our evaluation testbed (§4). Tigon is designed for CXL devices with some hardware cache-coherent memory. Designing a database to be efficient without hardware cache-coherent memory is worthwhile future work.

Comparison to NUMA and RDMA-based architectures. NUMA and CXL memory share some architectural properties, but detailed studies show that NUMA behavior often differs significantly from CXL [31, 64]. In our experience building Tigon, we found that a NUMA platform served as an informative proxy for CXL, but much of our system tuning was specialized to CXL (e.g., CXL bandwidth is much lower than NUMA bandwidth on our testbeds). RDMA-based distributed databases are more scalable in terms of the number of nodes in the system because they use explicit addressing and switches, but they have a higher latency, in the microseconds range.

Hardware limitations of CXL memory. Three properties of CXL memory make it challenging to use for a database: (1) it has higher latency than local DRAM; (2) it has lower bandwidth than local DRAM; (3) it has limited hardware cache-coherent memory capacity. The high latency and low bandwidth means any system that uses CXL memory must lean heavily on the performance of local DRAM. Data can be copied into and out of CXL memory, but too much data movement will overwhelm its limited bandwidth.

Why inter-host hardware cache coherence is limited. The CXL standard, starting from 3.0, provides support for inter-host hardware cache coherence through back-invalidations, that is, the CXL device includes a snoop filter (similar to processor snoop filters) for managing coherence. However, providing cache coherence for the entire CXL memory address space will be too expensive to be practical due to the size of the snoop filter required and the metadata overhead, as shown by AMD [30]. There is no theoretical reason for the limitation, it is purely practical. There is a fixed area budget for the CXL

controller that is consumed by ports and control logic [11]. Snoop filters for the entire CXL memory address space would be large because they must track all cacheable data for every host. As an extreme example, Intel's Granite Rapids 6980P processor would require tags for 16×504 MB, or 7.9 GB of cacheable data. Snoop filters that are cost effective will cover a much smaller region. In order to control costs and complexity, vendors will limit the size of the hardware cache-coherent region of CXL memory devices. Because we do not have exact figures, our study varies the amount of available hardware cache-coherent memory to evaluate its impact (§4).

Failure model. We assume a fail-stop model, and achieve durability using logging. Logs are written to local SSD devices. A failure of any component causes a failure of (and subsequent recovery for) the entire system.

3 Tigon Design and Implementation

Tigon is a distributed in-memory database designed to run transactions efficiently on a CXL pod. Unlike traditional distributed databases, Tigon exploits unique features of the CXL pod to lower the overhead of cross-host coordination and significantly increase transaction throughput.

3.1 Tigon Overview

Architecture. Tigon adopts the Pasha architecture [29], where data is initially partitioned across the hosts of the CXL pod and dynamically moved between local DRAM and CXL memory. Each host is the *owner* of a disjoint partition of the data. It stores its partition in local DRAM and accesses this partition with low latency and high bandwidth. When data is accessed by its owner host, no cross-host coordination is required. When a host wants to access data it does not own, it requests the owner to move the data to shared CXL memory such that Tigon can maintain the *cross-host active tuples* (CAT), the set of tuples that are concurrently read or written by active transactions running on different hosts, in CXL memory. Shared data requires synchronization across hosts; hosts synchronize using latches and locks in the hardware cache-coherent part of CXL memory. Hosts communicate with each other by sending messages using CXL memory as a transport, similar to HydraRPC [50].

Software cache coherence (§3.2)**.** Tigon introduces a novel software cache coherence protocol for CXL memory because most of the physical CXL memory space will lack hardware cache coherence support. The chief insight is that hardware support for cache coherence is *only required* for key metadata, such as latches and locks, that are frequently accessed by multiple hosts; by carefully limiting the size of such metadata and strategically placing it in the hardware cache-coherent region, Tigon can provide software cache coherence using the database's existing concurrency control techniques. Software cache coherence allows Tigon to use much more CXL memory than the limited hardware cache-coherent region.

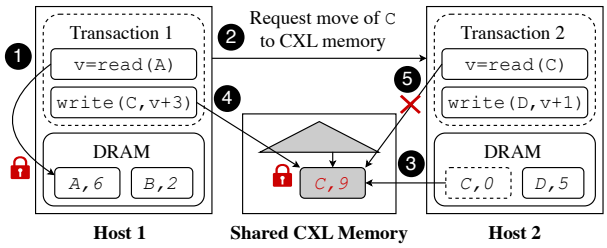

Figure 2: An example transaction workflow in Tigon.

Handling concurrency (§3.4)**.** Tigon needs to manage concurrency: both among threads within a host, and between hosts. Tigon utilizes database latches and indexes to efficiently access the CAT even when data is dynamically moving between local DRAM and CXL memory. Tigon adapts concurrency control protocols, two-phase locking (2PL) and next-key locking, to ensure serializability while maintaining the CAT.

Avoiding two-phase commit (2PC) (§3.3 and §3.5)**.** 2PC adds considerable overhead to transactions as it requires two rounds of message exchanges. Avoiding 2PC requires a single host to execute and log all database modifications involved in a transaction, enabling a host to commit its transaction locally. Tigon avoids 2PC based on two insights. First, by maintaining the CAT in CXL memory, a single host can complete all modifications to database tuples required by a transaction (e.g., by taking locks on CXL-resident structures). Second, although transaction execution in Tigon may involve modifying indexes of other hosts, indexes can be *reconstructed* from the database tuples during recovery, avoiding the need to log index modifications. As a result, only tuple changes need to be logged at the host executing the transaction to ensure atomicity and durability. Combining these two insights, a single host executes all transaction operations (excluding data movement and modifications to indexes of other hosts) and logs tuple modifications. We adapt a logging protocol [82], which was designed for scalability, to avoid 2PC.

Example transaction workflow. Figure 2 shows an example transaction workflow in Tigon. The database stores key-value pairs (e.g., tuple (A, 6) has key A and value 6). The example transaction (transaction 1) reads tuple *A* and writes tuple *C*, and is executed by a worker thread on Host 1 (its transaction worker).

1. The transaction worker acquires the read lock for tuple (A, 6) using 2PL. It then reads tuple (A, 6).
2. To write to tuple (C, 0), which is stored in Host 2, the transaction worker sends a message to Host 2 to request a move of (C, 0) to CXL memory.
3. A worker thread on Host 2 moves (C, 0) to CXL memory.
4. The transaction worker acquires the write lock on tuple (C, 0) and updates it to (C, 9).

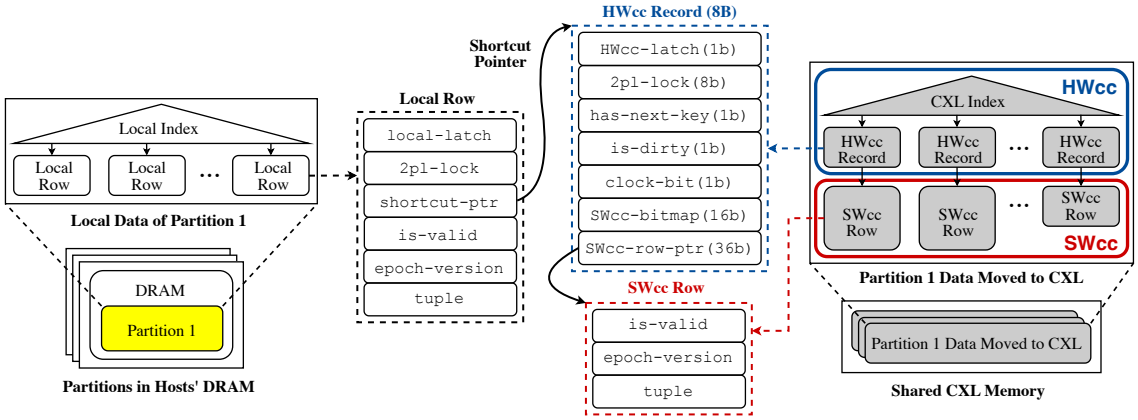

Figure 3: Data organization in Tigon.

5. The transaction worker of transaction 2 needs to access the tuple for key C at the same time; it finds (C, 9) in CXL memory is locked and aborts transaction 2 to prevent deadlocks (using the NO_WAIT policy).

After the transaction worker finishes transaction 1, it commits the transaction without any further messages to Host 2 or using 2PC, since it executes all operations of transaction 1 itself and has all the log records of the changes transaction 1 has made to the database. In this example, the CAT is the single tuple with key C.

3.2 Data Organization & SW Cache Coherence

We now describe how Tigon organizes data and implements software cache coherence. Figure 3 shows an overview of the data organization in Tigon.

Partitions and local row. Tigon organizes data into tables and partitions them across hosts. Tigon stores the partitioning function in a shard map and replicates it across hosts (not shown in the figure). Each host uses the shard map to find the host that owns a certain tuple, as do many partition-based distributed databases [1, 18, 33, 77]. Partitions are initially stored in each host's local DRAM. Data is stored in the form of *local row*. Each local row contains the following:

- Latch for mutual exclusion (`local-latch`)
- Locking metadata for 2PL (`2pl-lock`)
- Pointer to the tuple in CXL memory (`shortcut-ptr`)
- Flag indicating whether the tuple is valid (`is-valid`)
- Field used for logging (`epoch-version`)
- Database tuple (`tuple`)

Data and metadata in CXL memory. Tigon maintains the CAT in CXL memory. To minimize hardware cache-coherent (HWcc) memory usage while still enabling efficient cross-host synchronization on tuples moved to CXL memory, Tigon stores the metadata needed for intensive cross-host synchronization in the HWcc region and everything else (i.e., databse tuples and other metadata) in the CXL memory region that is not hardware cache-coherent (non-HWcc). If a local row is moved to CXL memory, Tigon divides it into an *HWcc record* stored in the HWcc region and an *SWcc row* stored in the non-HWcc region. We develop a software cache coherence protocol to enable cacheable reads of the SWcc rows.

HWcc record and SWcc row. Each SWcc row contains the `is-valid`, `epoch-version`, and `tuple` fields, similar to a local row. Each HWcc record occupies 8 bytes and contains the following fields:

- 1-bit exclusive latch for mutual exclusion (`HWcc-latch`)
- 8-bit locking metadata for 2PL (`2pl-lock`)
- 1-bit flag supporting next-key locking (`has-next-key`)
- 1-bit flag indicating whether the tuple has been modified since being moved to CXL memory (`is-dirty`)
- 1-bit supporting the CLOCK policy (`clock-bit`)
- 16-bit bitmap for software cache coherence (`SWcc-bitmap`)
- 36-bit pointer to SWcc row (`SWcc-row-ptr`)

The `SWcc-row-ptr` stores an offset relative to a base memory pointer. It can represent up to 64 GB of memory space, and is large enough for storing the data that needs to be frequently accessed across hosts in a transactional database. If the offset is defined at the granularity of cachelines, the addressable tuple storage expands to 2 TB (i.e., $2^{36} \times 2^{6}$ bytes).

The `is-dirty` bit allows the owner host to read clean tuples from local DRAM instead of CXL memory, significantly reducing CXL memory bandwidth usage.

Indexes and shortcut pointer. Tigon maintains two types of indexes: local index and CXL index. Each host maintains a local index in DRAM, which maps a primary key to a local row, for its own partition of each table. Local indexes are used by each host to find the tuples that it owns. Tigon maintains a primary index in the HWcc region (the *CXL index*) for tuples from the same table and partition that are resident in CXL memory. If a tuple is moved to CXL memory, the local row includes a pointer, `shortcut-ptr`, that points to the corresponding HWcc record, which in turn has the `SWcc-row-ptr` that points to the SWcc row. Otherwise, the `shortcut-`

ptr is NULL. Tigon pays the price of storing the shortcut-ptr in a local row to efficiently access a tuple moved to CXL memory without searching the CXL index. As tuples are moved between local DRAM and CXL memory, the owner host updates the CXL index while each non-owner host uses the CXL index to find tuples that it does not own.

Example. We use the example in Figure 2 to explain the data organization. Initially, the table is partitioned across the two hosts. Tuple (A, 6) belongs to the partition owned by Host 1 and is stored in the local DRAM of Host 1. So the shortcut-ptr of the local row is NULL. When transaction 1 from Host 1 needs to access tuple (C, 0), Host 2 moves this tuple to CXL memory by creating an HWcc record and an SWcc row, setting the SWcc-row-ptr of the HWcc record to point to the SWcc row, and inserting the HWcc record to the CXL index. It will also set the shortcut-ptr of the local row to point to the HWcc record. Host 1 can now get tuple (C, 9) using the CXL index.

Data movement policy. Tigon moves tuples to CXL memory upon request. If a host's HWcc memory usage exceeds a predefined threshold, it will move a tuple it owns from CXL memory back to local DRAM. Ideally, a host prioritizes moving tuples least likely to be accessed by non-owner hosts in the future back to local DRAM. This makes the Least Recently Used (LRU) policy a natural fit. Under LRU, the tuple least recently accessed by a non-owner host is moved back to local DRAM. However, maintaining the metadata required for LRU is expensive; LRU requires maintaining a linked list across tuples in CXL memory and updating this list for every access from a non-owner host.

To reduce overhead and minimize the HWcc memory usage, Tigon adopts the CLOCK policy [16]. Each tuple in CXL memory is associated with a bit (the clock-bit, as shown in Figure 3) stored in the HWcc record. The clock-bit is set whenever a non-owner host accesses the tuple. To move a tuple back, the owner host maintains a circular cursor to scan the tuples in CXL memory. If the clock-bit for a tuple is set, the host unsets it and moves the cursor forward. Otherwise, the host moves the tuple back to local DRAM.

Software cache coherence. We co-design a novel software cache coherence protocol that works with the database's internal synchronization. Tying coherence to synchronization has the advantage that the coherence granularity is large (i.e., a tuple, which is larger than a cacheline) and the maintenance of coherence metadata is less expensive because it is combined with synchronization tasks that are already part of the database's operation. The disadvantage is that the mechanism requires source code changes and is specific to the database, so it cannot be directly reused by other applications.

A database thread needs to take a latch before accessing a tuple to ensure only one thread can read or modify this tuple. Therefore, Tigon reuses this latch, HWcc-latch, to support software cache coherence by embedding the metadata, SWcc-bitmap, within the HWcc record.

The SWcc-bitmap uses a bit for each host (Tigon supports up to 16 hosts) to track the hosts that can do cacheable loads to SWcc rows, because cacheable loads have much lower latency than non-temporal loads. When a host reads an SWcc row, it looks at its bit in the SWcc-bitmap to determine how to access the data in the row. If the host's bit is set, it uses cacheable loads. Otherwise, its cached copies might be out of date. So it flushes the relevant cachelines, and reads the SWcc row from CXL memory into the CPU cache, and sets its bit in the SWcc-bitmap. So long as no other host updates the SWcc row (i.e., so long as the bit remains set), the host can use cacheable loads to read the SWcc row. A host that updates an SWcc row will unset the bits for all other hosts.

3.3 Transaction Execution

Transactions in Tigon use epoch-based group commit similar to SiloR [82]. Tigon breaks transactions into epochs and ensures that transactions in smaller epoch numbers are serially ordered and committed before those in larger ones.

Workers. Each host in Tigon includes multiple threads for executing transactions. A transaction is initially assigned to a thread, called a *transaction worker*, for executing and committing this transaction. The transaction worker may ask another host to do work (e.g., move data into CXL memory) to complete the transaction it is currently executing. We call the host the transaction worker runs on the *local host* and the partition owned by the local host the *local partition*. Similarly, we call the other hosts and the other partitions *remote hosts* and *remote partitions*, respectively, with respect to the transaction worker.

Read, write, and range query. Algorithm 1 shows the process of reading or writing a tuple in Tigon. If the tuple is in the local partition, the transaction worker gets the local row through the local index and further gets the HWcc record if the tuple resides in CXL memory (Lines 1-11 in Algorithm 1). To read or write a tuple (i.e., the ReadOrWrite function in Algorithm 1), the transaction worker checks the 2pl-lock to take a read or write lock or abort the transaction based on the 2PL protocol. For example, if the write lock bit of the 2pl-lock is already set, the transaction will be aborted. Otherwise, the transaction worker proceeds to perform read or write.

To read or write a tuple owned by a remote host (Lines 13-22 in Algorithm 1), the transaction worker will ask a remote host to move the tuple to CXL memory if it cannot find it in the CXL index. Note that we use a while loop to retry the data move in request because it is possible that the remote host moves the tuple back to local DRAM before the worker accesses this tuple. In practice, the worker will almost never retry due to the data movement policy of Tigon.

Processing range queries is similar to processing read operations. If a range query is on the local partition, the transaction worker searches the local index to get the local rows within the range and optionally follows the shortcut-ptr to access the tuples moved to CXL memory. Otherwise, the transaction

Algorithm 1: Read or write a tuple in Tigon.

```
Input: k – key of the tuple to be read or written
if k belongs to local partition then
    localRow ← Get(k, local index);
    Acquire local-latch for localRow;
    if shortcut-ptr of localRow is NULL then
        ReadOrWrite(localRow);
    else
        hwccRecord ← shortcut-ptr of localRow;
        Acquire HWcc-latch for hwccRecord;
        ReadOrWrite(hwccRecord);
        Release HWcc-latch for hwccRecord;
    Release local-latch for local row;
else
    hwccRecord ← Get(k, CXL index);
    while hwccRecord is NULL do
        Ask the owner host to move k to CXL memory;
        if the host replies k does not exist then
            return NOT_EXIST;
        else
            hwccRecord ← Get(k, CXL index);
    Acquire HWcc-latch for hwccRecord;
    ReadOrWrite(hwccRecord);
    Release HWcc-latch for hwccRecord;
```

worker will search the corresponding CXL index. If the CXL index does not include all tuples for the queried range, the worker asks the corresponding remote host to move all tuples in that range to CXL memory and searches the CXL index again.

Insert and delete. Inserting a tuple to local partition requires creating a local row for the tuple and inserting it into the local index. The challenge is inserting a tuple to a remote partition. To address this challenge, our key idea is to let the remote host prepare the index entry and metadata for the insert and let the transaction worker perform the actual insert operation. Specifically, the remote host is requested to create a local row with the `is-valid` flag set to False, insert the local row to its local index, and move the local row to CXL memory (the value of the `is-valid` flag is copied from the local row to the SWcc row). The `is-valid` flag prevents other transaction workers from reading or writing this tuple. Afterward, the transaction worker gets the HWcc record from the CXL index, acquires the write lock, completes the insert by copying the tuple to SWcc row and setting the `is-valid` flag to True.

The algorithm for deleting a tuple is similar to the one for reading or writing a tuple. If the tuple belongs to the local partition, the transaction worker acquires the write lock and sets the `is-valid` flag to False to delete the tuple. To delete a tuple from a remote partition, the transaction worker asks the remote host to move the tuple to CXL memory, gets the HWcc record from the CXL index, and sets the `is-valid` flag to False. Deleted tuples are reclaimed using epoch-based reclamation (details in 3.6).

3.4 Concurrency Control

Tigon manages concurrency at two levels: 1) maintaining and accessing the CAT under concurrent accesses across hosts; 2) providing serializability for concurrent transactions.

3.4.1 Maintaining and accessing the CAT

Tigon has the following synchronization goals for maintaining the CAT. (1) Even during data movement, HWcc records can be safely inserted and deleted; (2) a worker thread on the owner host can safely use the `shortcut-ptr`, even when tuples are moving between CXL memory and local DRAM; (3) workers from different hosts can concurrently and efficiently get HWcc records by caching and reusing the pointers to HWcc records within a transaction.

Tigon achieves these goals using (1) the `local-latch`, which can only be accessed by a thread on the owner host; (2) the CXL index, which can be accessed by any host; and (3) the `HWcc-latch`, which can be accessed by any host.

Data movement. In Tigon, only threads on the owner host can insert and delete HWcc records for data movement. If a non-owner thread wants to insert or delete a record, it sends a message to the owner host. The owner host will make inserted HWcc records visible to non-owner hosts by putting their entry in the CXL index, which it only does after all of its metadata structures are valid. Deleted HWcc records are removed from the CXL index by the owner host. HWcc records are moved from CXL memory to local DRAM by the owner host following a data movement policy.

Shortcut pointer. Owner hosts in Tigon can use the `shortcut-ptr` of the local row to find and update a tuple in CXL memory without searching the CXL index. Owner hosts can also move their own tuple into or out of CXL memory by inserting or deleting an HWcc record to/from the CXL index. The key challenge is to ensure that the value of the `shortcut-ptr` always reflects the latest state of an HWcc record, even when a worker thread accesses it while another thread wants to move it. The `shortcut-ptr` must either point to the correct HWcc record or it must be `NULL` if the tuple is not resident in CXL memory. Tigon solves this challenge by reusing the database latch for mutual exclusion. Each operation (i.e., data movement and tuple get) needs to take the `local-latch` of the local row before executing, ensuring that only one worker from the owner host can proceed at a time. Given that a non-owner host cannot move a tuple directly, the tuple get operation can then safely follow the `shortcut-ptr` to get the HWcc record. For data movement operations, they will then insert the newly created HWcc record into the CXL index, update the `shortcut-ptr` to point to the HWcc record, and release the `local-latch`.

Non-owner get. Non-owner hosts get an HWcc record through the CXL index and cache the pointer to the HWcc record for subsequent accesses within a transaction. When a tuple is being moved from CXL memory back to local DRAM, the non-owner host must be able to safely dereference the pointer to the HWcc record. At the start of a CXL memory to local DRAM move, Tigon marks the SWcc row as invalid by setting the `is-valid` flag to 0, allowing the non-owner host to know that if they read this entry, they have followed a stale pointer to an invalid entry. Tigon eventually reclaims invalid entries using epoch-based reclamation (details in §3.6), when it knows there are no more possibly stale pointers that point to these invalid entries.

3.4.2 Serializing transactions

Two-phase locking. We adapt 2PL to Tigon, as described in §3.3. 2PL requires a transaction to acquire either a read or write lock before accessing a tuple, depending on the type of the access. Lock acquisitions and releases are broken into two consecutive phases: the transaction only acquires or upgrades locks in the first phase and only releases or downgrades locks after all locks are acquired. Tigon uses Strong Strict 2PL (SS2PL), which acquires locks during transaction execution and releases them only upon completion [12, 24]. Tigon prevents deadlocks by aborting a transaction when a lock request is denied (NO_WAIT policy), following prior research [76] showing that this approach yields better scalability than deadlock detection for in-memory databases with a similar setup to Tigon.

As the first work to leverage CXL memory for building efficient distributed transactional databases, we choose to support conventional concurrency control protocols, 2PL and next-key locking, rather than optimistic concurrency control (OCC) and multi-version concurrency control (MVCC), even though OCC and MVCC may yield better performance for read-heavy workloads as shown in prior research [38, 68, 77, 79]. Supporting these protocols in Tigon requires addressing non-trivial technical challenges and goes beyond the scope of this paper.

Phantoms and next-key locking. Phantom problems [24] occur because 2PL locks only individual keys but does not lock the gaps between them. For instance, when a transaction scans a range, it locks only the tuples encountered during the scan, but allows other transactions to modify the range's membership (e.g., through inserts), violating serializability.

The classic solution to addressing phantom problems is *next-key locking* [55]. Records are accessed via an ordered index (such as a B$^+$-tree) and for inserts, deletes, scans, and point queries on non-existing keys, locks are acquired for both the key or key range and the *next* key in order.

We adapt next-key locking for Tigon. Supporting next-key locking for a local index is straightforward, but a challenge arises when a transaction worker needs to access data in a remote partition. In this case, the worker relies on the CXL index to perform next-key locking. Unfortunately, the CXL index may not include the next key as it only includes a subset of tuples from the local index.

To address this limitation, we enhance the CXL index with additional next-key information. Each tuple in the CXL index is augmented with the `has-next-key` flag indicating whether its next key in the CXL index is also the next key in the local index. With this mechanism, the transaction worker can safely determine whether it can directly lock the next key in the CXL index or needs to request a remote host to move the tuple for the next key to CXL memory.

The `has-next-key` information may be updated whenever an insert or delete operation is performed on the local index or a tuple is moved into or out of CXL memory. Additionally, the `has-next-key` information can be used to determine whether the CXL index has missing keys with respect to the local index for a given range, which can be used to support range queries on the CXL index.

3.5 Logging and Recovery

As mentioned in §3.1, to avoid 2PC, Tigon maintains the CAT to ensure each host can perform and log all modifications to tuples involved in a transaction. Our logging protocol is adapted from SiloR [82], a fast and scalable logging protocol for in-memory databases. Since SiloR is designed for an optimistic concurrency control protocol, we adapt its key ideas to design a logging protocol for 2PL in Tigon.

Key ideas. Tigon shares high-level ideas with SiloR [82], including epoch-based group commit and parallel value logging. Specifically, Tigon guarantees that transactions with a smaller epoch number are serially ordered and committed before those with a larger epoch number. Transactions of each epoch are committed by flushing the buffered log records to local storage. To support parallel logging, each worker thread independently generates a log record for each write at the commit phase, including the value of the tuple being modified and the epoch number and version number associated with the tuple. The log records are sent to dedicated logger threads for persistence. To support recovery, the protocol guarantees that the log record with the highest epoch and the highest version number within that epoch represents the most recent value for the tuple.

Logging. Tigon associates each transaction with an epoch number, and each tuple with an epoch number and a version number (i.e., `epoch-version` in Figure 3). The epoch number of a tuple indicates the epoch of the most recent transaction that modified it, while the version number specifies the most recent version within that epoch.

Tigon maintains a global epoch number, E, that advances periodically and is shared across all hosts via the HWcc region of CXL memory. Since E advances slowly (e.g., every 10 ms in our prototype), synchronizations on E will not be a bottleneck as SiloR shows [82].

During transaction commit, the transaction worker sets the epoch number of the transaction by reading the current

E from CXL memory. When applying writes to the tuple, the transaction worker updates the epoch number and version number as follows. If the transaction's epoch number equals to the tuple's, the version number is incremented. Otherwise, the tuple's epoch number is updated to the transaction's epoch number and the version number is reset to 0, indicating the start of a new epoch.

Log records. A log record is generated for each write, insert, and delete. It includes the identifier of the tuple (i.e., table ID and primary key), the `epoch-version`, and the corresponding value of the tuple or the delete operation. Each transaction worker stores the log records in a memory buffer and passes it to the logger thread when it fills or at an epoch boundary. Each logger thread reads log buffers and flushes them to local storage. In additional to the global epoch number, Tigon maintains a local epoch number, e_l, for each logger thread, in the HWcc region. Each logger thread increments e_l as it flushes the log buffers, indicating that all log records with an epoch number less than e_l are persisted to local storage. Transactions in an epoch e are regarded as committed if e is less than e_l of all logger threads.

Recovery. With this logging protocol, Tigon can adopt the same parallel recovery algorithm as SiloR. That is, Tigon can move all log records of committed epochs to CXL memory and then divide them across worker threads such that each thread applies assigned log records in parallel. For a log record that corresponds to a database tuple, it is applied to the tuple if it has a larger `epoch-version` than the last log record applied to this tuple. Otherwise, this log record is skipped.

3.6 Implementation

We implement Tigon in C++ by building on the Lotus [85] codebase, which has ∼18,000 LoC. We added ∼5,000 LoC. Tigon provides read, write, delete, insert, and range query APIs for developers to implement transactions or parameterized transactions. We implement local index and CXL index using an existing B$^+$-tree implementation [84], which adopts the optimistic crabbing index concurrency control protocol [42]. We extend the B$^+$-tree to support next-key locking. Tigon adopts offset pointers [14] to make CXL-resident data structures position-independent. CXL memory is exposed as a CPU-less NUMA node by Linux. We modify the mimalloc [41] memory allocator to use the CXL memory region.

Each host in Tigon includes multiple worker threads for processing transactions and data movement requests. If a transaction needs to access data of another host, its worker thread will send a data movement request using CXL memory as a transport. A dedicated input thread pulls these requests and dispatches them round robin to the local message queues of worker threads. The worker thread will process data movement requests from other hosts when it waits for the result of a data movement request it makes, or after a transaction is finished. If a transaction aborts due to a conflict, Tigon retries it until success.

We implement Tigon's CXL-based transport layer as lock-free multi-producer single-consumer (MPSC) ringbuffers in CXL memory. The metadata of the ringbuffer (e.g., head and tail) is stored in the HWcc region while the buffer entries are stored in the non-HWcc region. Each input thread is assigned a ringbuffer for receiving messages from other hosts.

Tigon uses epoch-based reclamation (EBR) [25] to ensure memory safety. To adapt EBR to the CXL pod, Tigon stores a local epoch number for each worker thread (in addition to the global epoch number and the per-logger local epoch numbers in §3.5) in the HWcc region and maintains per-worker retired objects list in the local DRAM of each host. Worker threads check the global epoch number periodically to determine the current epoch and update their local epoch number. Worker threads reclaim the memory objects retired in a given epoch only after all workers have exited that epoch.

4 Evaluation

We seek to answer the following questions:

- What are the end-to-end performance benefits of Tigon compared with the state-of-the-art? (§4.2)
- How does varying the hardware cache-coherent (HWcc) memory budget impact Tigon's performance? (§4.3)
- What is the performance benefit of software cache coherence compared with using HWcc memory only? (§4.4)
- How does logging impact the throughput and latency of Tigon? (§4.5)
- How effective are our optimizations? (§4.6)

4.1 Experimental Setup

CXL pod emulation. We emulate a CXL pod on a machine that includes an Intel Xeon Platinum 8568Y+ CPU, 512 GB local DRAM, and a 128 GB CXL 1.1 memory device. Both the local DRAM and CXL memory use DDR5 4800 DRAM. The CXL memory module has a single memory channel and is connected to the CPU via a PCIe 5.0 x8 link. This CXL memory device has a 1.6× higher latency than the local DRAM (259 ns vs. 159 ns), and its bandwidth is 13% of the bandwidth of the local DRAM (31.8 GB/s vs. 238.3 GB/s) using Intel's Memory Latency Checker [3] under a 3:1 read/write ratio. The machine is equipped with a Samsung Datacenter SSD [5] for persistent storage and a 100 Gbps Mellanox MT42822 BlueField-2 ConnectX-6 NIC.

We run 8 virtual machines (VMs) on this machine, each with 5 vCPUs and 10 GB local DRAM. We use SR-IOV to create the virtualized network for our VMs, using TCP over Ethernet. We configure the VMs to share the CXL memory device to emulate a CXL pod that includes 8 machines sharing CXL memory. There are currently no physical CXL devices that support inter-host cache coherence. For our setup, the inter-VM cache coherence is implemented by the physical machine's cache coherence, which will be faster than real inter-host hardware cache

coherence (when it becomes available). We analyze the potential impact of higher-latency inter-host cache coherence in §4.3.

We limit the HWcc region of the emulated CXL pod to 200 MB for all experiments. That is, our CXL memory allocator is configured to allocate no more than 200 MB of HWcc memory, despite the emulated CXL pod offering 128 GB. We study the impact of varying HWcc memory budgets in §4.3 and adjust the size of the HWcc region for that experiment only.

Baselines. We compare Tigon with three distributed databases, Sundial [77], DS2PL [85], and Motor [79]. We do not compare with Lotus [85] because it does not support all five transactions in TPC-C. We choose Sundial and DS2PL as representatives of traditional partition-based shared-nothing databases that support general-purpose transactional workloads, just as Tigon supports them. DS2PL uses two-phase locking (2PL) for reads and writes, similar to Tigon. Sundial includes an advanced concurrency control protocol that uses OCC for reads and 2PL for writes. Both Sundial and DS2PL are vulnerable to the phantom problem [24] that Tigon correctly addresses. Motor is a state-of-the-art distributed database that uses RDMA-based shared disaggregated memory and achieves persistence via replication.

Improved baselines. For a fairer comparison with Tigon, we enhance our chosen baselines in a number of ways. We implement next-key locking in DS2PL to avoid the phantom problem. We enhance Sundial and DS2PL to support durability using our logging protocol (§3.5). Sundial and DS2PL support only two of the five transactions in TPC-C, so we added implementations of insert, delete, and scan so they could execute all five.

Sundial and DS2PL originally use the network as their transport layer as they adopt the shared-nothing architecture, whereas Tigon uses a queue in CXL memory. To demonstrate that Tigon's superior performance is not simply due to its faster transport layer, we upgrade Sundial and DS2PL to also pass messages over CXL memory (*i.e.,* Sundial-CXL and DS2PL-CXL). Tigon uses 16 MB of CXL memory that is not hardware cache-coherent (non-HWcc) for its message buffers and we give the baselines 512 MB because they pass larger messages.

Using a memory queue for message passing allows us to make another improvement: we repurpose an I/O thread as a worker thread (for executing transactions). The IO thread was necessary because it wrote to a network device and could block in the OS, while our memory queue is non-blocking. We name these improved baselines Sundial+ and DS2PL+. We later show that these improved baselines outperform the original Sundial and DS2PL, and only compare Tigon with these improved baselines (§4.2).

Configurations and metrics. We run Tigon, Sundial, and DS2PL in the VMs of the emulated CXL pod. For each test, we run each system for 30 seconds to warm up and report the performance for the following 30 seconds. We mainly present throughput since Tigon prioritizes throughput over latency using group commit, a common practice widely adopted in transactional databases [9, 33, 69, 75, 77, 85]. We set each epoch to be 10 ms for the group commit protocol.

We run Motor on four machines, each including two Intel Xeon Platinum 8380 CPUs, 256 GB local DRAM, and a 25 Gbps Mellanox ConnectX-6 NIC. We use one machine as the compute server and three machines as memory servers, as the paper specifies [79]. Motor replicates its data in the three memory servers to achieve durability. We configure Motor to use 40 CPU cores to match the configuration of Tigon and the other two baselines.

Benchmarks. We use the full TPC-C [7] and a variant of YCSB [15] as our benchmarks. We configure TPC-C to use 24 warehouses (2.2 GB total), where each warehouse is a partition, and store 3 warehouses in each host (one warehouse per worker thread). We evaluate the standard mix for TPC-C's five stored procedures: 45% NewOrder, 43% Payment, 4% OrderStatus, 4% Delivery, and 4% StockLevel. We configure YCSB to generate a table including 2.4M tuples, each with one 4-byte key column and ten 100-byte value columns (2.2 GB total) [15]. The table is range-partitioned into 8 partitions across hosts. Each transaction performs 10 read or write operations with a configurable read/write ratio. The key accessed by each operation is generated using the Zipfian distribution with skewness factors of 0.7 and 0.99. We use 0.7 and 0.99 to simulate medium-contention and high-contention workloads, respectively, as done by prior research [79].

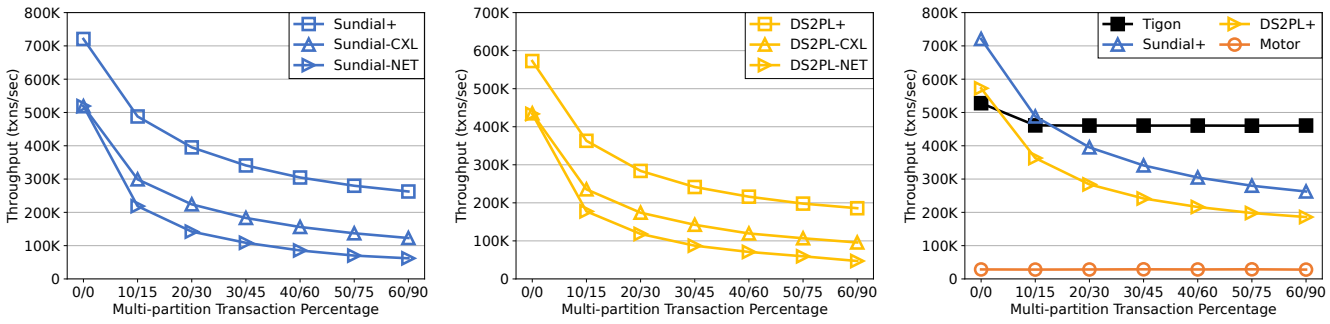
4.2 End-to-End Performance

We evaluate Tigon's end-to-end performance using TPC-C and YCSB.

TPC-C setup. The performance of the compared systems changes significantly based on how many transactions access data from multiple partitions. In the default configuration of TPC-C, 10% of NewOrder and 15% of Payment transactions access multiple warehouses (i.e., multi-partition transactions). Therefore, we vary the two percentages proportionally, up to 60% remote NewOrder and 90% remote Payment transactions (and we refer to this configuration as 60/90).

Performance of improved baselines. We measure the performance benefits of the improved baselines using TPC-C with varying percentages of multi-partition transactions. Figure 4a and 4b show that replacing the network with CXL memory increases the transaction throughput for the workloads that involve multi-partition transactions since these transactions need to exchange network messages during transaction execution and 2PC. For the 60/90 configuration, performance improves by 2.0× for both Sundial and DS2PL. Repurposing the I/O thread as a transaction thread brings the total improvement to 39% and 32% when there are no multi-partition transactions (0/0), and 4.2× and 3.9× at 60/90. The rest of our evaluation compares only against the optimized baselines.

TPC-C performance. Figure 4c shows TPC-C throughput under varying percentages of multi-partition transactions.



(a) Improved Sundial **(b)** Improved DS2PL **(c)** Tigon comparing with improved baselines

Figure 4: TPC-C performance comparison, varying percentages of multi-partition transactions. We optimize (a) Sundial and (b) DS2PL by replacing the original network transport layer (*-NET) with CXL (*-CXL), and again by replacing an I/O thread with a worker thread (Sundial+ and DS2PL+). (c) Then, we compare Tigon with Sundial+, DS2PL+, and Motor.

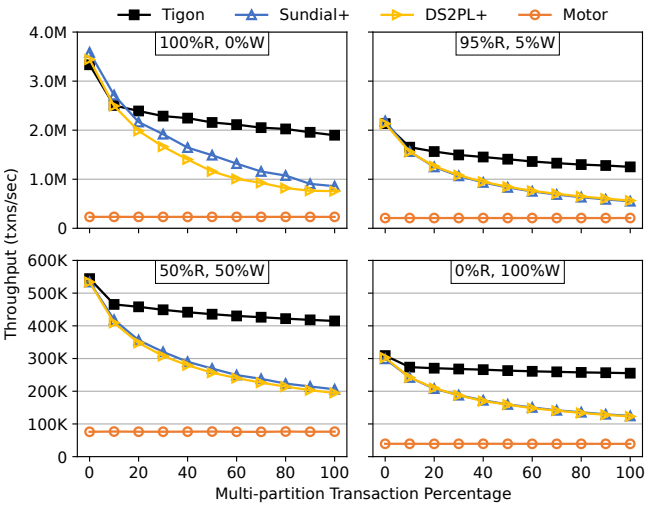


Figure 5: YCSB throughput, varying both read/write ratios and percentages of multi-partition transactions.

When there are no multi-partition transactions, Sundial+ and DS2PL+ are 37% and 8.5% faster than Tigon, respectively. The performance benefit of Sundial+ is due to its optimistic concurrency control protocol and the fact it does not avoid phantoms. Avoiding phantoms using next-key locking (§3.4.2) costs Tigon 10%-12% of its performance across all tested percentages of multi-partition transactions; for TPC-C's default configuration of 10/15, a variant of Tigon that allows phantoms (not shown in the figure) outperforms Sundial+ by 5.8%.

As the percentage of multi-partition transactions increases to 60/90, Tigon outperforms Sundial+ by 75% and DS2PL+ by 2.5×. The throughput of Sundial+ and DS2PL+ drops significantly due to the overhead of inter-host communication during transaction execution and 2PC. For instance, in the 60/90 case, Sundial+ and DS2PL+ send 3.3 and 4.1 messages per transaction, respectively, whereas Tigon moves the data that will be accessed across hosts to CXL memory (during the warmup phase) and does not send messages during transaction execution. More specifically, Tigon moves the `CUSTOMER` and `STOCK` tables to CXL memory, with `CUSTOMER` containing 720K tuples and `STOCK` containing 2.4M tuples. The two tables consume 176 MB of HWcc memory (for metadata) and 1.6 GB CXL memory in total. No data is moved from CXL memory to local DRAM during the experiment. For TPC-C, supporting software cache coherence allows Tigon to use 8.2× more CXL memory for sharing data.

Compared with Motor, Tigon achieves 15.9×-18.5× higher throughput mainly because Motor shares and replicates data in RDMA-based memory servers and suffers from the high latency of one-sided RDMA operations. We observe that the performance of Motor, approximately 30K/s, is constrained by the limited network bandwidth (25 Gbps) of the machines available to us. The original paper [79] reports that Motor achieves a maximum TPC-C throughput of approximately 100K/s with 24 warehouses and 40 CPU cores. Tigon uses the same configuration and its throughput ranges from 460K/s to 528K/s, as shown in Figure 4c.

YCSB setup. We run YCSB with a skewness factor of 0.7 under varying percentages of multi-partition transactions and different read/write ratios (i.e., 100R/0W, 95R/5W, 50R/50W, and 0R/100W). To generate a multi-partition transaction, we randomly choose a remote partition and have half (5) of the operations access that remote partition.

YCSB performance. Figure 5 shows the results. When there are no multi-partition transactions, the evaluated systems (except Motor) perform similarly (within 3.3%) for workloads with writes. For the read-only workload, Tigon outperforms both Sundial+ and DS2PL+ once the percentage of multi-partition transactions reaches 20% or higher. Comparing Tigon with Sundial+ at 100% multi-partition transactions, Tigon is 2.0×–2.3× faster. Tigon moves all 2.4M tuples to CXL memory as they are accessed across hosts. These tuples consume 112 MB of HWcc memory and 2.6 GB CXL memory in total. No Data is moved from CXL memory back to local DRAM, as HWcc memory usage remains well below the 200 MB limit.

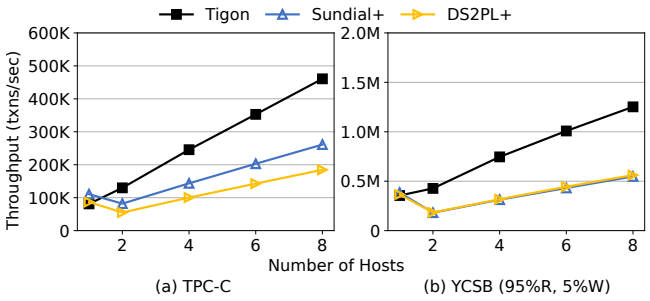

Figure 6: Throughput of TPC-C (60% remote NewOrder and 90% remote Payment) and YCSB (95%R, 5%W, 100% multi-partition transactions) on 1, 2, 4, 6, and 8 hosts.

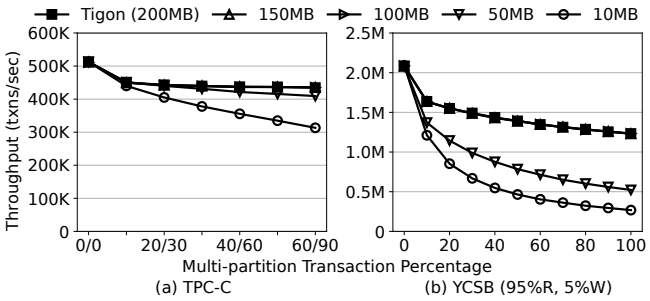

Figure 7: Throughput of TPC-C and YCSB (95%R, 5%W), varying both hardware cache-coherent memory budgets and percentages of multi-partition transactions.

Motor's performance is independent of the percentage of multi-partition transactions, but it is 5.4×–14.3× slower than Tigon. Results with a skewness factor of 0.99 show a similar trend. For example, with 100% multi-partition transactions, Tigon outperforms Sundial+ and DS2PL+ by 2.7× and 3.5× for the 50R/50W workload, respectively. We use a skewness factor of 0.7 for all remaining tests.

Scalability. We evaluate the scalability of Tigon, Sundial+, and DS2PL+ by running TPC-C with 60/90 multi-partition transactions and YCSB (95% reads, 5% writes) with 100% multi-partition transactions on configurations with 1, 2, 4, 6, and 8 hosts. As shown in Figure 6, Tigon scales efficiently, achieving a 5.7× throughput improvement for TPC-C and a 3.5× improvement for YCSB as the number of hosts increases from 1 to 8. In comparison, Sundial+ and DS2PL+ exhibit significantly lower scalability, with throughput gains of only 2.4× and 2.1× for TPC-C, and 1.4× and 1.5× for YCSB, respectively. The slope of Tigon's TPC-C scaling graph from 2 to 8 processors is 55.1Ktx/s per processor, while Sundial+ is 29.9Ktx/s per processor and DS2PL+ is 21.6Ktx/s per processor. For YCSB the slopes are 137.5Ktx/s per processor for Tigon, and 61.1Ktx/s per processor for Sundial+ and 63.0Ktx/s per processor for DS2PL+.

We are unable to empirically determine the scalability limit of Tigon due to hardware constraints that prevent large-scale experiments. Performance could plateau for many reasons: limited scalability of atomic instructions over CXL memory, especially under contention, limited scalability of hardware cache coherence, or the fixed size of the HWcc region could all become bottlenecks. Identifying and analyzing these limits is an important direction for future research.

4.3 Impact of Limited HWcc Memory

We measure TPC-C performance while varying the HWcc memory budget from 10 MB to 200 MB. Figure 7 shows the results. It is encouraging that even with as little as 50 MB of HWcc memory, Tigon performs only 5.8% slower than the configuration with unlimited HWcc memory.

With only 10 MB of HWcc memory, performance suffers because transactions wait for data to be moved into and out of CXL memory. When running TPC-C with a 60/90 mix of multi-partition transactions, 10 MB of HWcc memory requires Tigon to move 16K tuples in and out of CXL memory every second. Bandwidth is not a factor limiting performance; Tigon consumes only 367 MB/s of CXL bandwidth (approximately 1.1% of device bandwidth) in this configuration.

YCSB with a 95/5 read/write mix requires 100 MB to achieve full performance because there is more multi-partition sharing in YCSB than TPC-C—YCSB has only a single table and every data tuple has a probability of being remotely accessed. At 100% multi-partition transactions and with 10 MB HWcc memory, Tigon moves 110K tuples every second and consumes 2.9 GB/s of CXL bandwidth (approximately 9.1% of device bandwidth).

Inter-host cache coherence. We emulate the latency of inter-host cache coherence (i.e., back invalidations [2]) using inter-core cache coherence on our hardware prototype. This underestimates the cost of inter-host cache coherence for our evaluated systems. We cannot directly measure the number of back-invalidates our workloads would generate, because there are no hardware counters that report it and accurate modeling would require knowing the cache state. However, we can measure inter-host invalidates for our software cache coherence protocol (§3.2) for 60/90 TPC-C. We measure 12.0 million tuple accesses that require inter-host invalidations (which is 14.5% of total accesses, due to locality). If we conservatively estimate back-invalidations to be 4× slower than local invalidations, they would reduce performance by 41.4% (computed using the CXL miss latency times four). Tigon would be 2.8%, 45%, and 9.6× faster than Sundial+, DS2PL+, and Motor, respectively.

4.4 Software Cache Coherence

We evaluate the performance impact of software cache coherence by running TPC-C and YCSB (95% reads, 5% writes) in four configurations: only using HWcc memory (NoSWcc), using HWcc memory and only using non-temporal loads/stores to access CXL memory in the software cache-coherent (SWcc) region (NonTemporal), using HWcc memory and only allowing a

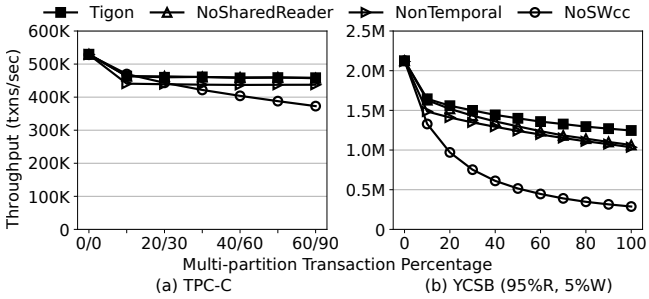

Figure 8: Throughput of TPC-C and YCSB (95%R, 5%W) with different software cache coherence protocols and varying percentages of multi-partition transactions.

	1ms	10 ms	20 ms	30 ms	40 ms	50 ms
TPC-C						
Tput (Ktx/s)	508	525	532	535	537	540
p50 (ms)	17.7	22.6	26.0	31.6	37.3	43.3
p99 (ms)	345.0	54.9	57.0	64.7	75.2	86.8
YCSB (50% read and 50% write)						
Tput (Ktx/s)	516	534	538	541	542	545
p50 (ms)	12.4	24.6	30.8	36.8	41.5	45.0
p99 (ms)	373.1	62.3	72.3	82.6	89.6	95.4

Table 1: Throughput, in Ktx/s (1,000 × transactions/second) and latency (in ms) for different epoch durations, running TPC-C and YCSB (50% reads, 50% writes) without multi-partition transactions.

single host to read data in the SWcc region (NoSharedReader), and Tigon with all optimizations for software cache coherence. NoSWcc avoids cache coherence problems by only using HWcc memory, but it suffers from the limited size of the HWcc region. NonTemporal provides cache coherence by avoiding the cache; accesses to the SWcc region use non-temporal loads and stores which bypass the CPU cache. NoSharedReader only allows reads of SWcc data for a single host at a time.

TPC-C. Figure 8 shows the benefits of Tigon's software cache coherence. When there are no multi-partition transactions, no data is moved to CXL memory and all variants perform identically. Across all tested percentages of multi-partition transactions, the NonTemporal configuration shows 4.5%-5.1% less performance than Tigon. The small performance win is because Tigon already caches tuples in local DRAM, which obviates the performance advantage of cacheable access to CXL memory. NoSWcc performs well at low multi-partition transaction percentages because it uses the HWcc region to store data; this data can be cached, leading to higher performance. However, as the number of multi-partition transactions increases, the performance of NoSWcc drops because it requires frequent data movement. At 60/90, NoSWcc is 19% slower than Tigon. The loss of performance comes from the latency of moving 9K tuples in and out of CXL memory every second. The workload consumes 641 MB/s of CXL bandwdith, well within the device's capabilities. TPC-C does not have read-shared data, so NoSharedReader has almost identical performance with Tigon.

YCSB. YCSB has significant read-sharing and shared data. NoSWcc is 19% slower than Tigon for 10% multi-partition transactions, but it is 4.3× slower (and the lowest performing option) at 100% multi-partition transactions. At 100% multi-partition transactions NoSWcc's performance is limited by the latency of data movement to the HWcc region—115K tuples/s (but only 3.0 GB/s bandwidth use; ∼9.4% of CXL bandwidth). Across all tested percentages of multi-partition transactions, Tigon is 11%-20% faster than NonTemporal because data is repeatedly accessed and Tigon can cache the tuples, which is much faster than non-temporal reads. But the advantage is small because Tigon caches tuples in local DRAM. At 100% multi-parition transactions, NoSharedReader is 15% slower than Tigon. NoSharedReader's performance suffers because it manipulates the `SWcc-bitmap`, and the read-sharing of data in YCSB means that NoSharedReader incurs 2.6× more cacheline flushes than Tigon.

4.5 Logging and Latency

Tigon uses epoch-based group commit (based on SiloR [82]) to ensure that it can maintain high throughput at reasonable latency. Committing logs at end of each transaction would provide low latency, but the resulting small, synchronous writes would severely under-utilize storage bandwidth. The use of virtualization further drops the storage bandwidth realized inside the VMs (from 600 MB/s to 380 MB/s, tested using `dd` with 4MB block size). To better utilize storage performance, Tigon collects 4 MB of logs before flushing them to SSD.

Table 1 shows the throughput and latency for a variety of logging epochs, running TPC-C and YCSB (50% reads, 50% writes) with no multi-partition transactions. For a 10 ms epoch, when compared with a 50 ms epoch, throughput for TPC-C drops only 2.8%, while its p50 latency drops by 48%. With a 10 ms epoch, Tigon has only 6.0% lower throughput for TPC-C compared with Tigon without logging. YCSB shows a similar result. Since Sundial+ and DS2PL+ adopt the same logging protocol, their latencies are similar to Tigon. Motor does not do group commit, but instead uses three in-memory replicas to achieve durability, so their p50 latencies are in the hundreds of microseconds. Tigon, instead, prioritizes throughput over latency using group commit.

4.6 Optimizations

Using CLOCK. Tigon moves data into CXL memory on demand, and uses the CLOCK algorithm to determine which data to move back to local DRAM (§3.2). Tigon uses CLOCK to minimize its use of HWcc memory and reduce the overhead of maintaining the replacement metadata; we compare its performance to the more accurate LRU policy to quantify the accuracy sacrificed for metadata efficiency.

Implementing LRU requires more CXL memory and more synchronization (than CLOCK) to maintain the LRU list. If we place the LRU list pointers in HWcc memory, YCSB will require 149 MB of HWcc memory to move all its tuples into CXL memory, which is 33% more than CLOCK (112 MB). If we limit the HWcc memory budget to 100 MB, LRU is 2.4× slower than CLOCK for YCSB with a 95/5 read/write mix and 100% multi-partition transactions because HWcc memory is oversubscribed. If we set the HWcc memory budget to unlimited and run the same experiment, LRU is 17% slower than CLOCK because of lock contention while manipulating the LRU list. CLOCK is therefore preferred due to its metadata efficiency.

Shortcut pointer. Tigon maintains the `shortcut-ptr` in the local row (Figure 3) to allow the owner host to find the tuple in CXL memory without looking through the CXL index. Across varying percentages of multi-partition transactions (excluding 0%), shortcut pointers improve throughput by 16% for TPC-C, and by 8.3%–24% for YCSB with 95% reads and 5% writes.

Tracking tuple modifications. Tigon allows the owner host to read CXL-resident tuples from local DRAM rather than CXL memory when the tuple is clean (i.e., the `is-dirty` flag in Figure 3 is False). This optimization is important for read-heavy workloads; YCSB read-only throughput improves by 60% for 10% multi-partition transactions and by 27% for 100% multi-partition transactions.

5 Related Work

CXL-enabled memory tiering. A lot of recent work on CXL memory management focuses on system software moving memory pages between local and CXL memory on behalf of applications [22, 54, 59, 65, 83]. Much of the work focuses on accurate detection of hot pages and policies for moving pages. Some hot pages only contain a few hot lines [63], making it difficult to recoup the cost of migration and motivating systems where hardware migrates cachelines [83].

CXL-enabled memory pooling and sharing. Recent work explores how CXL-enabled memory pooling and sharing can reduce cost in datacenters and HPC systems [11, 28, 45, 70], benefit serverless computing [28, 57], and accelerate distributed applications [50, 51, 81]. Distributed applications sharing CXL memory are vulnerable to partial failures [81, 86]. CXL-SHM [81] describes a distributed memory management system based on reference counting that tolerates partial failures.

Databases over CXL memory. Many papers consider optimizing databases using CXL memory [8, 10, 39, 60] such as elastically allocating CXL memory [39] or leveraging it for data shuffling [10]. One paper considers mapping SSD to the memory address space through CXL protocols and adopting hardware-based optimizations (e.g., (de)compression) when databases interact with this memory address space [40]. Two papers discuss the research opportunities of building databases over CXL memory [27, 43], but neither considers building a distributed transactional database over CXL memory. Pasha [29] describes a database architecture for CXL pods, but Tigon is the first system designed, implemented, and evaluated for a pod.

Distributed databases. Traditional distributed databases adopt a partition-based shared-nothing architecture, but their performance degrades quickly as the number of multi-partition transactions increases [17, 33, 56, 66]. Many papers optimize this architecture by reducing the number of multi-partition transactions [18, 49, 58, 61], optimizing concurrency control protocols [37, 52, 77, 85], or eliminating or reducing the cost of 2PC [23, 34, 46, 48, 67]. Tigon's performance remains robust because it uses CXL memory to synchronize multi-partition transactions instead of relying on message passing.

Many papers study RDMA-based distributed transactional databases [4, 13, 19–21, 32, 44, 62, 71–73, 75, 78–80, 87]. Some of them optimize partition-based databases [13, 20, 21, 32, 62, 71–73] while more recent papers adopt a shared disaggregated memory architecture to avoid multi-partition transactions [4, 19, 44, 75, 78–80, 87]. Motor [79] is a recent instance of this design and our evaluation shows the limits of its performance due to the high cost of RDMA relative to CXL memory access (§4).

6 Conclusion

This paper introduces Tigon, the first distributed in-memory database that synchronizes cross-host concurrent data accesses via atomic operations on CXL memory. Tigon addresses the inherent limitations of CXL memory, including higher latency, lower bandwidth, and limited hardware support for cache coherence, through three key innovations: a novel software cache coherence protocol for extending the cache-coherent region, efficient concurrency control protocols for maintaining and accessing data in CXL memory, and a scalable logging protocol for avoiding two-phase commit. Tigon is publicly available at `https://github.com/ut-datasys/tigon`.

Mako: Speculative Distributed Transactions with Geo-Replication

Weihai Shen[†] Yang Cui[§] Siddhartha Sen[‡] Sebastian Angel[⋆] Shuai Mu[†]
[†]*Stony Brook University,* [§]*Google,* [‡]*Microsoft Research,* [⋆]*University of Pennsylvania*

Abstract

This paper introduces Mako, a highly available, high-throughput, and horizontally scalable transactional key-value store. Mako performs strongly consistent geo-replication to maintain availability despite entire datacenter failures, uses multi-core machines for fast serializable transaction processing, and shards data to scale out. To achieve these properties, especially to overcome the overheads of distributed transactions in geo-replicated settings, Mako decouples transaction execution and replication. This enables Mako to run transactions speculatively and very fast, and replicate transactions in the background to make them fault-tolerant. The key innovation in Mako is the use of *two-phase commit* (2PC) speculatively to allow distributed transactions to proceed without having to wait for their decisions to be replicated, while also preventing unbounded cascading aborts if shards fail prior to the end of replication. Our experimental evaluation on Azure shows that Mako processes 3.66M TPC-C transactions per second when data is split across 10 shards, each of which runs with 24 threads. This is an 8.6× higher throughput than state-of-the-art systems optimized for geo-replication.

1 Introduction

Highly available and reliable serializable transactional storage systems (e.g., Google's Spanner [20]) are the foundation of many Internet services. To achieve high availability despite datacenter failures, data is replicated across datacenters [7, 20, 30, 98]. To support ever-increasing amounts of data and request volumes, data is partitioned into many shards. A distributed transaction is used to guarantee consistency whenever the application needs to access data across shards.

The main drawback of these systems is that the coordination required by distributed transactions introduces great inefficiencies, to the point that the throughput that one can achieve with a single in-memory multi-core transactional key-value store is thousands of times higher than what distributed transactional systems typically provide [50, 55, 59, 60, 95]. At the same time, we cannot just replace a distributed transactional system with a fast single-machine variant because of the need for fault-tolerance and scalability.

Since an obvious bottleneck in distributed transactions is that the network latency is orders of magnitude higher than the CPU-memory latency, a trend in accelerating distributed transactions is to adopt ultra-low latency networking technologies such as RDMA and smart NICs [11, 17, 25, 46, 74, 90, 91, 106]. However, these techniques are most effective within a datacenter. In geo-replicated systems, the benefits of kernel bypass and faster local networks are negligible compared to the long latencies that are fundamental to wide-area networking.

Given the above, in this work we ask the question: *can the throughput achieved by distributed transactions in geo-replicated settings approach that of transactions within a single machine?* Answering this question in the affirmative has the potential to reduce the amount of machines that existing storage systems need to meet their current demands, while also empowering new applications that require high-throughput strongly consistent geo-replicated transactional storage (e.g., Nimble [5], Zanzibar [75]). But to realize this promise, we need to fundamentally rethink how we design distributed transaction protocols in the first place.

After a close examination, we conclude that a key limitation of current designs of distributed transaction protocols is the *tight* dependence between the two main building blocks: the *transaction coordination* and the *replication* protocols. Consider for example Spanner [20], which uses *two-phase commit* (2PC) as its coordination protocol to perform distributed transactions. Since 2PC is not fault-tolerant, Spanner synchronously geo-replicates all of the decisions made by 2PC participants (storage shards) after every step of the protocol. This ensures that failures are recoverable.

Several distributed transaction systems such as Tapir [109], Ocean Vista [30], and Janus [69] argue that transaction coordination and replication should be coalesced into a single protocol (an even tighter coupling) in order to avoid paying for common functionality twice. We argue that the opposite should be the case in WAN settings: that transaction coordination and replication should be decoupled even further! Our observation is that fully decoupling these two components allows the system to perform work speculatively, thereby masking the high overhead introduced by geo-replication.

To explore the benefits and limitations of this idea, we build *Mako*.[1] Mako is the first transactional sharded key-value store that hides the cost of geo-replication by speculatively processing distributed transactions. Of course, the idea of using speculation in transactional databases is not new. Prior to Mako, works like Rolis [85] and Amazon Aurora [98] leverage speculation to speed up transaction processing. But Rolis only has a single shard (and therefore cannot scale to

[1] Mako sharks are known for migrating long distances.

large databases), while Aurora does not support transactions across shards. The fundamental reason for this is that in an ideal world, when one performs a speculative cross-shard transaction, as soon as the transaction finishes executing one wants to start processing the next transaction without having to wait for the geo-replication to complete (otherwise we are back to square one where the geo-replication is the bottleneck for transaction processing). But if one starts executing other transactions that depend on values written by a speculative transaction before it has been geo-replicated, then the system can end up in a situation where a speculative transaction fails and then all transactions that depend on it must abort (and the transactions that depend on the aborting transactions also must abort, etc.). Such a *cascade of aborts* is troubling in part because in a concurrent and asynchronous system it is hard to efficiently track *which transactions depend on the failed transaction*. Without enough information, the cascade could become unbounded [28, 36, 79], and require pausing the system and aborting all pending transactions.

Mako's key technical contribution is precisely to introduce an architecture that allows it to safely speculate without having to wait for the results of geo-replication, while keeping track of very little information that is efficient to collect and yet sufficient to avoid unbounded cascading aborts.

Overview of Mako. Mako first executes and certifies the transactions among shard leaders. Shard leaders are in-memory multi-core stores that run a fast concurrency control protocol tailored for single-machine multi-core databases [85]. If some (or all) of these leaders are in the same datacenter, Mako uses a fast networking stack (DPDK) to connect them. At this stage, there is no replication so all transactions have been executed speculatively and the clients have not yet received a response. In the background, Mako performs parallel state-machine geo-replication across datacenters while also continuing to speculatively execute new transactions. On successful replication, the multi-core follower replicas will deterministically replay the execution results of the leader shards. Should something happen that prevents the replication from completing, Mako rolls back the speculatively executed transactions and makes sure that all live replicas are in a consistent state [38, 76] before moving on. Clients are notified after the replication completes.

For transaction coordination, Mako uses *two-phase commit* (2PC) speculatively. This means that if a shard leader fails before the 2PC result is replicated, the transaction's result becomes unrecoverable and the transaction must abort. To avoid unbounded cascading aborts, Mako uses a *distributed vector clock* (§4.2) as a coarse-grained dependency tracking method, and combines it with a *vectorized watermark* technique to selectively roll back only the affected transactions (§5.2).

Our evaluation of Mako on Azure as well as several state-of-the-art baselines show that Mako's throughput is the highest among all in the setting of geo-replication by at least 8.6× (at 10 shards) while introducing little additional latency. When we consider a setting without geo-replication (a single datacenter, which is not the setting for which we designed Mako), Mako's throughput is 50% lower than prior RDMA-based systems that tightly couple replication and concurrency control.

2 Background and motivation

In this paper, we study sharded and geo-replicated in-memory key-value stores that support transactions at very high throughput (close to a single-machine multi-core database) and with strong isolation (serializability). To the best of our knowledge, no existing data store achieves all of these goals. We discuss why this is the case next.

2.1 Limitations of existing designs

We take a closer look at existing designs to see where the core issues arise. One thing we find is that systems like Spanner [20] and FaRM [25] follow a classic approach: overlay the distributed transaction protocol on top of the replication protocol. That is, they use replication to checkpoint the key steps in transaction execution and commit.

The workflow of these systems is roughly as follows. A transaction first executes: it accesses data from different shards. During the execution, the system applies locking or optimistic concurrency control to avoid inconsistent accesses. At the end of execution, the system tries to certify (commit) the transaction. This is done via a two-phase commit (2PC) across all participating shards. To make the system fault-tolerant, the system applies replication (e.g., primary-backup in FaRM; Paxos [13, 21] in Spanner) to each critical step. For example, Spanner replicates the prepare phase and the commit phase in 2PC. Since this is expensive, prior works [30, 69, 109] optimize the geo-latency by mixing the replication and transaction protocols. But overall, the transaction certification decision is not known until replication finishes.

By looking at this design we can make two observations. First, it explains why distributed transactions can be a thousand times slower than multi-core transactions: the transaction execution and 2PC involve network messages, whose latency is a thousand times higher than the CPU-memory latency. In recent years, with the deployment of advanced networking hardware and kernel bypassing techniques, this issue can be mitigated within a datacenter. For example, FaRM [25, 26] equipped with RDMA can reduce the remote access latency and achieve very high per-shard throughput.

However, our second observation is that this problem cannot be addressed by advanced hardware in the setting of geo-replication, because the latency across datacenters will nevertheless remain high. In this case, the latency introduced by replication will result in a distributed transaction requiring tens (hundreds, or even thousands) of milliseconds to finish the certification. If we stick to the conventional architecture, there is no obvious way to address this issue.

One might argue that we can perhaps address the problem by increasing the number of concurrent requests to hopefully saturate the system's throughput. Normally, even though the latency is high, a system can still achieve high throughput if it can process many concurrent requests. This is unfortunately not true in the case of transactional systems. The throughput of transactional systems is sensitive to the contention in its workload. In most cases, increasing the number of concurrent requests increases contention too. For example, many Amazon customers buying the same items. As has been noted in a lot of prior work [42,68,82,105,109] and our own experiments (§7.6), more concurrency actually lowers throughput.

3 Challenges and key ideas

Given that in geo-replication the high latency of the transaction certification will inevitably decrease throughput, one way forward is to remove replication from the critical path of transaction coordination [78,94]. One example of a prior work that follows this principle is Calvin [94], which pre-determines the order of transactions into a totally ordered log, and then ships this log to remote replicas. The challenge with a design like Calvin's is that if the servers are fast multi-core machines, it is really hard for the log replay to be as fast as a multi-core storage server (e.g., Silo [95]) that processes the transactions without any pre-determined order. Therefore, the system's throughput is limited. We demonstrate this empirically in our evaluation (§7). Mako avoids this issue by decoupling transaction coordination and replication in a different way.

In a nutshell, Mako works as follows. A transaction executes and uses 2PC to certify the transaction among the shard leaders. No replication takes place during the execution and 2PC. Since the leaders accessed by a transaction are very often strategically deployed in the same datacenter [18,20,83,86,89], we use kernel bypass network acceleration (DPDK) to reduce the intra-datacenter latency. When Mako successfully certifies a transaction, the transaction's writes become speculatively visible to later transactions, and its log entry is replicated in the background to other datacenters. In the foreground, Mako goes on to execute the next transaction speculatively without being blocked by the replication. Note that *Mako does not return the results to the client until the replication finishes*. In this way, Mako can increase the throughput of the system, while maintaining a similar latency as prior works that provide strong consistency.

Challenges. We face three main challenges.

Challenge 1: How to speculate with 2PC in the presence of failures? A problem with speculative execution is that roll backs are required when speculation fails. For example, if there was a problem replicating the transaction's result, we may need to revert the transaction. Mako faces the extra challenge that the speculation spans multiple shards. Consider the following example. Suppose that we speculatively execute transaction T_0 over shards S_0 and S_1, then speculatively execute transaction T_1 (which depends on T_0) over shards S_1 and S_2, and finally speculatively execute transaction T_2 (which depends on T_1) over shards S_2 and S_3. Suppose that before T_0 finishes its replication protocol, shard S_0 fails. If we are using 2PC for the coordination (as is the case in Mako), losing a participant in 2PC means the transaction is now unrecoverable and must be aborted. But notice that even though T_1 and T_2 operate on shards that did not fail and their replications may have even succeeded, because they transitively depend on T_0—which is unrecoverable—they too must abort.

The crux of the issue is that 2PC does not interact well with speculation and failures. One may think that we could instead use a fault-tolerant version of 2PC, namely *three phase commit* (3PC) [87], but this is also not the case. In the above example, if shards S_0 and S_1 fail, transaction T_0 cannot be recovered since 3PC cannot handle *all* of its participants failing. And while T_1 can recover from S_1's failure, it depends on T_0, so it too must abort. Finally, T_2 had nothing to do with any of the failing shards but it also must abort because it depends on failed transactions. In other words: the *per-transaction fault tolerance* of 3PC [49] does not extend across transactions, and hence it does not preclude cascading aborts.

Challenge 2: How can we avoid the overhead of serializing transaction results into a sequential log?[2] This is the main challenge in achieving high throughput. One reason that multi-core transactions are fast is that they *avoid* generating a global serialization order among all transactions. If we adopt the traditional approach of using one log per shard (e.g., Spanner), this will limit performance [8,15,19,20].

Challenge 3: How can we sequence conflicting log entries from different logs? As different cores may access the same data, they could write conflicting entries to different logs. When followers replay these logs, how do we guarantee that the replay will lead to the same state as the leader?

Key ideas. Mako cannot prevent cascading aborts. What Mako does, however, is to bound the impact of failed speculation. To address challenges 1 and 3 while retaining good performance, Mako introduces a distributed vector clock as a coarse-grained dependency tracking method, and a vectorized watermark to selectively rollback affected transactions, while allowing uninvolved transactions to continue executing. To address challenge 2, Mako uses one log per core and ideas from prior work [85], but data is *not* sharded across cores (multiple cores may access the same data).

4 Design of Mako

In this section, we will describe the main ideas of Mako. We first give an overview and then provide the details of how Mako processes transactions.

[2] Serialization here refers to ordering concurrent requests into a sequence, not converting a data structure into a byte stream.

4.1 Overview

Figure 1 shows the architecture of Mako. A Mako deployment splits its data (key-value pairs) into multiple shards. Each shard is replicated to multiple datacenters with a leader-follower architecture. Similarly to Spanner [20] and other geo-replicated databases, the leaders of different shards ("shard leaders") in Mako can be in different datacenters, but it is advantageous for performance reasons to ensure that the shards that are often accessed together in transactions have their leaders co-located in the same datacenter. In practice, many workloads show such a strong data locality [14, 18, 53, 96]. For example, in a car sharing application such as Uber or Lyft, each ride could be expressed as a transaction between the user, the driver, and the start and destination. The data of all of these entities could be sharded and distributed according to geographic locations [96]. Most transactions will happen locally within a city and hence within the same datacenter, while a few transactions will cross datacenters (e.g., travel from one city to another).

A transaction enters Mako and goes through the following phases before it is finished.

Execution: A shard leader serves as the *coordinator* for the transaction execution. The coordinator executes the transaction by optimistically reading from different shard leaders (as needed), and buffering the writes. Reads for some key at a given shard leader return the most recent writes to that key, including those that are *certified* (explained below) but not yet replicated, but they will not return uncertified writes.

Certification: After the execution, the coordinator will run a 2PC-based procedure among the shard leaders to confirm that there are no conflicting transactions. The transaction will be assigned a version vector clock. This vector clock represents the serialization order of the transaction. Note that so far no replication has happened, and the transaction is not considered done. Therefore, the transaction "commit" is speculative, with a chance of rollbacks in case of failures. But after certification, writes are speculatively installed and are ready to be read by later transactions. Hence, if rollbacks happen, they can have a *cascading* effect (one rollback triggering another rollback).

Replication: Each shard runs multiple Paxos instances, one for each core (worker thread), to replicate transactions' logs to followers after certification. To maximize throughput, the replication process is completely independent for each shard/core—different shards/cores have zero coordination.

Replay: The followers need to replay from the per-core log to reconstruct the same state as the leader. Because the replication phase skips coordination across shards and cores, the dependency information across shards and cores is missing. Without such information, the replay could lead to inconsistent states. To address this, Mako designs a decentralized and lightweight mechanism, the *vector watermark*, to track dependencies of distributed transactions for safe replay (§4.3).

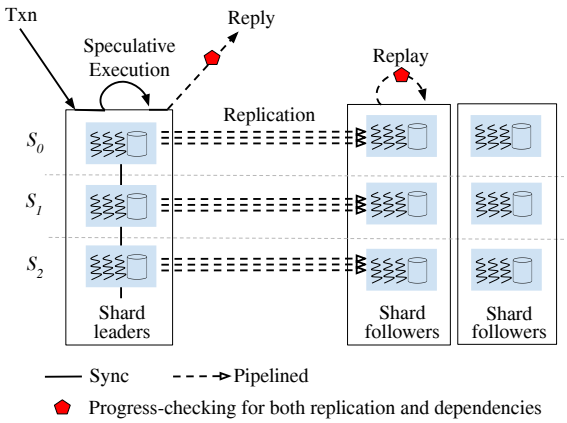

Figure 1: The architecture of Mako. Shard leaders can be in the same datacenter or in different datacenters. Shard followers are in other geographic locations. Results are returned to the client only after replication completes.

4.2 Speculative execution and certification

Mako extends Silo's [95] single-node optimistic concurrency control (OCC) protocol to a distributed variant of OCC. Every shard leader in Mako can receive a *one-shot transaction* (i.e., a transaction that includes all operations, sometimes termed a non-interactive transaction) from a client. Upon receiving that request, the shard leader becomes the transaction coordinator and will execute the transaction on behalf of the client. For reads, the transaction coordinator performs optimistic reads of key-value pairs. It maintains a ReadSet, which includes all the records read with their *versions* (defined below). For writes, the coordinator buffers them into a WriteSet that stores the new state of the record locally without explicitly coordinating with other transactions; these are not installed until they have been validated. Records that have been both read and modified are present in both the ReadSet and WriteSet. In the absence of failures, reads recorded in the ReadSet reflect the latest version of the corresponding keys.

Version vector clock. The version in Mako is a vector clock that consists of n individual logical clocks $(c_0, c_1, ..., c_{n-1})$, where n represents the total number of shards in the deployment. Each element represents a logical clock value generated by a shard. The logical clock on each shard increases monotonically. In our implementation, this is generated by an atomic `fetch_and_add` instruction as it fits our needs. If higher per-shard scalability is desired, one can use the `rdtscp` instruction as done in previous works [51, 66, 85, 92]. Further, Section 6.1 discusses how Mako represents this clock when there are thousands or millions of shards to keep the system scalable.

Transaction certification. After a transaction executes, the system needs to certify that there are no conflicts with concurrent transactions. The certification includes 4 rounds of RPCs among the leaders of involved shards (single-shard transactions perform no RPCs).

1. *Lock*. The coordinator attempts to acquire locks for the records in the WriteSet from the involved shards. Lock requests are sent in parallel. During the lock acquisition, if any lock is already held by another transaction, the lock request fails and the attempting transaction is aborted.

2. *GetClock*. After locking the WriteSet, the coordinator asks each involved shard to increase and return its latest logical clock to create a vector clock. The coordinator then combines this vector clock with all the vector clocks in the ReadSet to generate a vector clock that serves as the transaction's commit version. The rule for combination is choosing the maximum clock value for each shard.

3. *Validate*. The coordinator then contacts the relevant shards to check all the records in the transaction's ReadSet. If there is a conflict on any of the keys (i.e., the latest version has changed or the lock bit has been taken), the coordinator will abort the transaction. This is to ensure that the versions of all read data at the serialization point are the same as the versions seen during the execution phase.

4. *Install*. If all validations succeed, the coordinator sends RPCs to the relevant shard leaders to speculatively install the writes. Old versions are not discarded immediately in case the speculatively installed versions need to be rolled back.

Validate and *Install* are essentially 2PC's prepare and commit phases. We choose not to use 2PC's naming to avoid confusion about the commit point, as the transaction is not fully "committed" yet since it is pending replication.

After the above 4 RPCs are done the certification phase is complete and the transaction's state moves to `CERTIFIED`. So far, all communication has occurred among the shard leaders. If the leaders are co-located, this means that no cross-datacenter communication needs to take place and Mako can use fast networking (DPDK).

Use vector clock to coarsely track dependencies. Mako needs to track read dependencies between transactions that have been certified and speculatively installed to prepare for possible rollbacks. If transaction T_1 reads T_2's write, then T_1 (read-)depends on T_2; if T_2 reads from T_3, then T_1 transitively depends on T_3. If T_1 (transitively) depends on T_N, Mako ensures that T_1's version vector clock is always greater than T_N in a pair-wise manner. *This is the key invariant in Mako that ensures the correctness and the efficiency of rollbacks*. (If T_1 is a read-only transaction, T_1's version could equal T_2's.)

For example, in Figure 2 there are 3 shard leaders S_0–S_2, and each shard stores 3 keys respectively. The dependency relationships are as follows: T_2 depends on T_1, T_1 depends on T_0, and there is a blind write between T_3 and T_2. A possible set of versions for this scenario could be T_0: (1,0,0), T_1: (1,1,0), T_2: (1,2,1), T_3: (0,3,0). In this example, $T_0 \leq T_1 \leq T_2$ in pair-wise comparison, while T_3 and T_2 are incomparable, indicating that they are not read-dependent with each other (e.g., commutative or blind write). Note that T_2 must be pair-wise comparable to T_0 as they are transitively read-dependent.

	Operations	ReadSet	WriteSet	Vector Clock
T_0	W(a);		(1,0,0)	(1,0,0)
T_1	R(a);W(d);	(1,0,0)	(0,1,0)	(1,1,0)
T_2	R(d);W(d);W(g);	(1,1,0)	(0,2,1)	(1,2,1)
T_3	W(e);		(0,3,0)	(0,3,0)

Figure 2: Transitive transactions: version vector clocks reflect all potentially explicit or implicit dependencies. There are 3 shard servers $S_0 - S_2$, and 4 transactions: T_0–T_3.

If two transactions are incomparable, our vector clock still reflects the correct serialization order from the leader (e.g., T_3 has to be replayed after T_2 on the followers of shard S_1).

4.3 Replication with Paxos streams

There are two types of logs in Mako: a *transaction log* and a per-core *replication log* (which we call a *stream* to avoid ambiguity). A transaction log contains the key-value pairs in the WriteSet of the transaction, and its commit version vector clock. In contrast, each entry in a stream corresponds to a batch of transactions (400 in our implementation).

Once a transaction is speculatively installed in the shard leaders, the transaction enters the replication phase. During this phase, each worker thread within each shard maintains a separate stream of the transactions that will be replicated. Mako then uses MultiPaxos [16] for replication (a separate instance for each core), but it could use any leader-based replication protocol that is safe under an asynchronous network.

Note that we use per-core streams rather than a single stream for the entire shard because prior works [85, 90] have shown (and we have confirmed) that the throughput of a single MultiPaxos stream plateaus after $\approx$ 10 worker threads due to expensive thread synchronization overhead. Further, the reason that each stream entry corresponds to a batch of transactions instead of a single transaction is to eliminate the frequent RPC overhead; all other works in the literature do the same. While batching could introduce additional latency, Mako operates at high throughput so it builds batches fast; the geo-latency of replication is by far the dominant contributor to the end-to-end latency experienced by clients.

4.4 Record-Replay on the followers

When a new Paxos stream entry is durable, a follower cannot replay the entry just yet since this might lead to an inconsistent state in the event of failures. Consider two transactions T_1 and T_2 in Figure 3. The system has two shards to store bank checking and saving information separately. Initially, Alice's savings account holds \$100, while Bob has a bank balance of \$0. In T_1, Alice transfers her balance from the savings account to the checking account, and then in T_2, Alice transfers \$100 from her checking account to Bob's checking account. T_1's two operations will be replicated independently by two Paxos streams as they are on different shards. However, in the event that the saving account shard fails, two potential outcomes may arise, both of which can lead to an inconsistent

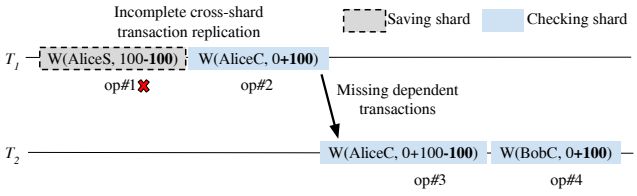

Figure 3: Alice withdraws $100 from her savings account to her checking account and then transfers it to Bob.

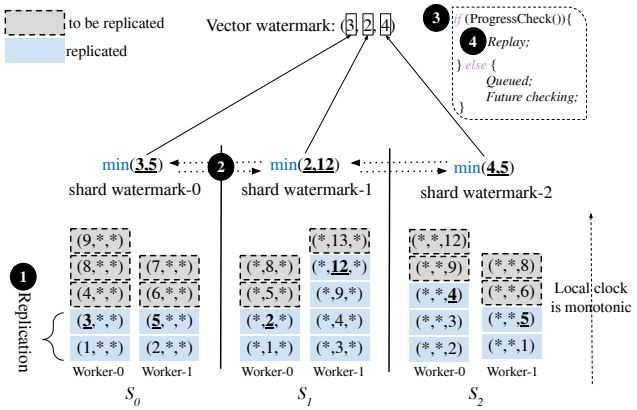

Figure 4: Example replay procedure for shard followers with 2 worker threads per shard. Replay is performed by advancing the vector watermark. Mako only tracks the clock relevant to each shard (we mark the irrelevant entries with *).

state. The first outcome is *incomplete cross-shard transaction replication*. For instance, op#2 in T_1 is successfully replicated, while op#1 is lost after a failure. It is unsafe to only replay op#2 on one shard follower. The second outcome involves *missing dependent transactions*. Although all operations in T_2 are replicated, T_1's may not be (i.e., op#1 is lost). Mako cannot replay T_2 either, as otherwise the system will be in a state where Alice never sends money, but Bob receives $100.

To address this issue, Mako borrows the idea of Aurora [99], Rolis [85], and Query-Fresh [99] in which system performance is optimized by pipelining replication and utilizing one monotonically increasing number to track the durability of concurrent transactions within one shard or one database instance. However, this approach will not work out of the box in multi-shard, geo-replicated systems since the monotonically increasing number would become a centralized bottleneck. To correct this, Mako introduces a lightweight, decentralized *vector watermark* scheme to enable safe replay.

A vector watermark is an array of shard watermarks (w_0, w_1, ..., w_{n-1}) where n equals the number of shards. Each shard watermark w_i is calculated by shard-i independently. On shard-i, Mako maintains an invariant that each Paxos stream has a local and monotonically increasing clock value that represents the shard clock of the most recently replicated transaction. Shard-i chooses the minimum of these clock values from all worker threads. Figure 4 shows an example.

❶ Each watermark w_i represents the current replication progress of shard-i in the system. It is monotonically increasing. ❷ All shards will periodically gossip with each other to exchange their latest vector watermark. The gossip is performed in the background and does not block transactions' execution. ❸ Once *progress-checking*, a safety-checking mechanism, succeeds at the followers, ❹ the transactions are sent to the replay threads for concurrent replay. We discuss progress checking and concurrent replay in detail later.

For a coordinator to acknowledge the transaction's result to the client, Mako waits for the system's vector watermark to advance beyond the transaction's version. This ensures that the transaction and all transactions it depends on have been durably recorded on all relevant shards, providing a consistent and reliable commit acknowledgment to the client. More formally, if a transaction with version vector clock $(c_0, c_1, ..., c_{n-1})$ has $c_i \leq w_i, \forall i \in [0, n-1]$, its transaction log must be already replicated in the Paxos stream of shard-i. With this guarantee, a transaction can transition to `COMMITTED` and return back to the client.

Progress-checking phase. In this phase, Mako actively verifies whether a transaction's version falls below the latest vector watermark. If it does, the transaction proceeds to the replay phase, indicating that all transactions it depends on, from other cores or shards, have also been replicated to a majority of replicas. At this stage, Mako can assert that the transaction is `COMMITTED`. On the other hand, if the version does not fall below the vector watermark, the transaction is unsafe to replay since some of its dependencies may be missing, or some transactions might only be partially replicated. In such cases, the transaction is queued for future checking.

Replay phase. We employ Thomas's write rule [90, 93] (e.g., last writer wins) to replay replicated writes on each shard follower concurrently without any additional coordination. Each replicated write corresponds to one transaction. If the transaction tries to write a data item that has already been written by another transaction with a newer *shard clock*, the write operation is ignored.

Optimization: summary vector clocks. Since we batch transactions to avoid RPC overhead, we also find it helpful to do watermark updates and comparisons at the granularity of batches instead of individual transactions. We do this by assigning each batch a *summary vector clock*. Mako computes this summary vector clock by using the highest c_i for all $i \in [0, n-1]$ in all vector clocks in the logs of the stream entry. For example, if we have a batch that is made up of the 4 transactions in Figure 2, the batch's summary vector clock would be $(1, 3, 1)$. This vector clock is used when the followers replay operations.

5 Handling failures in speculative 2PC

The speculative transaction execution and pipelined replication strategy discussed so far assumes no failures. This section discusses how Mako deals with the cases where speculation fails due to server failures. We only discuss failures of shard leaders as failures of followers do not require special handling other than normal recovery.

5.1 Why is this hard?

A conceptually simple strawman solution is to pause the entire system, sync all replicated transaction logs, track which speculatively executed transactions are not fully replicated, rollback these transactions and any transactions that depend on them, and then resume execution. While straightforward, this approach is not ideal in practice as a single failed server can halt the entire system. Furthermore, in multi-shard systems used today such failures do not impact healthy shards. Mako preserves this arrangement by ensuring that unaffected shards can continue processing transactions.

Our original intent was to find and then adapt an existing technique in order to avoid freezing the entire system in the event of speculation failures. We were confident that given the long history of work in speculative execution, such a solution must exist. To our surprise, we found no prior solution that could be applied to Mako, and realized that Mako faces unique challenges. Below is a summary of prior solutions and why they do not apply to Mako.

- *Single-shard speculation*. Many speculative execution and replication works only consider a single shard [33, 81, 85]. In speculation failures, the system freezes to recover. There is no need for a better solution because there is only one shard in the system so the system would have to freeze anyway when the shard fails.
- *Re-execution*. Two recent designs, Morty [12] and Hackwrench [24], use speculative execution on transactions and re-execute the transaction if the speculation fails. An important reason why they can do this is that their speculation failure is not caused by server failures but by conflicting access in transactions. That is, even though the speculation fails, the transaction requests/logs are still present to support the re-execution. But in Mako, the servers can fail before the replication completes, so transactions could be lost; Mako cannot re-execute transactions in the way that Morty and Hackwrench do.
- *Fine-grained dependency tracking*. By recording the fine-grained dependencies (e.g., T_1 reads T_2), the system can accurately abort transactions in a cascading manner. However, recording such dependencies has a high overhead and thus is only used in distributed systems [68, 105] where the baseline throughput is relatively low (i.e., thousands of transactions per second) so there is room to tolerate the overhead. In contrast, multicore transactional systems have much higher throughput (millions of transactions per second), so introducing fine-grained dependency tracking can easily kill more than half of the throughput, as is discussed by prior works [23, 28, 34, 100]. Hence, if we want Mako to be fast, it cannot take this approach.
- *Group-commit*. Designs that execute transactions speculatively and commit all of them as a group [54, 64, 101] track replication progress with a single timestamp. But if a shard leader fails, the entire system blocks until the failure is detected and fixed (e.g., several seconds). Mako cannot use this approach because we want healthy shards unaffected by the failure to continue executing transactions.

Our literature survey leads us to conclude that no existing solution can meet Mako's goals. A deeper reason for the absence of techniques in this domain is that the key building block in most distributed transaction protocols, 2PC, is not fault-tolerant. If a shard in 2PC loses its state, the healthy shards will also get stuck [87]. The usual approach to address this problem is to replicate every decision in 2PC [20] or rely on fault-tolerant disaggregated storage [35] so that we can assume that every shard is always alive. But since Mako chooses to invert the layering between 2PC and replication, we must invent a new failure recovery mechanism to support recovering 2PC with incomplete past decisions.

5.2 Mako's solution

As Mako does not replicate 2PC's decision before it finishes, Mako cannot recover decisions at the level of individual transactions when there are failures. But such fine-grained failure handling is not necessary anyway. Instead, Mako groups transactions into *epochs*. When failures happen, Mako advances the epoch and makes a collective decision about which transactions in the previous epoch must roll back.

Mako has a configuration manager (CM) that manages the epochs (which is also sometimes called a view manager in other works). CM itself is replicated so it is considered always alive. CM maintains heartbeats with every shard. When a shard leader fails, CM will detect it and trigger a leader election to elect a new leader. CM also advances the epoch number and broadcasts the epoch increment to all shards. The Paxos streams on all shards also use the epoch number to group log entries, which is a classic approach in consensus systems [16, 72, 73]; we are not introducing algorithmic changes in reaching consensus.

The newly elected leader will first try to retrieve all replicated log entries in the previous epoch from its peers, recommit them if needed, and commit any remaining slots with no-ops if the entries are not recoverable (any entries after the no-op will be ignored). We call this *closing* the previous epoch, because after this step no more log entries can be added to the previous epoch. When an epoch is closed on a shard, its *finalized* shard watermark can be computed by choosing the minimum shard clock of all its streams.

Healthy shards also advance their epochs on receiving the broadcast from the CM. A major difference between a healthy

shard and a recovered shard is that a healthy shard usually does not lose any transactions in its log, so its rollback is expected to be less aggressive. To reflect this, the healthy shard has an extra step to close the old epoch. The shard first tries to finish speculative execution and certification of all transactions in the old epoch, then it replicates a special ending entry into all its Paxos streams. The ending entry has a INF shard clock value, indicating that: (1) this is the maximum clock; (2) there are no more transactions of this epoch on this shard; and (3) all previous transactions have successfully been replicated without lost dependencies. When the replication of INF entries finishes, the leader considers the old epoch closed, and declares its finalized shard watermark is INF. Note that INF is also the minimum shard clock of all of its streams, so the rule for computing the finalized shard watermark is the same on recovered shards and healthy shards.

If the shard has a hanging transaction in the old epoch that cannot finish before a timeout (due to network delays or waiting on the failed shards), it will terminate the hanging transaction, but not replicate the INF entry in the Paxos stream, and then computes the watermark normally.

After a shard computes its finalized watermark, it broadcasts the watermark to all other shards. Eventually, all shards exchange their finalized watermarks to form the *finalized vector watermark* (FVW), which represents a consistent and maximum global cut across all shards for the old epoch. Given an epoch, all possible vector watermarks are smaller than the epoch's FVW in a pair-wise manner. Computing the FVW is a deterministic and reentrant process, meaning it can be safely restarted and re-executed in case of failures, always yielding the same result. If a shard fails during the steps of closing an old epoch, the CM will initiate a further configuration change with a higher epoch. The new leader will always compute the same FVW for the old epoch as they were computed before.

After the FVW for the old epoch is established, any transactions that are not below the FVW are rolled back on shard leaders and forever abandoned by the system. One might wonder why we cannot re-apply the transactions using the logs from healthy shards. This is because although healthy shards may have a transaction's WriteSet, these writes can depend on lost transactions, so re-applying them would lead to anomalies (§4.4). Note that the number of transactions above the FVW in the old epoch does not grow once the FVW is established, which means the rollbacks are bounded; there are no unbounded and expensive cascading aborts into new epochs.

During this failure recovery, transaction execution on healthy shards should not be blocked if transactions do not involve the failed shard. To reflect this, a healthy shard does not need to wait for the old epoch to close, and the finalized vector watermark to be computed, before processing new-epoch transactions. It does need to wait until all old-epoch transactions are certified or aborted (but not replicated), so that no old-epoch transactions read new-epoch transactions. This switch is very quick. To prevent new-epoch transactions

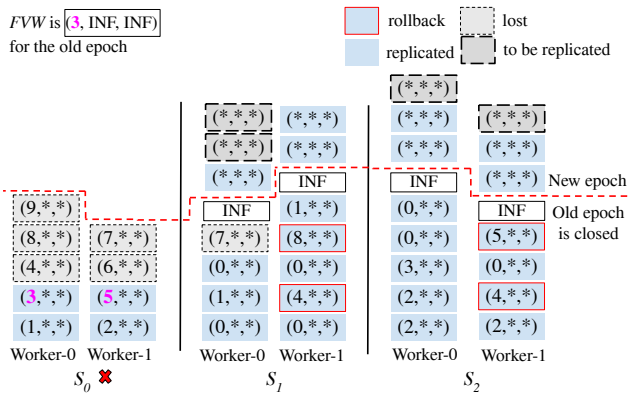

Figure 5: Single-shard failure: S_0 fails; S_1 and S_2 are healthy (irrelevant information is marked with asterisks).

from being affected by the old-epoch rollbacks, we add a rule that before the FVW is computed and the rollback is done, new-epoch transactions cannot read from transactions that are certified but are uncertain if they will be below FVW.

Figure 5 shows an example. There are 3 shards with shard S_0 failing and triggering a rollback. The computed FVW is (3, INF, INF). All healthy shards (S_1 and S_2) can eventually replicate their transactions in the old epoch. For any transactions on the healthy shards that are not below the FVW, such as (4,*,*), they are rolled back because they could transitively or directly depend on one of the lost or incomplete transactions.

Additional details. After all shards have advanced to the new epoch and all old-epoch transactions have finished, the healthy shards can clean up leftover work by the failed shard, mainly its pre-owned locks. Further, if a healthy shard launches a transaction that accesses a shard that is in the process of recovering from a failure, the healthy shard may be blocked because Mako has a synchronous threading model. To prevent this, Mako puts this transaction into a wait queue based on timeouts until the failed shard recovers.

Correctness. We give a proof of the correctness of Mako's design and failure recovery in Appendix A.

6 Practical considerations

In this section we discuss critical extensions to Mako that are needed for Mako to be useful in practice.

6.1 Scalability with more shards

Recall that Mako creates shards for 2 reasons: to achieve higher throughput and to support increasingly large datasets that cannot fit in one machine. As we show in our evaluation (§7), Mako achieves very high throughput with just a handful of shards and hence there is no need to use many shards to get high throughput. On the other hand, Mako absolutely needs to scale to support larger datasets.

But adding more shards to Mako brings overheads that can prove problematic. In particular, there are two components of Mako that scale with the number of shards: (1) the vector

watermark introduced in Section 4.4 that tells followers when it is safe to replay operations; and (2) the version vector clocks that track the version of objects across transactions. *The vector watermark is not a scalability bottleneck*, because each shard maintains a single vector watermark (the number of entries is linear in the total number of shards), and each entry in it is a 32-bit integer. Even if we had 10,000 shards, each vector watermark would be only 40KB.

On the other hand, there is a version clock for every object in every transaction. *Version vector clocks are a scalability bottleneck*. To address this issue, when the number of shards gets large, Mako compresses the vector clocks to a small size similarly to prior works [57, 102, 106, 110]. We provide a complete pseudocode for the algorithm in the Appendix D, and evaluate the scalability of vector clocks in Section 7.7. The high-level idea is as follows.

When installing a new version vector clock, multiple shards' clocks can be merged into one entry by choosing the maximum of these shards' clocks (the shards' logical clock is also updated to the maximum value on installing the version). This compression is lossy, but it still preserves correctness because it maintains the key invariant in Mako: if transaction T_2 (transitively) depends on T_1, T_2 must have a greater vector clock. The merging strategy is flexible: Mako can merge any group of clocks into one. For simplicity, we implemented a $K:M$ strategy that groups K shards into M-sized vector clocks.

Note that compression has its downsides: it degrades performance when a shard fails or slows down. Consider the extreme case when the vector clock is compressed to a single timestamp. In this case, when a shard wants to replay a transaction, it needs to wait for the watermark of every other shard to surpass the transaction's timestamp. If any shard is laggy or faulty, the whole system is affected. In contrast, in the uncompressed case, replaying only needs to wait for relevant shards, not all shards. Mako uses a full-sized vector clock as its default; when there are many shards it sets the vector clock to a constant number (e.g., 20) and merges clocks.

6.2 Shard management

Similarly to most works in this space, we use static sharding in our prototype implementation to focus on our primary research question. However, shard management, such as resharding, is an important topic in practice [20, 41]. Prior works [1, 6, 48] have shown that thoroughly addressing shard management requires an entire research project.

We leave the complete design and implementation of a dynamic sharding solution for Mako to future work. However, we argue that this problem is not fundamentally more difficult in Mako than in prior systems. In particular, in Mako, there is no need for cross-epoch vector clock comparisons and cross-epoch vector watermark computations, which eliminates concerns about mismatches between vector clocks across epochs. Leveraging this insight, Mako is able to handle shard management in a way analogous to failure recovery. Once a FVW is computed (§5.2), the entire database can be treated as a read-only snapshot, serving as the initial state with all vector clocks conceptually reset to zero as vector clocks from the higher epoch always have a higher priority. We provide more details in Appendix B.

6.3 Quick failure recovery

Learners. To speed up failure recovery, Mako co-locates a shard learner in the same datacenter as the shard leader. A shard learner is essentially the same as a shard follower, except that it does not vote on consensus. This allows Mako to recover from the failure of a leader more quickly than having to make one of the followers the leader (which would cause shard leaders to no longer be co-located) or provision a new leader in the existing datacenter which would take some time for this new machine to catch up from scratch.

Datacenter failures. A special case in deployment is when all shard leaders are co-located in the same datacenter, and the entire leader datacenter fails. In such a case, the failure recovery process can be expedited by skipping all rollbacks on healthy shard leaders since there are none.

Stragglers. A benefit of using a vector clock is that it is resilient to stragglers. A straggler shard in Mako does not block the system entirely. Note that the all-to-all communication in Mako for vector clocks is non-blocking. If a shard is very slow, transactions that do not involve such straggler shard are not affected. Recall that the watermark is a vector: the straggler's entry in the vector would stay the same until the straggler makes progress, but the other entries in the vector would be incremented. So transactions that do not touch the straggler can continue to be replayed at followers and can return to the client. Only when cross-shard transactions touch the straggler, would they incur any delay.

7 Evaluation

The evaluation aims to answer the following questions:

- What is the base performance of Mako and does it scale?
- How does Mako compare to the state-of-the-art geo-replicated transactional systems?
- How fast can Mako recover from failures?

7.1 Experimental setup

We implemented Mako in C++. Mako is based on a few existing works, including Silo [95] for each server's database engine, eRPC [45] for accelerated networks, and the Janus framework [69] for replication. Mako adds ∼10K new lines of code. Mako is open sourced at `https://github.com/stonysystems/mako`.

Testbed. Experiments were conducted on Azure. Each VM has 32 Intel vCPU cores, 128GB of RAM, and Mellanox 4 Lx accelerated networking (16 Gbps). The latency within a datacenter is mostly between 20 and 30 μs, with occasional

peaks over 100 μs.[3] To simulate WAN, we make 3 groups of servers and inject a 50 ms RTT between groups.[4]

Baselines. We evaluate nine baselines: (1) five systems that support scalable sharding and geo-replication, including Calvin [94], D2PC [113], TAPIR [109], a Spanner-like 2PC over Paxos, and Janus [69]; and (2) four systems that lack full sharding or geo-replication features but are optimized for multi-core settings, including Silo [95], Meerkat [90], Rolis [85], and DrTM+R's Optimistic Replication (OR) [104]. For Calvin, D2PC, TAPIR, Janus, Silo, Meerkat, and Rolis, we use their existing implementations with modifications required to get them to run in our testbed (e.g., we had to port Meerkat's networking drivers to work with the network cards in Azure). We implement our own version of OR because the original implementation does not support geo-replication. We add this support by combining OCC with DrTM+R's optimistic replication protocol (we call it OCC+OR). We also implement a Spanner-like 2PC over Paxos since Spanner is not open source (we call it 2PC).

Sharding in Mako and baselines. The database is split across anywhere from 1 to 10 servers. Given that many of the baselines were not designed to run on many-core machines, we need to be careful with how we shard the data as otherwise we could be very unfair to them. We do the following.

- **Mako, OCC+OR, 2PC**: 1 server is 1 multi-core shard with 24 worker threads.
- **Janus, D2PC, TAPIR**: 1 server is 24 shards, each with 1 worker thread.
- **Calvin**: 1 server runs 3 shards (called "partitions" in Calvin), and each shard has 8 worker threads.

The goal of the above arrangement is to ensure that, to the best of our ability, we are giving the same amount of hardware resources to all of the different systems. There is however, another issue that arises. When we run many of these baselines with many servers, they end up having a lot of shards. For example, if we run Janus, D2PC, or TAPIR with 10 servers, that is equivalent to running them with 240 shards. The research prototypes of these systems were never tested with such high number of shards, so at this scale all of them experience issues (e.g., can't establish socket connections, abort rates are too high, most RPCs time out) when performing cross-shard transactions (we have confirmed this with several of the authors of these systems). We therefore make the decision to be **generous** to these baselines and disable all cross-shard transactions for Janus, D2PC, TAPIR, and Calvin. In other words, they only perform single-shard transactions, whereas Mako, OCC+OR, and 2PC will perform cross-shard transactions.

To ensure fault-tolerance, we also replicate each server so we have one leader, one learner (§6.3), and two followers (this means in total we have up to 40 servers). Unless otherwise noted, all shard leaders are deployed in the same datacenter, and all clients are co-located with the shard leaders.

Benchmarks. We evaluate two benchmarks:

- **TPC-C**. This benchmark simulates an e-commerce site. TPC-C consists of a mix of five concurrent transactions that represent different types of activities, including new orders (NEW), payment processing (PAY), order status checking (ORDER), delivery scheduling (DLY), and stock level checking (STOCK). TPC-C scales by sharding a database into multiple warehouses spread across multiple cores and shards. Transactions in TPC-C are configurable to span multiple warehouses to evaluate the performance and scalability of distributed database systems. This type of transaction is more complex and resource-intensive than transactions that access data within a single warehouse, as it requires coordination and communication between multiple cores and servers. We run the standard mix on the default configuration unless otherwise mentioned.
- **Microbenchmark of small-sized transactions**. Because Mako introduces overheads at the transaction level, its performance is penalized more with small-sized transactions. We demonstrate cases like this using a microbenchmark with two transaction types: Read-Only (READ) and Read-Modify-Write (RMW). Each READ transaction has 4 read operations and each RMW transaction has 4 read-modify-write operations. The total data space for the microbenchmark is 1 million keys for *each* shard. We conduct 50% of RMW transactions and 50% of READ transactions. Each operation randomly selects a key in a given shard. There is a 95% chance of selecting from the shard where the coordinator is running, and a 5% chance of the coordinator performing a cross-shard key access.

7.2 Throughput and scalability

This part evaluates the performance and scalability of Mako.

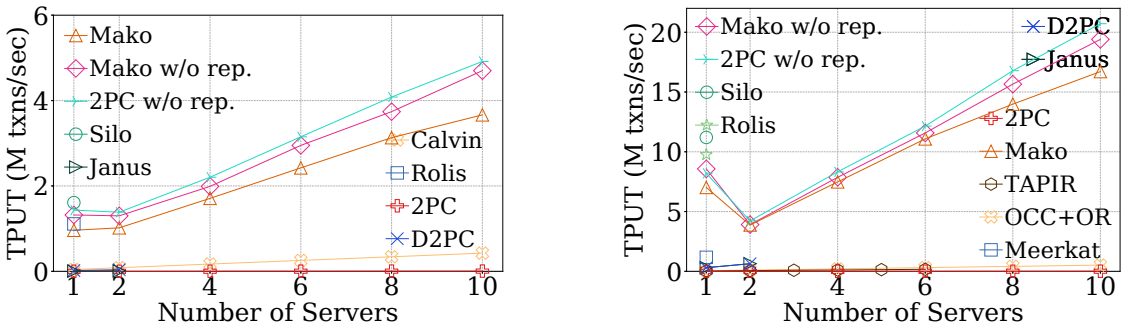
TPC-C Benchmark. Of the 10 systems that we are evaluating, only 7 systems readily support TPC-C. These include: Mako, 2PC, Janus, D2PC, Calvin, Silo, and Rolis. TAPIR and Meerkat do not support TPC-C in their existing code bases, and we did not implement TPC-C for OCC+OR.

We run TPC-C on the 7 systems that support it with an increasing number of shards. The number of warehouses is set to be equal to the number of worker threads in the system.

Mako is able to scale well in Figure 6a. Mako's throughput at 10 shards (10 servers) is 3.66M transactions per second (TPS), which outperforms Calvin by 8.6×. As a side note, Mako also has good single-shard performance reaching 0.96M TPS, which outperforms Calvin by 22.5×. The major reason for the slowness in Calvin is that it uses a central se-

[3] Note that this is higher than the usual single-digit microseconds latency one would observe in a local cluster with the same high-end networks. After consulting with Azure administrators as well as authors of other works using Azure [27], we learned that the higher latency on Azure is the norm and we assume it is related to the virtualization infrastructure.

[4] We inject latency instead of deploying in multiple datacenters since we were limited by Azure quotas. We tested small-sized deployment in multiple datacenters and the results are consistent with the injected-latency test.



(a) TPC-C Workload **(b) Microbenchmark workload**

Figure 6: Throughput and scalability of Mako and the baselines. In Mako, the number of shards is equal to the number of servers (x-axis). In other systems, the number of shards is larger than the number of servers (see Section 7.1).

quencer to pre-determine the order of a batch of transactions, which are then sent to all replicas to execute deterministically through Zookeeper.

There is a noticeable per-shard throughput drop when increasing the number of shards in Mako from 1 to 2. The reason for this decline is that 1% of the items accessed in the `NewOrder` transaction (10 items accessed on average) trigger a cross-warehouse access, which results in 5.11% cross-shard transaction coordination. This overhead is considerably more expensive compared to the local in-memory operations.

The performance of Mako scales almost linearly after 2 servers. As the number of servers increases, Mako's throughput per shard slightly decreases with increasing shards from 2 to 10 shards, because the ratio of cross-shard transactions increases. For example, `NewOrder` goes from ∼5% to ∼9% (the theoretical bound is 10%). While 2PC scales well up to 10 servers, its throughput is lower than Mako because geo-replication is on the critical path of concurrency control. This same effect of having geo-replication in the critical path affects D2PC and Janus, which can only reach 38.5K TPS and 10.4K TPS with 2 servers, respectively.

Ablation testing. To understand the contribution of different components in Mako, we disable various parts of Mako and some of the baselines.

First, we disable all replication for Mako and 2PC. We observe that both Mako and 2PC without replication perform much better than their respective variants with replication (as is expected). For example, the overhead of replication in Mako is around 23%. 2PC, without the geo-latency to slow down its transaction processing, gets a massive performance boost and is even better than Mako because it has fewer RTTs for cross-shard transactions.

Second, we measure Silo, which is the system on top of which we built Mako, to investigate the cost of adding sharding and replication to a single-machine database. Mako preserves 68.4% of the throughput of Silo on a single machine.

Third, we evaluate Rolis, which extends Silo to support geo-replication efficiently. Rolis achieves higher throughput than Mako with 1 shard since it does not have multi-version overhead. However, Rolis can only support one shard so if the database gets too big or if the system requires more throughput, there is nothing that Rolis can do besides using bigger machines. Adding support for sharding is precisely Mako's contribution over Rolis.

Microbenchmark: We further study the performance and scalability of Mako on the microbenchmark with a fixed 5% cross-shard key access, as shown in Figure 6b. In this experiment, we also include the results for OCC+OR, Meerkat, and TAPIR. In this simple but high throughput scenario, Mako can still scale well beyond 2 shards. The throughput of Mako at 10 shards is up to 16.7M TPS. Both Mako and OCC+OR can scale well with more shards, but Mako is able to achieve 32.2× higher throughput than OCC+OR at 10 shards (10 servers). OCC+OR can only achieve up to 0.52M TPS because transactions in OCC+OR always optimistically read and abort if the replicas are not ready during the commit phase, which is often the case under geo-replication. As in the TPC-C benchmark, Rolis achieves 39% higher throughput than Mako when using a single shard.

Meerkat does not support sharding, so we test its single-shard performance with 24 worker threads. All servers are connected via DPDK. Meerkat achieves 1.17M TPS, a lot lower than Mako at 1 shard. In fairness, Meerkat supports interactive transactions which are more costly to handle than the "one shot" (or non-interactive) transaction model used by Mako and the other baselines. So this comparison is not apples-to-apples and should be treated qualitatively (Mako is very competitive) rather than quantitatively.

We test Janus, D2PC, and TAPIR up to 2, 2 and 6 servers, respectively. All systems scale well, with Janus achieving 640K TPS, D2PC attaining 137K TPS, and TAPIR reaching 168K TPS. We could not test beyond these configurations because the prototype implementations of these systems could not support more shards. Nevertheless, assuming they continue to scale in the same fashion, Mako still achieves orders

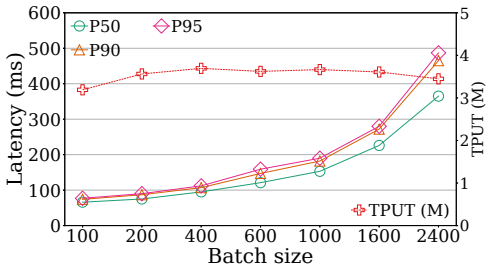


Figure 7: Mako's latency and throughput on TPC-C with varying batch size.

of magnitude better performance by decoupling transaction coordination and replication.

7.3 Latency

Mako's latency has three dominant sources: the RTT between datacenters, the batching window to gather transactions and put them into a stream entry, and the advance time of the vector watermark to go beyond the vector clock. We measure Mako's latency with 10 shards on TPC-C. The results are shown in Figure 7. Median latency with batch size of 600 is 121 ms, of which ∼50 ms are for RTT between datacenters, 13 ms for batching, and the rest to advance the vector watermark. In contrast, 2PC (not shown in the figure) has a much higher latency (∼ 10×) at high throughput because of aborts.

As shown in the results, batch size has an obvious impact on latency but the impact on throughput is minimal once the batch size is large enough (a few hundred). Compared to a batch size of 100, the throughput of Mako with a batch size of 400 increases by 15.8%. This throughput remain roughly constant up to batches of 1600. Based on this, we set Mako's batch size to 400 by default, and used this in all experiments.

We also evaluate the latency of Mako, Janus, and Calvin under a light workload (microbenchmark) using a single replicated shard. This helps us understand the communication overhead of the various systems. Figure 8 gives the results.

The median latency of Mako is 60 ms, comprising approximately 50 ms for one WAN RTT, 3.5 ms for batching, and 6.5 ms for waiting on the watermark advancement. In comparison, Janus achieves a best-case latency of around 50 ms as expected (one WAN RTT), while Calvin exhibits a latency of 166 ms using ZooKeeper-based replication, which matches the number reported in the Calvin paper. All tail latencies are not significantly affected under the light workload.

7.4 Impact of cross-shard transactions

In this experiment, we evaluate Mako on the microbenchmark using 10 shards while varying the ratio of cross-shard transactions to measure the impact of distributed transactions. As depicted in Figure 9, in the absence of cross-shard transactions, Mako achieves a peak throughput of 60.3M TPS, which then declines. When all transactions are cross-shard,

Percentile	Mako	Janus	Calvin
10%	57 ms	50.3 ms	146 ms
50%	60 ms	50.5 ms	166 ms
90%	64 ms	50.7 ms	202 ms
95%	65 ms	50.8 ms	206 ms
99%	66 ms	51.3 ms	212 ms

Figure 8: Latency measurements for Mako, Janus, and Calvin on the microbenchmark under a light workload.

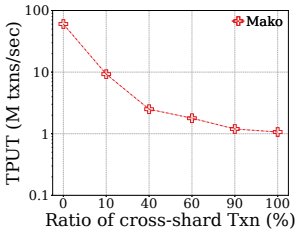

Figure 9: Varying ratio of cross-shard transactions on the microbechmark.

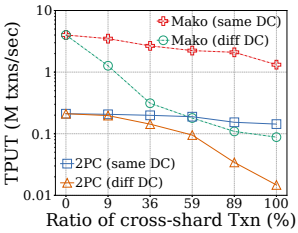

Figure 10: Effect of leader placement on Mako's throughput.

the throughput drops by 98.2% to 1.1M TPS primarily due to the significant time consumed by RPCs.

7.5 Leader placement

We distribute leaders evenly into two datacenters to evaluate how the conflict windows for cross-shard transactions is prolonged and how this affects performance.

We use the `NewOrder` transaction in TPC-C as the benchmark. The ratio of cross-shard transactions is controlled by varying the cross-warehouse access. Since the `NewOrder` transaction accesses an average of 10 items, a 1% cross-warehouse access results in approximately 9.04% distributed transactions, while a 50% cross-warehouse access leads to more than 99% distributed transactions.

In Figure 10, we increase the ratio of cross-shard transactions while fixing the number of clients (24K clients) for Mako and 2PC to test intra-/inter-datacenter transactions. As expected, if there are no cross-shard transactions, the performance of Mako and 2PC are not impacted, reaching 4.0M and 52K TPS respectively. As the cross-shard transaction ratio increases, the throughput of both systems drops significantly. However, even with leaders in different datacenters Mako achieves much higher throughput than 2PC.

7.6 Effect of concurrency on throughput

In the introduction, we remarked that a common way in systems to increase throughput is to process more client requests at the same time. We also stated that this is not actually the case in transactional systems. To gather support for this claim, we follow the experimental setup described in Section 7.5 and evaluate the performance of 2PC on `NewOrder` transactions when the leaders are placed in different datacenters. We in-

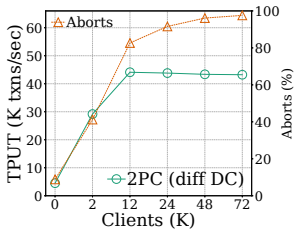

Figure 11: 2PC throughput with varying concurrency.

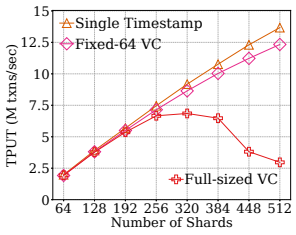

Figure 12: Scalability of vector clock

crease the concurrency (number of clients) while maintaining a fixed ratio of cross-shard transactions (∼9%) in Mako.

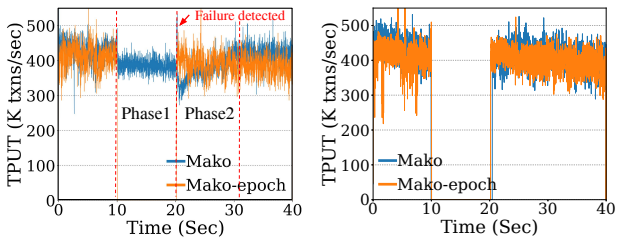
As shown in Figure 11, the throughput of 2PC plateaus, starting with 12K clients. This result shows that simply increasing concurrency for a transactional system does not necessarily lead to higher throughput; instead, it may actually result in lower throughput due to an increased number of aborts. Beyond 12K clients, the throughput remains flat, and the transaction abort rate escalates to an astonishingly high level of 98%. As the contention footprint increases, concurrent transactions are more likely to be aborted due to prolonged conflict windows (at least 1 WAN RTT).

7.7 Scalability of vector clocks

As we discuss in Section 6.1, vector clocks can become a scalability bottleneck when Mako has many shards. To explore this effect and also the improvement of our proposed optimizations, we perform an experiment where we run Mako with hundreds of shards. One caveat is that we do not have thousands of machines available, so our ability to experiment with hundreds of shards (plus their replicas) is limited. We do the following: we limit each shard to use only one CPU and run the microbenchmark. The expectation here is that the throughput numbers will be lower than a standard deployment of Mako, but it should help us appreciate the overhead from the vector clock. Each transaction consists of four RMW operations and 5% of accesses span a different shard.

We test 3 strategies: the full-sized vector clock (VC), a VC that is compressed to a single timestamp, and a VC that is compressed to a VC with exactly 64 entries. The results are shown in Figure 12.

The full-sized VC approach can scale to 320 shards before its performance starts to degrade. This shows the full-sized VC is enough to support many database deployments since Mako is a very high-throughput database, even with a few shards. Of course, if the datasets are massive and the database requires many shards to fit all that data in memory this does mean that the full VC could become a scalability bottleneck. Both the timestamp approach and Fixed-64 VC achieve near linear scalability because the VC-related overhead is independent of the number of shards.



(a) Healthy shard S_1 **(b) Failed shard S_0**

Figure 13: Single-shard failure: TPC-C.

7.8 Single-shard failure recovery

In the case of a single-shard failure, Mako minimizes the impact on uninvolved shards §5.1), which is a key distinction between Mako and systems that perform group or epoch-based commits such as Primo [54] and COCO [64]. To show this difference, we implement a variant of Mako that we call Mako-epoch, which implements the failure recovery strategy of epoch-based commit protocols. Our experiment simulates a shard failure by shutting down shard leader S_0, triggering a learner takeover. Figure 13 reports the throughput of a healthy and failing shard during the failover.

As outlined in Section 5.1, Mako in Figure 13a exhibits 2 phases during failure recovery. Phase 1: the healthy shard remains unaware of S_0's failure and continues sending cross-shard transactions to it. These transactions trigger eRPC timeouts (usually very short, e.g., 5ms) and are queued. After a heartbeat timeout, the healthy shard is aware of S_0's failure. Phase 2: FVW has been computed, and the healthy shard replays transactions from the queue, causing the throughput to gradually climb back to the pre-failure level. Mako in Figure 13b shows the throughput changes in the failed shard. The throughput first drops to 0 for 10 seconds because of the heartbeat timeout, and recovers to a pre-failure level once the new leader takes over.

In Mako-epoch, the behavior for a failed shard is similar to Mako's. However, the behavior for a healthy shard is very different. As shown in Figure 13a, no transactions execute successfully in Mako-epoch during Phase 1 because healthy shards remain unaware of the failed shard(s), and all transactions that execute in the old epoch eventually need to roll back upon failure detection. This is because, in epoch-based protocols like Mako-epoch, an epoch is the commit unit.

7.9 Factor analysis

In Section 7.2 we had an initial ablation study. Here we expand on it to understand exactly how each component contributes to Mako. This test is done with 10 shards.

	Silo	+Multi Version	+Distr. Trans.	+Rep.	+Replay (Mako)
TPUT (M)	1.66	1.48	0.47	0.36	0.36

The starting point of Mako is Silo, which achieves 1.66M

TPS on a single machine without any sharding or replication. The versioned values technique for rolling back results introduces a 11.1% overhead because each data item must now store a list of all its versions, which takes up additional memory operations. In addition, cross-shard coordination for distributed transactions accounts for a significant loss of 68.1%. Mako then needs to use CPU resources to serialize transactions into batched logs and use Paxos streams for replication, which causes a further 22.5% throughput loss. Replay in contrast has no impact on throughput because Mako replays transactions on shard followers asynchronously.

8 Further discussion

Read-only transactions. Our current implementation does not let read-only transactions execute directly at the followers—which is a common optimization. But Mako is compatible with this optimization by employing the high-level approach proposed in Silo [95]. The idea is to keep a dedicated checkpointing thread that periodically snapshots the databas so that read-only transactions can read from this snapshot. To do this in Mako, we would maintain two special versions of each key: one reflecting the latest value and the other storing the most recent value up to the last all-agreed vector watermark for read-only transactions.

High contention workloads. High contention workloads lead to high abort rates in all systems, including Mako. That said, Mako's pipelined replication and smaller conflict window (due to decoupled replication) lead to fewer aborts compared to other systems where replication is in the critical path. While high contention workloads would increase the transaction abort rate, they do not increase stress on Mako, as fewer transaction logs are generated.

9 Related work

This section reviews works in the literature on transactional, geo-replicated, multi-core systems from the various angles.

Distributed systems within the datacenter. Many works improve the performance of distributed transactions within a datacenter [4, 9, 10, 17, 25, 46, 67, 74, 84, 90, 103, 107, 110, 112]. These systems use advanced hardware, such as HTM, RDMA, and DPDK, to deliver good performance, strong consistency, and fault tolerance. A key feature shared by these systems is that replication happens side-by-side with transaction execution and/or commit, making transaction backup part of the critical path. In contrast, Mako is specifically optimized for geo-replicated databases and can therefore withstand full datacenter failures (whereas these works cannot), while still achieving high performance through speculative execution.

Geo-replicated distributed systems . Recent state-of-the-art distributed systems [7, 31, 40, 43, 44, 55, 56, 62, 70, 83, 97, 111, 113–115] pursue fast geo-replication. For example, Ocean Vista [30], TAPIR [109], and Janus [69] only need one WAN RTT if no conflicts are present by combining concurrency control and replication. However, they integrate replication into transaction execution, significantly impacting performance due to high WAN latency.

Speculative replication. Speculative replication [47, 54, 64, 81, 85] is a common optimization technique used in geo-replicated transactional systems to enhance throughput and reduce latency. Besides the discussion in Section 5.1, many systems [3, 32, 58, 61, 77, 88, 108] resort to weaker consistency semantics (e.g., causal consistency) that permit an asynchronous replication strategy in geo-replicated systems. Epoch-based commit systems, such as COCO [64] and Primo [54] speculatively execute transactions within each epoch while asynchronously replicating writes only at epoch boundaries to enhance performance. Compared to these systems, Mako's major advantage is that it does not have to stop healthy shards during a failure recovery as we show in Section 7.8.

Deterministic algorithms. Deterministic databases [29, 37, 39, 80, 94] can execute transactions deterministically across multiple replicas with either asynchronous or synchronous replication. In systems like Calvin [94] and C5 [37], transactions undergo a sequencing phase before execution. This sequencing layer establishes the ordering of submitted transactions and replicates them asynchronously in batches. In contrast, Mako adopts a different approach that eliminates the need for a predetermined order during execution.

Vector clock and watermark. Vector clocks and watermarks are widely used techniques to track dependency and maintain consistency in distributed systems [2, 22, 52, 61, 63, 65, 71]. Despite using the same techniques, Mako generally has a different goal and therefore an overall different system design. For example, CURE [2] is a geo-replicated store that uses vector clocks in transaction execution and watermarks to control stable snapshots. It targets transactional causal consistency, while Mako implements serializability, so the goals and techniques are different.

10 Conclusion

This paper presents Mako, a highly-available, fast, and scalable transactional database system, specifically optimized for geo-replication. Mako decouples transaction execution and replication, makes execution speculative, and leverages multi-core machines. Our experimental evaluation shows that Mako outperforms state-of-the-art geo-replicated transactional systems by an order of magnitude in throughput.

Appendix

A Proof of Correctness

In this proof, we assume the correctness of exisiting well-known protocols (OCC, Paxos) and mainly aim to prove two properties: commit/rollback atomicity and rollback safety.

Informally, commit/rollback atomicity means if a transaction is committed or rolled back on one shard, all its WriteSet spanning different shards will be committed or rolled back unanimously. There are two cases to discuss. The normal case is that a transaction successfully finishes speculative transaction execution and certification, its WriteSet appears in all relevant shards, and all shards need to unanimously commit or roll back this WriteSet. The abnormal case is that a transaction does not finish speculative transaction execution or certification, e.g., a shard times out waiting for an install call.

The rollback safety means, if a transaction is rolled back, all transactions that depend on this transaction also have to be rolled back. It also implies that if a transaction is replayed or released to client, it cannot be rolled back any more. There are mainly two cases to consider: the transaction and its descendant are in the same epoch, and when they are in different epochs.

Definition 1 (dependency)**.** If transaction T_0 writes to a key and subsequently transaction T_1 reads from the same key, we refer to this as T_1 being read-dependent on T_0. Throughout this proof, the term "dependency" specifically refers to read-dependency.

Definition 2 (writes-*i*)**.** A distributed transaction may update data stored across many shard leaders. Throughout this proof, the term "writes-*i*" refers to the data in the WriteSet for the transaction on shard server-*i*.

Definition 3 (vector clock/vector watermark)**.** Throughout this proof, we consistently denote the vector clocks for transactions T_0 and T_1 as $(p_0, p_1, \ldots, p_{n-1})$ and $(q_0, q_1, \ldots, q_{n-1})$ respectively, and FVW is (w_0,w_1 ... w_{n-1}), where n is the number of shards.

Fact 1. Mako's distributed OCC protocol shares similarities with widely used OCC and 2PC protocols in system designs, and its correctness is straightforward. The core principle of Mako's distributed OCC protocol is that a transaction is considered to have reached a serializable point if it can satisfy two key conditions during the commit phase, consistent with other OCC protocols: (1) All write locks are successfully acquired, and (2) No read items have been modified by other concurrent transactions.

Fact 2. Vector clock of a transaction can reflect the serialization order on shard(s), ensured by our our distributed OCC.

Lemma 1. *If transaction T_1 depends on T_0, then their vector clocks satisfy: $vc_1 \geq vc_0$.*

Proof. If the transaction T_1 depends on T_0, in *GetClock* phase, the vector clock of T_0 must be included in T_1's ReadSet. This allows the Mako to determine T_1's vector clock by selecting the maximum of shard clocks among all vector clocks in its ReadSet, resulting in $p_i \leq q_i$ where $i \in [0, n-1]$. □

Lemma 2. *If T_1 transitively depends on T_0, then $vc_1 \geq vc_0$.*

Proof. The transitivity is obvious. Assume the chain of dependency is $T_1, T_2, \ldots T_k, T_0$. We have $vc_1 \geq vc_2 \geq \ldots \geq vc_k \geq vc_0$. □

Fact 3. For a Paxos stream on the shard leader-*i*, the shard clock-*i* of Paxos entries within this Paxos stream is monotonically increasing within the same epoch, until the end of the epoch.

Lemma 3. *For each shard, w_i in its local view of the vector watermark (w_0, w_1, ..., w_{n-1}) consistently increments, and represents the replication progress of shard leader-i within the same epoch.*

Proof. According to Fact 3, the shard clock-i within the same Paxos stream consistently increases on shard-*i*. Combining this with the fact that w_i is picking up the *minimum* among all shard clock-*i* from the vector clocks of replicated transactions across all Paxos streams on the shard-*i*, we can infer the following. (1) The replication progress (w_i) of shard-*i* is always advancing, and (2) If a transaction updates at least one key on shard-*i* and its shard clock-*i* smaller than w_i, the writes-*i* of this transaction on the shard-*i* has been successfully replicated. □

Lemma 4. *For an epoch e, computing its FVW is a re-entrant and deterministic process. The FVW is the epoch's maximum vector watermark, i.e., for any vector watermark vw in this epoch, $fvw \geq vw$.*

Proof. Given an epoch *e*, the FVW is computed only during the epoch advancement in the failure recovery to ensure its maximum. Once a shard leader receives an epoch advancement request from CM, it needs to address in-flight transactions (*they would be the last transaction for each worker thread within the old epoch*) before advancing to the new epoch:

Case 1 (the good case): All transactions from epoch *e* finished speculative certification or abort before timeout. Then the shard replicates INFs as the end of the epoch. The finalized watermark for this shard is INF.

Case 2 (the abnormal case): Some transactions cannot finish before timeout due to contacting the failed shards or network anomalies. Or all transactions finish but the shard does not successfully replicate INFs. In such cases, at least one Paxos stream of the shard cannot end with INF, either ending with a no-op or with a normal transaction log entry. In both cases, the Paxos stream in this epoch cannot grow any further; its last log entry has the largest clock on this stream (Fact 3). Without loss of generality, assume this clock is the lowest of all streams on this shard. The clock is the shard's watermark in FVW.

In both Case 1 and 2, FVW is computed by choosing for each shard the largest acceptable clock value (the minimum of all streams), which is a fixed value once an epoch ends. Computing FVW is hence a re-entrant and deterministic process, and any other vector watermark in this epoch must be lower than FVW.

□

Fact 4. All of the writes-i of transaction T have the same vector clock.

Lemma 5. *A writes-i of a transaction T is rolled back by shard-i if and only if T's vector clock is not lower than FVW.*

Proof. Given Lemma 4 states that the FVW is a deterministic value for each epoch, if T's vector clock is not lower than FVW, it will be rolled back. Otherwise, T would be replayed (or on the leader becomes visible) and not be rolled back. □

Lemma 6. *If a transaction T partially commits (timeout on some shards), T's vector clock is not lower than FVW.*

Proof. A transaction T partially commits due to timeout on some shard, and will pause the worker thread that processes T on that shard. Assume the Paxos stream this worker threads maps to has its last entry as T'. T' has a lower shard clock than T. In computing the FVW, FVW's w_i must be equal to or lower than than T''s shard clock. This means T cannot have a lower vector clock than FVW and thus T will be rolled back. □

Theorem 1. *(Atomicity) A speculatively certified transaction will either commit or rollback on all relevant shards.*

Proof. Based on Lemma 6, if a transaction partially commits, its vector clock will not be lower than FVW, and hence will be rolled back. Based on Fact 4 and Lemma 5, if a transaction is rolled back, it is rolled back on all relevant shards. □

Lemma 7. *A transaction in a lower epoch cannot depend on any transaction that is in a higher epoch.*

Proof. This is guaranteed by the protocol aborting a transaction if it reads a higher-epoch transaction. □

Lemma 8. *A transaction in a higher epoch cannot depend on any transaction that is or will be rolled back in a lower epoch.*

Proof. This is guaranteed by how our protocol processes the new-epoch transactions:

Case 1: Before FVW is computed, transactions in a new epoch delay accessing versions from the prior epoch e that may be subject to potential rollback.

Case 2: Afterwards, once (e, FVW) is established, transactions in the new epoch only read versions from epoch e defined by the (e, FVW). □

Theorem 2. *(Rollback safety) If a transaction T_0 is rolled back, any transaction T_1 that depends on T_0 will also be rolled back.*

Proof. First, based on Lemma 7, T_1 is either in the same epoch or in a higher epoch than T_0. Further based on Lemma 8, T_1 cannot be a higher epoch, so T_0 and T_1 must be in the same epoch.

Given Lemma 2, T_1 has a greater vector clock than T_0, i.e., $vc_1 \geq vc_0$. Based on Lemma 5, vc_0 is not lower than FVW. Since $vc_1 \geq vc_0$, vc_1 is not lower than FVW. Again based on Lemma 5, T_1 will be rolled back as well.

□

B Shard management in detail

This section provides a detailed explanation of our shard management approach. To enable operations such as shard deletion, addition, and key partition reassignment, we use a management configuration that encapsulates crucial details, such as whether keys remain on the same server (compared to the previous configuration), the total number of shards in the new setup, and the identifiers of those shards.

Two key observations shape our approach: (1) cross-epoch vector clock and vector watermark computations and comparisons are unnecessary in Mako, and (2) transactions in the old epoch are not dependent on those in the new epoch. Once Mako obtains the FVW for the old epoch, the entire database can be treated as a read-only snapshot, serving as the initial state with all vector clocks reset to zero (vector clocks from higher epochs have a higher priority). This still ensures that dependency relationships are preserved, as vector clocks only track dependencies, and vector watermarks track replication progress to prevent data loss.

Building on these observations, our solution treats shard management similarly to failure recovery. The Configuration Manager (CM) oversees the management process by broadcasting a *MIGRATE-START* message containing the new configuration to all shards, including those being deleted or newly added. Upon receiving this message, shard leaders transition to the new epoch and reject any RPCs from the old

epoch or from invalid shards (e.g., those deleted in the new configuration).

Shard leaders then begin executing most transactions speculatively, with two constraints: (1) keys must be below their current view of vector watermarks to avoid potential data loss, and (2) keys scheduled for migration cannot be accessed to ensure safety in the event of a shard failure during the shard management. Since there is no need for all vector clocks from the old epoch to compare with new epoch vector clocks, eliminating concerns about mismatches between vector clocks across epochs.

In the background, shards in the old configuration close the old epoch and exchange shard watermarks to compute a FVW. This process removes the first constraint, and the computed FVW is persisted in the CM for future retrieval, eliminating the need for independent recomputation.

Simultaneously, each shard migrates key-value pairs to other configured shards while retaining the original copies. Once a shard completes its migration task, it reports back to the CM. A background thread reclaims the original copies only *after* the migration tasks for all shards are complete. Shards marked for deletion are only responsible for closing Paxos streams in the old epoch.

When *all* migration tasks are completed, the CM issues a *MIGRATE-END* RPC, lifting the second constraint and enabling full transaction execution under the new configuration. In the event of a shard failure during the migration procedure, the CM initiates a failure recovery procedure, assigning a new epoch. After recovery, the CM can safely restart migration procedure from the beginning.

C Implementations

Multi-version and lazy memory de-allocation. As described in the paper, Mako stores multiple versions of each key to support rollbacks in shard failures. This is implemented as a linked list. Each version contains a pointer to the previous version on this key. The key index stores the pointer to the latest version. We choose this implementation for the multi-version to enable more efficient rollbacks. When rolling back due to shard failures, the operation often requires reclaiming memory for all versions that are incomparable to or above the *FVW* of the old epoch, which can be very expensive. Instead, Mako defers this operation to the future, usually the next time the key is accessed. In our experience, we find this is an engineering effort that can greatly reduce the rollback time. Note that, some unnecessary rollbacks remain unavoidable due to the lack of fine-grained dependency tracking between individual transactions, which would incur high overhead.

Event-driven helper threads. In Mako, the limitation of available CPUs makes it impractical to maintain a large number of busy-polling server threads simultaneously for receiving DPDK messages. As a solution, Mako adopts an event-driven strategy for managing *helper threads* responsible for processing RPC requests from other shard leaders, thereby saving CPU resources. This approach entails temporarily suspending threads and resuming them when required, which regrettably results in additional latency. Despite this trade-off, the event-driven method can efficiently allocate CPU resources and preserve the overall system performance. In our implementation, we use two polling server threads that continuously receive DPDK messages and delegate those messages to the corresponding threads for execution. Mako's RPC relies on eRPC [45] and a private RPC library.

D Pseudocode: transaction execution lifecycle with compression optimization

```
// Execute the transaction in a worker thread.
// Exclude failure recovery logic.

/**** Immutable variable definitions ****/
int nShards;  // Number of shards
int nThreads; // # of worker threads per shard

// Local counter using fetch and add
int localCounter;
// Local shard index
int locShardID;

/**** Mutable variable definitions ****/
int localW; // Local shard watermark
// Replication progress per worker thread
vector<int> replicateProgress(nThreads);

// Size of compressed vector clock (e.g., 10)
int compSize;
// Local view of the compressed vector watermark
vector<int> compVW(compSize);
// Key-value store (simplified as a map)
map<int, ValueType> masstree;

/**** Utils ****/
// Get compressed shard clock index from shard ID
// We assume a simple mapping case
int getCompSIdBySId(int shardId) {
  return shardId / (nShards / compSize);
}

/**** Execute a transaction T0 in Mako ****/
// The worker thread index
int threadID;
// The current epoch for T0
int currentEpoch;

// Execution phase
{
  // Read() optimistically, and buffer writes
  // ...
}

// Commit phase
{
  {
    // Phase1: lock keys in writeset
    // ...
  }

  // Get the vector clock for T0
  vector<int> compVC = getClock();

  {
    // Phase2: Validate keys in readset
    // ...
  }

  // Replicate transaction logs (batch for the
      optimization)
  // Inovke the callback func once a log is durable
  asyncPaxosRep(/*resultant values of transactions*/,
                /*compVC*/,
                /*threadID*/,
                /*locShardID*/,
                callbackAsyncPaxosRep);

  // Phase3: Install & Release locks
  Install(writeSet, currentEpoch, compVC);
}

// Read from all relevant shards according to keys
// T0 always reads latest version if no failures
tuple<int,vector<int>,ValueType>
  Read(key, currentEpoch) {
    _epoch, _compVC, _value = masstree[key][0];
    return {_epoch, _compVC, _value};
}

// Get compressed vector clock for the transaction
vector<int> getClock() {
  vector<int> _compVC(compSize);

  // Merge compressed vector clocks in ReadSet
  for (auto _cvc : readSet) {
    for (int i=0; i<compSize; i++) {
       _compVC[i] = MAX(_compVC[i], _cvc[i])
    }
  }

  // Broadcast a RPC to each remote shard once in
      WriteSet to increment remotes' local counter
  for (auto shardId: writeSet) {
    compSId = getCompSIdBySId(shardId);
    sclock = remoteIncrement(shardId);
    _compVC[compSId]= MAX(_compVC[compSId], sclock);
  }

  return _compVC;
}

void Install(writeSet, currentEpoch, compVC) {
  for (auto k, v: writeSet) {
    {// Execute on all relevant shards
      masstree[k].insert(0,(currentEpoch, compVC, v));
      compSId = getCompSIdBySId(locShardID);
      // Ensure subsequent transactions observe a
          larger value
      int delta = compVC[compSId] - localCounter;
      if (delta > 0)
         localCounter.fetch_add(delta);
    }
  }
}

void callbackAsyncPaxosRep(int threadID, vector<int>
    compVC, int locShardID, const string&
    resultantValue) {
  compSId = getCompSIdBySId(locShardID);
  replicateProgress[threadID] = compVC[compSId];
  localW = MIN(replicateProgress);
  compVW[compSId] = MIN(compVW[compSId], localW);

  {
    // Exchange shard watermarks periodically to
        update compVW
    // ...
  }

  recvQueues.push_back((resultantValue, compVC));

  // Replay on shard followers
  while (!recvQueues.empty()) {
    bool safeToReplay = true;
    for (int i=0; i<compSize; i++) {
      if (recvQueues.front().compVC[i] > compVW[i]) {
        safeToReplay = false;
        break;
      }
    }

    if (!safeToReplay) break;

    // It is safe to return back the client and replay
    replay(recvQueues.front());
    recvQueues.pop_front();
  }
}

Abstract

Vector search, the task of finding the k-nearest neighbors of a query vector against a database of high-dimensional vectors, underpins many machine learning applications, including retrieval-augmented generation, recommendation systems, and information retrieval. However, existing approximate nearest neighbor (ANN) methods perform poorly under dynamic and skewed workloads where data distributions evolve. We introduce Quake, an adaptive indexing system that maintains low latency and high recall in such environments. Quake employs a multi-level partitioning scheme that adjusts to updates and changing access patterns, guided by a cost model that predicts query latency based on partition sizes and access frequencies. Quake also dynamically sets query execution parameters to meet recall targets using a novel recall estimation model. Furthermore, Quake utilizes NUMA-aware intra-query parallelism for improved memory bandwidth utilization during search. To evaluate Quake, we prepare a Wikipedia vector search workload and develop a workload generator to create vector search workloads with configurable access patterns. Our evaluation shows that on dynamic workloads, Quake achieves query latency reductions of 1.5–38× and update latency reductions of 4.5–126× compared to state-of-the-art indexes such as SVS, DiskANN, HNSW, and SCANN.

1 Introduction

Vector search, the task of finding the k-nearest neighbors (KNN) of a query vector against a database of high-dimensional vectors, is fundamental to modern machine learning based search [9, 11, 12, 36] and recommendation systems [21, 22, 32, 33, 43]. In these applications, a vector represents an item in a metric space, and the distance between vectors reflects semantic similarity. However, performing exact KNN search becomes computationally infeasible on large datasets due to the high dimensionality and volume of data.

To address this challenge, practitioners use approximate nearest neighbor (ANN) indexes, which trade off a controlled amount of search accuracy (recall) for significant reductions in latency. Among these, two broad classes dominate in practice: graph-based and partitioned indexes, each with distinct performance characteristics under dynamic workloads.

Maintaining low latency, high recall vector search under **dynamic and skewed workloads** remains a significant challenge for existing indexes. Real-world applications often exhibit non-uniform query distributions and evolving data. For example, in an example Wikipedia search application, popular pages like *Lionel Messi* or *LeBron James* receive disproportionately more queries, resulting in *skewed read patterns*. Additionally, pages are frequently added, updated, or deleted, causing *skewed update patterns* that change over time [6]. These factors degrade the performance of existing indexes, leading to increased query latency and reduced recall.

Graph-based indexes, such as HNSW [24], DiskANN [38, 39], and SVS [5] construct a proximity graph where each node (vector) is connected to its approximate neighbors. Queries traverse the graph to find approximate nearest neighbors, typically achieving high recall with low latency. However, these indexes face challenges with dynamic workloads because updating the graph structure to accommodate frequent insertions and deletions is computationally intensive [45], due to the random access patterns involved in graph traversal and modification.

Partitioned indexes, such as SCANN [10, 40], SPANN [7, 45], and Faiss-IVF [8], partition the vectors using a clustering algorithm (e.g k-means). Queries are processed by scanning a subset of partitions, balancing recall and latency by adjusting the number of partitions scanned (denoted as *nprobe*). While attractive due to their simplicity, partitioned indexes face a significant search latency gap when compared with graph indexes. For example, on the MSTURING10M benchmark [2], we found Faiss-IVF takes 44ms per search query while Faiss-HNSW takes only 6.8ms. On the other hand, supporting updates in partitioned indexes is less expensive than for graph indexes, as the index structure needs minimal modification when adding or removing vectors. But, existing approaches struggle with dynamic and skewed workloads because they do not adapt to changing access patterns, leading to *imbalanced* partitions that degrade query latency.

Recent work has been proposed to resolve imbalances in dynamic workloads by splitting and reclustering imbalanced partitions [6, 45], however, we find these methods degrade recall as nprobe needs to change as the index structure changes.

In this work, we study the problem of minimizing query latency to meet a fixed recall target for dynamic vector search workloads, where both the queries and the base vectors can change over time. To address this problem, we develop **Quake**, a partitioned index for ANN search that minimizes query latency by adapting the index structure to the workload. Quake's two primary algorithmic contributions are:

First, Quake employs an **adaptive hierarchical partitioning** scheme that modifies the partitioning by minimizing the cost (derived from a proposed **cost model**) of a query. The cost model tracks partition sizes and access frequencies as the workload is processed and determines which partitions are most negatively contributing to overall query latency. Once identified, we split or merge these partitions based on expected cost reduction derived from our proposed cost model. We also demonstrate that our maintenance procedure is stable and converges to a local minimum of the cost model.

Second, we design an **adaptive partition scanning** scheme that adjusts the number of partitions scanned on-the-fly to meet recall targets for individual queries. We do this by maintaining a recall estimate during query processing based on A) the geometry of the partitioning and B) intermediate results of the query, and once the estimate exceeds the recall target, query processing terminates and the results are returned.

Furthermore, Quake utilizes NUMA-aware parallelism to maximize memory bandwidth usage on multi-core machines.

It is a significant challenge to evaluate indexing approaches due to the lack of availability of benchmarks for online vector search. To address this challenge and comprehensively evaluate our approach, we A) prepare a **Wikipedia vector search workload** derived from publicly available query and update patterns of Wikipedia pages and B) develop a **workload generator** for creating workloads with configurable query and update patterns. We will publicly release the Wikipedia workload and workload generator as evaluation tools for the community to use. Using these, we conduct a comprehensive evaluation of Quake in comparison to seven baseline approaches.

1. Quake achieves the lowest search time across all dynamic workloads compared to state-of-the-art graph indexes, with 1.5-13× lower search latency than HNSW, DiskANN, and SVS while having 18-126× lower update latency.
2. We also find that APS matches the nprobe of an oracle across recall targets on SIFT1M, with only a 17-29% increase in latency relative to the oracle.
3. APS performs on-par or better than existing early termination methods [7, 18, 48] and requires no offline tuning.
4. Quake's NUMA-aware query processing exhibits linear scalability and high memory bandwidth utilization on the MSTURING100M dataset. Quake achieves 20× and 4× lower query latency compared to single-threaded and non-NUMA aware configurations, respectively.

2 Motivation and Challenges

Efficient vector search is critical for large-scale systems used in recommendation, semantic search, and information retrieval. These applications demand the ability to process a high volume of nearest neighbor queries with low latency, even as the underlying data evolves. To meet these requirements, vector databases—such as Milvus [42], Pinecone [3], AnalyticDB-V [44], VBASE [47], and Qdrant [1]—utilize specialized vector indexes (e.g., Faiss-IVF, HNSW, Vamana) that support fast approximate nearest neighbor (ANN) queries. However, serving these dynamic workloads introduces significant challenges in maintaining query performance and accuracy as data and query patterns shift over time.

2.1 Vector Search Workload

A vector search workload is a continuous, evolving stream of **queries** and **updates**:

- **Queries:** Given a query vector q, the goal is to find the top-k nearest neighbors in a set $\mathbf{X}$. Exact linear search is too slow for large, high-dimensional datasets, so ANN indexes are used. These indexes approximate nearest neighbors with controlled recall to lower latency by orders of magnitude.
- **Updates:** The dataset evolves over time. Insertions add new vectors representing fresh content (e.g., new products, trending news articles), and deletions remove outdated entries. Typically, updates are applied in a batched fashion.

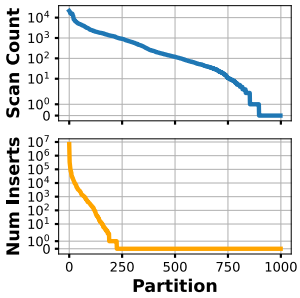
Recall@k is the standard metric for accuracy, defined as: $\frac{|\mathbf{G} \cap \mathbf{R}|}{k}$ where $\mathbf{R}$ is the vectors returned by the approximate search, and $\mathbf{G}$ is the ground truth set. Maintaining a consistent recall target (e.g., $> 90\%$) and low latency (e.g., milliseconds per query) as both data and query patterns shift is a key challenge. The complexity of these workloads stems from their inherently dynamic and skewed nature, which few existing indexing methods handle gracefully.

2.2 Why Real-World Workloads are Hard

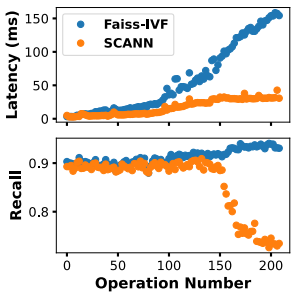
Skewed Read Patterns In practice, user queries concentrate on popular items. For example, queries against a Wikipedia-derived dataset tend to focus on a small subset of entities at any given time. As a result, certain partitions or graph regions of the index are accessed disproportionately often.

Skewed Write Patterns Insertions and deletions are also rarely uniform. New data often arrives in bursts—e.g., new Wikipedia pages added monthly, new products introduced ahead of a shopping season, or newly relevant embeddings generated by continuously updated language models.

Real-World Example: Wikipedia-12M In our evaluation, we prepared WIKIPEDIA-12M, a workload based on a subset of Wikipedia articles derived from publicly available monthly pageview statistics [4]. Over 103 months, the dataset grows from millions to tens of millions of vectors. Popular articles



(a) Read (top) and write skew.



(b) Query performance.

Figure 1: Skewed access patterns of Faiss-IVF index partitions in the WIKIPEDIA-12M workload and their effect on query performance for Faiss-IVF and SCANN

Table 1: Comparison of updatable vector indexes. **Tuning**: Requires manual parameter tuning in indexing/query processing. **Maintenance**: Modifies index with incremental updates. **Adaptive**: Uses query information to inform indexing.

Method	Tuning	Maint.	Adaptive
Quake **(Ours)**	✗	✓	✓
Faiss-IVF [8]	✓	✗	✗
DeDrift [6]	✓	✓	✗
SpFresh [45]	✓	✓	✗
SCANN [10,40]	✓	✓	✗
DiskANN [31,38]	✓	✓	✗
Faiss-HNSW [24]	✓	✗	✗
SVS [5]	✓	✓	✗

dominate query traffic, while embeddings of newly created pages accumulate in certain regions of the embedding space. This workload shows read skew and write skew, as evidenced by Figure 1a, reads and writes predominantly affect a small portion of the index.

2.3 Shortcomings of Existing Approaches

Existing indexes were often developed and evaluated under assumptions of static data distributions; conditions not met in real-world use cases. Table 1 compares a range of state-of-the-art vector indexes. Although widely adopted in vector databases, none fully solve the problem of maintaining low-latency, high-recall search under dynamic, skewed workloads without constant manual intervention or offline tuning.

Graph Indexes Graph-based index systems, such as HNSW [24], DiskANN [31, 38], and SVS [5] construct a proximity graph where each node represents a vector connected to its approximate neighbors. These indexes achieve high recall with low latency in static settings by efficiently traversing the graph to locate nearest neighbors using a process known as *greedy traversal*. However, maintaining the graph structure under frequent updates is computationally intensive, as each update may require rewiring multiple edges to preserve graph connectivity and proximity properties. Our evaluation (Table 1) shows that update latency can be multiple orders of magnitude higher than partitioned indexes.

Partitioned Indexes Partitioned indexes such as Faiss-IVF [8], SCANN [10, 40], and SpFresh [45] divide the vector space into disjoint partitions using a clustering algorithm such as k-means. Queries are processed by scanning a subset of partitions to retrieve approximate nearest neighbors. Partitioned indexes are more update-friendly than graph-based method since insertions and deletions leads to sequential access. For write skewed workloads some partitions become significantly larger, degrading query latency, this can be exacerbated by read skew if large partitions are also more frequently accessed ("hot partitions"). Query processing is *memory-bound*, as achieving high recall requires scanning many megabytes of data across multiple partitions, for example reaching a recall target of 90% on the MSTURING100M dataset requires each query to scan 1GB of vectors. Moreover, most partitioned indexes use a fixed number of partitions to probe (*nprobe*), which does not adapt to changing data distributions or query patterns, leading to either insufficient recall or excessive data scanning. The challenges yield subpar performance for partitioned indexes on real-world workloads. For example, Figure 1b shows the degradation of latency and recall over time when using Faiss-IVF and SCANN with a fixed nprobe on WIKIPEDIA-12M (workload details in Section 7).

Early Termination Early-termination methods have been proposed to reduce query latency or meet recall targets in partitioned indexes by dynamically adjusting the number of partitions scanned per query. **SPANN** [7] applies a simple rule: it prunes partitions once the centroid distance exceeds a user-tuned threshold relative to the closest centroid. **LAET** [18] is a learning-based approach that predicts the required *nprobe* per query using a trained model, but still requires dataset-specific training and calibration for each recall target. **Auncel** [48] uses a geometric model to estimate when recall for a given query, setting *nprobe* per query, but its conservative estimation leads to substantial overshooting of the recall target (See Figure 13 in [48]). All three methods require tuning or calibration and do not adapt to changes in the index structure or data distribution.

2.4 Technical Challenges for Partitioned Indexes

The following technical challenges are yet to be solved by existing partitioned indexes

1. **Adaptation to Queries** Query adaptivity is overlooked by existing partitioned index approaches and exhibits an opportunity for optimization, particularly for maintaining hot partitions induced by read skew.
2. **Online Adjustment of Nprobe** As the index structure and data change, partitioned indexes need to adjust the number of partitions scanned or recall will suffer. Existing early termination works are insufficient as they assume a static index and require retuning as the index and data change.

3. **Performance Gap with Graph Indexes** Standard partitioned indexes such as Faiss-IVF are memory bound, and exhibit an order of magnitude higher query latency in comparison than graph indexes.

Quake is our solution to these technical challenges. Quake A) adapts the index structure to queries by utilizing maintenance that minimizes a cost model for query latency, B) using a recall estimation model, Quake individually sets nprobe for queries to meet recall targets as the index structure changes, and C) uses NUMA-aware parallelism in order to saturate memory bandwidth during query processing, closing the performance gap with graph indexes. We next briefly discuss other related work before covering Quake in detail.

3 Solution Overview

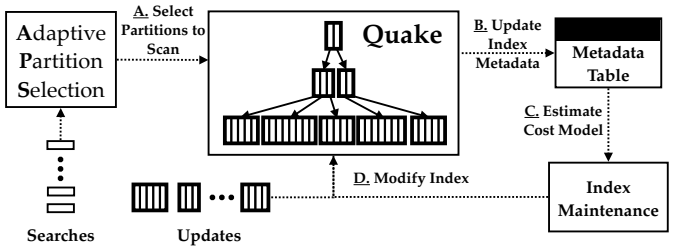


Figure 2: Quake Architecture Diagram. Search queries use Adaptive Partition Selection (APS) to determine which partitions to scan (**A**). Scanning partitions modifies access patterns of the index, tracked in the metadata table (**B**). A cost model is used to determine which maintenance actions to take (**C**) where the chosen maintenance actions modify the index (**D**). This process operates in a continuous online fashion as search and update queries (inserts/deletes) are issued to the index.

Index Structure Quake organizes the vectors in a multi-level index, where each level is a partitioned index similar to Faiss-IVF [8]. The lowest level in the index is constructed by organizing the vectors into disjoint partitions (using k-means clustering) where each partition has a representative centroid. These centroids can be further partitioned in a similar manner to create additional levels in the index. Search queries scan the index in a top-down fashion, finding the nearest centroids at each level to determine the partitions to scan in the next level. Partitions in the lowest level contain the actual vectors and subsets of these partitions are scanned to return the k-nearest neighbors. Utilizing a multi-level design enables us to employ fine-grained partitioning of vectors at large scale (shown to improve search quality [7]), while mitigating the high cost of scanning centroids.

Adaptive Incremental Maintenance Inserts and deletes modify the Quake data structure by appending vectors to and removing vectors from index partitions. Insertions traverse the index structure top-down to find the nearest partition in the lowest level to the inserted vector and append to that partition. Deletes use a map to find the partition containing the vector to be deleted and the vector is removed from the partition with immediate compaction. As demonstrated in Section 2, modifications can negatively affect index performance over time, requiring maintenance (Figure 1b). Quake uses the following maintenance actions in order to minimize query latency:

1. **Split Partition:** Uses k-means clustering to split a partition into two, removing the old partition and its centroid and adding two new partitions and centroids. To mitigate potential overlap due to the new partitions, we perform additional iterations of k-means clustering over the partitions neighboring the split partitions (by centroid distance).
2. **Merge Partition:** Removes a partition and its centroid, reassigning the vectors of the removed partition to the remaining partitions in the index.
3. **Add Level:** Adds a level of partitioning to the index by partitioning the current top-level using k-means clustering.
4. **Remove Level:** Removes current top-level and merges the partitions in the next level.

Quake uses a cost model that estimates query latency to determine if maintenance actions should be taken and which partitions to apply them to. The cost model is a function of partition access patterns and sizes to determine which partitions are contributing most to the overall query latency. We check for maintenance after each operation by evaluating the cost model, but the maintenance frequency is configurable. Partitions with the largest cost contribution are considered for split or deletion. Intuitively, frequently accessed and/or large partitions are split and infrequently accessed and/or small partitions are merged as they do not justify the overhead of maintaining a centroid. See Section 4 for details on the cost model and maintenance methodology.

Adaptive Partition Scanning In order to determine the number of partitions a search query should scan to reach a given recall target, we apply *Adaptive Partition Scanning* (APS) at each level of the index. APS solves a critical problem for partitioned indexes when applied to dynamic workloads: as the number and contents of partitions change, the number of partitions scanned needs to change, otherwise recall will degrade (Figure 1b). APS maintains a recall estimator based on the intermediate top-k results of the query and the geometry of neighboring partitions. As more partitions are scanned, the intermediate results and recall model are updated and when the recall estimate exceeds the target recall, the results are returned. To mitigate overheads introduced by the estimator, we use pre-computation of expensive geometric functions and only update the estimate when the intermediate results have changed significantly. APS supports both Euclidean and inner-product distance metrics. We cover APS in Section 5.

NUMA-Aware Query Processing Modern multi-core servers often use Non-Uniform Memory Access (NUMA) architectures, where memory close to a processor's local node is faster to access than remote memory. Quake is designed to capitalize on this heterogeneous memory. It distributes

index partitions across NUMA nodes. To minimize remote memory access, Quake employs affinity-based scheduling, and supports work stealing within a NUMA node to mitigate workload imbalances. By co-locating computation with the relevant data, Quake reduces remote memory accesses, saturates memory bandwidth, and thus lowers query latency. See Section 6 for details on Quake's NUMA-aware optimizations.

4 Adaptive Incremental Maintenance

We present our adaptive maintenance methodology, beginning with a cost model that estimates each partition's contribution to query latency and guides maintenance decisions. Next, we describe the available maintenance actions, analyzing their impact on the cost model. We then detail the multi-stage decision workflow that prioritizes beneficial actions and conclude with a concrete example.

4.1 Cost Model

The cost model estimates the query latency contributed by each partition, in the index. Estimating the per-partition latency contribution enables targeted maintenance to the partitions most affecting query performance.

Partition Properties Consider an index with L levels, numbered $l = 0, 1, \ldots, L-1$. Level l contains N_l partitions. The base level corresponds to $l = 0$ and contains partitions of the original dataset vectors. Higher levels contain partitions of centroid vectors that summarize the partitions in the level below. At the top level, $l = L-1$, there is a single partition containing top-level centroids.

Each partition j at level l has a size s_{lj} (the number of vectors it contains) and an access frequency $A_{l,j} \in [0.0, 1.0]$. $A_{l,j}$ denotes the fraction of queries, measured in a sliding window W, that scan the partition j at level l. The cost model is primarily driven by these sizes and access frequencies.

Partition Cost A partition (l, j) contributes latency proportional to its size and how frequently it is accessed. Let $\lambda(s)$ be the latency function for scanning s vectors. We measure $\lambda(s)$ through offline profiling. The cost of partition (l, j) is:

$$C_{lj} = A_{lj} \cdot \lambda(s_{lj}) \tag{1}$$

Total Cost The overall query latency (cost) estimate is the sum across all levels and partitions

$$C = \sum_{l=0}^{L-1} \sum_{j=0}^{N_l-1} A_{lj} \cdot \lambda(s_{lj}) \tag{2}$$

Interpretation The cost model reflects the relationship between partition size, access frequency, and query latency. The fundamental trade-off that needs to be balanced is the number and size of partitions. Larger partitions require more time to scan, increasing latency, but reducing the total number of partitions and the overhead of scanning centroids. Conversely, smaller, fine-grained partitions reduce the number of vectors needed to scan to reach a high recall but increase the overhead of scanning centroids. The model further captures that frequently accessed partitions dominate the total cost, motivating targeted maintenance actions to balance these trade-offs.

Guiding Maintenance Decisions Maintenance actions such as splitting or deleting aim to reduce the total cost C. Each action is evaluated based on its predicted change in cost:

$$\Delta C = C_{\text{after}} - C_{\text{before}} \tag{3}$$

where C_{before} and C_{after} are the total costs before and after the action, respectively. Actions are applied only if $\Delta C < -\tau$, where τ is a non-negative tunable threshold, ensuring monotonic improvement in query performance. By focusing on reducing C, the index is dynamically restructured to maintain efficient query performance under varying workloads.

4.2 Conducting Maintenance

Maintenance at each level of the index proceeds in three phases—*estimate*, *verify*, and *commit / reject*. We first list the available actions, then derive their cost deltas, describe the workflow, and finally walk through a concrete example.

4.2.1 Maintenance Actions

To minimize query latency, Quake employs a series of maintenance actions that dynamically adjust the index structure in response to evolving workloads. Here we define the maintenance actions and then analyze the impact of each maintenance action on the overall cost model.

Split Partition If a partition (l, j) is too large or frequently accessed, we consider splitting it into two partitions (l, j_L) and (l, j_R). We apply k-means clustering within that partition, forming two smaller partitions with their own centroids. The original partition is removed and its vectors are reassigned. A subsequent *partition refinement* step adjusts vector assignments to ensure minimal overlap and balanced partition sizes.

Partition Refinement After a split, refinement uses k-means (seeded by current centroids) on nearby partitions to mitigate overlap and ensure that each vector is assigned to its most representative partition. Nearby partitions are determined by finding the r_f nearest centroids to the split centroids, where r_f is a tunable parameter (typically between 10 and 100). This is a generalization of the reassignment procedure used in SpFresh/LIRE [45], using additional rounds of k-means prior to reassignment, and has been applied successfully by recent index maintenance works [23] and [25]. Refinement avoids performance degradation by mitigating overlap and ensuring vectors are assigned to their most representative partition.

Merge Partition If a partition is rarely accessed and below a minimum size threshold, we consider deleting it to remove the cost of maintaining its centroid. After deletion, the vectors are reassigned to their respective nearest existing partitions. This can reduce total cost by removing a low-benefit partition, although the reassignment may increase the size (and thus cost) of other partitions, and therefore careful consideration is needed before conducting a merge.

Adding and Removing Levels If the number of centroids in the top level grows beyond a threshold, we add a new top level by clustering those centroids. Conversely, if the top level becomes too sparse (below a configured lower threshold), we remove the top level and merge its centroids in the level below. Both actions help maintain hierarchy balance and control centroid-scanning overhead. We defer discussion of this to our technical report [27].

4.2.2 Cost Deltas

The maintenance loop treats every candidate action as a *proposed edit* to the index and scores it by the change it would induce in the total cost (Eq. (3)).

We tentatively accept an action whenever $\Delta C < -\tau$. Below we give the exact ΔC formulas for the primary maintenance actions: *split* and *merge*. Full derivations are in the technical report [27]; here we show only the final expressions.

Exact Split Delta Splitting a hot or oversized partition (l, j) into children (l, j_L) and (l, j_R) inserts one new centroid at the parent level, changing the overhead by $\Delta O^+ = \lambda(N_l + 1) - \lambda(N_l)$. The resulting cost difference is

$$\begin{aligned}\Delta\text{Split}_{l,j} = \underbrace{\Delta O^+}_{\text{new centroid}} - A_{l,j}\,\lambda(s_{l,j}) \\ + A_{l,j_L}\,\lambda(s_{l,j_L}) + A_{l,j_R}\,\lambda(s_{l,j_R})\end{aligned} \tag{4}$$

where the first term pays for the extra centroid, the second removes the old scan cost, and the last two add the costs of scanning the new, smaller partitions. Note that we do not explicitly model the effect of refinement, as refinement does not change the number of partitions. Its impact is captured automatically as statistics are collected from future queries, so we omit it from the Δ-formula and let later maintenance iterations adjust if necessary.

Exact Merge Delta Deleting a cold, tiny partition (l, j) removes a centroid $(\Delta O^- = \lambda(N_l - 1) - \lambda(N_l))$ and redistributes its vectors to a receiver set $R_{l,j}$. Let Δs_m and ΔA_m be the resulting size and frequency bumps for each receiver m. Then

$$\begin{aligned}\Delta\text{Merge}_{l,j} = \Delta O^- - A_{l,j}\,\lambda(s_{l,j}) \\ + \sum_{m \in R_{l,j}} \left[(A_m + \Delta A_m)\,\lambda(s_m + \Delta s_m) - A_m\,\lambda(s_m)\right]\end{aligned} \tag{5}$$

captures both the benefit of deleting the partition and the penalty of swelling its neighbors.

Estimating Deltas At decision time we do not yet know the post-action quantities $\{s_{l,j_L}, A_{l,j_L}, \dots\}$ or the true $\Delta s_m, \Delta A_m$. We therefore use a lightweight *estimate* based on two assumptions: 1) **Balanced Split:** $s_{l,j_L} \approx s_{l,j_R} \approx \frac{s_{l,j}}{2}$, and 2) **Proportional-Access Scaling**: each child inherits a fixed fraction α of the parent's frequency.

Under these assumptions the split estimate becomes

$$\begin{aligned}\Delta'\text{Split}_{l,j} = \Delta O^+ - A_{l,j}\,\lambda(s_{l,j}) \\ + 2\alpha A_{l,j}\,\lambda\left(\tfrac{s_{l,j}}{2}\right).\end{aligned} \tag{6}$$

and the analogous merge estimate, derived with a uniform redistribution assumption, is located in the technical report [27]. Immediately after a tentative action we measure the *actual* sizes (and, for merges, the exact receiving partitions) and re-evaluate Eqs. (4) or (5). If the recomputed gain is still below $-\tau$ the action is committed; otherwise it is rolled back (§4.2.3). This "estimate-then-verify" strategy is crucial for ensuring monotonic cost improvement.

4.2.3 Decision Workflow

Maintenance is a *bottom-up* pass over the hierarchy. Each level executes the five stages below starting from the base level. This workflow is triggered by the user. An avenue for future work is to develop scheduling policies to call this workflow and limit its scope. In our evaluation, we trigger maintenance after a set amount of queries have been run.

Stage 0: Track Statistics At the end of each query batch we update, for every partition (l, j): (i) size $s_{l,j}$, (ii) access count over the sliding window of queries W, giving $A_{l,j} = \text{hits}(l, j)/|W|$. These values are inputs of the cost model.

Stage 1: Estimate For the current level l compute the estimate Δ' (§4.2.2) of splitting and deleting for every partition. Tentatively apply any action with $\Delta' < -\tau$.

Stage 2: Verify Immediately after performing a tentative action, we measure the actual resulting partition sizes (and the exact receiver partitions for merges). We recompute the cost delta using these known values but retain the original frequency assumptions from Stage 1.

Stage 3: Commit / Reject

$$\Delta < -\tau \;\rightarrow\; \textit{commit}, \quad \Delta \geq -\tau \;\rightarrow\; \textit{reject}.$$

Rejection discards the action and keeps the previous state of the partition(s), in order to prevent cost increases.

Stage 4: Propagate Upward. Repeat Stages 1-3 on the next level $l+1$,

Safety: Because every level enforces the same $\Delta < -\tau$ guard, total cost across *all* levels monotonically decreases and the hierarchy converges to a stable state under a fixed workload distribution (proof in technical report [27]).

4.2.4 Example Maintenance Workflow

Below we walk through the *estimate → verify → commit / reject* loop for two example partitions and show how an imbalanced split is automatically rejected to prevent accidental cost increases.

Set-up: Consider partitions P_1 and P_2 with identical size and access frequency, where both contain $s = 500$ vectors and appear in $A = 0.10$ of queries. From profiling we observe non-linear [1] scan latencies for the following partition

[1] Scan latency is non-linear w.r.t. size due to top-k sorting overhead.

sizes: $\lambda(50) = 250\mu s$, $\lambda(250) = 550\mu s$, $\lambda(450) = 1050\mu s$, $\lambda(500) = 1200\mu s$ Adding a centroid costs $\Delta O^+ = 60\mu s$. We use a decision threshold of $\tau = 4\mu s$ and $\alpha = .5$

1. **Estimate** For P_1 and P_2 the estimate assumes a balanced 250/250 split and $\alpha = 0.5$ traffic per child:

$$C_{\text{before}} = 0.10 \times 1200 = 120\mu s,$$
$$C_{\text{est}} = 0.05 \times (550 + 550) = 55\mu s,$$
$$\Delta' = 60 - 120 + 55 = -5\mu s.$$

   Because $\Delta' < -\tau$, *both P_1 and P_2 are tentatively split*.
2. **Verify** After splitting we see that P_1 has a 250/250 split, but P_2 comes out 450/50:

$$C_{\text{verify}}(P_2) = 0.05 \times (1050 + 250) = 65\mu s,$$
$$\Delta(P_2) = 60 - 120 + 65 = +5\mu s.$$

3. **Decide**
   - P_1: *commit* because $\Delta = -5\mu s < -\tau = -4\mu s$
   - P_2: *reject* because $\Delta = +5\mu s > -\tau = -4\mu s$

   The verify step therefore blocks an imbalanced split that would otherwise *increase* query latency.

5 Adaptive Partition Scanning (APS)

Adaptive Partition Scanning (APS) dynamically determines the number of partitions to scan per query to achieve a specified recall target τ_R with minimal latency. APS adapts to evolving workloads and changing index structures, making it particularly effective in dynamic data settings. We first introduce the geometric model underlying APS, followed by a detailed description of the scanning algorithm, and conclude with key performance optimizations. We apply APS at each level of the index independently. For clarity we focus on the Euclidean distance, we discuss inner product metrics in the technical report [27].

Geometric Model To estimate the probability that each partition contains one of the query's k nearest neighbors, APS uses a geometric interpretation. Given query $\mathbf{q}$ and ρ the distance to the k-th nearest neighbor, consider the hypersphere $\mathcal{B}(\mathbf{q}, \rho)$. Under a uniform-density assumption, the fraction of this sphere's volume intersecting partition $\mathcal{P}_i$ estimates the probability that $\mathcal{P}_i$ holds a nearest neighbor:

$$p_i = \frac{\text{Vol}\big(\mathcal{B}(\mathbf{q}, \rho) \cap \mathcal{P}_i\big)}{\text{Vol}\big(\mathcal{B}(\mathbf{q}, \rho)\big)}, \tag{7}$$

Because we do not know the true distance of the k-th nearest neighbor apriori, we set ρ to the current k-th nearest neighbor observed and update it online as partitions are scanned.

Intersection Volume Approximation Exact computation of intersection volumes between a sphere and high-dimensional Voronoi partition boundaries is infeasible, as partitions are intersections of multiple half-spaces. Instead, we approximate each partition as a single half-space, defined by the perpendicular bisector between the query's nearest centroid $\mathbf{c}_0$ and each neighboring centroid $\mathbf{c}_i$. This simplification results in a hyperspherical cap whose volume v_i has a closed-form expression via the regularized incomplete beta function [16, 19] (see technical report [27]).

Nearest Partition Volume Approximation The half-space approximation is invalid for the nearest partition $\mathcal{P}_0$, since the query lies within it. Instead, we first compute hyperspherical cap volumes v_j for the remaining $M-1$ candidate partitions and normalize these so that $\sum_{j=1}^{M-1} v_j = 1$. The probability p_0 that no neighbor is located outside $\mathcal{P}_0$ is:

$$p_0 = \prod_{j=1}^{M-1} (1 - v_j), \tag{8}$$

with the remaining probability distributed proportionally among other partitions according to their volumes v_i:

$$p_i = (1 - p_0)\, v_i. \tag{9}$$

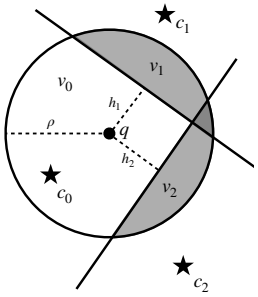

Figure 3: The query hypersphere (centered at $\mathbf{q}$ with radius ρ) intersecting partition boundaries. The intersection volumes v_1 and v_2 correspond to the probability of finding a nearest neighbor in partitions $\mathcal{P}_1$ and $\mathcal{P}_2$, respectively.

5.1 APS algorithm

Algorithm 1 details the APS procedure. Given query $\mathbf{q}$, recall target τ_R, and the initial candidate fraction f_M:

1. Scan partition $\mathcal{P}_0$, initializing the query radius ρ.
2. Compute probabilities p_i for each remaining candidate partitions based on radius ρ.
3. Iteratively scan partitions in descending probability order until cumulative recall exceeds target τ_R, updating radius ρ and recomputing probabilities whenever ρ shrinks significantly (beyond threshold τ_ρ).

This process is conducted at each level of the index. To avoid propagating errors from searching higher levels, we fix the recall target to 99% for the higher levels (Table 6).

Performance Optimizations APS incorporates two optimizations to minimize computational overhead. First, it precomputes values of the regularized incomplete beta function at 1024 evenly spaced points in $[0, 1]$ and linearly interpolates

Algorithm 1 Adaptive Partition Scanning (APS)

Input: query $\mathbf{q}$, centroids $\mathcal{C}$, recall target τ_R, initial candidate fraction f_M, recompute threshold τ_ρ, k
Output: k nearest neighbors of $\mathbf{q}$

$R \leftarrow$ empty max-heap of size k
$\mathcal{S} \leftarrow f_M * N_l$ nearest centroids to $\mathbf{q}$
scan $\mathcal{P}_0$; update R; set ρ
for each $(\mathbf{c}_i, \mathcal{P}_i) \in \mathcal{S} \setminus \{\mathbf{c}_0\}$ **do**
    compute p_i
$r \leftarrow p_0$; $m \leftarrow 1$
while $r < \tau_R$ **and** unscanned candidates remain **do**
    choose i with maximal p_i; scan $\mathcal{P}_i$; update $\mathcal{H}$
    $m \leftarrow m + 1$
    $\rho' \leftarrow$ distance to k-th in $\mathcal{H}$
    if $|\rho' - \rho| > \tau_\rho \rho$ **then**
        $\rho \leftarrow \rho'$; recompute p_j
    $r \leftarrow r = \sum_{i=0}^{m-1} p_i$
return R

Table 2: Mean single-threaded query latency and recall for APS variants on SIFT1M dataset at recall target 90%. **APS-RP:** recomputes probabilities after each partition scan without precomputation. **APS-R:** recomputes after each partition scan with precomputation. **APS:** recomputes probabilities only if query radius changes by more than $\tau_\rho = 1\%$, using precomputed beta function values.

Configuration	Recall	Search Latency
APS	91.2%	.48 ms
APS-R	91.2%	.59 ms
APS-RP	91.2%	.68 ms

during queries. Second, partition probabilities are recomputed only when the query radius ρ shrinks by more than a relative threshold τ_ρ. Table 2 shows these optimizations reduce query latency by 29% on SIFT1M without sacrificing recall.

6 Quake Implementation

Here we discuss NUMA-aware query processing and implementation details of Quake.

NUMA Data Placement and Query Processing Query processing in partitioned vector indexes is memory-bound, and therefore increasing the effective memory bandwidth available to the system will reduce query latency. NUMA-aware intra-query parallelism has been applied in the context of relational database systems to great success [17, 35], but has yet to be applied to vector databases.

In order to maximize memory bandwidth utilization, Quake distributes index partitions across NUMA nodes and ensures that cores only scan partitions resident in their respective node. Quake assigns index partitions to specific NUMA nodes using round-robin assignment. This assignment procedure allows for simple load balancing as partitions are added to the index by the maintenance procedure.

To maximize the benefits of data placement, Quake employs partition affinity and NUMA-aware work scheduling. Partitions are bound to specific CPU cores. This binding ensures that partitions are always scanned by the same core to maximize cache utilization. Queries are scheduled to worker threads based on the location of the data partitions they need to access. When a query requires scanning multiple partitions, the work is divided among threads on the relevant NUMA nodes where the partitions reside. By aligning thread execution with data placement, Quake minimizes remote memory accesses to maximize memory bandwidth utilization.

NUMA-Aware Query Execution with APS Quake integrates NUMA-aware processing with Adaptive Partition Selection (APS) to dynamically select which partitions to scan based on query requirements and desired recall. The query processing involves both worker threads scanning local partitions and a main thread coordinating the process.

Algorithm 2 NUMA-Aware Query Processing with Adaptive Partition Selection

Input: Query vector q, Index partitions P_i with locations $Node_j$, Recall threshold τ_R, Period to check recall T_{wait}
Output: Top-k nearest neighbors to q satisfying recall threshold τ

Initialize: $R \leftarrow \emptyset$ (global result set), $S \leftarrow$ sorted list of partitions based on distance to q (obtained from searching parent)
Distribute q to local memory of NUMA nodes
for all NUMA nodes $Node_j$ **in parallel do**
    $W_j \leftarrow$ worker threads on $Node_j$
    $P_j \leftarrow$ partitions on $Node_j$ from S
    Enqueue partitions P_j to local job queue
while not **all** partitions in S have been processed **do**
    Main Thread:
    Wait for a predefined interval T_{wait}
    Merge partial results from worker threads into R
    Estimate current recall r using Eqn. 7
    if $r \geq \tau_R$ **then**
        Break and terminate worker threads
Return top-k results from R
function WORKERTHREAD(q, Local Job Queue)
    while Job Queue not empty **do**
        $P_i \leftarrow$ **Dequeue** next partition from Job Queue
        Compute distances between q and vectors in P_i
        Update local partial results R_j
        Signal Main Thread about new partial results

Algorithm Explanation: In Algorithm 2, the main steps are:

1. **Initialization**: The query vector q is distributed to the local memory of NUMA nodes with relevant partitions. Partitions are sorted using their centroid distance to q.
2. **Worker Threads Execution**: Each NUMA node has worker threads that process partitions assigned to that node. They compute distances between q and vectors in their local partitions, updating their local partial results.
3. **Main Thread Coordination**: The main thread periodically merges partial results from all worker threads. It uses

the APS recall model to estimate the current recall based on the results accumulated so far.

4. **Adaptive Termination**: If the estimated recall meets or exceeds the threshold τ_R, the main thread returns the top-k results and signals the worker threads to terminate the processing of remaining partitions.

This adaptive approach ensures that the system processes only as much data as needed to meet the recall requirements, improving efficiency and reducing query latency.

Implementation Details We implemented Quake in 7,500 lines of C++ and provide a Python API for ease-of-use. We used primitives in Faiss [8], PyTorch [20], and SimSIMD [30] to enable high-performance management of inverted lists, efficient batch tensor operations, and AVX512 intrinsics for fast distance comparisons. We also used a high performance concurrent queue [29] to prevent contention during coordination of query processing. In addition, we developed a workload generator and evaluation framework in Python to create and evaluate vector search workloads. Quake is open-sourced at https://github.com/marius-team/quake.

7 Experiments

We evaluate Quake using a number of benchmarks and summarize our main findings:

1. Quake achieves the lowest search time across all dynamic workloads compared to state-of-the-art graph indexes, with 1.5-13× lower search latency than HNSW, DiskANN, and SVS while having 18-126× lower update latency.
2. We also find that APS matches the nprobe of an oracle across recall targets on SIFT1M, with only a 17-29% increase in latency relative to the oracle.
3. APS performs on-par or better than existing early termination methods [7, 18, 48] and requires no offline tuning.
4. Quake's NUMA-aware query processing exhibits linear scalability and high memory bandwidth utilization on the MSTURING100M dataset. Quake achieves 20× and 4× lower query latency compared to single-threaded and non-NUMA aware configurations, respectively.

7.1 Workloads

We performed our evaluation on a diverse set of real-world and synthetic workloads.

Wikipedia-12M This dataset and workload trace are derived from monthly Wikipedia page additions and page-view [4] frequencies between April 2013 and December 2021. We consider only pages about people or those linking to people. The dataset begins with 1.6 million pages and grows to 12 million after 103 updates, and therefore the average update size is ≈ 100,000 vectors. Embeddings are generated by training DistMult [46] graph embeddings (via Marius [28, 41]) on the Wikipedia link structure, and use the inner product metric.

The workload simulates monthly inserts of new pages, followed by 100,000 search queries sampling page embeddings with probability proportional to their page views corresponding to roughly a 50/50 read/write ratio. This setting imitates evolving interest and periodic growth of the dataset.

OpenImages-13M Using the methodology described by SVS [5], we generate a workload of 13M images from the Open Images dataset [15]. Embeddings are produced using Clip [37] in an inner product metric space. The workload maintains a sliding window of 2 million resident vectors and inserts and deletes vectors based on class labels until all 13 million vectors have been indexed at least once. Each insert and delete affects roughly 110K vectors. After each insert and delete operation, we run 1,000 queries randomly sampled from the entire vector set. This scenario stresses both insertion and deletion performance as well as sustained query latency.

Workload Generator To test performance under varying workload properties, we employ a configurable workload generator applicable to any vector dataset. The key parameters are: number of vectors per operation, operation count, operation mix (read/write ratio), and spatial skew. For skewed workloads, vectors are clustered and sampled from to produce queries and updates, reflecting hot spots in the vector space.

We construct two example workloads from a 10M vector subset of the MSTuring [2] dataset using L2 distance:

- **MSTuring-RO**: A pure search workload. We uniformly sample from 100,000 provided query vectors and execute 100 search operations, each querying 10,000 vectors. This setup tests search efficiency in a static setting.
- **MSTuring-IH**: A dynamic workload interleaving inserts and searches. Beginning with 1 million vectors, the dataset grows to 10 million as we process 1,000 operations with a 90% insert and 10% search ratio. This tests the ability to handle large-scale growth while maintaining query quality.

We use the datasets SIFT1M [13], SIFT10M, and MSTURING100M [2] to conduct microbenchmarks.

7.2 Experimental Setup

Large-scale experiments are run on a 4-socket server with Intel Xeon Gold 6148 CPUs (80 cores, 160 threads), 500 GB RAM across 4 NUMA nodes, and 300 GB/s total memory bandwidth. Some microbenchmarks (Tables 2, 5, 7, and 6) are run on a 2023 MacBook Pro with a M2 Max chip.

Search queries are processed one at a time and we report the total time to process all queries to reach a target of 90% recall for $k = 100$. Unless otherwise stated, all search numbers use a single worker thread. Quake additionally reports a multi-thread configuration **Quake-MT** (16 threads) where partition scans are parallelized for individual queries, while **Quake-ST** uses a single thread for search. For updates we report the total update and maintenance time, where both Quake and the baselines process updates in batches using 16 threads. This setup simulates an online environment where queries arrive individually, and updates are applied in batches. We report maintenance time separately from update latency, as maintenance can be conducted in the background in online

systems [45].

Baselines: We compare Quake against several state-of-the-art methods, including both partitioned and graph-based indexes:

- **Faiss-IVF** [8]: A popular inverted file (IVF) index in Faiss. It handles updates but does no maintenance.
- **DeDrift** [6]: An incremental maintenance strategy designed to reduce clustering drift by periodically reclustering large partitions together with small ones. We implement DeDrift's logic within Quake.
- **LIRE** [45]: Maintenance procedure used by SpFresh. LIRE incrementally splits large clusters and deletes small clusters after updates, followed by local reassignments. We implement LIRE's approach within Quake.
- **ScaNN** [10]: A state-of-the-art highly optimized partitioned index system. It uses an unpublished incremental maintenance procedure similar to LIRE.
- **Faiss-HNSW** [24]: A graph-based approach (HNSW) implemented in Faiss. It supports incremental inserts but not deletes. Thus, for workloads with deletions, we omit Faiss-HNSW from those comparisons.
- **DiskANN** [38]: System built around the Vamana [39] index with support for dynamic updates.
- **SVS** [5]: A recently released optimized implementation of the Vamana index with support for dynamic updates.

We configure the main parameters of Quake and the baselines as follows. We disable vector quantization/compression for all baselines, as not all baselines support it. For partitioned indexes we use $sqrt(|X_0|)$ partitions where $|X_0|$ is the initial number of vectors in the workload. For the graph indexes, we use a graph degree of 64. For LIRE and Quake, we set the partition refinement radius $r = 50$. For Quake we use a single level of partition, set $\tau = 250ns$, use one iteration of k-means for refinement and set f_M between 1%-10%. All systems use 16 threads for updates and maintenance (if applicable). SCANN, DiskANN, and SVS perform maintenance eagerly during an update, therefore we do not measure maintenance time separately from update time. We consider maintenance after each operation for all methods. Throughout all experiments, indexes search parameters are tuned to achieve an average of 90% recall for $k = 100$ across the workloads.

7.3 End-to-End Evaluation

Comparison with Baselines Table 3 shows that Quake consistently achieves lower search, update and total time on all workloads. On the WIKIPEDIA-12M workload, where the dataset grows over time and partitions can become unbalanced, the multi-threaded Quake-MT takes 1.53 hours to process searches, while single-threaded Quake-ST takes 9.48 hours. In contrast, Faiss-IVF climbs to 165 hours due to the lack of maintenance, DeDrift reaches 132 hours despite its rebalancing efforts, LIRE is unable to meet the recall target and takes 44 hours and SCANN performs similarly with poor update latency due to over-eager maintenance applied during updates. Even the best-performing graph-based method, DiskANN, takes 12 hours. Thus, Quake-MT is 8× faster to search than the strongest baseline on this workload derived from real-world access patterns.

On the OPENIMAGES-13M workload, which includes both insertions and deletions, Quake's multi-threaded and single-threaded search times are .03 and .14 hours respectively. The best competing approach, DiskANN, records .22 hours, making Quake-MT 7.3× and Quake-ST 1.6× faster. Faiss-HNSW does not support deletions so it is omitted. Both SVS's and DiskANN's delete consolidation is expensive, leading to orders of magnitude higher update latency than partitioned indexes, illustrating that graph-based indexes struggle with dynamic operations. Quake's continuous maintenance keep partitions balanced, achieving low latency and stable recall.

For the static, read-only, MSTURING10M-RO workload, Quake's maintenance improves the index structure even without data changes, adapting partitions to the query pattern. For Quake-MT, this yields a search time of .63 hours and Quake-ST takes 2.43 hours to conduct the search. However, the MSTURING10M dataset is especially challenging for partitioned indexes, as they need to scan roughly 10% of all partitions in order to meet the recall target. In contrast, the well-optimized SVS library exhibits a superior search time of .33 hours, demonstrating that in static settings, well-optimized graph indexes are strong competition.

On MSTURING10M-IH, where the dataset grows from one to ten million vectors, Quake-MT achieves a total search time of .54 hours. DiskANN, the second-best performer, has a search time of .81 hours, making Quake-MT 1.5× faster due to intra-query parallelism. However, single-threaded Quake is 2.6× slower than DiskANN, further illustrating the search efficiency of graph indexes. The other baselines fail to maintain the recall target or suffer from high latency due to their static parameters and inability to prevent partition skew.

Overall, these results demonstrate that Quake's combination of adaptive partition scanning, incremental maintenance, and NUMA-aware parallelism consistently delivers low-latency queries at the desired recall. Systems without maintenance (Faiss-IVF) suffer from skew-induced latency increases, those tied to static search parameters (LIRE) struggle to maintain recall without incurring higher query times, and graph-based methods (Faiss-HNSW, DiskANN) face substantial overheads when handling updates and deletions. By integrating these components, Quake matches the low update cost of partitioned indexes while outperforming graph indexes in search latency in dynamic workloads. Our design is an advancement to the state-of-the-art, providing stable, efficient performance across diverse, and evolving workloads.

Comparison with Partitioned Index Maintenance Methods Here we perform a detailed comparison with LIRE and DeDrift, measuring the latency, recall, and number of partitions over time on the WIKIPEDIA-12M workload. For a fair comparison, we use a single-thread to highlight the advantages of APS and maintenance in Quake. The results are

Table 3: Total workload time breakdown **in hours**. **S**: search, **U**: update, **M**: maintenance, **T**: overall total. Recall target = 90% and k=100. Search queries are processed one-at-time, updates are processed in batches, maintenance is conducted after each batch of search or update operations. *Denotes the method is unable to meet the recall target with static query parameters. $^{+}$Denotes the method did not finish in a 24 hour time budget, for these we estimate the runtime based on a 10% subsample of search queries.

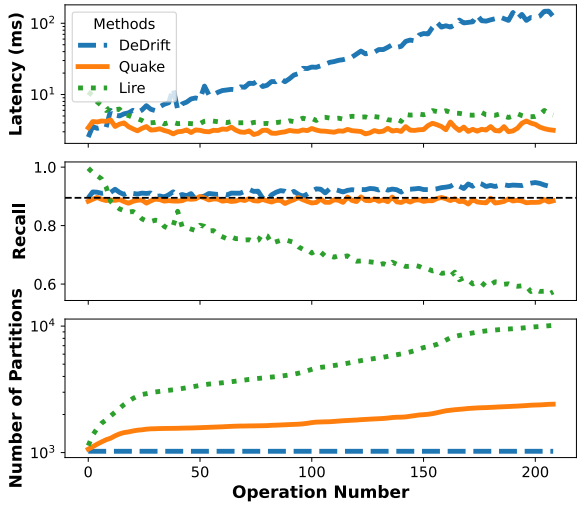

Figure 4: Comparison of single-threaded search latency, recall and number of partitions for Quake vs. maintenance approaches LIRE and DeDrift on WIKIPEDIA-12M. Quake maintains stable latency and recall throughout the workload.

shown in Figure 4. First looking at recall, we see that Quake maintains a stable recall of near 90%, while LIRE's recall degrades over time as it uses a static nprobe. DeDrift's recall stays relatively constant, as it does not adjust the number of partitions and therefore does not need to adjust nprobe. However, when turning our attention to latency, we see that Quake has near-constant stable latency, even as the dataset grows, while DeDrift's latency increases significantly with time. In terms of the number of partitions, we see DeDrift stays constant while Quake and Lire increase by 2.5× and 10× respectively. LIRE uses significantly more partitions because it uses size thresholding to determine when to split, regardless of whether a given partition is hot or not. Quake on the other hand only splits partitions if their contribution to the cost model is high, allowing for more efficient maintenance.

These results show that Quake's approach to maintenance is superior to existing methods for partitioned index maintenance in minimizing query latency and recall stability.

Table 4: Ablation Study on WIKIPEDIA-12M showing mean search latency and the standard deviation of recall.

Configuration	Search Latency	Recall Std.
Quake-MT	0.53 ms	.008

Wikipedia-12M Ablation To quantify the contributions of Quake components, we disabled key features and measured the impact on WIKIPEDIA-12M workload in Table 4. We see that disabling APS has little impact on the query latency, as Quake can achieve a low latency even in the static nprobe setting. However, APS provides significantly more recall stability, as evidenced by the increase in standard deviation when APS is disabled. Disabling NUMA-aware multi-threading, however, shows a 6× increase in query latency, demonstrating the benefit of parallelization of partition scans. Finally, we disable maintenance and see a significant increase in latency, similar to the latency of Faiss-IVF; here partitions become extremely imbalanced due to the skew in the workload (see Figure 1a) causing queries to scan more vectors and therefore increasing latency. This further demonstrates the necessity for maintenance for dynamic workloads. In conclusion, each piece of Quake contributes to its performance in terms of both recall stability and minimal query latency.

7.4 Multi-Query Processing

Here we compare the search performance of Quake and baseline methods in a static batched query setting. Figure 5 shows the QPS at a recall of 90%, varying the number of queries in a batch on the WIKIPEDIA-12M workload. The dataset includes all 12M vectors, with 10,000 queries sampled accord-

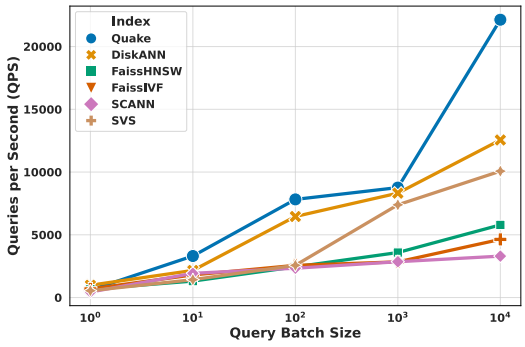

Figure 5: Multi-query evaluation on WIKIPEDIA-12M with 10,000 search queries. QPS @ recall=90% is measured for all baselines while varying the batch size. All methods use 16 threads to process queries.

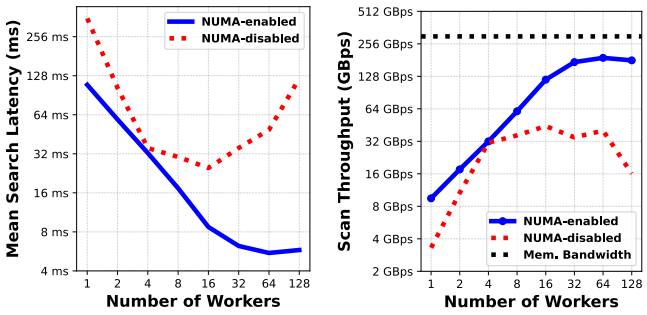
ing to Wikipedia page views from December 2021. For Quake, FaissIVF, and SCANN, we use 3,500 partitions; for FaissHNSW, SVS, and DiskANN, we set the graph degree to 64. All experiments use 16 threads for query processing. Quake employs the multi-query execution policy in [26] and [34], grouping queries by the partitions they access and scanning each partition exactly once per batch in parallel.

Quake consistently outperforms all baselines across every batch size, with an increasing advantage as batch sizes grow. At the largest batch size (10,000 queries), Quake achieves a 6.7× speedup over FaissIVF and SCANN. This performance gain stems from Quake's efficient multi-query execution strategy, where it scans each partition once per batch, in contrast to FaissIVF and SCANN, which scan partitions individually per query. Compared to DiskANN, the strongest graph-based competitor, Quake still maintains a substantial 1.8× speedup. These results demonstrate that Quake delivers high performance not only in single-query scenarios but also in large multi-query workloads.

7.5 Scalability

We tested Quake's parallel scalability by varying the number of threads. In Figure 6 we measure the mean search latency and scan throughput (bytes scanned / query latency) on MSTURING100M to reach a recall of 90%. Note that this dataset has 100 million vectors and is 10× larger than the datasets we compared against previously. We compare our NUMA-aware parallelism with one in which NUMA is disabled. For both configurations, we see near linear scalability up to around 8 workers, where the non-NUMA latency performs best (28ms). The NUMA configuration however further improves and at 64 workers achieves a latency of 6ms. Looking at the scan throughput, we see that NUMA achieves a peak throughput of 200GBps. We do not completely saturate memory bandwidth due to other overheads involved in query processing (topk sorting, memory allocations, coordination). In conclusion, NUMA-aware intra-query parallelism is an effective mechanism for decreasing query latency by utilizing the full memory capabilities of multi-core machines.



(a) Mean Search Latency (b) Scan Throughput

Figure 6: MSTURING100M: Scaling the number of threads with and without NUMA.

Table 5: Early-termination methods on SIFT1M with a partitioned index with 1000 partitions. Each row shows the average recall, nprobe, and mean per-query latency in milliseconds over 10000 queries after tuning for a specific recall target for $k = 100$. We also report the total offline tuning time in seconds, where APS needs *no* offline tuning.

Method	Target	Recall	*nprobe*	Latency	Offline Tuning
APS	80%	82.1%	11.8	0.34ms	**0**
	90%	91.2%	20.2	0.48ms	**0**
	99%	98.9%	50.1	0.96ms	**0**
Auncel [48]	80%	85.7%	16.4	0.41ms	66.3s
	90%	98.1%	73.8	1.29ms	73.8s
	99%	99.7%	95.9	1.61ms	83.2s
SPANN [7]	80%	81.6%	11	0.31ms	173s
	90%	90.2%	19	0.43ms	183s
	99%	99.0%	70	1.07ms	259s
LAET [18]	80%	81.3%	10.5	0.29ms	81s
	90%	90.5%	18.2	0.42ms	104s
	99%	99.0%	58.3	1.03ms	232s
Fixed	80%	81.7%	11	0.33ms	318s
	90%	90.3%	19	0.44ms	330s
	99%	99.0%	65	1.16ms	424s
Oracle	80%	83.3%	11.5	0.29ms	320s
	90%	92.4%	19.3	0.41ms	331s
	99%	99.2%	42.0	0.74ms	368s

7.6 Comparison with Early Termination Methods

Table 5 compares early-termination methods on SIFT1M, highlighting the tradeoff between query latency, tuning time, and recall, we do not include ground truth generation time in the tuning time for the baselines. APS analytically estimates recall at query time, **eliminating offline tuning entirely**, while achieving latency within 30% of the oracle across all recall targets. Fixed selects a static *nprobe* per target via an

expensive offline binary search (up to 424s), and SPANN similarly performs a binary search and tunes a centroid-distance threshold; both closely match recall targets but incur higher latency at 90% and 99% recall. LAET trains a per-query prediction model, incurring moderate tuning overhead (81–232s), and matches recall targets with slightly higher latency compared to APS. Auncel is the most similar method to APS, as it aims to analytically estimate recall using partition intersection volumes, however its volume estimation requires calibration, and it is a conservative method, overshooting recall. We tune Auncel by binary searching a geometric parameter (a), overshooting recall significantly (up to 8.1 pp) and increasing latency by up to 169% compared to APS. Finally, the Oracle, which scans the minimal amount of partitions per-query, serves as a practical lower bound on achievable latency, though with prohibitively high tuning cost. The tuning overhead of the baselines demonstrates a significant burden for online scenarios where the queries, data, and index change. The tuning burden worsens at scale, where ground truth generation cost grows linearly with the data size, and running queries multiple times to conduct binary search takes longer. APS thus provides near-optimal performance without tuning overhead, matching or exceeding all baselines.

Table 6: SIFT10M: Recall and per-level search latency (ℓ_0, ℓ_1, total) for a single-level baseline (L_0: 40,000 partitions; L_1: 1 partition) and two-level index (L_0: 40,000 partitions; L_1: 500 partitions), where recall targets are varied at each level. The single-level baseline is the first row of each $\tau_r(0)$ block.

$\tau_r(0)$	$\tau_r(1)$	Recall	ℓ_0 (ms)	ℓ_1 (ms)	Total (ms)
80%	—	81.2%	2.07	4.85	6.92
	80%	74.8%	1.44	0.72	2.16
	90%	78.3%	1.56	1.19	2.75
	95%	80.1%	1.67	1.69	3.37
	99%	81.0%	1.75	2.57	4.33
	100%	81.1%	1.82	3.81	5.63
90%	—	91.3%	2.85	4.89	7.86
	80%	84.1%	2.07	0.77	2.84
	90%	88.2%	2.26	1.24	3.50
	95%	90.1%	2.38	1.72	4.10
	99%	91.0%	2.48	2.60	5.08
	100%	91.2%	2.62	3.88	6.50
99%	—	99.0%	4.82	5.5	10.3
	80%	91.4%	4.11	0.77	4.88
	90%	96.0%	4.59	1.27	5.86
	95%	97.7%	4.80	1.75	6.55
	99%	98.7%	5.08	2.65	7.74
	100%	98.9%	5.28	3.93	9.21

7.7 Multi-Level Recall Estimation

Here we evaluate the effectiveness of APS in a two-level partitioned index by measuring the impact of varying per-level recall targets on overall recall. Table 6 reports results on SIFT10M using 40,000 partitions at level L_0 and 500 partitions at level L_1. We use an initial search fraction of $f_M = 1.5\%$ at L_0 and 25% at L_1.

We observe that overly aggressive early termination at L_1 by setting $\tau_r(1)$ too low leads to a clear degradation in total recall. For instance, at $\tau_r(0) = 90\%$, reducing $\tau_r(1)$ from 99% to 80% lowers overall recall from 91.0% to 84.1%. This confirms that accurate recall estimation at the upper level is necessary to maintain accurate end-to-end recall estimates. These results justify our design decision in Section 5.1 to fix $\tau_r(1) = 99\%$ in multi-level configurations so that only the base recall target $\tau_r(0)$ needs to be provided.

In addition, the two-level index substantially reduces centroid scanning overhead. The single-level baseline must evaluate distances to all 40,000 centroids per query. In contrast, the two-level configuration performs an approximate search over the centroids. For example, at a recall target of $\tau_r(0) = 90\%$ with $\tau_r(1) = 99\%$ the total query latency drops from 7.86ms to 5.08ms, a 35% reduction, driven mainly by the drop in L_1 latency from 4.89ms to 2.60ms.

7.8 Maintenance Ablation

To understand the effectiveness of the primary components of adaptive incremental maintenance (cost-model, partition refinement, and rejection), we replay a dynamic SIFT1M trace (30% inserts, 20% deletes, 50% queries) with different components disabled. All methods use a single-thread and search using APS with k=100 and a 90% recall target. We also include LIRE as a baseline. Table 7 reports cumulative times in seconds. For configurations with refinement we use a refinement radius of $r_f = 50$. The full Quake policy delivers the lowest search cost (86s) while meeting the recall target. If we keep the cost model but skip refinement (NoRef), maintenance time decreases significantly from 21s to 5s, yet recall slips by 2.4 pp and the search time increase by 15.4s. This shows that while refinement is the dominant cost in maintenance, it is necessary for minimizing search latency. Disabling the cost model and instead using size-based thresholding (NoCost) shows why naive size thresholds are inadequate: search time rises 8% despite similar maintenance effort. The rejection mechanism is critical; once removed (NoRej), recall collapses to 66% even though search and maintenance appear cheap. LIRE, which relies solely on size thresholding, is 17% slower in search latency, confirming that the cost model, rejection mechanism, and partition refinement are essential for maintaining both index performance and quality.

8 Discussion

Here we offer a discussion of Quake's system parameters, how the design extends to new hardware and use-cases.

8.1 Setting System Parameters

Quake exposes a few search and maintenance parameters, which we fix across all workloads unless otherwise stated. These defaults give stable performance with minimal tuning.

Table 7: Maintenance ablation on the SIFT1M workload. Times are cumulative (in seconds) over the course of the workload. Recall is averaged over all queries.

Maintenance Variant	Search	Update	Maint.	Recall
Quake (Full)	86.3s	21.7s	21.4s	90.5%
NoRef	101.7s	22.2s	5.2s	88.1%
NoRef+NoRej	85.5s	21.0s	1.0s	73.0%
NoRej	84.2s	19.6s	18.5s	66.2%
NoCost	93.5s	20.0s	20.4s	90.1%
NoCost+NoRef	100.7s	21.2s	0.8s	87.9%
LIRE	100.5s	21.2s	11.9s	90.0%

Search parameters. The *initial candidate fraction* f_M determines the number of partitions to consider in APS. It has the largest impact on performance. If set too low, APS may not meet the recall target; if too high, the initial scan dominates latency. We set this between 1% and 10%. In future work, we aim to remove this parameter entirely. The *number of worker threads* is best set to the number of physical cores. For large problem sizes, Quake scales linearly with thread count until memory bandwidth is saturated (Figure 6). The *recompute threshold* controls how often APS updates its recall estimate. We set this to 1%, which avoids unnecessary recomputation with negligible impact on recall (Table 2).

Maintenance parameters. The *split/merge threshold* τ sets the minimum predicted latency improvement required to trigger a split or delete. We set $\tau = 250$ns. Lower values increase maintenance cost and may cause over-splitting; higher values can allow imbalance to persist. The *split access scaling parameter* α estimates the drop in access frequency after a split. We fix $\alpha = 0.9$, which worked well across all benchmarks. If maintenance tuning is needed, we recommend keeping α fixed and adjusting τ. *Refinement* is controlled by two parameters: the refinement radius r_f (number of nearby partitions considered) and the number of refinement iterations. We use one iteration over the 50 nearest partitions. From our ablation study, disabling refinement reduces maintenance time by 75% but increases query latency and reduces recall (Table 7). The *window size* for access frequency statistics is set equal to the maintenance interval. For example, if maintenance runs every 100,000 queries, the window also spans 100,000 queries. Smaller windows adapt faster but are more volatile.

Most parameters are fixed across workloads. In practice, only the initial candidate fraction f_M and the maintenance threshold τ benefit from tuning; however, their defaults are sufficient for the workloads we evaluated.

8.2 Deployment Considerations

Quake's design can be extended to support a range of hardware and use-cases through minor changes to the cost model and APS logic. We reserve these extensions for future work.

Heterogeneous Hardware To adapt to devices with varying scan throughput such as CPUs, GPUs, or disk-backed storage, the cost model can be modified by profiling per-device scan latency (e.g., $\lambda_{\text{CPU}}(s)$, $\lambda_{\text{GPU}}(s)$, $\lambda_{\text{Disk}}(s)$) and updating partition cost estimates accordingly.

Distributed Environments In a distributed setting, each machine can run APS and maintenance independently on its local partitions. The cost model can account for partition locality and inter-node variation. A separate load balancer would be required to assign and replicate partitions across machines in a way that minimizes total query cost.

Vector Compression Vector compression techniques, such as Product Quantization [14], reduce scan cost. Quake can support compression by profiling scan latency over partitions of compressed vectors and updating $\lambda(s)$ in the cost model.

Filters Filtered queries can be supported by scaling per-partition recall probabilities in APS, based on the estimated number of items that pass the filter in each partition. This will enable Quake to avoid scanning partitions unlikely to contain matching results while preserving recall targets.

Concurrency The current implementation executes searches, updates, and maintenance serially. Quake can support concurrency through copy-on-write semantics, allowing background operations to build new index views while readers continue on the current one without blocking.

9 Conclusion

Experimental results show that Quake reduces query latency compared to baseline approaches under dynamic and skewed workloads, without requiring manual tuning. It achieves high recall, matching the performance of an oracle for setting the query parameter nprobe. Compared to existing partitioned indexes like Faiss and SCANN, Quake reduces query latency by A) adaptively maintaining index partitions and B) maximizing memory bandwidth during query processing. Compared to graph indexes like SVS, HNSW, and DiskANN, Quake offers more efficient indexing and updates while matching or reducing query latency. In summary, our evaluation shows Quake minimizes query latency while meeting recall targets on dynamic workloads with skewed access patterns.

A Artifact Appendix

Abstract

This artifact provides the experimental setup for Quake to reproduce key results. See the artifact's README for full details.

Scope

This artifact enables validation of Quake's core experimental findings, such as those related to Adaptive Partition Scanning (APS), NUMA-aware searching, and maintenance policies. Refer to the artifact's README for specific experiments.

Contents

The artifact includes Python scripts (e.g., `experiment_runner.py`, individual experiment `run.py` files), system installation scripts (`install.sh`), experiment configurations (`configs/`), Conda environment files, and the paper PDF. The README details the full directory structure and contents.

Hosting

The artifact is part of the Quake repository in the `osdi2025` branch. located at https://github.com/marius-team/quake/tree/osdi2025/test/experiments/osdi2025. Use the latest commit on this branch.

Requirements

Python 3.9+ and Conda are required. Tested on Linux (Ubuntu 22.04). Some experiments (e.g., NUMA evaluations) require a machine with NUMA for meaningful reproduction. The `install.sh` script lists system-level dependencies. Refer to the README for comprehensive requirements.

A.1 Installation

Follow the detailed installation instructions in the artifact's README. Options include a comprehensive setup using `install.sh` or a Quake-only Conda environment setup.

A.2 Experiment Workflow

All experiments are launched via `experiment_runner.py` from the repository root. Experiments will typically download and prepare required datasets if not found locally. Experiments are run as follows:

```
python3 -m test.experiments.osdi2025.experiment_runner
-experiment kick_the_tires - config sift1m
```

After execution, experiments print status updates and save results (e.g., CSV files, plots) to an output directory, as indicated in the console output. The artifact's README provides the complete command structure, detailed explanations of all parameters (including `-output-dir`), further examples, and a full summary of available experiments with their specific configurations.

Achieving Low-Latency Graph-Based Vector Search via Aligning Best-First Search Algorithm with SSD

Hao Guo Youyou Lu*

Tsinghua University

Abstract

We propose PipeANN, an on-disk graph-based approximate nearest neighbor search (ANNS) system, which significantly bridges the latency gap with in-memory ones. We achieve this by aligning the best-first search algorithm with SSD characteristics, avoiding strict compute-I/O order across search steps. Experiments show that PipeANN has 1.14×–2.02× search latency compared to in-memory Vamana, and 35.0% of the latency of on-disk DiskANN in billion-scale datasets, without sacrificing search accuracy.

1 Introduction

High-dimensional vectors with tens or hundreds of dimensions are powerful data representations [17, 19]. Vector search, which searches a dataset for the closest neighbors given a target vector, is used in various scenarios such as recommendation [14, 15, 27] and retrieval augmented generation (RAG) [12]. It is not efficient to do accurate vector searches for high-dimensional vectors [9], so *approximate nearest neighbor search* (ANNS) is preferred, which returns an approximated set of k nearest neighbors (i.e., top-k). Among all types of ANNS indexes, graph-based indexes [6, 16], where vectors are organized as a directed graph, are favored for their low search latency under high accuracy.

To support large-scale datasets (e.g., billions of vectors [6, 14, 21, 27]), an increasing number of organizations [4, 21, 33] prefer solid-state drives (SSDs) for storing ANNS indexes, due to their cost-efficiency. However, graph-based indexes fail to maintain low search latency on disk as in memory. As shown in Figure 1, the on-disk DiskANN has significantly higher search latency than the in-memory Vamana (e.g., 4.18× for 0.9 recall and 3.14× for 0.99 recall).

By analysis, we find the high latency is caused by the intrinsic mismatch between graph-based ANNS algorithms and the I/O characteristics of SSDs, namely *long I/O latency* and *asynchronous, parallel I/O*: Graph-based ANNS follow the

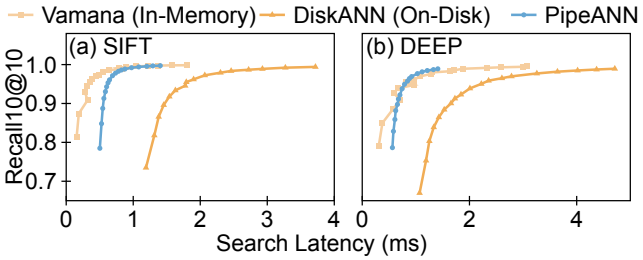

Figure 1: Latency gap between in-memory (Vamana [23]) and on-disk (DiskANN [23]) graph-based indexes in two datasets. Our system (PipeANN) significantly bridges the gap.

best-first search algorithm to explore vectors in the graph — in each search step, it explores the best neighbors (i.e., the nearest ones) of all the explored vectors, to reduce the number of accessed vectors per search. However, two issues prevent it from achieving low latency on disk. First, the best-first algorithm incurs *ordered compute and I/O* across search steps. It harms search latency because of the long (e.g., 7.43× than compute latency, §2.2) but wasted I/O latency which fails to overlap with compute. Second, the best-first algorithm forces *synchronous I/O* in each search step, where it batch-reads the nearest neighbors synchronously. It induces an underutilized I/O pipeline (e.g., 76% utilized, §2.2) when waiting for slow reads in the batch.

In this paper, **we seek to align the search algorithm with SSD I/O characteristics**. We find this idea feasible without affecting search convergence, by observing that the best-first algorithm is not a must: Unlike scalar indexes (e.g., B$^+$-tree) where objects have one search path, graph-based ANNS indexes have multiple search paths for each vector, considering its multiple in-edges. The best-first algorithm only estimates one short search path, not the unique one. Thus, a tweaked search algorithm can exploit other paths for convergence.

We propose PipeSearch, an on-disk graph-based ANNS algorithm that achieves low latency by aligning the best-first search algorithm with SSD I/O characteristics. The key ob-

*Youyou Lu is the corresponding author (luyouyou@tsinghua.edu.cn).

servation for such alignment is *the pseudo-dependency of compute and I/O in best-first search*: In each search step, the neighbors to be read can be decided by only the in-memory *candidate pool* containing the neighbor IDs, without waiting for ongoing I/O or compute (i.e., neighbor exploration) to finish. Thus, PipeSearch avoids strict compute-I/O order across search steps: When the I/O pipeline is not full, PipeSearch fills it by asynchronously reading the current nearest neighbors in the candidate pool, regardless of ongoing I/O or unfinished compute. Overlapped with I/O, PipeSearch explores the pre-read neighbors in a best-effort manner.

PipeSearch brings significant performance benefits. On the one hand, compute and I/O are overlapped, which accelerates ANNS as they show close (the same order of magnitude) latency. On the other hand, the I/O pipeline is better utilized. Experiments demonstrate the low latency of PipeSearch, which has ~50% latency compared to best-first search.

PipeSearch achieves low latency but at the cost of throughput. There are two challenges to increasing its throughput. *The first* is how to dynamically adjust to suitable pipeline widths during a single search, in order to leverage the high throughput of narrow pipelines and the low latency of wide ones simultaneously. *The second* is how to avoid the accumulation of read-but-unexplored neighbor vectors caused by wide pipeline and slow neighbor exploration, which induces sub-optimal I/O decisions and reduced search throughput.

To this end, we implement PipeANN, a low-latency ANNS system with high search throughput. PipeANN tackles the two challenges in PipeSearch with two techniques:

First, we dynamically increase the I/O pipeline width during the search, instead of keeping a static pipeline width, to benefit from high throughput and low latency simultaneously. The throughput drop in large pipeline widths mainly arises from *I/O waste*, which makes it easier to saturate SSD IOPS because of more I/O per search. However, we find that I/O waste decreases as the search progresses. This is due to the growing number of unexplored top-k neighbors during the search. In later search steps, the candidate pool contains more unexplored top-k neighbors, which allows a wider I/O pipeline with little I/O waste.

Second, we ensure an upper bound for the number of missed neighbors (i.e., ongoing I/O and read-but-unexplored neighbors) when deciding on each I/O, instead of ensuring a full I/O pipeline at all times, to avoid neighbor accumulation. Specifically, when multiple I/Os finish simultaneously, we repeatedly explore one neighbor and issue one I/O, instead of issuing multiple I/Os to fill up the pipeline. Thus, we strike a balance between a full I/O pipeline (PipeSearch) and reduced I/O waste (best-first search), increasing throughput while sacrificing little latency.

We evaluate PipeANN to show its efficiency in low-latency ANNS. As shown in Figure 1, PipeANN significantly bridges the latency gap between in-memory and on-disk ANNS, especially for high recall (≥ 0.9). Compared with state-of-the-art ANNS indexes on disk, PipeANN shows at least 70.6% lower latency and 1.35× higher throughput for 0.9 recall. In billion-scale datasets, PipeANN has 35.0% latency and 1.71× higher throughput compared to DiskANN [23].

While primarily designed for SSDs, PipeANN's techniques could also be adopted to other storage media, such as remote memory. These storage media exhibit similar I/O characteristics as SSDs, namely μs-scale I/O latency and parallel I/O, so ANNS indexes stored on these media [5] could improve their performance by adopting PipeANN.

PipeANN has its limitations. Despite the techniques for throughput, PipeANN's speculative I/O still leads to lower search throughput than the greedy I/O in best-first search. However, we believe PipeANN's latency-throughput tradeoff is worthwhile in applications with ms-scale latency budgets (e.g., large-scale search and recommendation [6, 21]), where PipeANN could benefit from lower search latency or higher search accuracy with the same latency.

In summary, this paper makes the following contributions:

- We find the best-first search algorithm restricts the design space in exploiting SSD characteristics, inducing high latency for on-disk graph-based ANNS (§2).
- We design PipeSearch, a low-latency graph-based ANNS algorithm on disk by aligning the best-first search algorithm with SSD (§3).
- We implement PipeANN, a low-latency ANNS system with high search throughput. PipeANN increases the throughput of PipeSearch by dynamic pipeline and algorithm optimization (§4).
- We evaluate PipeANN to demonstrate its efficacy in achieving low-latency and high-throughput ANNS on disk (§5).

2 Background and Motivation

In this section, we first provide a primer for on-disk graph-based ANNS. Then, we characterize the best-first search algorithm to show its mismatch with SSD characteristics.

2.1 Graph-Based ANNS and Best-First Search

The k-nearest neighbor search problem aims to find the k nearest vectors of the target vector in a dataset. However, accurate search is challenging in high-dimensional vector spaces (e.g., hundreds of dimensions), which is known as the curse of dimensionality [9]. To tackle this challenge, approximate nearest neighbor search (ANNS) algorithms are proposed. Given the target vector, ANNS finds an approximate set of its top-k nearest vectors. Of all the ANNS algorithms, graph-based ones [6, 16, 23] show promising performance and accuracy. They organize the vectors as a directed graph, and vector search is conducted by graph traversal.

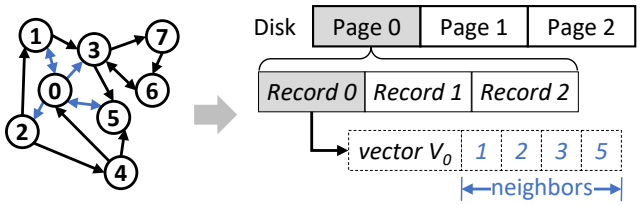

Figure 2: Index layout of on-disk graph-based ANNS.

Algorithm 1 Best-first search

```
1:  G ← graph, q ← query vector, W ← I/O pipeline width
2:  procedure BestFirstSearch(G, q, W)
3:      s ← starting vector, L ← candidate pool length
4:      candidate pool P ← {<s>}, explored pool E ← ∅
5:      while P ⊆ E do
6:          V ← top-W nearest vectors to q in P, not in E
7:          Read V from memory or disk
8:          E.insert(V)
9:          for nbr in V.neighbors do
10:             P.insert(<nbr, Distance(nbr, q)>)
11:         end for
12:         P ← l nearest vectors to q in P
13:     end while
14:     return k nearest vectors to q in E
15: end procedure
```

Graph layout. To support billion-scale vector search [6,21], existing systems [23,25] store the graph index on disk and do on-disk graph-based ANNS. As shown in Figure 2, the graph is stored on disk as multiple *records*. Each record consists of a vector and all its neighbor IDs.

Best-first search algorithm. Existing graph-based vector search systems, either in memory [6, 16] or on disk [23,25], take a best-first search algorithm for graph traversal [1,26]

As shown in Algorithm 1, best-first search maintains a candidate pool with a fixed *candidate pool length* (denoted as L in this paper), containing current top-L nearest vectors. The search starts with a fixed starting vector and contains multiple search steps. Each step explores the top-W nearest unexplored vectors in the candidate pool, by reading them in a batch and inserting their neighbors into the candidate pool. The search terminates when all the vectors in the candidate pool are explored. We use W to represent *I/O pipeline width* (i.e., the maximum number of parallel I/O requests) in this paper. This definition equals the beam width in best-first search [23].

For in-memory indexes [6, 16], reading the vectors (line 7) takes a short time, so they use $W = 1$ to reduce the waste of compute and I/O. However, SSD has high I/O latency, so it takes more time to read a vector than explore it for on-disk indexes [23, 25]. Therefore, they use $W > 1$ to utilize the SSD I/O pipeline. Also, they use PQ-compressed vectors in memory to calculate the distance with neighbors (line 10), without disk reads. In each search step, only W disk reads are conducted. In this paper, best-first searches with $W = 1$ and $W > 1$ are also called *greedy search* and *beam search*.

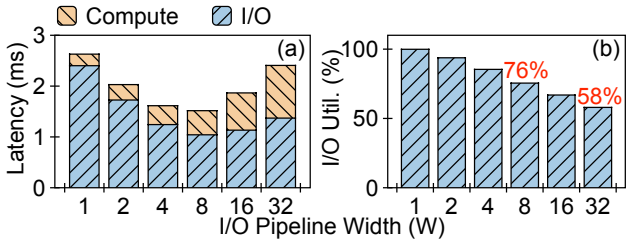

Figure 3: (a) Search latency breakdown. (b) I/O pipeline utilization rate (average #ongoing I/O ÷ I/O pipeline width).

Low-latency ANNS. Achieving low latency ANNS is beneficial for real-world applications. First, real-world systems have strict latency demands. In large-scale search or recommendation systems [6,21], billion-scale, or even larger, vector searches should complete within ~10ms to meet response time requirements. Second, for ANNS systems, a longer search time allows exploring more vectors, thus leading to higher search accuracy. Therefore, if we could reduce the search latency at the same accuracy, we could simultaneously increase search accuracy within the same latency demands.

2.2 Best-First Search Mismatches with SSD

Graph-based ANNS shows low latency in memory [6, 16], but fails to maintain such latency on disk. We conduct experiments to demonstrate this issue. We do best-first searches with different Ws, using a graph index built on 100 million vectors in the SIFT dataset [10]. The target recall is 90%, as recommended by the BigANN benchmark [20].

As shown in Figure 1(a), the search latency on disk is 4.18× compared to that in memory. By analysis, we find the cause of long latency is that *best-first search algorithm mismatches with SSD I/O characteristics*. Specifically, we focus on the following two SSD I/O characteristics:

- **Long I/O latency.** Microsecond or tens of microseconds latencies, common to flash-based SSDs.
- **Asynchronous, parallel I/O.** The ability to handle multiple (e.g., 32) in-flight read requests in parallel.

We find two issues as follows.

Issue 1: Ordered compute and I/O across search steps. The best-first search algorithm naturally causes data dependency, inducing ordered compute and I/O. In each search step, the best-first search batch reads and explores the W nearest unexplored neighbors to the target vector. Therefore, the current I/O batch depends on the previous search step, namely the previous compute and the previous I/O batch.

Such ordered compute and I/O show little overhead in memory but harm the ANNS latency on disk. This is because, when

conducting ANNS in memory, the memory access latency is orders of magnitude lower than compute, which is typically executed serially in a search thread. When on disk, I/O latency is higher than compute, which shifts the bottleneck to I/O. Figure 3(a) demonstrates this issue by breaking down the latency. When $W = 1$ (i.e., greedy search), compute latency is only 9.5% of I/O latency. Even when using $W = 8$ (the lowest overall latency) to utilize I/O parallelism, compute latency is still 45.6% of I/O latency. Unfortunately, the long I/O latency is wasted, as it fails to overlap with compute.

Issue 2: Synchronous I/O in each search step. Best-first search uses $W > 1$ to batch-read multiple records in each search step, to utilize I/O parallelism. However, it still requires synchronously waiting for all the I/Os to finish.

Such synchronous I/O causes an *under-utilized I/O pipeline*. Figure 3(b) shows the I/O pipeline utilization rate (the average number of ongoing I/Os during I/O time ÷ W). During I/O time, the pipeline is only 76% full for $W = 8$, and 58% full for $W = 32$. This is because the I/O latency fluctuates in SSDs. Best-first search waits for a whole I/O batch to finish, so the latency depends on the tail latency of the I/Os. When waiting for some slow I/Os, the I/O pipeline is not fully utilized.

3 PipeSearch

Based on the observations above, we propose PipeSearch, a low-latency ANNS algorithm by aligning the best-first search algorithm with SSD hardware. In this section, we first show that this idea is feasible. Then, we introduce PipeSearch and analyze its performance benefits. Finally, we evaluate it to demonstrate its dilemma in latency and throughput.

3.1 Tweaking Best-First Search is Possible

One may think that tweaking the best-first search algorithm may prohibit the search from convergence. However, we argue that **the best-first algorithm is not a must and can be tweaked without affecting search convergence.**

This is enabled by multiple search paths in graph-based indexes: Unlike scalar indexes (e.g., B^+-tree) where each object has only one search path, in graph-based ANNS indexes, each vector can be found in multiple paths using its multiple in-edges. The best-first search only estimates a short search path in the graph, but not the unique path. Therefore, tweaking the search algorithm is possible. Although it may lengthen the search path, it does not prohibit search from convergence and brings more opportunities for reducing latency.

3.2 PipeSearch Algorithm

We propose PipeSearch, a low-latency algorithm for graph-based ANNS on disk. The key idea of PipeSearch is to align the best-first search algorithm with SSD characteristics. As shown in Figure 4, best-first search executes compute and

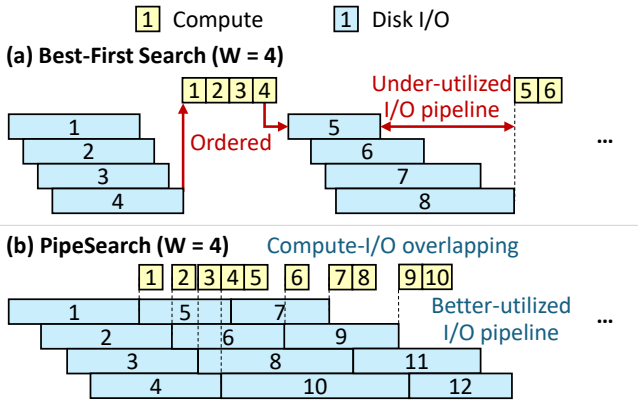

Figure 4: Comparison of PipeSearch with best-first search.

I/O in order, unfriendly to SSDs. In contrast, PipeSearch tweaks the algorithm to avoid such strict order, thus achieving compute-I/O overlapping and a better-utilized I/O pipeline.

Key observation: pseudo-dependency of compute and I/O. In each search step, the best-first search issues I/O and explores the nearest neighbors in order. However, such an order is not necessary: I/O can be decided only by the in-memory candidate pool, regardless of ongoing I/O and unexplored neighbors. Thus, when there are ongoing I/O, we can directly issue I/O for the nearest unread neighbor in the candidate pool, there is no need to wait for all the ongoing I/O to finish (like best-first search). Neighbor exploration can be executed in a best-effort manner, independent from disk I/O.

Algorithm overview. PipeSearch avoids strict compute-I/O order across search steps. Specifically, it maintains a candidate pool with a fixed length L, similar to best-first search. Also, it maintains an I/O pipeline Q with a specific width W, containing ongoing I/O. The search iteratively executes the following steps: If the I/O pipeline is not full, PipeSearch issues I/O to fill up the pipeline based on the current candidate pool. Overlapped with I/O, it explores the nearest vector in an unexplored set U and updates the candidate pool using its neighbors. Then, it polls for I/O completion and adds all the vectors acquired to the unexplored set U.

3.3 PipeSearch Reduces Search Latency

PipeSearch achieves low-latency graph-based ANNS on disk by tackling the two issues in §2.2. We analyze it as follows.

PipeSearch achieves compute-I/O overlapping, which accelerates ANNS as they show close latency. Both short and long I/O latencies may make pipelining inefficient. If I/O latency is short like in memory, greedy search shows low latency. If I/O latency is long, pipelining will degrade to best-first search due to short compute. However, in graph-based ANNS on disk, compute and I/O latencies are of the same order of magnitude, making PipeSearch efficient. As

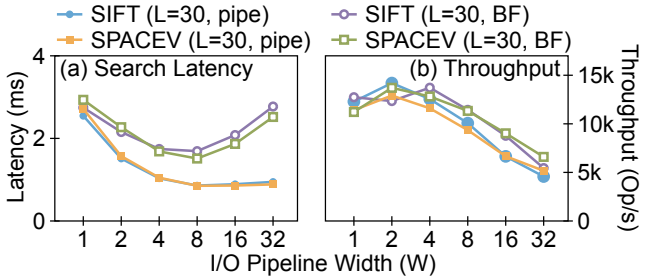

Figure 5: Latency and throughput of PipeSearch and best-first search (BF) with different Ws. With $L = 30$, both algorithms achieve 90% accuracy in terms of recall10@10.

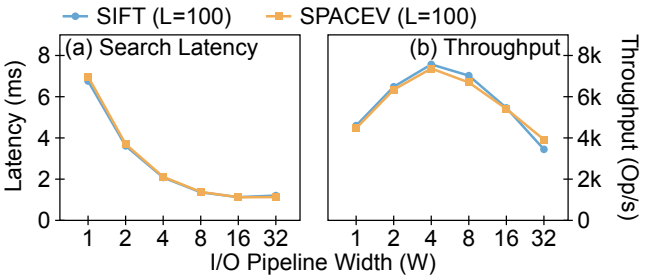

Figure 6: Latency and throughput of PipeSearch with different Ws and $L = 100$. PipeSearch achieves 99%/97% accuracy in terms of recall10@10 in SIFT/SPACEV.

shown in Figure 3(a), when $W = 32$, the compute latency is 75.6%/72.7% of the I/O latency. Overlapping them is possible to provide a 1.7× performance boost.

The I/O pipeline can be saturated by enough I/O, because of the navigation graph feature. In a typical navigation graph, each vector contains hundreds of neighbors, so the candidate pool contains hundreds of unexplored vectors after the first search step, which can be used to fill up the pipeline. It is possible to provide another 1.7× performance boost when $W = 32$, as in Figure 3(b). There may not be enough vectors to fill up the pipeline in the later search steps when most vectors are recalled. However, in §4.2, we find it does not last long.

3.4 Dilemma of Latency and Throughput

PipeSearch reduces the latency of best-first search but fails to achieve low latency and high throughput simultaneously. We evaluate PipeSearch using 100 million vectors in two datasets, SIFT [10] and SPACEV [4], using 1 thread for latency and 56 threads for throughput. As a comparison, we evaluate the best-first search with the same W. The results are shown in Figure 5, and we make the following observations:

(1) PipeSearch fails to ensure low latency and high throughput simultaneously, with a static pipeline width. On the one hand, the pipeline width with the lowest search latency (i.e., $W = 8$) fails to achieve high throughput simultaneously. It has 71.0%/72.4% lower throughput compared to $W = 2$. On the other hand, the optimal pipeline width varies in different configurations. Figure 6 shows the results with $L = 100$, where $W = 16$ shows the lowest latency (82.7%/81.1% compared to $W = 8$), and $W = 4$ delivers the highest throughput.

(2) Compared to best-first search, PipeSearch reduces latency but degrades throughput. When $W = 8$, PipeSearch has 50.7%/56.3% lower latency than best-first search in the SIFT/SPACEV dataset. However, the throughput degrades to 88.1%/82.5%. This issue is more significant for larger pipeline widths. When $W = 16$, PipeSearch only achieves 75.8%/73.8% of the throughput of best-first search.

The throughput degradation results from I/O waste. I/O waste, which increases average I/O per search, makes PipeSearch easier to saturate SSD bandwidth and thus causes a throughput drop. It arises from two aspects. The first is large pipeline widths. For PipeSearch, $W = 32$ has 2.44×/2.24× average I/O per search compared to $W = 8$, due to more speculative I/O. Although a small pipeline width reduces I/O waste, it leads to more sequential accesses, thus increasing the number of search steps and search latency.

The second is the accumulation of read-but-unexplored neighbor vectors. When the neighbor exploration is slow, the pre-read neighbors may be accumulated in memory but unexplored. This causes sub-optimal I/O decisions because of missed neighbor information, and thus intrinsic I/O waste of PipeSearch. Compared to best-first search, PipeSearch shows 1.34×/1.43× average I/O per search when $W = 8$.

We raise a question: **Can we reduce the I/O waste in PipeSearch, to achieve low latency and high throughput simultaneously?** Based on the analysis above, we summarize two challenges for this question. *The first* is to dynamically adjust to suitable pipeline widths in a single search. *The second* is to avoid the accumulation of neighbor vectors.

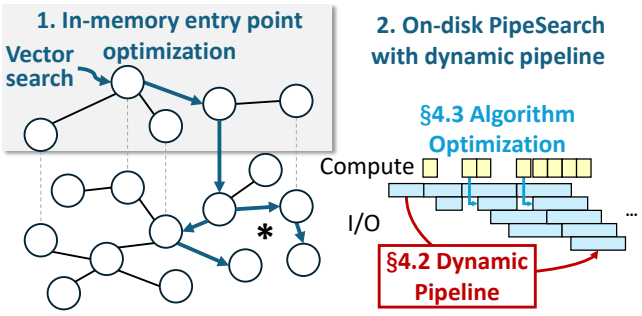

Figure 7: PipeANN overview.

4 PipeANN Design and Implementation

We design PipeANN, a low-latency graph-based ANNS system on disk with high search throughput. PipeANN integrates

Algorithm 2 Optimized PipeSearch in PipeANN

```
1:  G ← graph, q ← query vector, L ← candidate pool length
2:  L_m ← candidate pool length of the in-memory index
3:  procedure PipeSearch(G, q, L)
4:      W ← 4                                   ▷ Starting pipeline width.
5:      // Approach phase: entry point optimization.
6:      candidate pool P ← InMemSearch(q, min(L, L_m))
7:      explored pool E ← ∅
8:      unexplored set U ← ∅, unfinished I/Os Q ← ∅
9:      // Converge phase: dynamic pipeline.
10:     while P ⊊ E do
11:         if Q.size() < W then                ▷ I/O pipeline not full.
12:             V ← top-1 nearest vectors to q in P, not in E
13:             Q.insert(V)                     ▷ send read requests.
14:         end if
15:         v ← nearest vector to q in U        ▷ overlap with I/O.
16:         E.insert(v), U.remove(v)            ▷ explore v.
17:         for nbr in v.neighbors do
18:             dis ← PQ_distance(nbr, q)
19:             P.insert(<nbr, dis>)
20:         end for                             ▷ update candidate pool.
21:         P ← l nearest vectors to q in P     ▷ PQ distance.
22:         F ← finished I/Os in Q              ▷ poll for completion.
23:         W ← AdaptPipelineWidth(P, F)
24:         U.insert(F), Q.remove(F)
25:     end while
26:     return k nearest vectors to q in E      ▷ exact distance.
27: end procedure
```

PipeSearch and improves it using dynamic pipeline width (§4.2) and algorithm optimization (§4.3).

4.1 PipeANN Overview

Figure 7 shows the overview of PipeANN.

Graph layout. On disk, PipeANN stores the graph as adjacent lists (§2.1). In memory, it stores PQ-compressed vectors for neighbor distance comparison and a small graph-based index for entry point optimization.

Vector search. PipeANN uses PipeSearch for vector search but increases its throughput (Algorithm 2). It separates a single vector search into two phases, *approach* phase and *converge* phase, based on the key observation that I/O waste decreases across steps (§4.2).

In the approach phase, the vector search gradually approaches the target vector, when I/O waste is significant and thus PipeSearch is inefficient. Therefore, PipeANN uses an in-memory index (line 6) for entry point optimization, and then starts PipeSearch (lines 7–25) with a small pipeline width.

In the converge phase, the vector search recalls vectors near the target vector, when I/O waste gradually decreases and thus PipeSearch shows efficiency. Thus, PipeANN dynamically increases the pipeline width (line 23) by estimating the number of recalled vectors and the current I/O waste, based on the candidate pool state and the finished I/O.

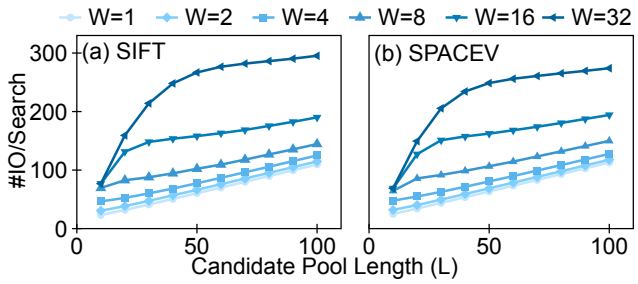

Figure 8: I/O waste of PipeSearch decreases across search steps. In general, it contains a turning point for each W, after which the I/O waste is similar to the ideal case (i.e., $W = 1$).

Also, PipeANN reduces the I/O waste of PipeSearch by not ensuring a perfect pipeline at all times (lines 11–14, §4.3). When multiple I/Os finish simultaneously, PipeANN does not immediately fill up the pipeline. Instead, PipeANN repeatedly issues one I/O and explores one vector in the candidate pool. In this way, it ensures that the nth I/O is decided by the neighbor information of the $(n-W)$th compute, thus increasing the I/O accuracy. The perfect pipeline can be finally ensured, as the I/O completion times tend to differ in this strategy.

4.2 Dynamic Pipeline

PipeSearch fails to ensure low latency and high throughput simultaneously with a fixed pipeline width. Therefore, we propose to adapt the pipeline width dynamically in search. In this section, we first introduce the key observation that motivates us to adapt the pipeline width. Then, we describe the two phases of vector search separately.

4.2.1 I/O Waste Decreases Across Search Steps

In §3.4, we demonstrate the dilemma of PipeSearch in latency and throughput. With higher pipeline width, PipeSearch shows low latency but low throughput, because of high I/O waste. However, we observe that this dilemma is not fundamental: It considers ANNS at a coarse granularity of a whole search, instead of each search step.

To consider ANNS at the granularity of each step, we evaluate the average I/O per search with different Ls, as shown in Figure 8. This evaluation is based on an observation: PipeSearch *with a small L is approximately a subprocess (in other words, an early termination) of one with a large L.* Therefore, the slope in Figure 8 reveals the average I/O for recalling the Lth vector; a smaller slope means less I/O waste.

In Figure 8, we observe that the I/O waste across search steps shows two stages. At the beginning of the search, PipeSearch shows a significant I/O waste, which increases with W. Then, it reaches a turning point, after which the I/O

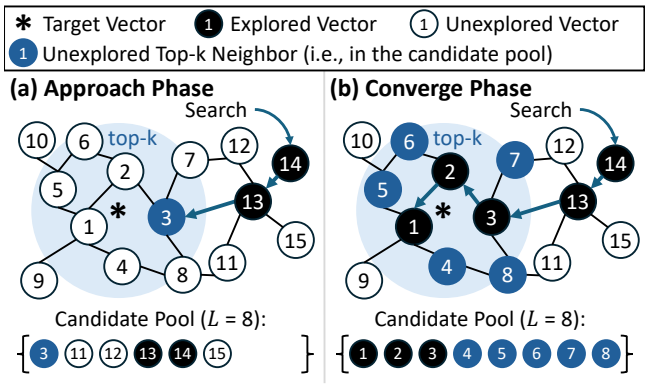

Figure 9: Two-phase search of graph-based ANNS indexes.

waste is similar to the ideal case (i.e., $W = 1$). The turning point arrives later (i.e., a larger L) for a larger W.

We use Figure 9 to further demonstrate this observation. The best-first policy of vector search naturally divides it into two phases, *approach phase* and *converge phase*. In the approach phase, the vectors in the candidate pool quickly approach the target vector. During this phase, PipeSearch with large pipeline widths fails to recall more vectors that are likely in the search's critical path, inducing I/O waste.

In the converge phase, the nearest vector in the candidate pool remains stable, and the top-k nearest vectors are gradually recalled. The more recalled vectors (larger L in Figure 8), the more top-k neighbors they connect. Thus, there are more "unverified" top-k vectors in the candidate pool, which allows using a large pipeline width for fast verification. During this phase, the average I/O for each vector remains stable.

Method: two-phase graph traversal. Based on the observations above, we use different approaches in the two phases, in order to reduce the I/O waste in PipeSearch. We seek to quickly pass the approach phase, where PipeSearch shows inefficiency. Therefore, we optimize the entry point (§4.2.2) and start PipeSearch with a small pipeline width. In the converge phase, we dynamically increase the pipeline width of PipeSearch, based on the candidate pool state (§4.2.3).

Pipeline draining does not last long. This recalls the Observation 2 in §3.1. In the later search steps, most vectors are recalled, so PipeANN fails to ensure a full pipeline. However, as shown in Figure 8, the I/O waste is not significant in the later search steps. We conclude that most remaining vectors are accurate top-k neighbors of the target vector: New vectors are less likely to be inserted into the candidate pool when reading them. Therefore, this process does not last long.

4.2.2 Approach Phase: Entry Point Optimization

PipeANN uses an in-memory graph-based index for entry point optimization, similar to previous works [25]. Specifically, PipeANN samples a portion of entry points in the dataset and builds an in-memory graph-based index using them. The index is built offline and is thus static. For the online vector search, PipeANN first traverses the in-memory index to select entry points and then conducts on-disk PipeSearch.

Parameter selection. In-memory index traversal lies in the critical path of the whole vector search. Therefore, we should carefully select its parameters to ensure its low latency.

Following previous work [25], PipeANN uses a 1% sample rate for the entry points to balance entry point quality and memory usage. We use Vamana (i.e., in-memory DiskANN) as the graph index structure. The index is only used to efficiently find the top-k sampled entry points, so other indexes (e.g., HNSW [16] and NSG [6]) show similar tradeoffs to Vamana. This is also demonstrated in previous work [25].

Here, we discuss the maximum out-degree, which contributes most to the search latency. We build the in-memory index using the Vamana algorithm [23], which is an approximation of a Monotonic Relative Neighborhood Graph (MRNG) [6]. Its search complexity linearly increases with the average out-degree. As this in-memory index is only used for entry point selection, not the overall indexing, we can use a smaller maximum out-degree, tolerating the connectivity loss of some points for lower search latency. By default, we use 32 as the maximum out-degree of in-memory indexes, smaller than in previous works [6, 25].

4.2.3 Converge Phase: Pipeline Width Adjustment

PipeANN dynamically adjusts the pipeline width during the search. To achieve this, two questions should be answered. The first is when to start adjusting the pipeline width, and the second is which pipeline width should be selected.

When to start adjusting. We approximate the number of vectors that are already recalled n_v. When the number reaches a threshold, we consider the search to reach the converge phase and start to increase the pipeline width.

Specifically, after exploring one vector, we iterate over the candidate pool to find the first vector whose read request has not been issued. Its index is used as an approximation of n_v's upper bound. This is not an accurate estimation because there may be unexplored vectors that have been already read. Exploring them may add new nearer neighbors.

We further understand this estimation. In the approach phase, there are usually new nearest neighbors after exploring a vector, so the estimated n_v typically equals 0. In the converge phase, it is hard to find nearer neighbors than the already explored ones by exploring a new vector, so the estimated n_v gradually increases.

After the estimated n_v reaches a threshold (5 in our evaluation), we start adjusting the pipeline width. Before that, the pipeline width is set to a fixed value of 4 to reduce I/O waste.

How to adjust. We propose two approaches for this, static approach and dynamic approach, and we use the dynamic approach by default.

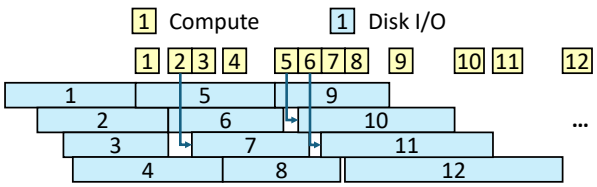

Figure 10: When multiple I/O finish simultaneously, we issue one I/O after exploring one record, instead of issuing multiple I/O to saturate the pipeline. Therefore, every disk I/O misses the neighbor information in no more than W records.

The static approach first profiles the dataset by PipeSearch with different Ws and Ls to get the results like Figure 8. Then, it generates a fixed (#vectors recalled – W) mapping based on the results. In this mapping, each "#vectors recalled" corresponds to the largest W after its turning point. During a vector search, it adjusts W based on the estimated n_v.

The dynamic approach uses another metric: the percentage of I/O that the vector fetched is in the candidate pool. Specifically, after starting pipeline width adjustment, we re-calculate this ratio when there exists finished I/O. When the ratio is greater than a threshold (0.9 in our evaluation), we increase the pipeline width by 1.

4.3 Algorithm Optimization

Compared to beam search, naive PipeSearch shows a throughput drop, especially with large pipeline widths, due to I/O waste caused by accumulated neighbor vectors. Here, we describe this in detail.

The root cause of I/O waste is missing neighbor information in the fetched vectors. Less missed neighbor information induces more accurate I/O decisions, thus less I/O waste. For example, greedy search issues I/O after exploring all the vectors, so it misses no neighbor information and shows less I/O waste compared to beam search and PipeSearch.

Ideally, if compute and I/O are perfectly overlapped, each I/O in PipeSearch misses the neighbor information in no more than W records (in W on-flight I/Os). However, this is based on the assumption that I/Os are finished uniformly in the timeline, which is not true in SSDs.

When multiple I/Os finish simultaneously, filling up the pipeline may make I/O miss the neighbor information in more records (W on-flight I/Os and multiple read-but-unexplored vectors). To avoid this, we limit the I/O rate by handling multiple I/Os one by one, as shown in Figure 10. Specifically, after multiple I/O finishes, we repeatedly send one I/O, explore one nearest vector, and update the neighbor set. This way can reduce I/O waste and gradually scatter the I/Os uniformly in the timeline, thus not incurring much overhead.

4.4 Implementation and Other Optimizations

Overlapping initialization. PipeANN needs to wait for the first disk I/O to finish, to get neighbor information for filling up the pipeline. This process has a latency of $\sim 50\mu$s in our NVMe SSD. We overlap it with local PQ table initialization, which is performed for each query to enable fast PQ distance lookup. However, local PQ table initialization needs to read the global PQ table, which is not used in search and thus causes cache pollution. We use non-temporal load in AVX512 instruction to avoid this issue.

Asynchronous I/O. PipeANN uses `io_uring` [11] to issue I/O requests, due to its performance and compatibility. Specifically, each thread uses its private `io_uring` to send I/O requests asynchronously, with the `prep_read` command (line 13 in Algorithm 2). It polls for I/O completion (line 22) using the non-blocking `peek_batch_cqe` command.

Polling-based I/O. Existing systems adopt interrupt-based I/O for best-first search. They do not use polling-based I/O as its latency advantage does not boost the performance. They synchronously wait for all the I/Os in a batch to finish before compute, thus interrupt overhead is minor compared to I/O latency. However, PipeANN needs to issue and poll I/O with low latency, as it could use the saved I/O time for computation. Hence, we enable SQ polling of the `io_uring` engine.

4.5 Discussion

Beyond SSD. PipeSearch is designed for on-disk graph-based ANNS but is not restricted to it. The mechanisms can be used for other hardware with μs-scale access latency, such as remote memory using remote direct memory access (RDMA) or compute express link (CXL). In this case, the whole graph-based index is stored in remote memory. PQ-compressed vectors and the small index for entry point optimization are stored in local memory. Asynchronous I/O could be implemented by replacing `io_uring` commands with corresponding remote memory commands (e.g., using RDMA read or CXL prefetch instead of `prep_read`). As the remote memory latency (e.g., 2μs for RDMA) is still the same order of magnitude with compute (μs-scale for each record), PipeSearch is expected to boost ANNS performance on remote memory.

Two-phase search in other works. VBASE [31] also observes a similar phenomenon of two-phase vector indexing, called relaxed monotonicity. It leverages this for efficient similarity search with tags, by designing an interface that returns the next vector in replace of the interface that returns top-k vectors. We exploit this phenomenon to reduce I/O waste in PipeSearch, aiming to ensure both low latency and high throughput. Specifically, we observe that I/O waste decreases during the search process, given a fixed pipeline width.

Memory usage. PipeANN requires <40GB of memory for billion-scale datasets, including:

- 32GB for PQ-compressed vectors, 32 bytes per vector.

- <4GB for the in-memory graph index. In our evaluation, it uses 2.4GB for the SIFT1B [10] dataset and 3.1GB for the SPACEV1B dataset [4].
- Minor overheads for other in-memory data structures.

In comparison, DiskANN [23] requires ~32GB of memory, mainly for the PQ-compressed vectors.

PipeANN's memory-to-disk size ratio is ~1:15, considering that billion-scale graph indexes on disk typically require over 600GB of disk space (e.g., 636GB for SIFT1B and 892GB for SPACEV1B). PipeANN's primary memory constraint lies in the PQ-compressed vectors, similar to DiskANN. Therefore, memory-efficient quantization (e.g., RaBitQ [7]) methods could reduce their memory usage.

5 Evaluation

In the evaluation, we seek to answer the following questions:

- How does PipeANN perform in latency and throughput compared to other on-disk ANNS indexes? (§5.2)
- Can PipeANN scale to billion-scale datasets? (§5.3)
- Is PipeANN comparable with the in-memory graph-based ANNS index in terms of search latency? (§5.4)
- How do the techniques in PipeANN contribute to its performance? (§5.5)
- How do the approaches for pipeline width adjustment impact search performance? (§5.6)
- How much does PipeANN trades throughput and accuracy with the same search parameters for latency? (§5.7)

5.1 Experimental Setup

Basic configuration. We use one server for evaluation, which has the following configuration:

- **CPU**: 2× 28-core Intel Xeon Gold 6330 @ 2.00GHz;
- **RAM**: 512GB (16× 32GB DDR4 2933MT/s);
- **SSD**: 1× Samsung PM9A3 3.84TB;
- **OS**: Ubuntu 22.04 LTS with Linux kernel 5.15.0.

Compared systems. We compare PipeANN with on-disk ANNS indexes, including graph-based DiskANN [23] and Starling [25], as well as cluster-based SPANN [4]. DiskANN is a graph-based ANNS index using best-first search. Starling optimizes the I/O of DiskANN by reordering the on-disk records to improve search locality and using an in-memory index to optimize the entry point.

SPANN is an on-disk cluster-based index. It separates the vectors into clusters and maintains an in-memory navigation graph to index the cluster centroids. To conduct ANNS, it first searches the nearest clusters in the in-memory graph and then re-ranks all the vectors in the clusters to get the results.

Parameters. We use the same in-memory and on-disk graph indexes for PipeANN, DiskANN, and Starling, except that Starling reorders the on-disk records. The graph indexes are built using the parameters in Table 1. For search parameters, the candidate pool size of in-memory index traversal L_{mem} is fixed to 10 for PipeANN and Starling. We use `io_uring` [11] as the I/O engine of PipeANN and enable SQ polling. For fairness, we also replace the original I/O engine (`libaio`) with `io_uring` for DiskANN and Starling. We disable SQ polling for them. We use $W = 8$ for DiskANN and $W = 4$ for Starling, which shows the lowest latency separately. We limit the maximum W of PipeANN to 32.

Graph Type	R	L	B
On-Disk (100M)	96	128	32
On-Disk (1B)	128	200	32
In-Memory	32	64	/

Table 1: Parameters used for Vamana (i.e., DiskANN) graph building [23]. R: maximum out-degree. L: candidate pool size for finding neighbors. B: PQ-compressed vector size (bits/vector). The in-memory index is used by PipeANN and Starling for entry point optimization.

Name	#Vectors	Type	Dim	#Queries
SIFT1B [10]	1B	`uint8`	128	10,000
SPACEV1B [4]	1.4B	`int8`	100	29,316
SIFT100M [10]	100M	`uint8`	128	10,000
DEEP100M [2]	100M	`float`	96	10,000
SPACEV100M [4]	100M	`int8`	100	29,316

Table 2: Datasets used in the evaluation. SIFT100M, DEEP100M, and SPACEV100M are subsets of SIFT1B, DEEP1B, and SPACEV1B.

For SPANN, we build cluster-based indexes using the same parameter in the SPFresh [29] repository. Specifically, for SIFT and SPACEV, we set their maximum cluster size to 16KB. For DEEP, we set it to 48KB. Each vector is replicated to its nearest 8 clusters.

Datasets. We use five public datasets in the evaluation, including 100M-scale and billion-scale datasets. Detailed configurations of the datasets are shown in Table 2.

Metrics. We mainly compare the latency and throughput for 0.9 recall, which is recommended by the BigANN benchmark [20]. Low recall (e.g., 0.8) and high recall (e.g., 0.99) are also used in some experiments for more thorough comparison. We evaluate the recall by searching the top 10 nearest neighbors (i.e., recall10@10).

5.2 Overall Performance

In this section, we evaluate the latency and throughput of PipeANN using datasets with 100M vectors. We do not use billion-scale datasets, where the graph reordering algorithm in Starling has huge time and memory overhead. We will

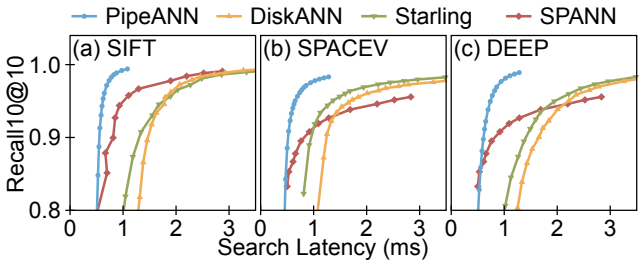

Figure 11: Search latency on datasets with 100M vectors.

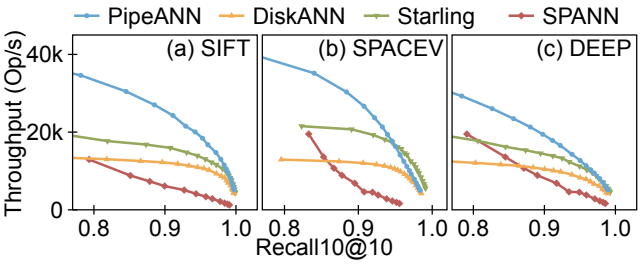

Figure 12: Search throughput on datasets with 100M vectors.

show the results in billion-scale datasets in §5.3.

5.2.1 Latency

We use 1 thread to conduct ANNS in the compared systems. Figure 11 shows the results. From the figure, we make the following observations:

(1) Compared with graph-based indexes, PipeANN shows lower latency. To achieve 0.9 recall10@10, PipeANN has 39.1%/48.5% latency on average, compared to DiskANN/Starling. This is because PipeANN efficiently uses dynamic PipeSearch to overlap compute and I/O and increase the average I/O depth, thus reducing latency. Starling has lower latency compared to DiskANN. This is because Starling uses the in-memory index for entry point optimization and reorders the on-disk graph to reduce the average I/O per search.

(2) Compared with cluster-based indexes, PipeANN shows lower latency when recall $\geq$ 0.9. To achieve 0.9 recall10@10, PipeANN has 70.6% lower latency compared to SPANN. SPANN shows lower latency than other graph-based indexes, because of its I/O friendliness. SPANN first traverses an in-memory graph-based index for the nearest clusters of the target vector. Then, it sends I/O to fetch the clusters in parallel. In contrast, existing graph-based indexes traverse the graph by issuing I/O batches in sequential, where I/O latency significantly harms the overall search latency. PipeANN greatly eliminates this issue by pipelining, which makes it faster than SPANN for recall $\geq$ 0.9. However, when the recall is smaller (e.g., 0.8), PipeANN suffers from the overhead of approaching the target vector, making it slower than SPANN.

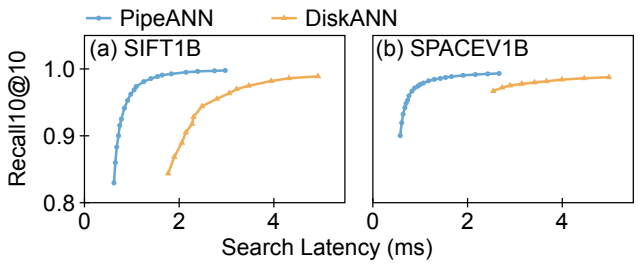

Figure 13: Search latency in billion-scale datasets.

5.2.2 Throughput

We use 56 threads (all the cores of our CPU) to conduct ANNS in the compared systems. Figure 12 shows the results. From the figure, we make the following observations:

(1) When recall = 0.9, PipeANN consistently shows the highest throughput. To achieve 0.9 recall10@10, PipeANN outperforms other systems by 1.35× on average. In this case, the disk bandwidth is not saturated, because other tasks (e.g., PQ table initialization) account for a high time percentage. The extra I/O of PipeANN does not harm the overall throughput much. PipeANN's high throughput owes to its shorter critical path, because of pipelining.

(2) For higher recall, PipeANN has a lower throughput than Starling. To achieve 0.99 recall10@10, PipeANN has 0.80× lower throughput than Starling on average, because of the wasted disk I/O. In this case, the search procedure takes up most of the time, which saturates the disk bandwidth. For each search, PipeANN requires 1.94× average disk I/O on average compared to Starling, which results in lower throughput. This is because of the reordering technique of Starling. Starling reorders the on-disk index for more neighboring records on the same page, thus reducing disk I/O.

Note that the design of PipeANN is orthogonal with Starling. In PipeANN, we can directly adopt the same reordering technique to reduce I/O. However, considering the huge time and memory overhead for reordering in billion-scale datasets, we do not adopt this technique in PipeANN.

Compared with DiskANN, PipeANN shows higher throughput. PipeANN has a similar (0.98× for 0.99 recall) average I/O per search compared to DiskANN, but it can better utilize the disk bandwidth because of pipelining. This results in PipeANN's higher throughput.

5.3 Overall Performance: Billion-Scale

In this section, we show the performance of PipeANN in billion-scale datasets. We compare PipeANN with DiskANN. We do not compare PipeANN to other baselines because building or searching them exceeds the memory capacity in our setup. Figures 13 and 14 show the results. In SPACEV1B, we do not show DiskANN with accuracies less than 96%,

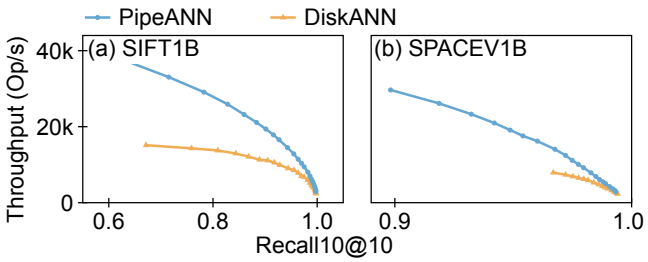

Figure 14: Search throughput in billion-scale datasets.

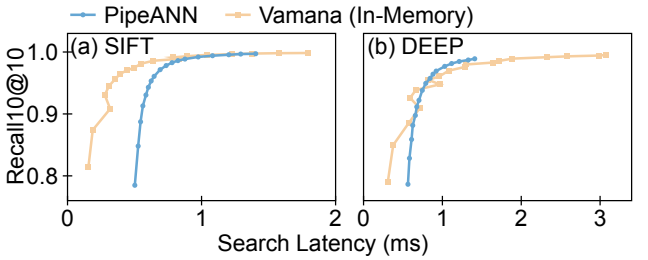

Figure 15: Search latency of PipeANN compared with Vamana (in-memory DiskANN).

because its accuracy only achieves 60% using a smaller L.

Latency. As shown in Figure 13, to achieve 0.9 recall10@10, PipeANN has latencies of 0.719 ms and 0.578 ms in SIFT1B and SPACEV1B, which are 1.28×/1.09× compared to SIFT100M and SPACEV100M. Compared to DiskANN, PipeANN achieves 35.0% latency in SIFT.

Throughput. As shown in Figure 14, to achieve 0.9 recall10@10, PipeANN has 19.4K and 26.1K QPS in SIFT1B and SPACEV1B, which are 79.9% and 98.0% compared to SIFT100M and SPACEV100M. Compared to DiskANN, PipeANN achieves 1.71× higher throughput.

Analysis. The search path is longer for billion-scale datasets than 100M-scale datasets, which incurs a higher search latency to achieve the same recall. However, it also brings more opportunities for pipelining, which contributes to a more significant performance boost compared to DiskANN.

5.4 Compare with In-Memory Index

In this section, we show the performance gap of PipeANN with an in-memory graph-based index. We directly store the on-disk index of PipeANN in memory and use it for searching. We call this baseline Vamana. We compare PipeANN with Vamana using SIFT100M and DEEP100M datasets. Figure 15 shows the results, and we make the following observations:

(1) For low recall, PipeANN shows higher latency than the in-memory index. To achieve 0.8 recall10@10 in SIFT100M, PipeANN has 3.38× higher latency than Vamana. Because of a small L (e.g., 10), the search is mainly in the approach phase, where PipeSearch cannot maintain a large pipeline width. Therefore, PipeANN fails to hide all the I/O latency, which makes the performance of PipeANN lower than the in-memory index.

(2) For recall ≥ 0.9, the performance of PipeANN is close to the in-memory index. To achieve 0.9 recall10@10, PipeANN has 2.02×/1.14× latency compared to Vamana. In this case, both PipeANN and Vamana use a large L (e.g., 30). The converge phase accounts for a higher ratio, where PipeSearch maintains a large pipeline width for better overlapping of compute and I/O. Therefore, the performance gap between PipeANN and Vamana reduces.

PipeANN's slowdown is less significant in DEEP100M. This is because, in DEEP, distance comparison for Vamana is more costly than in SIFT. DEEP calculates 96 `floats` per vector, which has a higher overhead than the 128 `uint8`s per vector in SIFT. In contrast, PipeANN uses PQ distance for neighbors, which has similar overheads for distance comparison in the two datasets. We conclude that PipeANN is expected to have more comparable performance with in-memory ANNS with higher vector dimensions.

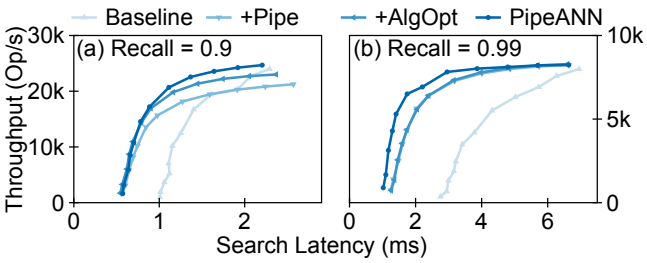

Figure 16: Breakdown analysis of PipeANN.

5.5 Breakdown Analysis

In this section, we break down the performance gap of Baseline and PipeANN. We accumulate key techniques into the Baseline and evaluate the latency-throughput graph with 0.9 and 0.99 recall10@10. We use the index built on the SIFT100M dataset, and the same configurations as in §5.2.

Baseline. We implement the Baseline based on the framework of PipeANN. It uses best-first search like DiskANN with $W = 8$ and adopts the same in-memory index as PipeANN for entry point optimization. As shown in Figure 16(a), the Baseline shows ms-scale latency to achieve 0.9 recall. Although adopted entry point optimization, its best-first search algorithm still incurs high search latency on disk.

+Pipe. We use PipeSearch (§3) with $W = 8$ in replace of best-first search in Baseline. It reduces latency to 55.1% for 0.9 recall. However, the throughput is also reduced to 88.5%. This is because PipeSearch has a 1.11× average I/O per search compared to best-first search. The I/O waste and throughput

#Vectors Recalled	0	10	20	30	40
Pipeline Width	4	8	16	24	32

Table 3: Pipeline width used by static approach.

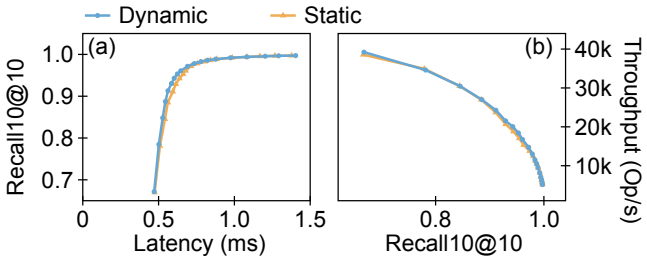

Figure 17: Performance of dynamic approach and static approach for pipeline width adjustment. Dataset: SIFT100M.

drop are less significant than in §3.4, as entry point optimization reduces the I/O waste during the approach phase.

+AlgOpt. We adopt the algorithm optimization for multiple finished I/Os (§4.3). It increases the throughput to 1.08× because it reduces the average I/O per search to 91.8%. The performance boost is more significant in high-throughput cases, which concludes that multiple I/Os are more frequent to finish simultaneously in such cases. The latency is slightly reduced to 97.5%, as the performance degradation of the unsaturated I/O pipeline is less significant than the performance boost of reduced I/O.

PipeANN. We adopt the dynamic pipeline (§4.2) in replace of the static one with $W = 8$. It reduces the latency to 81.1% for 0.99 recall and increases the throughput to 1.07×. This is because, in the converge phase, a large W allows more compute and I/O overlapping, while not inducing much I/O waste. It does not show much performance boost for 0.9 recall, as the search terminates early in the converge phase when W is not significantly larger than 8.

5.6 Approaches for Pipeline Adjustment

In this section, we compare the two approaches for pipeline width adjustment (§4.2.3), namely the static approach and the dynamic approach. For the static approach, we set the pipeline width according to the profiling results similar to Figure 8(a). The parameters used are shown in Table 3.

Figure 17 shows the results. We find that the dynamic approach slightly outperforms the static approach by up to 6.1%/9.1% for latency and throughput. This demonstrates that PipeANN is not sensitive to the approach for pipeline width adjustment. The dynamic approach successfully follows the decreasing trend of I/O waste to increase the pipeline width across the search steps.

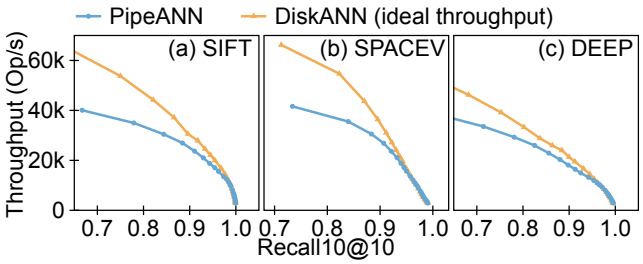

Figure 18: Throughput of PipeANN and DiskANN with ideal throughput (best-first search with $W = 1$).

5.7 Tradeoffs in PipeANN

PipeANN tweaks the best-first search algorithm for lower latency, but with some tradeoffs. In this section, we demonstrate them using experiments.

Throughput. Although PipeANN introduces techniques to reduce I/O waste, its $W > 1$ could still waste more I/O compared to the ideal best-first search with $W = 1$ (note that we use $W = 8$ for lower latency in §5.2), and thus lead to lower throughput. We implement this ideal baseline using DiskANN, which we call DiskANN (ideal throughput). To saturate SSD, this baseline uses asynchronous I/O; one CPU core executes multiple search requests simultaneously and switches across them to avoid I/O waiting. We compare PipeANN with this baseline using the same datasets as in §5.2.

Figure 18 shows the results. From the figure, we observe that: First, PipeANN shows lower throughput than the ideal DiskANN at low accuracy. When recall = 0.8, the throughput drop of PipeANN is 31.6%/34.1%/17.5% separately in the three datasets. This is because the approach phase accounts for a large percentage, when PipeANN's $W > 1$ leads to I/O waste. Second, the throughput drop becomes less significant at higher accuracy. When the recall reaches 0.95, the throughput drop becomes 14.7%/6.15%/4.90%. In such cases, the converge phase lasts longer, and some wasted I/O in the approach phase are also explored in best-first search. These two reasons contribute to less I/O waste of PipeANN. Third, at the same accuracy, PipeANN shows less I/O waste in DEEP than the other two datasets. This is because DEEP requires a larger candidate pool length L, and thus a longer converge phase. This leads to less I/O waste.

Search accuracy with the same parameters. PipeANN tweaks the best-first search algorithm, which may lead to an accuracy drop under the same search parameters. Here, we evaluate this issue in terms of quantity. We compare PipeANN with the same L as DiskANN, which uses best-first search with $W = 8$. Figure 19 shows the results. From the figure, we make the following observations:

(1) PipeANN shows little accuracy drop. PipeANN has at least 95.9% recall compared to DiskANN. When recall ≥ 0.9, this value is further increased to 98.8%. The accuracy drop

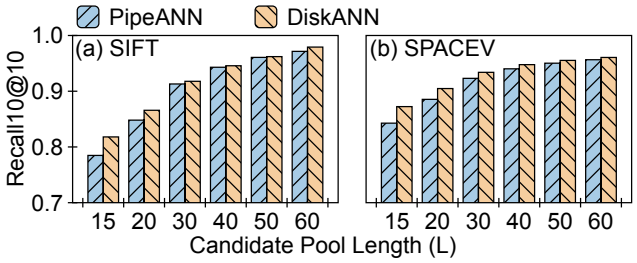

Figure 19: Accuracy of PipeANN and DiskANN with the same L. Note that the Y-axis does not start at zero.

is because PipeANN approximates the best-first search algorithm. However, the modification is slight enough to ensure similar behavior for search convergence.

(2) The accuracy drop is less significant for larger L. We understand this by regarding PipeANN as a "best-first search" with a candidate pool length $L-W$, noticing that each I/O in PipeANN misses at most W vectors. The search accuracy increases slower for larger L, so the accuracy gap of best-first searches with $L-W$ and L becomes less significant.

PipeANN achieves the same accuracy with DiskANN using a larger L, but benefits from lower latency.

6 Related Work

PipeANN targets on-disk graph-based ANNS with low latency. In this section, we introduce two types of related work, namely graph search optimization and on-disk ANNS.

Graph search optimization. Traditional graph-based indexes do ANNS in memory. They typically use greedy search to traverse from the starting vector to the target vector [6, 16]. Compared to distance comparison, memory access for vectors has orders of magnitude lower latency, so the greedy-based approach is favored for reduced vectors accessed per search. In such a scenario, distance comparison is the major bottleneck of graph-based ANNS, so some works focus on reducing the overhead of distance comparison for high performance [3, 30].

On disk, the best-first algorithm incurs high search latency when exploring one vector at a time (i.e., $W = 1$). Therefore, DiskANN [23] proposes to use beam search, where it reads the best k vectors in parallel for each search step. Beam search is also used by iQAN [18] to do intra-query parallelism among multiple cores, where each core explores one vector. Compared to greedy search, beam search reduces the latency but still follows a best-first algorithm, which induces compute-I/O order and limits the performance.

Some other works accelerate graph search by reducing the length of the search path, using entry point optimization and early termination. LSH-APG [32] and Starling [25] optimize the fixed entry point using an LSH table or a sub-graph. Proxima [28] and learned adaptive early termination [13] determine the search termination condition based on the search state and an ML model, separately. The design of PipeANN is orthogonal to these works. These works can be directly adopted by PipeANN for acceleration.

In contrast, PipeANN reduces the search latency by aligning the best-first search algorithm with SSD characteristics.

On-disk ANNS. To support larger datasets, recent works store ANNS indexes on disk. They can be mainly divided into two types, graph-based indexes and cluster-based indexes.

Graph-based indexes are favored for their search accuracy and I/O efficiency, which are suitable for high-throughput ANNS. They typically store compressed vectors in memory for navigation, and the full index on disk [8, 23, 25]. However, due to the best-first search algorithm, the critical path in search includes tens of sequential I/O. Therefore, graph-based indexes suffer from high search latency on disk, which motivates the designs of PipeANN. Also, updating the graph-based indexes induces high overheads [22, 29].

Cluster-based indexes [4, 24] have a simpler structure than graph-based indexes. They divide the vectors into multiple clusters, each of which contains tens of vectors. The clusters are stored on disk, and indexed by an in-memory graph. Vector search first finds the nearest clusters in memory and then reads them on disk in parallel. Therefore, only one parallel disk I/O lies in the critical path, which contributes to its low search latency. Also, updating the cluster-based indexes incurs a lower cost than graph-based ones [29]. However, cluster-based indexes are more coarse-grained than graph-based ones, which induces lower search throughput.

7 Conclusion

We propose PipeSearch, a low-latency algorithm for on-disk graph-based ANNS. PipeSearch accelerates on-disk ANNS by aligning the best-first search algorithm with SSD features. It benefits from compute-I/O overlapping and a better-utilized I/O pipeline compared to best-first search. We optimize PipeSearch and implement PipeANN, a low-latency ANNS system with high search throughput. Experiments show that PipeANN significantly bridges the latency gap between in-memory ANNS and on-disk ANNS. This work demonstrates that aligning the algorithm with the hardware characteristics brings performance benefits.

Abstract

Meta Platforms Inc. is a social media company whose products require high availability and low latency. Meta's services run in multiple geographic locations around the world and use asynchronous replication to keep the numerous cached copies of the datastore in sync. This setup reduces consistency in order to meet availability and latency requirements. Eventual consistency due to asynchronous replication causes issues for Meta's services, ranging from minor annoyances to product-breaking bugs. Therefore, we ask: *can we put meaningful bounds on how long it takes writes to be visible while maintaining the scalability afforded by eventual consistency?*

In this work we present Skybridge, an out-of-band replication stream for providing bounded staleness for distributed caches. Skybridge takes advantage of the fact that Meta's systems already have a reliable delivery stream and instead focuses on real-time delivery of updates. Skybridge is complementary to the main replication pipeline and avoids correlated failures while being lightweight. We show that Skybridge helps provide 2-second bounded staleness for 99.99998% of writes, while the main replication pipeline only achieves this 99.993% of the time. Skybridge is able to achieve this while only being 0.54% the size of cache deployments.

1 Introduction

Meta Platforms, Inc. is a social media company whose products are used by people around the world. Like other web-scale serving stacks, Meta's datastore hosts millions of database shards and handles billions of queries per second at sub-second latency [11, 15, 19, 45, 63]. Because of these stringent requirements, Meta operates instances of the serving stack in multiple geographic regions worldwide. Each region stores numerous copies of the data in the form of database (DB) replicas [19, 41, 44], in-memory caches [11, 22, 52, 63] and indexing systems [9, 57]. This architecture provides high scalability and close proximity to users for low latency.

While this architecture is highly scalable, it means there are dozens of copies of millions of shards around the world that are kept up to date. Meta uses asynchronous replication [15] to keep copies synchronized in order to meet our strict latency and high scalability requirements. Asynchronous replication provides *eventual consistency* [6] for clients, meaning all updates will eventually be reflected in all replicas but without bounds on how long it may take. Eventual consistency is problematic when there is non-trivial replication lag that delays when updates are visible to clients. Due to the scale of Meta's serving stack (both in traffic and geographic size), it is almost impossible to eliminate all sources of lag. An overloaded publisher, a hotly-written shard or a congested network hop can all cause replication lag for multiple shards and many downstream replicas.

Eventual consistency is a recurring pain point in many previous works [2, 39, 57]. For Meta, eventual consistency causes bad user experiences in products. Visibility controls are a prime example – for instance, *Alice* may add *Bob* to a closed group. However if the group's membership data is read from a lagging replica, *Bob* will not be able to participate in the group until the replica catches up. This violates *Alice* and *Bob*'s user expectations and causes frustration with our products. Eventual consistency can also have more serious side-effects. For example, Meta's serving stack allow triggering asynchronous actions outside of web request handling to avoid blocking when returning a response. Asynchronous actions may read from different replicas or even execute in different regions. In one instance a content enforcement system using asynchronous actions experienced an outage due to sustained replication lag. The action could not see data written during the web request, leading to a surge of retries that clogged up execution queues and caused system downtime.

Meta's product developers are aware there is replication lag in the system, but without stronger guarantees they build workarounds to deal with distributed systems issues that leak through datastore abstractions. Developers often ask "what is the maximum cross-region replication lag?" Infrastructure teams struggle to provide useful answers as lag can vary from

*Work done while at Meta Platforms Inc.

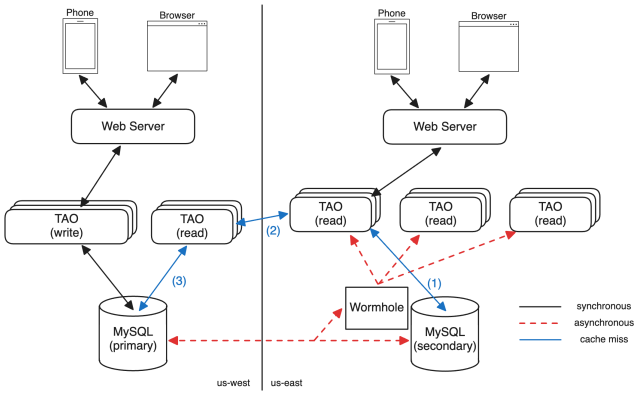

Figure 1: System architecture for Meta's serving stack.

milliseconds to hours (or longer). Developers cope with lag via patterns like retry loops, racy state machines and buggy distributed locks. For example, one developer added a retry loop that would poll the datastore for up to 40 minutes waiting for data. Better guarantees on when writes become visible obviate a whole class of developer issues. Thus, we ask *how can we put reliable and tight bounds on how long it takes for a write to be visible while maintaining the serving stack's high scalability and low latency?*

In this work we present Skybridge, an out-of-band replication system for providing 2-second bounds on eventual consistency. Meta's existing replication system, which provides strong durability and ordering guarantees, already replicates updates within 2 seconds in most cases. Skybridge instead targets the long-tail of lagging shards, where the strong guarantees of traditional replication systems cause replication lag. Our core insight is that Skybridge can implement replication with weaker guarantees while still enabling the system to holistically enforce staleness bounds. The weaker semantic, named *replication with gap detection*, allows out-of-order replication and known data loss. These properties allow Skybridge to side-step common sources of replication lag and focus on real-time replication, complementing the existing replication stream. While Skybridge builds upon existing distributed systems mechanisms, it combines them to provide a new replication guarantee and occupies a novel point in the replication system design space.

Skybridge is designed to be used by in-memory distributed caches, including TAO [11], the cache fronting Meta's serving stack. When the replication stream is lagging, TAO consults Skybridge to determine which individual cache items are stale and need refilling from the source of truth. Skybridge's protections are enabled by default for all TAO requests, transparently boosting consistency with minimal overhead.

In this work we make the following contributions:

- Explain why bounded staleness is important for TAO's users and why we did not target other forms of consistency,
- Define a novel replication guarantee called replication with gap detection that focuses on detecting cache staleness,
- Describe Skybridge's design and implementation, a system that provides fine-grained and efficient bounded staleness for distributed in-memory caches,
- Evaluate Skybridge's ability to provide reliable bounded staleness for TAO users, including demonstrating that TAO's 2-second consistency increases from 99.993% to 99.99998% using Skybridge. Skybridge helps TAO prove data is fresh without having to refill from the primary source for 99.9996% of requests while only requiring 0.54% of TAO's server footprint.

2 Background

2.1 Meta's system architecture

Meta's serving stack is similar to other web serving stacks like PNUTs [15] or Espresso [51]. The serving stack prioritizes high availability and low latency, meaning Meta operates many deployments around the world.

Storage. Meta stores its user data in MySQL [43]. The database is partitioned into millions of shards and replicated across regions. Meta uses primary-secondary replication [44] to keep regions up to date. For each shard, one region hosts the *primary* replica that accepts both read and write requests. Other regions host *secondary* replicas, which only accept read requests. Writes to the primary are *asynchronously* replicated to secondaries, i.e., MySQL acknowledges completed writes to the client before the change is guaranteed to have been replicated to all secondaries.

Caching. Meta's workload is skewed towards reads. This workload is amenable to caching, which allows scaling throughput with low latency. Meta operates an in-memory caching service named TAO [11] in every region. TAO is similar to Memcached [22] or Redis [52], but provides a graph [67] API for querying vertices and edges. TAO is separated into read and write tiers, which allows specialization (DB connection management for writers, high-throughput caching for readers) and independent scaling of resources. TAO uses a read- and write-through architecture. For writes, web servers issue requests to the in-region TAO write tier. If the primary replica for the shard is in-region, the write tier directly issues a request to MySQL; otherwise, the request is proxied to the write tier in the primary region to perform the write. Web servers similarly send read requests to the local TAO read tier. On cache misses, TAO goes "upstream" to fetch the data. Figure 1 shows the upstream path – TAO first attempts to obtain the data from the local replica (1), and if unsuccessful, attempts to obtain the data from the read tier in the primary region (2) before going to the primary DB replica (3).

Keeping caches up to date. Keeping caches up to date is a known difficult problem [49]. One strategy is to use time-to-live (TTL) caching [14]. However, TTLs cause caches to either hold updated data too long (stale data) or throw away unchanged data (spurious misses). Another strategy is

to rely on read/write-through architectures to update caches on the request handling path. However, relying on a fixed topology for consistency prevents evolving the architecture for operational benefits like availability and scalability [57].

Instead, Meta uses a pub-sub system named Wormhole [56], a system similar to Apache Kafka [3] or LinkedIn's Databus [18], to stream updates to caches. Wormhole ingests MySQL's replication stream and distributes updates to subscribers such as TAO read tiers. Wormhole guarantees *at-least-once* and *in-order* delivery of updates to subscribers. While Wormhole's strong guarantees ensure the system can reliably replicate data around the world, enforcing those guarantees often leads to replication lag. For example, a hot shard or an overloaded publisher will cause lag (and data staleness) on a large number of subscribers. While average replication lag is low, Wormhole provides no bounds on maximum lag. Because both the MySQL secondaries and caches are updated asynchronously with no bound on replication lag, users are subject to *eventual consistency with unbounded staleness* [6].

Load-based subscriptions. There are multiples types of TAO tiers per region, including main and "failover" tiers. Failover tiers help improve availability and handle traffic during maintenance events. Failover tiers lazily subscribe to shard replication streams when a shard's traffic reaches a minimum threshold. These *load-based subscriptions* reduce resource usage but are frequent sources of staleness.

Write versioning. Meta's datastores use hybrid-logical clocks (HLC) [32] as a building block for consistency primitives. HLCs are versioning metadata about writes that have both a physical and logical clock component. HLCs achieve properties of both types of clocks – they capture causality between events (like Lamport clocks [35]) while also being tied to the physical time when the write was performed. HLCs can be used to detect when a data item is stale and needs to be refreshed from a more up-to-date source.

Meta's MySQL deployment mints HLCs as part of committing transactions. MySQL guarantees HLCs are monotonically increasing per shard using the formula $HLC_{new} = max(Time_{now}, HLC_{Prev} + 1)$ (where $Time_{now}$ is the host's current physical time). Meta uses NTP [42] to synchronize physical time. HLCs propagate alongside changed data through Wormhole to TAO, which caches them alongside the data. Additionally, MySQL injects a *heartbeat* [31] message (with HLC) into the replication stream every 500ms. This allows downstream subscribers to disambiguate between inactive shards and unhealthy replication – a subscriber should at least see a heartbeat every 500ms, regardless of whether there are any writes to the shard. If the subscriber does not see one, the replication stream may be unhealthy.

TAO tracks per-shard heartbeats as monotonically increasing *watermarks* indicating the shard's replication progress. Because Wormhole guarantees in-order delivery, when TAO processes a heartbeat with HLC T_j, TAO is guaranteed to have processed all updates T_i where $T_i < T_j$. In essence, TAO is guaranteed to be "up to date" as of the watermark.

2.2 Bounded staleness

Bounded staleness [40] is a read consistency level exposed by asynchronously-replicated datastores. Unlike eventual consistency, which specifies that reads to the datastore will observe a write at some point without any conditions on timeliness, bounded staleness guarantees that reads will observe any write within some system-provided time bound. Concretely, if write W_T is performed at time T and the system provides staleness bound S, then any read R performed at or after $T + S$ is guaranteed to observe W_T regardless of whether the read is to the primary or a replica. Note that under bounded staleness the reader is allowed to observe subsequent writes $W_{T+1}, W_{T+2}...$ (i.e., fresher data) but reads must reflect all older writes $W_{T-1}, ...$ that preceded W_T.

Why bounded staleness? Bounded staleness is strong enough to be useful for developers while still being scalable enough to be enabled by default for all TAO reads. Bounded staleness matches most users' mental model of the system. Enabling it by default provides highly leveraged benefits for all of Meta's developers, including reducing product raciness and eliminating debugging pain. Others have recognized bounded staleness as a powerful consistency level for users – for example, Azure Cosmos DB [41] and Spanner [23] support bounded staleness (although they target DB replicas, not the caches fronting them).

Stronger forms of consistency like linearizability [27], sequential consistency [36] and causal consistency [1] are non-starters as defaults at Meta's scale as they introduce too much communication and synchronization overhead. Previously, Meta built and deployed FlightTracker [57] to provide read-your-writes (RYW) consistency for Meta's social graph. While RYW is enabled for all TAO reads, we observed several limitations that made us turn to bounded staleness. First, users are only provided guarantees about their own writes; they still get eventual consistency for writes performed by other users or non-users like automation. Second, RYW protections are only provided by default within a region, as adding cross-region latency on every session fetch adds too much overhead to be enabled by default [57]. Finally, integrating a FlightTracker-like system in the long tail of products and services operated by Meta is time consuming and not scalable.

We have found that RYW and bounded staleness together form a compelling semantic for datastore users – a user's writes are visible to them immediately and all other writes are visible within a reasonable delay.

Picking a staleness bound. The target staleness bound must both be useful for users and be achievable considering Meta's global deployment. Setting the bound to 2 seconds struck the right compromise between usability and feasibility – it is both a useful human-scale time bound and is achievable given speed-of-light delays for cross region replication.

We evaluate Skybridge's ability to reliably provide 2 second bounded staleness in Section 5.

Bounded staleness without Skybridge. TAO in principle can implement a simple form of bounded staleness on cache hits by comparing the staleness bound S against the physical component of the watermark HLC_{wm} and cached-item HLC_{item}. When checking a cache item:

1. If $Time_{now} - (S - \varepsilon) < max(HLC_{wm}, HLC_{item})$ (where ε is max NTP clock skew[1]) then the cache item is fresh
2. Otherwise, the cache item is stale and needs to be refilled

Note that TAO uses the max of the watermark and cache item HLC. In some instances, the cache item HLC may be older than the staleness bound. This does not necessarily mean that the item is stale – it may simply have not been written recently. The replication watermark helps TAO prove these cache items as up to date.

This condition can be checked upstream all the way to the primary DB, where the data is guaranteed to be fresh. This check is local to each cache host, meaning it adds minimal overhead to reads. However, this baseline implementation causes significant operational issues. It is not fine-grained – if the shard temporarily lags beyond the staleness bound, TAO will treat *all* data on the shard as stale and go upstream to guarantee freshness (even though all data has likely not changed). This degrades TAO into a proxy rather than a cache. It can also add significant latency as requests that should be served locally may be forced to go cross-region. Finally, it creates thundering herds [37] on the primary, adding additional DB load and potentially exacerbating replication lag.

Importantly, almost all cache misses due to staleness in this implementation are false positives. Because Meta's workload is highly read-skewed, most data on a shard has not been recently written and is actually up to date. The problem is TAO does not have fine-grained information about which particular cache items have changed since the last replication watermark. What TAO needs is a *staleness oracle* to identify which cache items have been recently written. When the replication stream is lagging, TAO could check the oracle to see whether a cache item has recently changed. This would allow TAO to filter out spurious staleness misses and only refill data that is truly stale.

3 Design

Skybridge's goal is to be a fine-grained staleness oracle for TAO. When TAO receives a read request for a cache item and the replication stream backing that item is lagging, TAO consults Skybridge to determine if the item has recently changed. Skybridge responds with HLCs of writes to that item, if any; usually, however, it responds there are no recent writes. With this information, TAO can figure out whether the cache is up to date or whether it needs to refill from upstream. TAO, Wormhole and Skybridge work together to enforce 2-second bounded staleness by default for all reads.

Skybridge is complementary to the existing Wormhole replication stream, helping make bounded staleness enforcement precise and scalable. Wormhole is able to replicate most DB updates within 2 seconds. Skybridge provides the most benefit for the problematic long tail of lagging shards, where Wormhole's strong replication guarantees cause lag. Skybridge implements an independent replication pipeline and is designed to avoid the same sources of replication lag. Skybridge achieves this by relaxing its replication guarantees, which allows it to focus on real-time replication instead of durability and in-order delivery.

Skybridge has several other goals in order to support bounded staleness checking for TAO's workload. Checking against Skybridge must be low latency, as TAO cannot spend significant time doing expensive bounded staleness checks that regress request latency for clients. Additionally Skybridge must prevent as many spurious upstream fills as possible, both to avoid cross-region latency and to avoid overloading the upstream path. This means that the vast majority of bounded staleness checks must be satisfied locally on TAO hosts. Finally, Skybridge should ideally require significantly fewer resources than either TAO or Wormhole so that it can be efficiently deployed alongside existing systems.

We first describe Skybridge's replication semantics. Then, we describe Skybridge's architecture and how it implements this semantic to enforce bounded staleness.

3.1 Replication with gap detection

Skybridge implements a replication semantic called *replication with gap detection* (RGD). Systems that implement RGD have several unique properties that avoid common sources of replication lag while still enabling caches like TAO to enforce bounded staleness.

Replicating write metadata. The first property relates to who is responsible for filling stale cache entries. RGD systems only focus on identifying which cache items are stale. They leave the responsibility of refilling cache to others, e.g., TAO's upstream fills. RGD systems only need the *write metadata*, i.e., cache key (node or edge ID) and DB HLC minted by the DB, to identify stale cache entries. Note that if RGD systems wanted to instead fill cache, they would need to replicate the changed data in addition to metadata. This would require significantly more CPU, memory and network resources. Additionally, this effort would be mostly wasted – recall from Section 2.2 that most cache items are up to date even if the backing replication stream is lagging. Only a small number of reads would actually use the changed data. It is more resource efficient to instead focus only on replicating write metadata; we evaluate the resource savings in Section 5.3.

[1] If maximum clock skew exceeds ε, TAO may silently violate bounded staleness and return stale data to users. We describe how Skybridge accounts for ε in Section 4.

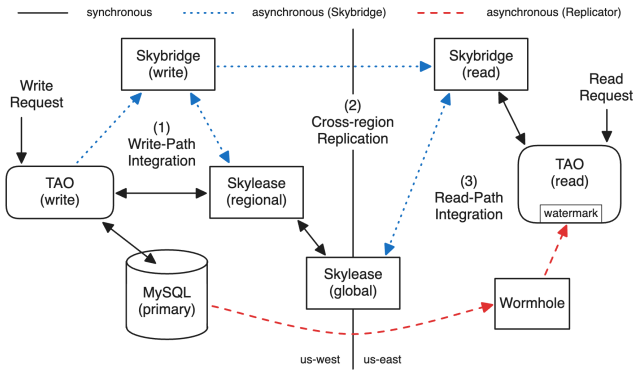

Figure 2: Cross-region replication architecture as (1) Skybridge ingests writes as they flow through TAO, (2) Skybridge replicates metadata across regions, and (3) Skybridge indexes metadata for reading from TAO.

Known data loss. The second property is that RGD allows data loss as long as it is detectable. When using an RGD system to check staleness, caches expect a "yes, write at HLC X" or "no recent writes" answer. However if the RGD system reports an "indeterminate" result (i.e., it is missing data), the cache can always conservatively assume it is stale and refill the entry. While the cache may have been unnecessarily refilled, the system as a whole still enforces bounded staleness. The system is correct as long as the RGD system can reliably detect when it is missing data. If, however, the RGD system cannot detect when it is missing data, it may falsely report "no recent writes" to the cache. The cache would silently return stale results to clients in violation of bounded staleness. Therefore the RGD system must be able to detect these "gaps" in order to provide bounded staleness. Note that this property follows directly from the first – data loss is allowable because the RGD system is not responsible for filling cache (the cache provides its own refill mechanism).

Out-of-order replication. The third property is that RGD allows out-of-order replication. This is possible because the data in the replication stream is a conflict-free replicated data type (CRDT) [55]. CRDTs are replicated data structures whose replicas are guaranteed to converge to the same state once all updates have been delivered, regardless of the delivery ordering. This requires updates be idempotent, associative and commutative. Because RGD systems implement a CRDT, they can replicate data in whatever order is most effective.

RGD replication streams are add-only set CRDTs [55] containing write metadata represented by <*key*, *HLC*> tuples. Essentially RGD systems implement a set that only ever accumulates knowledge of recent writes. The order in which write metadata is added does not matter – the set will have the same state if write A is added before write B or vice-versa. Additionally, the set will de-duplicate write metadata added more than once since the set already contains the tuple.

At read time, clients query the RGD system by *key*. If there are multiple <*key*, *HLC*> tuples in the set, the writes are merged using a last-write-wins strategy [50]. This is because the RGD system's only responsibility is to give the cache the versioning information required to produce a bounded staleness-compliant refill. Only the latest HLC matters – all previous writes will be reflected in the latest write. The RGD system returns the max of all found HLCs in order to make sure the cache observes the latest update.

Putting it all together. These three properties allow Skybridge to focus on replicating metadata about the most recent writes while de-prioritizing or even dropping older data. Skybridge's replication stream is significantly smaller than traditional replication streams and side-steps many of the traditional sources of replication lag. Because of these properties, Skybridge can focus on real-time replication of write metadata in under two seconds.

3.2 Skybridge architecture

Figure 2 shows an overview of Skybridge's architecture. Skybridge has three main components: 1) an integration with TAO's write tier to ingest write metadata about all DB writes, 2) a replication layer to fan-out write metadata to all read regions, and 3) an integration with TAO's read tier to check which cache items are stale.

Skybridge's write path (Section 3.4) ingests write metadata from TAO writers and detects gaps in the ingestion. Skybridge uses leases, which indicate when a TAO writer may write to a shard, to determine data completeness. Skybridge's client inside of TAO writers is responsible for opening leases with a system called Skylease and batching writes to send to Skybridge. Skybridge's write path receives these batches and reads lease holders from Skylease to determine when it has complete data and is therefore safe to replicate downstream.

Skybridge's replication layer (Section 3.5) is responsible for real-time replication of write metadata from the write path to the read path. Skybridge uses a pull-based model for replication – Skybridge readers pull batches of writes from the write path. This gives readers the flexibility to prioritize what data to fetch, including focusing on the newest metadata and de-prioritizing older data. The replication layer is designed to search for write metadata across multiple replicas, including write-path hosts and in-region read-path peers. If a particular window of data cannot be replicated, the replication layer will eventually give up and move on to newer data.

Skybridge's read-path (Section 3.3) indexes write metadata about all recent writes to all shards performed globally. Skybridge's indexes are designed for fast querying from TAO's read handling request path. TAO readers implement bounded staleness checks by first comparing replication watermarks to the staleness threshold (Section 2.2). If the cache item cannot be proven fresh, TAO calls into the Skybridge client for fine-grained checking. Skybridge's client sends requests to Skybridge to determine whether a cache item is stale. Addi-

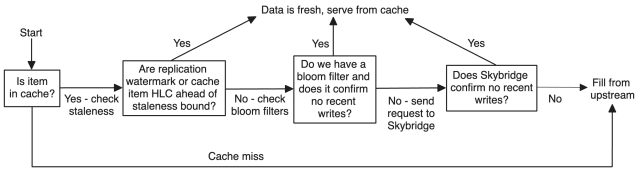

Figure 3: Request handling flow for TAO reads

tionally the client preloads Skybridge's indexes on the TAO host for lagging shards to minimize the number of required external requests. If Skybridge reports the item is stale or if Skybridge has missing data, TAO goes upstream to refill cache. Otherwise TAO serves the cache to clients.

3.3 Read path

TAO interacts with Skybridge during handling of read requests. The main goal is to determine whether the item that TAO has in cache is fresh with respect to the 2-second staleness bound. TAO achieves this through a combination of Wormhole watermarks, Skybridge requests and local caching of Skybridge metadata. This checking is designed to be precise and lightweight, limiting bounded staleness cache misses only to those cache items that have actually recently changed and without adding significant cache request latency.

Figure 3 shows TAO's bounded staleness control flow. First, TAO checks whether the item is in cache; if it is a cache miss, bounded staleness checking is not required. Next, TAO constructs a cache HLC, HLC_{cache} from the max of the watermark and cache item HLC (Section 2.2). If the physical component of this HLC is newer than the staleness bound, the item is fresh and TAO returns it to the caller. If not, TAO consults with Skybridge to determine whether the item was written between $[HLC_{cache}, StalenessBound]$, where $StalenessBound = Time_{now} - (2\ seconds - \varepsilon)$. This interval is referred to as the *lag interval*. Listing 1 shows the two Skybridge APIs that TAO uses to check whether there were any recent writes to the cache item within the lag interval.

Querying recent writes. Skybridge's main API, `getWrites`, takes a cache item key and lag interval as arguments and returns the latest HLC of all DB writes to that key within that interval (TAO also supports range scans [47], for which Skybridge returns the latest HLC for all keys in the range). `getWrites` also indicates whether it had complete data for the interval (discussed further below). If Skybridge's indexes were complete then TAO compares the cache HLC to the list of recent HLCs. If there are no recent writes or if the cache HLC is greater than any HLC in the list, then TAO can serve the data. If Skybridge returns an HLC higher than the cache HLC, TAO sends an HLC-conditional request upstream with that HLC; any upstream host that satisfies the HLC can fill the data. Finally, if Skybridge's indexes are incomplete or there was an error talking to Skybridge, TAO refills from upstream using *StalenessBound* as the condition. Note that Skybridge is only checked by the first cache host – other upstream hosts simply forward the request upstream if their cache HLC is too old. It adds too much latency to re-check Skybridge on every hop.

Bloom filters. TAO can only send `getWrites` requests to Skybridge after calculating cache HLCs, meaning Skybridge requests are on the cache read request critical path. However, TAO can actually predict when it will have to start checking staleness with Skybridge by monitoring replication stream lag. If TAO can proactively load Skybridge's indexes for lagging shards, it can perform staleness checks locally rather than sending requests to Skybridge. The main downside of this approach is that even though Skybridge's indexes are small, they are still large enough to compete with TAO's caches for memory. Storing Skybridge's indexes locally could regress TAO's hit rate and cache request latency.

Instead, Skybridge uses bloom filters [58] built from its indexes. Bloom filters can have false positives, i.e., the bloom filter may indicate the data has changed even when it actually has not. The bloom filters do not, however, have false negatives. This allows TAO to correctly enforce bounded staleness. The set of recent writes on a shard is sparse, meaning the generated bloom filters are minimal in size. TAO pre-loads bloom filters for lagging shards, helping prove a significant portion of read requests up to date without having to send a request to Skybridge. This also significantly reduces the request load on Skybridge. Note that Skybridge only sends bloom filters for complete windows; there is no reason to send them for incomplete windows since TAO would have to consult Skybridge or go upstream anyway.

Listing 1 shows Skybridge's bloom filter streaming API. Skybridge chunks its indexes into discrete intervals and builds bloom filters that are continuously streamed to clients. TAO monitors replication lag across all shards and opens a bloom filter stream for a shard when its replication watermark is older than 1.5 seconds. This allows TAO to pre-load bloom filters for checking if lag increases beyond 2 seconds. When the replication stream's lag drops below 1.5 seconds, TAO closes the bloom filter stream.

Similarly to `getTicket` requests, TAO checks local bloom filters for writes within the lag interval. If TAO has bloom filters covering the entire lag interval and they indicate no recent writes, TAO can prove it has fresh data and serve it from cache. Otherwise, TAO sends a `getTicket` request to Skybridge to get a definitive answer.

Skybridge server-side indexes. Skybridge's indexes are sharded by DB shard and store *write windows*. A write window is composed of a lower HLC bound, an upper HLC bound and a list of write metadata for all writes to that shard performed in that write window. Skybridge hosts replicate metadata from DB primary regions, where TAO hosts publish metadata about writes they performed to the local Skybridge tier. `getTicket` requests scan write windows overlapping the lag interval to search for any writes to the specified cache key.

```
struct Interval{i64 lower; i64 upper;};
struct Response{
  list<tuple<string, i64>> hlcs; bool complete;};
struct BloomFilter{
  Interval interval; binary serializedFilter;};
// Read recent writes from Skybridge
Response getWrites(string key, Interval lag);
// Stream bloom filters from Skybridge
stream<BloomFilter> openBloomFilterStream(
  i64 dbShard, i64 start);
```

Listing 1: Skybridge read API. TAO can request recent writes for a key and interval or stream serialized bloom filters constructed from Skybridge's indexes.

When responding to queries, Skybridge needs to determine whether it has complete knowledge of all writes to a shard (i.e., no gaps). Given a lag interval I_{lag}, index interval I_{index} (formed by the union of all write windows indexed by Skybridge), and write window D, Skybridge has complete data if:

1. $I_{lag} \subseteq I_{index}$ (the lag interval is covered by write windows indexed by Skybridge)
2. For all $D \in I_{lag} \cap I_{index}, D.complete = true$ (all indexed windows covering the lag interval are *complete*)

If both criteria are satisfied, Skybridge has complete information about every write to the shard for the lag interval and can provide definitive cache freshness answers to TAO. Section 3.4 describes how Skybridge's write-path integration determines whether write windows are complete and Section 3.5 describes how Skybridge drives replication of write windows from primary regions for every DB shard.

3.4 Write path

Skybridge's goal on the write path is to ingest metadata about all writes committed to the DB. Skybridge ingests write metadata by collecting *heartbeats* from TAO write hosts. TAO writer heartbeats are defined by a lower and upper HLC bound and a list of writes committed by that TAO writer within those bounds. TAO writers guarantee that heartbeats sent to Skybridge contain all writes to the DB performed by that writer during that interval. Skybridge hosts aggregate heartbeats from TAO writers into write windows to publish downstream.

Skybridge uses a leasing system called Skylease to track which hosts are writing to which shards. Any single TAO writer only serves traffic for a small fraction of DB shards. Leases [24], which indicate the time period when a writer may be writing to a shard, make heartbeating efficient by only requiring TAO writers to send heartbeats for shards they own (i.e., avoid sending heartbeats from the cross-product of TAO writers and DB shards). Skybridge's client is responsible for opening leases on hosted shards and batching write metadata into heartbeats to send to Skybridge. Skybridge must collect heartbeats from all of a shard's lease holders, i.e., writers, in order to have complete data for that shard.

Leases. Leases are a contract between TAO writers and Skybridge. A writer is only allowed to write to a shard if it has an open lease and the host promises to send heartbeats for the duration of the lease. If for whatever reason a lease holder fails to send a heartbeat (e.g., host crash), Skybridge will detect data loss by observing a gap in expected heartbeats. This is the core of how Skybridge implements replication with gap detection's known data loss guarantee.

Leases are denoted by a *lease holder* (e.g., TAO host), *lease object* (e.g., DB shard) and HLC interval. Leases are non-exclusive since multiple TAO writers may be handling writes for a given DB shard for higher availability. Lease HLC ranges are minted by Skylease hosts based on their physical clock and the lease duration requested by the client, i.e., $[Now, Now + Duration)$. We describe why using physical clocks does not violate correctness below.

Skylease must be 1) highly available to avoid blocking write handling, 2) durable to avoid losing leases and causing unknown data loss, 3) strongly consistent so that Skybridge knows the exact set of lease holders at a given time, and 4) scalable to leases on millions of lease objects. To satisfy these requirements, Skylease acts as a batching and sequencing control plane on top of strongly-consistent distributed consensus systems like Apache Zookeeper [60] or Delos [8].

Skylease employs a number of techniques to scale heavyweight consensus rounds to millions of leases. First, Skylease's protocol uses delta compression [30]. Because a writer's shards do not frequently change, Skylease's protocol only records changes between subsequent open lease requests. Second, Skylease scales out by using its own sharding, where lease objects are hashed to a Skylease shard and each Skylease shard is backed by a consensus group. Finally, Skylease batches writes to a Skylease shard from multiple writers to reduce the number of consensus rounds.

Skybridge must handle the situation where reading lease holders races with writers opening leases. For example, if a TAO writer is allowed to open a lease on a shard after Skybridge has read the lease holders, Skybridge could experience unknown data loss by missing a lease holder and therefore missing heartbeats. To prevent this situation, Skylease periodically *seals* leases on a shard by bumping a monotonically increasing watermark as part of consensus rounds. This watermark represents the lowest valid HLC of any newly opened leases. If a TAO writer tries to mint a new lease with an interval below or overlapping the watermark, Skylease rejects the lease by sequencing the operation through storage. Skylease also responds to Skybridge queries (e.g., "read lease holders for shard S between $[T_x, T_y)$") with "not sealed" until the interval is completely sealed. This ensures Skybridge sees the full lease holder set when building write windows.

Skylease maintains an in-memory view of lease holders, including materializing the current watermark and full set of TAO leases from delta compressed storage. Read queries against this view are fast enough to allow frequent polling by

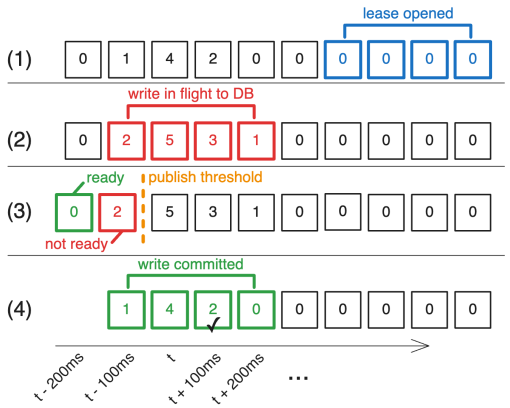

Figure 4: Skybridge's client maintains heartbeats (shown as boxes) sorted from old to new with counts of in-flight writes. (1) Leases opened with Skylease are divided into heartbeats and added to storage. (2) Before writing to the DB, TAO acquires and creates HLC bounds from heartbeats. (3) The client asynchronously scans for heartbeats to publish that are older than a threshold and do not have any in-flight writes. (4) After the write is committed, TAO releases heartbeats and stores the write in the appropriate heartbeat (check mark).

Skybridge until the queried interval is sealed. Skylease maintains watermarks per Skylease shard; watermarks apply to all lease objects on the shard. When advancing the seal watermark, Skylease keeps the new watermark behind the current physical time to avoid impacting open lease availability.

Building heartbeats. Leases ensure Skybridge is able to determine which writers should be sending heartbeats for which shards. TAO writers are responsible for sending complete heartbeats for the entire opened lease duration to Skybridge. A heartbeat H is *complete* if all writes W committed by the writer between the heartbeat's lower and upper HLC bounds are contained in the heartbeat's write set:

For all W such that $H_{lower} \leq W.hlc < H_{upper}, W \subseteq H.writes$

Note that this implies that once a heartbeat is sent to Skybridge, no more writes may be committed within that heartbeat's bounds so as to avoid violating the completeness property for the sent heartbeat.

TAO writers must only write to the DB within valid lease bounds to ensure that Skybridge correctly tracks all writers. To achieve this, TAO writers call into the Skybridge client before writing to the DB in order to read the current lease or block until one is acquired. TAO then attaches the lease HLC bounds to the DB request. Meta's MySQL deployment allows specifying HLC bounds on transactions – if the HLC minted by the DB for a transaction does not fall within the bounds, MySQL will abort the transaction. This ensures MySQL respects the leases opened by TAO writers. This HLC coordination with the DB is why it is okay to mint leases based on Skylease host physical times - the HLC bounds will ensure the write falls into the appropriate time range.

In order to build complete heartbeats, Skybridge's client 1) maintains HLC bounds for DB write requests to avoid minting new write HLCs outside of leases or already-sent heartbeats and 2) tracks outstanding writes (including in which heartbeats a write may land). The Skybridge write client achieves both goals using an *in flight write* storage for tracking heartbeats and writes. This data structure maintains a list of heartbeats to be sent to Skybridge for each DB shard. Each heartbeat in storage tracks how many in-progress writes that could land within that heartbeat's bounds. This storage ensures heartbeats are complete before being sent to Skybridge.

Figure 4 shows how the client uses this storage. (1) shows heartbeats getting added to storage based on leases opened with Skylease. Each lease gets divided into smaller discrete heartbeats since lease durations are much longer than individual heartbeats. The heartbeats in storage are what TAO promised to send to Skybridge but has not yet sent. Any interval outside of storage either does not correspond to an open lease or represents a heartbeat that has already been sent to Skybridge. In other words, future writes to be committed by the DB must land in one of the heartbeats in storage.

(2) shows a write request coordinating with the storage before going to the DB. The client generates HLC bounds for the transaction based on heartbeats in storage. To track outstanding writes, the client *acquires* heartbeats in which the write could land. This operation (maintained as a reference count on the heartbeat) blocks the heartbeat from being published until the write has been committed by the DB. (4) shows the post-DB processing – all heartbeats acquired in (2) are *released* and the completed write's metadata is stored in the heartbeat containing its HLC. If there was an error writing to the DB, the heartbeats are simply released without storing any metadata. While the client could acquire every single heartbeat in storage, most writes have HLCs that fall within a narrow range of heartbeats near the current physical time. The client is configured to only acquire a small subset of heartbeats, which also helps prevent straggler writes from blocking large numbers of heartbeats from being published.

(3) shows how the client determines when heartbeats are ready to be published to Skybridge. The client periodically scans all shards in storage looking for heartbeats that are older than a publish threshold (which lags the host's current physical time) and that do not have any outstanding writes. If there are still writes in flight that may land in a particular heartbeat, the client skips it. Otherwise the heartbeat is dequeued from storage and sent to Skybridge. At this point the heartbeat is sealed and all future writes will be prevented from landing in it through the HLC bounds created in (2). Note that the client takes advantage of out-of-order publishing to avoid delaying the sending of heartbeats. The client can send any heartbeat once it is ready for publishing, even if there are older heartbeats blocked due to straggler writes.

Tuning lease and HLC bound sizes. Lease durations and HLC bounds represent a trade-off between Skylease load and "blast radius" for when things go wrong. Lease duration should ideally be as low as possible, but is bounded by how quickly Skylease can run consensus rounds. Alternatively, TAO could open very long leases, e.g., on the order of minutes, to minimize Skylease load. However if the TAO host crashed shortly after opening a long lease, Skybridge would have minutes of data incompleteness. Similarly, for heartbeats acquired before going to the DB, the bounds should be as small as possible to minimize the number of heartbeats blocked on stragglers, but large enough to give the DB ample time to process the write (too small HLC bounds will cause spurious aborts). The Skybridge client is tuned to open leases on the order of tens of seconds and acquire HLC bounds on the order of hundreds of milliseconds.

Aggregating heartbeats. Skybridge aggregates heartbeats from in-region writers into write windows for a shard by 1) polling Skylease for the (sealed) list of all lease holders, and 2) waiting for heartbeats from TAO writers covering those leases. Skybridge knows it has a complete write window D if for Skylease watermark $S_{watermark}$ and heartbeats H corresponding to lease L:

1. $D_{upper} < S_{watermark}$ (Skylease has sealed the lease holder set past the write window's bounds)
2. For all L such that $D_{lower} \leq L_{lower} < L_{upper} \leq D_{upper}, H_L \subseteq D$ (Skybridge has all heartbeats from all lease holders for the write window interval)

Once Skybridge has all heartbeats from all lease holders for a given shard and interval, it builds a complete write window ready for publishing. Skybridge is configured with a timeout on how long it will wait for heartbeats. If the timeout expires and it still has not received all heartbeats, Skybridge will publish an incomplete write window to give subscribers some information about recent writes. Skybridge will, however, continue waiting and if the heartbeats later arrive it will republish the complete window downstream. Skybridge again takes advantage of out-of-order replication to avoid blocking complete windows from replication if an older window is waiting for data from TAO.

3.5 Cross-region replication

Skybridge's replication layer is responsible for replicating write windows from all primary regions to regions serving read traffic within 2 seconds. While Skybridge's correctness criteria allows gaps, Skybridge tries to replicate complete data as frequently as possible to be effective on TAO's read path. Because of the real-time nature of replication, Skybridge's replication layer fetches missing data out of order and from multiple replicas using a publisher-subscriber [3] model.

While TAO writers push windows to the local Skybridge tier, cross-region subscribers pull a continuous stream of write windows from publishers to fill their indexes. Using a pull model gives subscribers the ability to quickly detect gaps and re-fetch windows from another source. Because write windows are conflict-free replicated data types, subscribers have a lot of flexibility to reorder and retry data fetches. Using a push model would require publishers to discover missing data from subscribers, requiring too much coordination.

The replication layer builds a continuous stream of write windows with newer windows sent first. Early versions of the replication layer opened a single long-lived stream per shard using a protocol similar to gRPC streams [25]. However Skybridge frequently experienced head-of-line blocking and could not prioritize newer data while the stream tried to flush out older windows. Additionally, long-running streams caused load imbalance over time as Skybridge deployments rotated hosts through maintenance. Long-lived publishers accumulated more streams and eventually became overloaded until they were restarted (and streams moved to other hosts).

Instead, Skybridge's replication layer opens short seconds-long streams. This gives more load balancing opportunities across publishers and allows subscribers to de-prioritize older sections of the stream by either delaying re-fetching them or not re-fetching at all. Subscribers periodically open new streams to primary regions to stream the most recent data. Publishers may send write windows out-of-order, publish duplicate or incomplete windows or even leave gaps. None of these block subscribers from continuing to stream newer data. However when a subscriber detects missing data (e.g., an incomplete write window), it schedules another attempt to stream the data after some delay. This helps when heartbeats from TAO are delayed, e.g., blocked waiting on a DB write. Additionally this allows subscribers to try re-fetching from other sources. Each primary region contains two Skybridge replicas, meaning there are two possible sources of writes. In-region replicas ("peers") will also exchange write windows, which helps quickly warm up Skybridge hosts after a restart.

Finding primary regions. Subscribers need to know each shard's primary region in order to fetch that shard's writes. Similarly to TAO's write path, Skybridge uses leases at the global level to track each shard's primary region. For Skybridge to guarantee completeness, regional leases must only be opened within a global lease and therefore the region must have a global lease before any regional leases can be opened. When handling an open lease request from TAO, regional Skylease hosts implicitly open global leases for the DB shard and region with Global Skylease. Global leases are typically opened for much longer intervals (e.g., on the order of minutes) as shards rarely move between regions.

Subscribers drive replication for a shard by reading global leases from Global Skylease. The replication layer uses the region name (i.e., lease holder) and lease bounds to stream data from the appropriate primary region.

4 Implementation

Skybridge provides a means for TAO to enforce bounded staleness on read requests. Below we discuss a number of practical considerations regarding TAO and Skybridge.

Circuit breakers. Although TAO aims to provide bounded staleness for all requests, Skybridge cannot regress TAO's availability and performance. On the write path, too many writes blocked waiting for leases from Skylease will trip a circuit breaker and TAO will let writes proceed without leases. Similarly, too many read requests trying to go through the high-overhead portion of bounded staleness checking (requests to Skybridge, consistency misses upstream) will trip a circuit breaker and TAO will serve whatever is in cache. These circuit breakers prevent cascading failure modes. For example, if there is widespread Wormhole lag, bounded staleness checking can create a thundering herd on the upstream path towards the DB which could make lag worse.

TAO "fails open" when tripping circuit breakers. TAO fires an alarm whenever these rate limits are hit to notify Meta engineers about issues that need investigation. In fact these alerts have notified us about Wormhole and TAO problems before either of the teams knew there was an issue.

Fail-closed vs. fail-open While TAO defaults to failing open if it hits rate limits, sometimes product developers want stronger consistency at the expense of availability – they would prefer the request failed if TAO cannot guarantee bounded staleness. TAO provides a "fail-closed" API for this scenario. Clients opt in to the API by setting a flag on the TAO request that tells TAO to fail the request if it cannot guarantee bounded staleness. TAO reserves a portion of its rate limit budget for fail-closed requests to prioritize their availability.

Extended retention Skybridge is an in-memory service and is memory-capacity bound (see Section 5.3). Skybridge adjusts retention of its indexes to keep memory usage stable as write traffic fluctuates over time. Skybridge maintains a baseline retention for all DB shards, but TAO shard lag is not uniform – individual shards may have worse lag than others. Skybridge can selectively extend retention for a small set of these longer-lagging shards. Skybridge detects these shards based on TAO queries – if it sees multiple requests for a shard where the lag interval is approaching retention limits, Skybridge marks the shard as "extended" and maintains write windows for that shard for a significantly longer interval.

Clock skew Meta's hosts use NTP [42] to synchronize physical clocks. NTP is known to have on the order of hundreds of milliseconds of clock skew. Meta is investigating using more precise clock synchronization such as PTP [46, 54], but for now we move the staleness bound forward by 50ms to try to account for clock skew.

Emulating primary-only and causal reads TAO provides linearizable reads that bypass cache and read from the primary DB. To avoid DB overload issues, TAO actively discourages using them unless absolutely necessary. With fail-closed bounded staleness reads, however, TAO has a lightweight drop-in replacement. When clients call this replacement API, the web server sleeps for 2 seconds to wait out the staleness bound and then sends a fail-closed request to TAO. TAO either guarantees consistency or returns an error to the client if it cannot (e.g., hit upstream rate limits or network errors). This means clients get linearizable reads. Similarly, bounded staleness can provide a limited form of causal reads. If the client knows when a write occurred (i.e., HLC of the write) then it can wait until 2 seconds have passed to perform the read. TAO and Skybridge will ensure the write is visible. These APIs are highly efficient from TAO's perspective since the client waits for replication and TAO likely serves data from cache.

Clients can also use these APIs as a stronger backup when regular reads are not able to see a relevant write. Clients first issue a regular read, which succeeds most of the time. On the infrequent occasion that TAO is stale (e.g., clients do not see an object they created), they wait for 2 seconds then retry the read with stronger consistency. Bounded staleness enables these new APIs without any external synchronization or forcing clients to pass around HLCs.

Failure scenarios and fault tolerance. Like most distributed systems, Skybridge must contend with single-node failures. However, because of replication with gap detection semantics, individual Skybridge host failures do not cascade into replication lag or other outages. Skybridge's replication layer is resilient to these issues. There are multiple Skybridge write-path hosts per DB replica from which downstream subscribers can stream updates. Similarly, there are multiple Skybridge read-path hosts per DB replica from which TAO readers can open bloom filter streams and query for recent writes. Skybridge's replication layer is free to stream updates from multiple sources in whatever order is best.

While network partitions between TAO and Skybridge are technically feasible, we have not noticed them. Region drains and cuts are more likely in practice, especially as part of routine testing [10]. However, Skybridge's leasing system gracefully works around them. Recall that TAO writers (and Skybridge write-path hosts) are co-located in the same region as primary DB replicas. During a region cut, the region no longer receives any write requests. TAO writers no longer open leases and subscribers stop attempting to subscribe to updates from that region soon after. Therefore Skybridge, TAO and MySQL all share the same fate in a region outage and Skybridge in other regions still functions correctly.

Skybridge's read path has showcased several priority inversion [4] failures. A priority inversion exists when a higher priority task is impacted by a lower priority task. For Skybridge's read path, this manifests as read traffic from TAO affecting Skybridge's replication health. This typically occurs when Skybridge hosts have temporary spikes of incomplete data (e.g., a TAO writer crashing leading to a gap). In this scenario, Skybridge cannot send bloom filters to TAO since

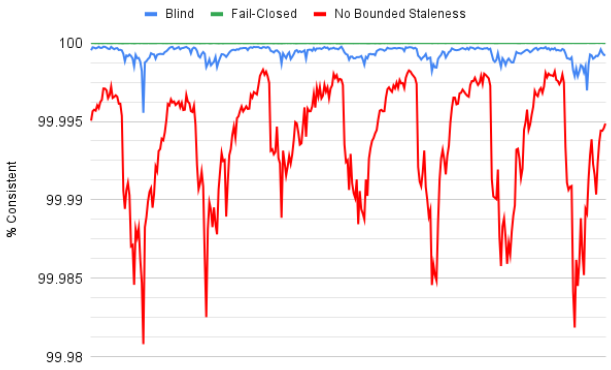

Figure 5: Bounded staleness consistency over 7 days with no bounded staleness (red), blind (blue) and fail-closed (green) reads. TAO's 2-second consistency without Skybridge is 99.993% but frequently drops below 99.985%. Skybridge significantly increases consistency to 99.9993% for blind and 99.99998% for fail-closed reads.

it has incomplete data. This causes TAO hosts to fall back to `getWrites` queries to Skybridge. `getWrites` queries are more expensive than publishing bloom filters, especially since bloom filters help TAO elide further `getWrites` calls. The increase in `getWrites` traffic starves hosts of processing resources to drive replication, leading to more data incompleteness, fewer bloom filters and more `getWrites` traffic. Skybridge gets stuck in a metastable failure state [29] in which the service is degraded until remediated by outside intervention. To avoid this cycle, we added a priority queue for threads in Skybridge hosts to prioritize replication, then bloom filter streams and finally `getWrites` traffic. This ensures replication and bloom filter streams are healthy, minimizing the number of `getWrites` calls from TAO.

Similarly, Skybridge write-path hosts also experienced priority inversion. Skybridge write-path hosts ingest heartbeats from TAO writers and publish write windows downstream to subscribers. As mentioned in Section 3.5, the replication layer attempts to re-fetch missing windows. Many downstream subscribers re-fetching data can compete with TAO writer heartbeats, causing Skybridge write-path hosts to drop heartbeats. This causes data loss, leading to more subscribers attempting to re-fetch and further competition for resources. Skybridge again solves this problem using a priority queue to ensure heartbeat ingestion takes precedence over downstream subscribers. Additionally, Skybridge write-path hosts rate limit the number of subscribers re-fetching windows.

Skylease demonstrated another interesting failure mode. When Skylease is unhealthy and cannot provide leasing functionality, TAO writers fail-open on write requests and handle writes without leases. Additionally, Skybridge is not able to read lease holders (since Skylease cannot seal shards), leading to Skybridge publishing all of its write windows as incomplete. Skylease can become overloaded when the mapping of DB shards to TAO writers rapidly changes. For example, in one instance a buggy TAO release caused write requests to get misrouted to TAO writers. Because TAO writers handle misrouted requests to maintain availability, they opened leases for the misrouted requests as well. Skylease's delta compression was ineffective in this situation, leading to a spike in throughput to Skylease's storage backend and out-of-memory crashes when materializing the set of lease holders. This caused excessive downstream incompleteness, leading to a large number of fail-open reads and writes. To prevent this situation, we added rate limits on how many lease changes can be sent per request. While this means there occasionally may be a brief spike in fail-open writes, it ensures Skylease is still able to seal shards and Skybridge is able to publish write windows downstream in a timely manner.

5 Evaluation

In this section we evaluate Skybridge's ability to reliably and efficiently provide bounded staleness for TAO.

Experimental setup. TAO runs in tens of regions around the world, handling millions of write queries and billions of read queries per second. For Skybridge to be effective on TAO's read path, it must be able to improve staleness for recently written data while filtering out almost all spurious staleness misses that would cause TAO to go upstream (and likely out of region). Below we describe Skybridge's effectiveness for Meta's production workload.

5.1 2-second staleness improvements

We built a staleness checking service (referred to as the *checker*) to monitor 2-second consistency. TAO writers send a sample of writes to an in-region checker instance. On receiving a write, the checker sleeps for 2 seconds from the write's HLC and then issues read requests for that write to all TAO tiers in all regions. The checker sends three types of requests:

- **No bounded staleness.** The checker explicitly disables bounded staleness protections. This is what users experience without Skybridge.
- **Blind.** The checker issues a normal read request. TAO implicitly applies bounded staleness protections but can fail open if it hits rate limits.
- **Fail-closed.** The checker issues a fail-closed request – TAO returns an error if it cannot guarantee bounded staleness.

Figure 5 shows the difference in 2-second consistency observed by the checker over a 7 day period. By default, TAO provides 99.993% 2-second consistency relying solely on Wormhole and frequently drops below 99.985%. With best-effort Skybridge, however, consistency jumps to 99.9993%, reducing the number of inconsistent reads without any user intervention. The main limiting factor preventing better consistency is TAO's bounded staleness rate limits, which limit the number of Skybridge and upstream queries and causes

Fail-open reason	% of fail-open requests
Long shard lag	95.9%
No replication stream	3.3%
Skybridge replication lag	0.3%
Missing data from write path	0.2%
Skybridge request error	0.2%

Table 1: Fail-open reasons by % of all fail-open requests

the read to fail open. When the checker opts into fail-closed mode however, the consistency rate climbs to 99.99998%. This means only a couple thousand out of billions of requests are stale after 2 seconds. At this scale, clock skew begins to make a difference (recall staleness thresholds are created by a host's physical time). Additionally the checker does not have a way to opt the associated writes into fail-closed behavior since it only observes writes after the fact, meaning it may be checking writes that are not tracked by leases. Regardless, this number has proven to be high enough to be used by products that require strong consistency guarantees for correctness.

We further investigated the reasons for inconsistency in the blind/fail open case. Table 1 shows fail-open reasons as reported by TAO. The biggest cause of inconsistency was long shard lag. Because Skybridge is an in-memory service, it only maintains the most recent writes (see Section 5.3 below). Skybridge's retention cannot cover shards that are lagging beyond several minutes, meaning TAO must fall back to going upstream. TAO hits upstream rate limits when a significant number of shards lag by more than several minutes.

The next biggest cause of inconsistency is reads to shards without a replication stream, i.e., shards whose load was too low to trigger a subscription (Section 2). Without a subscription, there is no replication watermark and the TAO host cannot check staleness (including using Skybridge) for that shard. The host must fall back to going upstream. Traffic on TAO failover tiers frequently hit these rate limits.

The remaining causes of inconsistency are lag in Skybridge's replication layer, missing heartbeats from TAO's write path and errors talking to Skybridge. Missing heartbeats from TAO writers is outside of Skybridge's control as windows cannot be sent to Skybridge until all outstanding writes are acknowledged by the DB. We are continuing to optimize the replication layer and Skybridge's request handling to address the other two sources of inconsistency, although they comprise only a small fraction of fail-open requests.

TAO's rate limits are tuned to avoid overloading the upstream path and regressing serving latency. Sending too many requests upstream can regress aggregate latency and cause an increase in timeouts for products. Because we wanted bounded staleness enabled by default, we tightened the rate limits to minimize user impact; the current limits strike a good balance between strong consistency without user-visible performance impact.

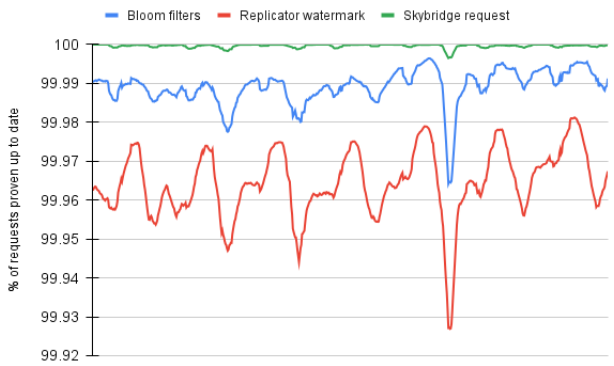

Figure 6: Percent of read queries proven up to date using the Wormhole watermark (red), host-local bloom filters (blue) and an in-region request to Skybridge (green)

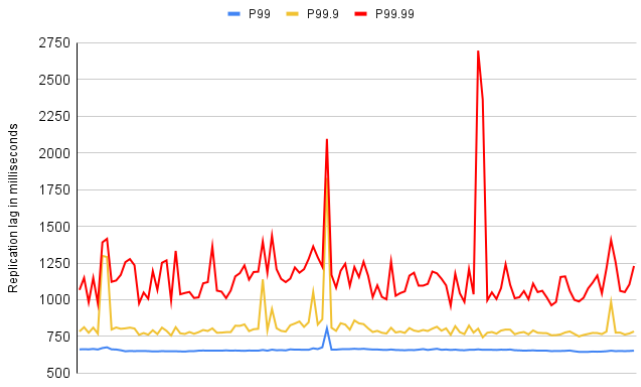
5.2 Traffic analysis

Skybridge helps TAO provide bounded staleness for all read queries because it dramatically reduces the number of queries that must be sent upstream to guarantee freshness. We evaluated how frequently Skybridge is involved in TAO's read handling and how effective Skybridge is in helping filter out upstream requests. Figure 6 shows the percentage of read requests proven up to date solely based on the watermark (i.e., the Wormhole replication stream is not lagging), percent of up-to-date requests with the addition of Skybridge's eagerly-streamed bloom filters (i.e., the bloom filter says there are no recent changes), and percent of up-to-date requests with an authoritative request to Skybridge. Note that these numbers exclude requests to shards without a replication subscription, i.e., load-based subscription.

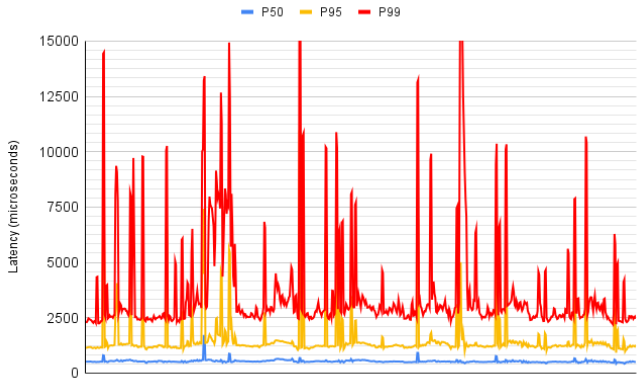
Using Wormhole watermarks allows TAO to prove 99.96% of reads up to date. Checking against host-local bloom filters increases that to 99.98%, meaning tens of millions of additional read queries per second can be proven up to date. Because bloom filters are in-memory on the TAO host, they incur almost no additional latency on the request handling critical path. Including requests to Skybridge, TAO is able to prove 99.9996% of requests up to date. While a request requires a network hop, it is low latency since it is an in-region request. Figure 7b shows P50, P95 and P99 request latency to Skybridge. Requests take on the order of milliseconds, meaning TAO can quickly get a staleness answer from Skybridge. Overall, Skybridge is able to provide staleness bound checking with low-overhead, with only 0.0004% of requests needing to go upstream to get fresh data.

5.3 Replication and footprint

Figure 7a shows Skybridge's P99, P99.9 and P99.99 replication lag, defined as the difference between the Skybridge host's physical time and the upper bound of the replicated



(a) Skybridge replication lag at P99, P99.9 and P99.99



(b) Skybridge latency at P50, P95 and P99 percentiles

Figure 7: Skybridge replication and query performance

write window. P99 replication lag is stable at around 700ms. Even at P99.99, Skybridge is able to replicate windows around the world within 1.5 seconds outside a few spikes. This real-time delivery is a combination of small payload size and out-of-order replication. Delivering 99% of the data in ∼700ms opens up possibilities for sub-2-second staleness bounds. For example, the primary read emulation API could offer tighter latency bounds for use cases that cannot tolerate waiting for 2 seconds, although there may need to be a cap on max throughput to avoid hitting rate limits and triggering errors.

Skybridge requires a relatively small number of servers. The entire Skybridge ecosystem (Skybridge read and write path, regional and global Skylease) uses 0.54% of TAO's server footprint. Skybridge is able to retain between 93 and 109 seconds' worth of recent writes as write traffic fluctuates throughout the day (Skybridge is memory-capacity bound). A single Skybridge tier pulls information about all committed writes from all primary regions, requiring between 4.8-7.9GB/s of network bandwidth. Wormhole's replication stream to TAO, meanwhile, requires between 170-300GB/s. These numbers demonstrate that Skybridge is lightweight compared to TAO and Wormhole.

RGD semantics allow Skybridge to be minimal in size while still providing staleness information about recent writes in real time. Skybridge takes full advantage of its core principles (only replicate metadata, known data loss, out-of-order replication, decoupling from Wormhole) to drastically boost TAO's 2-second bounded staleness up to 99.99998%. It is able to achieve these benefits while helping TAO avoid going upstream for 99.9996% of queries. Skybridge is a reliable and efficient means for boosting TAO's user experience.

6 Limitations and future work

Increased retention. Skybridge's indexes are memory capacity bound and only cover several minutes' worth of replication lag. Increasing the number of hosts or memory capacity per host would boost retention. Another strategy would be to spill older sections of indexes onto disk (e.g., flash drives). This would allow Skybridge to expand retention into the tens of minutes range but would require care to avoid regressing query latency. Other systems like Memcached [20] are able to support disk storage with minimal regressions, meaning it is likely a feasible solution for Skybridge.

Dynamic sharding. TAO statically assigns data to shards, but systems like Cockroach DB [33], BigTable [12], Spanner [16] and TiDB [28] are able to dynamically reshard data to balance load. Skybridge's leasing mechanism could be extended to handle dynamic resharding, but would likely require integration with the resharding control plane to safely coordinate changes.

Global secondary indices. Meta uses global secondary indices [9] to materialize queries that would require many TAO requests, e.g., inverted indexes on fields. A shuffle service ingests updates from Wormhole and generates updates for global secondary index leaf hosts. Skybridge would need to tackle several problems to provide bounded staleness for these indices. First, indexing systems need a way to track a replication watermark across the large fan-in (potentially millions) of input DB shards. Second, indexing systems must have a way to "repair" a given index when determined to be missing some writes (similarly to TAO filling from upstream). We leave both of these problems as future work.

7 Related Work

Strong consistency on eventually-consistent datastores. There are many works that augment eventually-consistent datastores with stronger consistency. Riak [53] and Cassandra [34] provide opt-in linearizability through quorum reads of replicas. Gemini [38] uses logical clocks to direct cross-replica reads for serializability. RAMP [5] (and Facebook's RAMP-TAO [13] variant) provides read atomicity for transactions. All of these these systems require opting in to heavyweight protocols, meaning only a small fraction of requests see improved consistency. Skybridge instead focuses on enabling bounded staleness by default for all reads.

Bounded staleness in datastores. There are a number of datastores that implement bounded staleness. Azure Cosmos DB [41] and Google Spanner [23] implement bounded staleness in multi-region setups. Both datastores provide bounded staleness as an opt-in mechanism and backpressure (i.e., throttle or block) if the local replica is stale. Skybridge instead provides on-by-default bounded staleness for distributed caches, which significantly more traffic.

C5 [26] and CRAQ [59] propose new replication and concurrency protocols for ensuring DB replicas are kept up to date and provide strong consistency. Query Fresh [61], Harmonia [68] and IONIA [62] propose using new networking and storage technologies to either prevent lag or eliminate conflicts between replicas. None of these works address lag in large-scale pub-sub systems such as faulty publishers or network congestion like what is present in Meta's serving stack (and what causes replication lag for TAO).

PolarDB-SCC [64], similarly to Skybridge, uses granular staleness information to allow serving consistent reads from replicas. The main difference between PolarDB-SCC and Skybridge are the target workloads – PolarDB-SCC targets strong consistency for a single DB replicated across multiple machines, whereas Skybridge targets bounded staleness for millions of DBs spread around the world. There are also implementation differences such as deriving staleness bounds by reading from the primary vs. using local physical time and waiting for the replica to become up to date vs. refilling from upstream. Nevertheless, both approaches optimize for workloads where most data on replicas is consistent.

Distributed cache consistency. Web-scale systems [11, 19, 34] frequently optimize for low latency and high availability at the expense of consistency. Many systems use caching to scale out to high throughput with low latency. While some systems use time-based mechanisms like leases [24] or TTLs [63] for cache consistency, others use invalidations [66] to keep caches up to date [11, 18, 56]. Even with invalidation streams, users are subject to replication lag without additional mechanisms for improved consistency. For example, FlightTracker [57] provides RYW consistency for users within a region by maintaining *tickets* representing the user's writes in a lookaside store. Similarly, Antipode [21] provides cross-datastore causal consistency by propagating *lineage metadata* alongside requests. These systems target different points in the consistency spectrum than Skybridge, but share common motivation in improving user experiences in a scalable manner.

Lu et al. [39] describe measuring consistency in Facebook's serving stack using both offline and online checking. Their offline framework reports a significantly lower rate of consistency violations vs. Skybridge's checker – this is likely due to their checker sampling user read requests (which may happen significantly later than writes) whereas Skybridge's checker injects read requests after 2 seconds. Their online checker injects reads similarly to Skybridge's checker and reports a significantly higher rate of inconsistency.

An and Cao describe *monotonic consistent caching* [2], a set of cache eviction policies that take consistency and atomicity into consideration. Like Skybridge, their lazy version selection strategy provides bounded staleness for users. MCC however is focused on cache evictions and targets lookaside cache systems whereas Skybridge targets systems with invalidation streams.

Bounded staleness variations. Bailis et al. describe *probabilistic bounded staleness* [7], a framework for users to determine "good enough" staleness for quorum-replicated datastores. Similarly, Ouyang et al. propose *probabilistic atomicity with well-bounded staleness* [48] for providing a probabilistic consistency level between eventual and strong consistency. While Skybridge does not guarantee bounded staleness by default due to rate limits, it seeks to provide as strong a bound as possible rather than forcing developers to reason about an acceptable probability of enforcement. Additionally none of these works target web-scale workloads like Meta. ACT [65] proposes a framework for application-specific consistency, but requires developers to augment applications to define the logical consistency units. There are other non-web workloads that benefit from bounded staleness, e.g., Cipar et al. [17] propose using bounded staleness for iterative AI algorithms.

8 Conclusion

In this work we introduced Skybridge, a system for providing bounded staleness for distributed in-memory caches. Skybridge acts as a staleness oracle, providing per-cache item staleness information when the DB replication stream is lagging. Skybridge is designed to complement the existing replication stream, optimizing for a flexible and compact replication format that enables real-time replication. Skybridge is efficient enough to enabled by default on billions of read requests per second, while simultaneously requiring only a small fraction of hosts. Skybridge is also effective, helping boost TAO's 2-second consistency up 99.99998%. Skybridge can provide significant developer and user experience benefits for Meta.

Acknowledgments

We would first like to thank the anonymous SOSP reviewers, OSDI reviewers and our shepherd Michael Stumm for their technical and editorial insights on improving the paper. We would also like to thank Audrey Chang, Aaron Kabcenell, Shilpa Lawande and Matt Pugh for their thorough review of the paper. Finally we would like to thank Amol Bhave, Arthur Charlton, Jinyu Han, Anwesh Joshi, Qiegang Long, Morgan McLain-Smith, Tushar Pankaj and Ilya Smirnov for their technical contributions to the systems in this paper.

Abstract

In this work, we propose KPerfIR, a novel multilevel compiler-centric infrastructure to enable the development of customizable, extendable, and portable profiling tools tailored for modern artificial intelligence (AI) workloads on modern GPUs. Our approach integrates profiling capabilities directly into the compiler workflow, allowing profiling functionalities to be implemented as compiler passes, offering a programmable and reusable framework for performance analysis. This design bridges the gap between compilers and profilers, enabling fine-grained insights into complex optimization challenges such as overlapping the execution of fine-grained function units on GPUs. KPerfIR is integrated into the Triton infrastructure to highlight the power of a compiler-centric approach to advance performance analysis and optimization in the ever-evolving landscape of AI compilers. Our evaluation shows that our tool incurs low overhead (8.2%), provides accurate measurements (2% relative error), and delivers actionable insights into complicated GPU intra-kernel optimizations.

1 Introduction

In the era of artificial intelligence (AI) [27], the popularity of AI compilers has increased dramatically [7, 13]. Modern AI compilers, such as Triton [47], have become popular in bridging the gap between high-level machine learning framework operators (e.g. general matrix multiplications (GEMMs) [31], softmax [40], etc.) and the low-level, target-specific machine code [35]. The diversity of workloads and the rapid evolution of hardware architectures, particularly in GPUs, pose significant challenges in developing frameworks that are both modular in development and performant "out of the box" for users. Addressing these demands requires a flexible compiler infrastructure, like LLVM [25]'s Multi-Level Intermediate Representation (MLIR) [26] with a modular design, and Triton for its customizable high-performance AI operators for diverse workloads and backends.

Despite significant advancements, existing compilers often struggle to outperform hand-tuned implementations like cuBLAS [31], rocBLAS [6], and CUTLASS [45]. This limitation stems from GPU architectures' rapid evolution and the continuous emergence of novel operator variants. For instance, Nvidia's Hopper architecture incorporates advanced acceleration units such as 5th generation Tensor Cores (TC) [30] and Tensor Memory Accelerators (TMA) [15], which require sophisticated compiler passes to fully leverage their potential with a dataflow-oriented programming paradigm [15]. Meanwhile, the latest Flash-Attention-3 [41] (FA3) kernel, crucial for large language models (LLMs) [11, 46, 51], employs complex tiling and pipelining techniques that traditional compilers cannot effectively handle.

To enhance the compilers with novel compute paradigms and hardware features, profiling tools are critical in developing high-performance AI kernels and optimization passes. They are essential for identifying performance bottlenecks, analyzing execution flow, and understanding memory access patterns. Developers depend on these tools to pinpoint instruction stalls, optimize kernel performance, and refine compiler passes. Even for feedback-guided auto-optimization compilers [52], the design space consists of manually articulated transformation primitives and requires precise performance insights to guide effective optimization. Without effective profiling tools, achieving peak performance on modern GPU platforms becomes a daunting challenge.

However, existing profilers are poorly aligned with the advancements of compiler infrastructure to assist in the development of themselves and AI kernels. **Our key observation is that prior profiler designs are isolated from the compiler system and lack key connections to the upper-level framework operations.** Profiling tools are usually developed as external tools, detached from the intricacies of the compilation process, and fail to provide framework operation-informed, actionable insights tailored to the unique challenges of AI compilers. This disconnection severely hinders the ability of operator and AI compiler developers to enhance the performance of ML workloads.

To address this, we propose a novel compiler-centric infrastructure, KPerfIR, to facilitate the development of customiz-

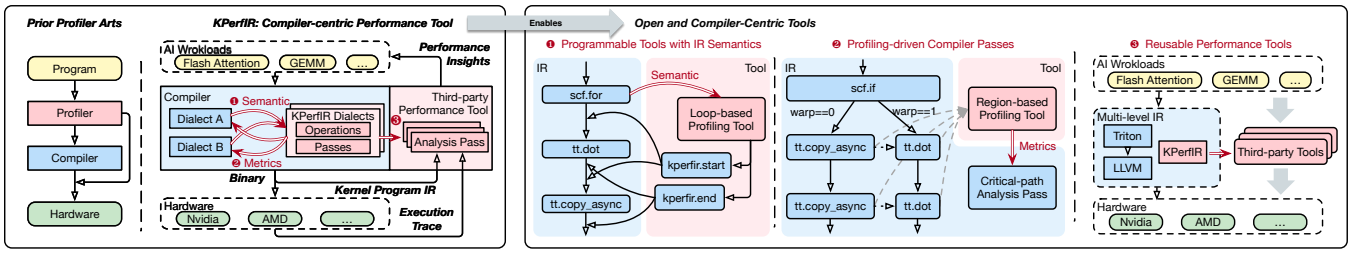

Figure 1: Concept of the KPerfIR infrastructure and ecosystem for compiler-centric performance tool. (Left) Overview and comparison of KPerfIR's compiler-centric design and prior profiler designs. (Right) Demonstrative examples of novel performance tools facilitated by the compiler-centric design of KPerfIR.

able and reusable performance tools[1], as illustrated in Fig. 1. Our approach establishes a seamless interplay between the compiler and profiler, enabling the exchange of program semantics and profiling metrics. Central to our methodology is incorporating multi-level compiler IR instrumentation into the profiling workflow. This allows performance tools to be composed as compiler passes with compiler-integrated profiling operations. This design fundamentally enhances performance tooling in three key ways.

❶ Programmable tools with IR semantics. Existing profilers have limited information on the program, restricting their ability to capture performance details tied to program semantics. For example, traditional tools cannot track how software pipelining [22] overlaps and evolves across pipeline stages due to missing loop-level information. By integrating IR-level instrumentation, KPerfIR enables profiling tools to capture these nuanced behaviors effectively.

❷ Profile-driven design of compiler passes. Many optimization techniques, such as autotuning [14, 43], rely on performance feedback to guide their tuning processes [52]. Traditional approaches treat compilers and profilers as isolated sub-modules, requiring standalone systems to coordinate optimization and evaluation. With KPerfIR, profiling passes can directly interact with compiler optimization passes, streamlining the feedback loop and enabling more optimizations.

❸ Reusable and extendable performance tools. By implementing tools native to the compiler IR, KPerfIR ensures their reusability and portability across frameworks and backends. Profiling tools can operate on shared upper-level representations used by AI frameworks and seamlessly lower to diverse backends, including Nvidia and AMD GPU platforms. Building on the MLIR philosophy of a shared set of infrastructure, we provide not only a powerful set of analysis tools but also a common set of building blocks and infrastructure for a community-driven ecosystem.

To showcase the capabilities of the KPerfIR infrastructure, we present the first region-based timing tool for GPUs to provide insights into intra-kernel behaviors. By leveraging the program's IR semantics, the tool efficiently updates the profiled regional timestamps to recover the inaccuracy caused by instrumentation, ensuring accurate profiling results while minimizing memory overhead. This level of precision was previously difficult to achieve because traditional profilers lack access to compiler-generated semantic information, such as loop structures and regional boundaries, making it challenging to attribute execution metrics accurately to high-level behaviors. This timing tool plays a crucial role in optimizing modern GPU kernels by enabling precise analysis of fine-grained overlapping and presenting an intuitive timeline visualization to guide performance optimizations.

We conducted an in-depth case study on the FA3 kernel. Leveraging the tool's fine-grained profiling results, we identified idle bubble regions in the baseline implementation and extracted key optimization insights. Based on these findings, we implemented novel compiler passes to enhance the kernel with an improved overlapping strategy, effectively reducing performance bottlenecks. In addition, we introduced performance modeling based on the profiling results to evaluate the efficiency of the optimized overlapping design.

This work makes the following key contributions:

- We propose KPerfIR, a compiler-centric infrastructure enabling customizable performance tools. Integrated into the Triton compiler, it supports AMD and Nvidia platforms, providing essential support for developers optimizing AI compilers and operators (Sec. 4).
- As a demonstration of the proposed infrastructure, we develop a novel region-based timing tool. This tool exemplifies the compiler-centric approach and offers fine-grained GPU profiling capabilities (Sec. 5).
- We perform an in-depth case study using the proposed timing tool to analyze GPU overlapping. The study reveals valuable insights into intra-kernel overlapping techniques, such as warp specialization (Sec. 6).

2 Background and Related Works

Although proposed methodologies support both Nvidia and AMD GPUs, we use the ones from Nvidia without any loss of generality unless discussing AMD platform-specific features. In the following, we describe the background of GPU compilers and profilers, focusing on their use in AI workloads.

2.1 GPU Compilers

The design of AI compilers has progressed significantly, with the introduction of MLIR [26] marking a pivotal step toward modularity, extensibility, and multi-layered abstraction. MLIR simplifies the complexity of modern computational workloads with a reusable framework that lowers the learning curve for compiler development while enabling custom components and third-party tool integration to drive innovation.

Building on the foundation of MLIR, Triton [47] is a groundbreaking compiler designed to bridge AI workloads and GPU hardware. With dialects specifically tailored for GPU programming, Triton offers high-level abstractions that simplify the development of efficient GPU kernels, addressing the needs of computationally intensive AI applications. Triton leverages MLIR's modular architecture to achieve reusability, seamless integration, and multi-level optimizations, exemplifying how domain-specific needs can be addressed within a unified framework. Triton's Intermediate Representations (IRs) encompass various dialects, including TTIR, TTGIR, Triton, TritonGPU, TritonNvidiaGPU, and TritonAMDGPU, each catering to specific stages of GPU programming.

2.2 GPU Profilers

GPU performance tools are indispensable for analyzing workload execution characteristics and identifying performance bottlenecks. They enable developers to understand application behavior and hardware utilization, which are critical for achieving optimal performance on GPU platforms. The GPU performance tools can be divided into two major categories.

Performance tools are ready-to-use profilers include NVIDIA's Nsight Compute (NCU) [33] and Nsight Systems (NSys) [34], as well as AMD's RocTracer and RocProfiler [4]. NCU provides detailed kernel-level analysis for CUDA applications, offering various metrics and actionable optimization suggestions. NSys delivers a holistic view of system-wide performance, capturing interactions between CPU and GPU to diagnose latency and synchronization issues. Similarly, RocTracer [5] supports performance optimization for AMD GPUs by tracing and analyzing applications in heterogeneous environments. An important aspect of these profiling tools is timing start and stop calls (e.g., cudaProfilerStart and cudaProfilerStop), which are implemented as host-side APIs *around* kernel launch calls and not directly within kernel code.

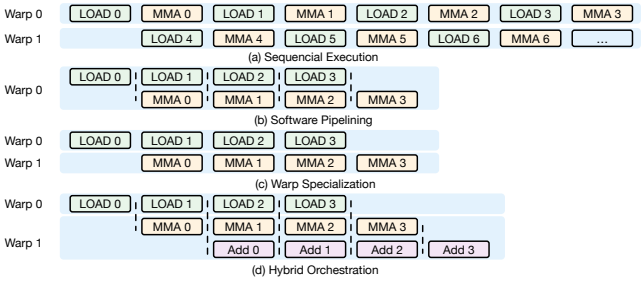

Figure 2: GPU overlapping techniques

MosaicGPU profiler [10], which inserts PTX instructions using high-level Python bindings, represents the closest idea to our approach. However, it operates at the assembly code level rather than on the high-level IRs, restricting its ability to provide comprehensive and reusable profiling capabilities. ThunderKitten (TK) [44], a promising DSL for the Nvidia platform, also developed a custom timing interface recently for region-based tracing. However, this tool is coupled with its DSL design and only supports the Nvidia platform.

Profiling infrastructures like CUPTI [32], NVBit [48], RocProfiler offer some level of instrumentation for customization. They allow developers to insert custom instructions at runtime, providing flexible profiling options. However, they are tightly coupled to the program and instrumentation framework [20]. This approach lacks portability and fails to integrate seamlessly with compiler workflows, limiting their ability to support cross-platform development.

2.3 GPU Overlapping Techniques

To effectively utilize GPU devices' resources and unleash their full potential, GPU kernels have to arrange diverse execution and memory units to overlap their execution to achieve better concurrency. With the introduction of dedicated on-chip acceleration units, such as Tensor Core [16] and Tensor Memory Accelerator [15], their overlapping is getting much more significant and difficult.

Wave Priority and Instruction Scheduling. The most straightforward solution for overlapping is to extend the scheduler with explicit priority setting. This is implemented as the wave priority technique mainly adopted by the AMD platform through compiler-based intrinsics (e.g., LLVM's `__builtin_amdgcn_s_setprio()`), which controls how wavefronts are scheduled and executed on the Compute Units (CUs) at compile-time. The CU will, at runtime, choose the wavefront with the higher priority when scheduling conflicting instruction types. By setting well-suited wave priorities, programmers can fully utilize the execution pipeline by explicit overlapping of memory loads on one wave and compute operations on another [3]. Overlapping can be further refined through compiler scheduling intrinsics such as `__builtin_amdgcn_sched_barrier()` to control

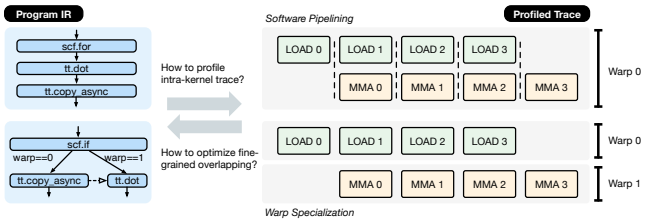

Figure 3: Motivating examples

the clustering and pipelining of matrix operations.

Software Pipelining (SWP) transforms the execution of independent loop iteration operations (i.e., memory and compute) into multiple stages to overlap between iterations, as shown in Fig. 2-(b). By using asynchronous instructions for data loading [8] and computation, different operations can be executed concurrently to overlap the latency. However, SWP requires extra scratchpad storage and registers in the loaded memory hierarchy to store the intermediate results for each stage. Software pipelining is usually adopted at multiple levels, such as global memory to shared memory and shared memory to register files, to hide the latency effectively. Besides the use for overlapping data loading and computation, SWP is also used for overlapping different sections of computations executed by separate hardware units. VALU, VMEM, and SMEM instructions [2, 3] can all be scheduled independently - the goal is to have these run entirely in parallel to tensor/matrix core operations. Due to its key advantage of enhancing utilization, SWP has gained widespread acceptance in high-performance operator libraries [45] and compiler optimizations [22].

Warp Specialization (WS) is another overlapping technique built with the producer-consumer model [8,23]. After splitting execution into stages, WS assigns stages to dedicated warps as producers and consumers. Instead of overlapping between different stages of loop iterations, WS overlaps between producer and consumer stages in different warps as depicted in Fig. 2-(c). WS was previously proposed as a solution for irregular and large problems to overlap unbalanced workloads and reduce register pressure [17]. Compared to SWP, where each warp acts as a producer and consumer, WS separates the roles so that registers can be assigned properly. For example, the data loading stage consumes much fewer registers compared to the heavy-lifting computation stage. However, this feature was not fully utilized due to the lack of hardware warp-level register allocation support. Recently, on the Nvidia Hopper architecture [15], novel features like register reallocation and asynchronous transaction barriers make WS achieve superior overlapping performance [42, 45].

3 Motivation

In this section, we analyze examples from current operator and compiler development that highlight the need for novel performance tooling, as illustrated in Fig. 3.

Fine-grained Comprehension. With the increasing complexity of heterogeneous execution units and asynchronous dataflow programming paradigms, it has become challenging to intuitively understand the execution pipeline. Users may choose SWP or WS to orchestrate data loading and computation for the cases shown in the example. However, to maximize hardware utilization, they must carefully determine stage partitions and the number of stages in SWP or decide execution orders and synchronization barriers in WS. Existing profilers provide aggregated results that lack the program semantics needed to correlate profiled metrics. To truly understand overlapping behavior, it is essential to parse the loop structure, analyze cross-warp dependencies, and track fine-grained metrics throughout the execution. Users struggle to identify and address inefficiencies effectively.

Takeaway 1: Performance profiling tools require the compiler's IR to provide fine-grained performance metrics.

Performance Optimization. Gaining a comprehensive understanding of execution behavior enables opportunities for manual optimizations. However, the challenge becomes even greater when implementing auto-optimizations within compiler passes. The compiler requires customizable performance feedback tied to the existing IR design to determine the optimal transformations. As shown in the example, selecting the appropriate overlapping design of WS and SWP requires stable performance estimations for each method. The compiler pass must rely on precise profiling data to guide its optimization choices effectively. A programmable performance tool embedded within the compiler infrastructure provides the essential first step in enabling this workflow.

Takeaway 2: Compiler optimization passes need programmable performance profiling tools to effectively guide their optimization decisions.

4 Compiler-centric Performance Tool

While it benefits compiler and kernel developers, the current compiler design lacks support for performance tooling. Existing MLIR dialects focus primarily on static, compile-time transformations and optimization passes, with little consideration for capturing dynamic traces or profiling semantics. This gap leaves developers without a native framework to analyze runtime behavior or fine-tune kernel performance within the compiler ecosystem.

Designing performance tooling infrastructure as MLIR dialects is a non-trivial task. For example, in Triton, such dialects must bridge the abstraction gap between the high-level tensor IR and the low-level target-specific IR while remaining clean abstraction to be consistent and compatible with existing multi-level program IR semantics. The ideal infrastructure should be able to handle diverse profiling demands with great extensibility for ever-evolving GPU architectures. Addressing this complexity, we introduce the KPerfIR dialect, the first of its kind, to integrate instrumentation passes directly

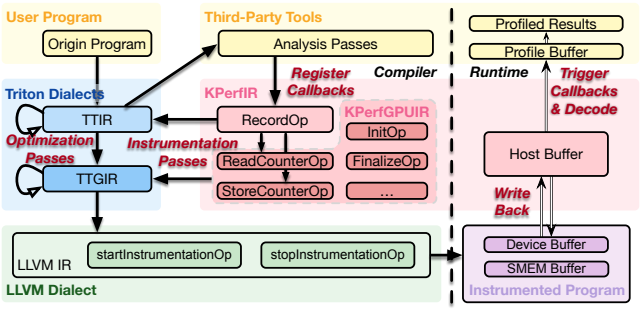

Figure 4: IR design and conversion passes

into the compiler IR as a performance tooling infrastructure. The system is implemented upon the mainstream AI compiler Triton [47], which adopts MLIR as its compiler infrastructure. We demonstrate the multi-level IR design and runtime convention of the KPerfIR infrastructure as shown in Fig. 4. We further discuss several representative use cases with KPerfIR.

4.1 IR Design

Within Triton's multiple-level IR structure, TTIR and TTGIR are the major program representations that developers interact with. We implement the KPerfIR as multi-layered MLIR dialects interacting with Triton's IR structure and link high-level MLIR operations to LLVM-IR level analysis. As shown in Fig. 4, we insert the record operations in MLIR dialects and lower them to architecture-specific TritonGPU operations. We also lower and instrument some scaffolding functions, such as data copy from local buffer to host memory, at the LLVM IR level. This architecture links the programming language constructs to hardware-related features for analysis. Specifically, we define novel operations at different levels to instrument profiling semantics and collect measurement data. The rewritten Triton program is then lowered into LLVM IRs for further analysis and code generation. This design balances programmability and complexity by higher-level IR design and lower-level code generation.

Instrumentation can be done at either the MLIR or LLVM IR level as a trade-off between flexibility and generality. MLIR level instrumentation can access high-level constructs, such as loops and data objects (e.g., tensors, matrices, etc.). However, the higher in the compiler pass pipeline instrumentation instructions are inserted, the more accuracy and reliability are influenced by the compiler backend's instruction scheduling and reordering. In contrast, LLVM IRs are closer to the low-level assembly code and provide more information about GPU devices. Nevertheless, instrumentation at the LLVM IR level may lose connection to high-level program semantics.

As such, we design the compiler-centric performance tool by linking the high-level MLIR dialects to LLVM IR level analysis as shown in Tbl. 2. We provide the profiling instrumentation interface at both the TTIR and TTGIR levels since they are general representations that hide low-level vendor-specific details and capture key optimizations such as software

Table 2: Main operations of KPerfIR

Operation	Inputs/Outputs	Attributes	Explanation
KPerfIR			
RecordOp	**In:** name, isStart	-	Main profiling IR.
KPerfGPUIR			
InitOp	**Out:** index_ptr	BufferType, BufferStrategy	Initialize and allocate memory.
FinalizeOp	**In:** index_ptr, global_ptr, data	-	Write back profiling to global memory and add metadata.
ReadCounterOp	**Out:** counter_ptr	MetricType, Granularity	Read a GPU metric counter into a scalar register.
StoreCounterOp	**In:** counter_ptr, index_ptr	isStart	Store a metric counter into a buffer.
LLVM			
startInstrumentationOp	**In:** instrumentation pass, index_ptr, buffer_size	-	Trigger low-level instrumentation.
stopInstrumentationOp	**In:** instrumentation pass	-	Stop low-level instrumentation.

pipelining, code motion, loop fusion, and warp specialization. KPerfIR is our highest abstraction level, which includes the key `RecordOp` operator, representing a general program marker, whose semantic interpretation solely depends on the KPerfIR to KPerfGPUIR lowering pass configurations. `RecordOp`'s inputs include `name` and `isStart`, specifying the annotation location and identifier in the program. An example of using `RecordOp` in the program is as follows.

```
kperfir.record <name, isStart=True>
// TARGET CODE REGION ...
kperfir.record <name, isStart=False>
```

Figure 5: An example of high-level record operations

The `RecordOp` at KPerfIR level abstracts away the hardware detail and is lowered to GPU-specific KPerfGPUIR operations. On the KPerfGPUIR level, we get vendor-independent but GPU-specific hardware features (e.g., shared memory abstraction). When lowering to KPerfGPUIR, various MLIR pass options are given to determine the conversion, such as the `MetricType` (specifying the performance counter) and the `Granularity` (e.g., warp-group, warp, thread, etc). For example, when profiling GPU cycles, each `RecordOp` is lowered to a `ReadCounterOp` and a `StoreCounterOp`, which can be scheduled separately by the compiler for the proper program location. `ReadCounterOp` collects the exact GPU cycle register values. `StoreCounterOp` stores the counter value into the profiling buffer with an offset. The corresponding buffer and bookkeeping resources are determined and allocated during the lowering pass given configurable constraints.

Tbl. 2 outlines key operators with inputs, outputs, and attributes presented in KPerfIR and KPerfGPUIR. The concrete operations instrumented are controlled by various MLIR pass options in the lowering/conversion passes, including `BufferType`, `BufferStrategy`, `MetricType`, `Granularity` and resource constraints (e.g., buffer size). Given these controlling knobs, the compiler generates specific KPerfGPUIR operations for performance tools whose profiling locations are specified by the `RecordOp` markers. For instance, specifying the `BufferStrategy` as circular, `MetricType` as clock, and `Granularity` as warp-group results in an intra-kernel profiler using a circular buffer to store the clock cycles of each warp-group (see

Sec. 5 for a detailed discussion of the profiler). In this case, the `StoreCounterOp` operation is converted to a `CircularStoreOp` to handle circular buffer event recording.

Besides, the compiler also generates scaffolding operations in KPerfGPUIR to setup and clean-up the environment of the profiling phase. `InitOp` initializes the profiling states (e.g., buffer index). We use stack allocation to enable the LLVM toolchain to apply register promotion for the buffer index, which sits in the critical path of clock measuring. This operation returns the address of the allocated index and the memory load/store operations will be optimized away by keeping the index value in the register with LLVM backend's optimization. `FinalizeOp` performs the clean-up and writes back the profiled records. Similarly, the exact buffer memory allocation operations (`LocalAllocOp`, `GlobalScratchAllocOp`, and `StackAllocOp`) are determined by the configurations during the lowering from KPerfIR to KPerfGPUIR as well[2].

Lastly, we have the LLVM level markers `startInstrumentationOp` and `stopInstrumentationOp` to control the low-level library-based instrumentation. The `startInstrumentationOp` tells the LLVM level to insert starting memory analysis/timestamp (including warp ID, SM ID). And the `stopInstrumentationOp` inserts ending memory analysis/timestamp and flushes data from the local buffer to the scratch buffer/host pinned memory. This allows instrumentation at lower IR levels to be linked to upper-level data objects and flow structures (e.g., inserting timestamps at the LLVM IR level around data objects and flow structures that only exist at higher IR levels).

Wrapping all instrumentation at the MLIR level makes the derived tools inextensible to ML frameworks due to their divergence on the supported operation set. In contrast, inserting instructions at the LLVM IR level allows for flexible and reusable tools. Analysis code can be written in any language, compiled to LLVM bytecode, and inserted into MLIR framework code. This feature is particularly attractive in MLIR frameworks that are not linked to Clang or its libraries but include C++ instrumentation functions. In other words, analysis functions can be written in HIP/CUDA and used in MLIR frameworks without C++ code (e.g., Triton, PyTorch).

4.2 Compiler Passes

We then leverage compiler passes to instrument the `RecordOp` to the target program and lower it to the underlying IRs. There are two main levels of compiler passes handling their insertion and conversion, including lowering KPerfIR into KPerfGPUIR and lowering KPerfGPUIR into LLVM.

The KPerfIR to KPerfGPUIR lowering pass converts the `RecordOp` to `ReadCounterOp` and `StoreCounterOp`, and inserts operations for resource allocation (e.g., `LocalAlloc`), and setup/clean-up operations (e.g., `InitOp` and `FinalizeOp`). At the entrance of the kernel function, we allocate the profiling buffer, global scratch memory, and bookkeeping resources. We defer the discussion of memory management in Sec. 5.2 and focus on the lowering pass explanation here. The allocated profiling buffer is associated with each `ReadCounterOp` to collect hardware performance counters (e.g., GPU cycle). The gathered raw data is written back to the GPU global memory by `FinalizeOp` in a predefined memory layout, which is inserted at the end of the kernel function. `FinalizeOp` has inputs including the number of the profiling records, base address of the profiling buffer, and base address of the profiler's global memory.

Triton lowers TTGIR into the LLVM backend to generate vendor-specific code (e.g., ptx and amdgcn) and perform low-level optimizations, such as redundant code elimination [18] and register promotion [28]. We develop a set of LLVM conversion patterns to handle the code generation of the instrumented profiling operations. Specifically, the `InitOp` is lowered to a stack allocation (`llvm.alloca`) of the buffer index. The `ReadCounterOp` is lowered to a read of a performance counter (e.g., %clock) to the register, and the `StoreCounterOp` is lowered to a register value store with tag creation and buffer index management. For the `FinalizeOp`, we compute the global memory offset for the current thread block and assign the first thread as a worker to write the entire profiling buffer back to the global memory.

We provide principal support regarding backends to reduce the interference of the high-level instrumentation in optimizations such as instruction re-ordering. For Nvidia GPUs, the impact is negligible since the hardware is responsible for instruction scheduling with the PTX mostly following the instrumented program with KPerfIR's operators associated. Instruction will not be scheduled around critical instruction like WGMMA. AMD GPUs expose instruction scheduling to software, even for instruction SMEM load and MFMA in amdgcm, making the instrumented operator a key factor. As such, we provide three levels of configurations adjustable by users: 1. manual adjusting with KPerfIR hints; 2. direct instrumentation on amdgcn, and 3. specifying instruction scheduling window with barrier mask explicitly.

4.3 Working with Third-Party Tools

We then demonstrate the interfaces for users to develop their third-party tools shown on the right side in Fig. 4, including the instrumentation APIs handling rewriting and the necessary memory management to decode the profiled raw data.

Instrumentation APIs. To build a customized performance tool with the KPerfIR dialect, the user must explicitly modify the kernel signature and update the IR with instrumentation passes. We provide two APIs for the user to interact with the KPerfIR, the command-line API and the Python API. With the command-line API, all Triton functions encountered at runtime with the command-line API are instrumented with the

[2]Please refer to the documentation for more details at https://triton-lang.org/main/dialects/ProtonOps.html.

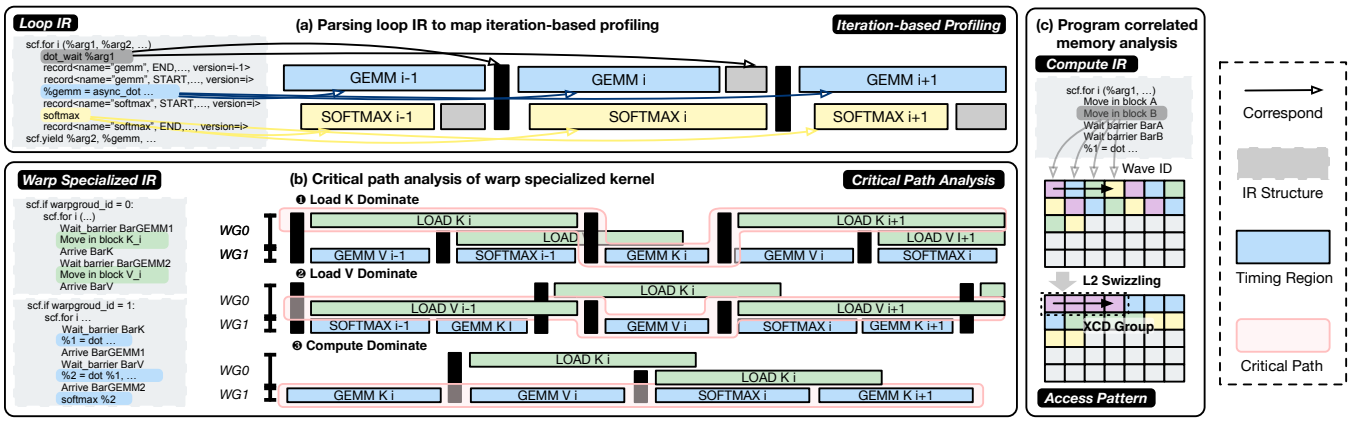

Figure 6: Novel use cases facilitated by KPerfIR's compiler-centric approach

specified analysis passes. This allows for handy manipulation of the target workload but lacks flexibility since users cannot skip kernels they are not interested in.

The Python API lets the user specify the instrumentation entry and the target function to be instrumented. The instrumentation entry here refers to the insertion position in the compilation process (i.e., before/after which pass). On the other hand, the instrumentation point specified by the `RecordOp` refers to the position in the IR. It encompasses the core API as `KPerfIR.patch(instrumentation_obj, fn)`, where `instrumentation_obj` identifies the compiler pass to be instrumented (either before or after) and `fn` is optional to select the instrumented kernel. If the `instrumentation_obj` specifies MLIR instrumentation, we adopt MLIR's pass infrastructure `PassManagement`. We will instrument LLVM at the end of the compilation passes. Additionally, we provide a `KPerfIR.unpatch()` API to restore all existing instrumentation. This involves maintaining the kernel's original and instrumented version within the KPerfIR runtime.

Runtime Memory Management. Another important part of the third-party tool involves the management of buffer storage and profiling results. At the top level, we rewrite the kernel signature with an extra last argument as a pointer to the device buffer and modify the calling convention. The accumulated profiling data is then returned to the host buffer managed by the KPerfIR runtime. Here, we adopt a discarding-based circular buffer design, which will be elaborated with an actual tool design in Sec. 5.2. We have two ways to manage GPU device buffer and host buffer communication, following prior studies [53, 54] The first approach is to use CUDA-managed allocation so that the device buffer is allocated in a memory space visible to both the GPU and the CPU. The second approach is to allocate a priority stream with a higher priority than the one used by PyTorch's runtime and use that stream to copy the data back to the CPU.

Once the data is copied back to the CPU, it is decoded into a similar format to the CUPTI Activity API as a C/C++ struct. Third-party tools will register a callback to process this data when the runtime is initialized. Callbacks are triggered once the host buffer is decoded to allow these tools to process the data, like CUPTI activities. As such, the tools can post-process the data to compatible formats with their own front-end visualizers, such as Chrome Trace [19] or Hatchet [9].

4.4 Use Cases

We then showcase several novel performance tools facilitated by KPerfIR infrastructure as shown in Fig. 6.

Iteration-based Timing. Understanding the synchronous behavior of warp groups across iteration boundaries is crucial for analyzing SWP. For instance, observing overlapping at specific iteration steps requires associating the loop induction variable `i` with a version argument in the timing records. However, traditional profiling tools lack access to the loop semantics necessary to determine iteration positions, making it challenging to comprehend the precise overlapping behavior of resources across iterations. By incorporating profiling passes into the compiler, we can instrument the IR to collect clock ticks alongside loop iteration index semantics, enabling post-processing to construct fine-grained timelines, as shown in Fig. 6-(a). While tools like MLIR's Python bindings can implement this functionality, they are ad-hoc and restricted to simple loop structures, underscoring the need for deeper integration of compiler semantics into profiling workflows.

Critical-path Analysis. Runtime feedback is invaluable for compiler passes, particularly for identifying execution critical paths in scenarios involving WS. For example, in the FA3 kernel, producer warp groups load input tensors, while consumer warp groups execute multiple GEMM operations and a softmax computation. The critical path—determined by factors like data movement and computation latency—varies with program tiling and access patterns, making static analysis insufficient for arrangement. For the FA3 case, there are three common critical paths dominated by different operations, as shown in Fig. 6-(b). By embedding profiling passes into the compiler, we can instrument timing records to capture runtime

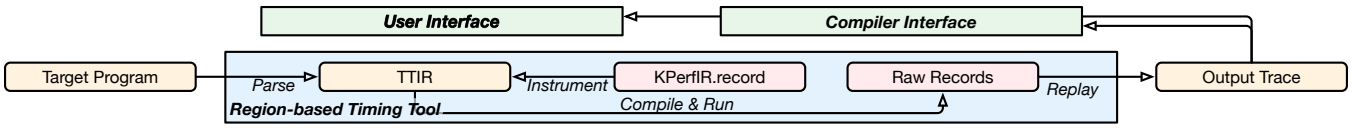

Figure 7: Workflow of the region-based timing tool

stage latencies and dynamically identify the critical path. This enables the compiler to strategically insert asynchronous barriers, reducing waiting bubble times and improving resource utilization. Such optimization passes highlight the value of integrating performance tooling with compiler passes.

Program Correlated Memory Analysis. Fine-grained memory profiling benefits significantly from a compiler-centric design, allowing developers to correlate memory performance metrics, such as access patterns, heat maps, and bank conflicts, with high-level program objects. Taking Fig. 6-(c) as an example, analyzing the memory access pattern of a specific data object, such as a tensor, requires parsing the program IR to insert profiling intrinsics that map high-level constructs to low-level hardware registers. This approach is particularly critical for optimizing L2-level scheduling, such as with AMD's chiplet designs [1]. Profiling warp-level memory access patterns and correlating them with program objects enables the design of optimized swizzling strategies for L2 access. Such capabilities, achievable only through compiler-centric profiling, demonstrate the necessity of integrating memory profiling tools into the compiler infrastructure.

5 The Region-based Timing Tool

In this section, we dive into a powerful third-party performance tool built upon the KPerfIR infrastructure that conducts region-based intra-kernel timing to assist in comprehending and optimizing the overlapping GPU hardware resources. To build a customized tool with KPerfIR, the users must implement the instrumentation passes, the profile data management, and the post-processing process as introduced in Sec. 4.3. These are elaborated with the region-based timing tools as its workflow for instrumentation (Sec. 5.1), its memory system (Sec. 5.2), and a trace replay post-processing (Sec. 5.3).

5.1 Workflow

We first introduce the workflow of the timing tool with two kinds of interfaces, the user interface and the compiler interface, as shown in Fig. 7. Depending on how the target program is parsed and the profiling regions are specified, different interfaces are invoked to instrument the profiling records. KPerfIR will then compile and execute the instrumented program to collect the raw performance counters. At last, we replay the trace with the raw metadata and produce the final timeline trace. This trace is output and feedback to different interfaces for visualization or profiler-guided compiler passes.

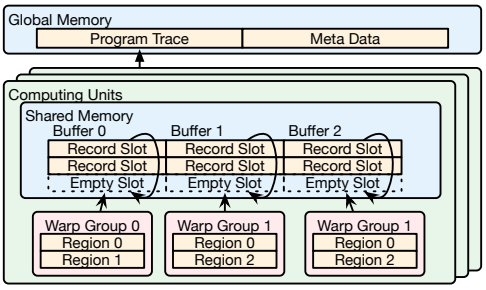

Figure 8: Memory management of the region-based tool

User interface is the basic usage for developers to profile interested regions of a target GPU program. We provide PythonDSL bindings in Triton kernels and also allow manual rewriting and overriding the dumped middle-level IR for the concerned regions. It is straightforward as the developer manually rewrites the dumped middle-level IR for the concerned regions. This is extremely useful when developing high-performance kernels and debugging efficiency problems. The KPerfIR will instrument the original program with rewritten program IR and produce the output trace. Developers can utilize visualization tools, such as Chrome Tracer [19], to get an intuitive view of the program timeline.

Compiler interface is how the compiler interacts with the profiler. Compared to the user interface, the compiler passes are responsible for parsing the middle-level IR and insert profiling record at concerned regions. Similarly, the instrumented program is compiled and executed, and the profiled traces are feedback to the compiler passes within the compiler.

5.2 Profile Data Management

We then introduce the specific management and decoding techniques of the tool. The system accommodating the storage at each memory hierarchy is shown in Fig. 8. We demonstrate the data structure and layout bottom-up in the following.

Warp-level Region Data Structure. For each fine-grained profiling region, there are two profiling records inserted, the region start record and region end record. Each record has 8 bytes, containing a 4-byte tag and a 4-byte payload, as shown in Fig. 9. The tag contains 1 flag bit as *START* or *END*, and 31-bit control bits that are dependent on the backend will be explained later. The payload contains a 32-bit time stamp metric captured from the hardware counter (cycle for %clock in Nvidia and the LSB 32 bits of `S_MEMTIME` instruction in AMD). This design achieves a good trade-off between space capacity and write speed. Because the storage consumption is

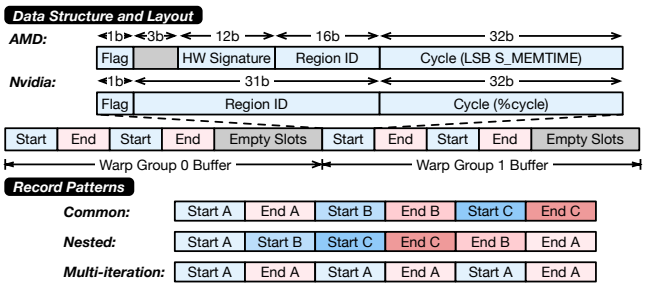

Figure 9: Circular buffer and record buffer

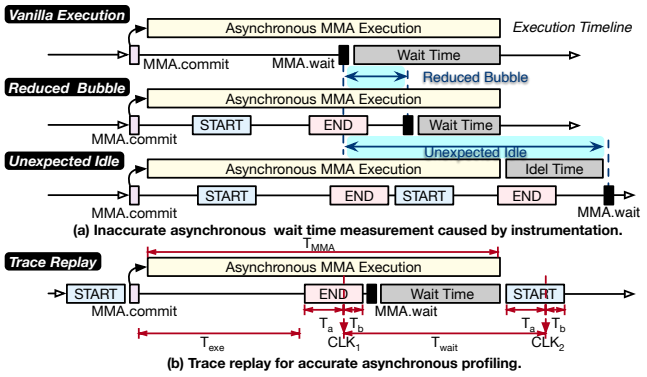

Figure 10: Trace replay

low and the store takes a vectorized store instruction.

We use a 32-bit clock to capture the cycle tick of the current record, which may cause value overflow. We address this in the post-processing procedure, where we detect and throw exceptions on overflows. The trace replay can compensate for the clock wrap-around overflow as long as each iteration runs less than 4 billion cycles (4 seconds under 1GHz). Since most of the execution is spent on loops, the restriction is relaxed to the loop iteration level, which is less than 1 millisecond for most cases, making 32-bit cycle data a safe choice. If necessary, KPerfIR could easily extend to a 64-bit clock by adding dedicated operators and attributes in the IR.

SM-level Data Layout. The record is then copied to the data buffer in shared memory from the local register file with a store instruction. The data buffer is split into profiling spaces by warp groups with non-overlapping record slots, as shown in Fig. 8. As such, the record index at compile time determines the store location offset in shared memory. For example, if we allocate 64 slots (0.5KB) and each thread block contains 2 warp groups (8 warps, 256 threads), then each warp group has 32 slots. During compile time, we pre-compute the base address of each profiling space and generate code to manage the indexes for each warp group.

The memory layout of each warp group buffer is shown in Fig. 9. Start and end records are interleaved in shared memory to support nested regions and multiple iterations. The lower part of the figure illustrates three profiling patterns: common, nested, and multi-iteration. Records are stored without pairing and aligned during trace replay to ensure correctness based on the profiling patterns.

Shared Memory Circular Buffer. Because shared memory has limited capacity, it may not be able to accommodate all profile data, especially with a long multi-iteration record pattern. For example, with 2 warp groups, 4 profiled regions, and a loop with 512 iterations, it takes up to 4096 record slots, translating to a 16KB shared memory storage. For the production-level kernels, we usually get the available shared memory capacity left ranging from 1KB to 4KB for intra-kernel profiling's data buffer, only up to 1.75% of a total of 228KB on H100 device [15].

We propose a *circular buffer* structure for each warp group's data buffer as a solution balancing accuracy and usability. The circular buffer keeps only the trace's tail record cyclically when reaching the shared memory limit. We overwrite the oldest results cyclically instead of flushing them to the lower-level memory. The insight is that visualizing a few recent iterations is sufficient to identify the bottleneck. We wrap around the index with a pre-calculated buffer capacity to implement the circular buffer. If the captured events are overflowing the buffer, it is redirected to an occupied slot. This causes extra instructions for index management, which is addressed during compile-time. We only need lightweight modular instructions to round the index at runtime.

Besides, this *circular buffer* is the default memory management behavior in the runtime. The user can switch to the naive flush strategy, where the captured events are instantly written back to the global memory when the buffer is fully occupied. This strategy can keep all the profile events with the overhead of many more frequent memory write instructions. In the KPerfIR's infrastructure, we provide a comprehensive operation to support the memory allocation at each hierarchy, including `Stack`, `Shared`, `Global`, and management strategies, including `Circular` and `Flush`. Users can make use of these abstractions to develop their tool, combining the use of the buffers and management strategies.

Specifically, we implement a collaborative store strategy for the AMD backend to minimize profiling overhead. Since only one timestamp record is profiled per warp or warp group, AMD GPUs utilize branching with thread masks to issue instructions with predication. However, this thread divergence can lead to unexpected instruction cache misses, causing overheads up to 600 cycles. To mitigate this, we enforce all threads to write to the same shared memory location, retaining only the last result. To align the records, we include an additional 12-bit signature derived from the least significant bits (LSB) of the `HARDWARE_ID REG`, as shown in Fig. 9. This signature encodes the `wave_slot_id`, `SIMD_id`, and `pipe_id` to annotate the profiled thread. At the warp group level, we ensure all four warps write to the same shared memory location.

Global Program Trace. Lastly, we gather the profiling data from all SMs back to the GPU global memory before returning from the kernel function. We keep the temporary profile

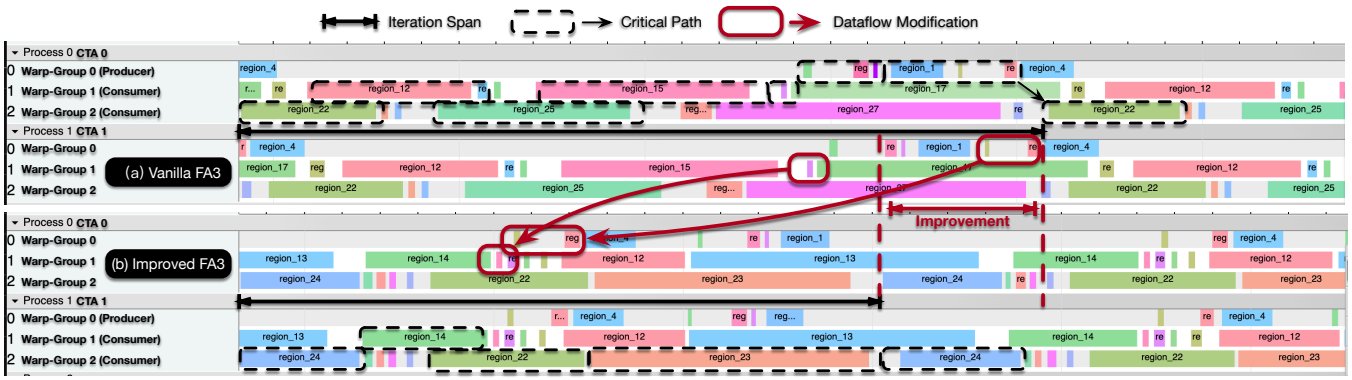

Figure 11: Region-based timing results for FA3 kernels and overlapping improvements guided by profiling

data in the shared memory and copy the entire data buffer at once by the end of the kernel. Several extra metadata are attached for reconstructing the trace as shown in Fig. 8, including thread block index, warp-level indices, and a number of recorded slots in each warp group. The Triton frontend automatically patches the kernel function with an extra argument (`profile_mem`), allocating the GPU scratch memory for such profile data.

5.3 Trace Replay

The major challenge in the region-based timing scenario of intra-kernel profiling is the perturbations caused by the profiling instructions. Post-processing techniques, such as periodic sampling [21], are usually used to mitigate the inaccuracies by sampling the performance metrics periodically and summarizing the results afterward to reduce the overhead associated with data collection. In the region-based timing tool, we propose a similar post-processing method *trace replay* to rescale the profiled regions according to the program semantics owing to the KPerfIR's design. We can get accurate visualized results using this trace replay mechanism by offsetting a constant to account for the clock measuring overhead.

For regions with only synchronous instructions, we can easily rebuild the region by subtracting the overhead of the record operation. For asynchronous instructions, we have two kinds of common inaccuracies as shown in Fig. 10. In the vanilla execution timeline example, we have a sequence of successive instructions executed after issuing an asynchronous MMA operation on the Tensor Core. After the program reaches the barrier in the instruction stream, there is a period of waiting time before the functional unit can produce results. To understand the asynchronous behavior here, users can insert profiling records in the successive execution to better align the operations. However, the introduction of such records causes inaccurate wait time measurements. In the *reduced bubble* case, the wait time is underestimated due to the extra overhead caused by profiling. Things are even worse in the *unexpected idle* case, where the functional unit's execution time cannot cover the profiling overhead. An unexpected idle time will be observed, and the optimization will be misleading.

Table 3: Profiled regions of the FA3 kernel

Tag	Function	Region ID	
		Vanilla	Improved
Load K	Load the K tensor.	3	3
Load V	Load the V tensor.	6	6
GEMM0	Compute QK on TC.	12,22	12,22
GEMM1	Compute PV on TC.	14,24	15,25
Softmax	Compute softmax on CUDA core.	13,23	17,27

To address this, we propose deducting the accurate wait time after profiling in the trace replay procedure as shown in Fig. 10-(b). Instead of placing one `END` record after the asynchronous instructions, we insert two `START` records before the asynchronous launch and after the wait barrier and one `END` record right before the barrier. This guarantees an accurate wait time T_{wait} measurement as $T_{wait} = (CLK_2 - T_a) - (CLK_1 - T_a) = CLK_2 - CLK_1$, where T_a and T_b are the elapsed time in the record region before and after the clock read instruction respectively. The profiling overhead is canceled out in the post-processing with the two carefully placed records. We can derive the T_{exe} time similarly. This method requires the $T_{MMA} - T_{exe} > T_a + T_b$. Since the profiling overhead is less than 25 cycles for most cases, as shown in Sec. 6.4, the execution time of the functional unit can cover only the record inserted here, which is usually about 1000 cycles.

6 Evaluation

In this section, we evaluate the performance of the designed region-based timing tool and the KPerfIR approach.

6.1 Experimental Setup

Testbed. The evaluation of KPerfIR was conducted on servers equipped with state-of-the-art GPU cards, including NVIDIA H100-HBM3 and AMD MI300X. The software environment included Triton 3.0.0 and LLVM 19.1, ensuring compatibility with the latest compiler technologies and GPU architectures.

Benchmarks. To assess the usability and performance of the proposed tool, we benchmarked it on key AI workloads, specifically GEMM [36] and experimental Flash Attention

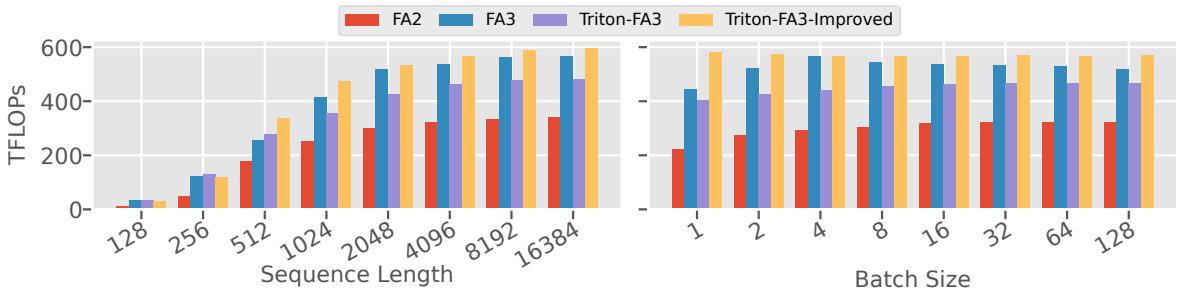

Figure 12: Benchmarking FA3 kernels with a head dimension of 128 and 16 heads. The batch size and sequence length are set to 16 and 4096 in the two benchmarks, respectively.

operators from Triton [29]. These operators are foundational to popular AI models, representing the majority of workloads in tasks such as training and inference. We selected mainstream implementations of these operators that deliver state-of-the-art performance and conducted sensitivity experiments to evaluate the method's effectiveness and scalability.

6.2 A Journey of Flash-Attention 3

We first demonstrate utilizing the region-based timing tool to improve the FA3 kernel. As FA3 involves many optimization techniques dedicated to the Nvidia platform, we focus on optimizing the H100 GPU first and conduct many more thorough benchmarks later.

6.2.1 Attention Overlapping Optimization

We begin by demonstrating the usage of the region-based timing tool to identify a particular inefficiency in the FA3 kernel's WS overlapping design. Using the proposed timing tool, we parse the FA3 kernel's IR structure and profile its asynchronous behavior to guide a better overlapping design. The critical stages of the FA3 kernel are identified and listed in Tbl. 3. Each stage is labeled with a unique region ID, providing a clear mapping for analysis. By employing the timing tool, we obtain a fine-grained timeline trace of the vanilla FA3 kernel from Triton, shown in Fig. 11-(a), which also illustrates the user interface with the Chrome Trace as the front-end. The trace identifies the critical path consisting of 4 GEMMs and 2 loading stages, including region 22, 12, 25, 15, 6 and 3. Specifically, the loading V stage of region 6 is blocked by the arrival barrier of region 16 in consumer 1, causing a longer critical path and lower hardware utilization.

Following this observation, we can advance the arrival barrier of V in region 16, as shown with the red arrows, to prevent it from stalling the issue of successive data loading. The GEMM1 regions are released from the critical path by fully overlapping it with the concurrent K tensor loading. This modification breaks data dependency between the arrival and computation and requires extra pre-loading in the prologue before the iterations. We can achieve a much more compact timeline where the softmax and GEMM computation are overlapped, shown in Fig. 11-(b). The improved overlapping results in a reduced wall time of each iteration in the kernel.

Table 4: Performance models

Category	Analytic Model
SWP Model	$\Delta = N_{WG} * N_{pipe} * \Sigma_i T_{comp} - Max_i(T^i_{load} + T^i_{comp})$ $\begin{cases} \Sigma_i T^i_{comp} * N_{loop}, \Delta >= 0 \\ Max_i(T^i_{load} + T^i_{comp}) \times N_{loop} / N_{pipe} \end{cases}$
WS Model	$\Sigma_{i \in CriticalPath} T^i_{load/comp}$
Compute Model	$FLOPs/Throughput$
Memory Model	$T_{read} + Bytes/Bandwidth$

6.2.2 Performance Modeling for GPU Overlapping

We then demonstrate how to adopt the proposed compiler-centric profiler design to build a compiler pass to determine the optimal overlapping design. This is achieved by extracting the critical path of the FA3 kernel with the profiling results and compute the utilization of the workload using an overlapping performance model. The performance model is outlined in Tbl. 4, focusing on compute and data loading stages while simplifying less relevant aspects such as initialization, epilogue, and overall kernel performance, which have been studied extensively in prior works [22].We emphasize the non-trivial parts of modeling the overlapping techniques.

For the SWP model, the discriminant Δ determines whether the bottleneck lies in data loading or computation. If $\Delta \geq 0$, the data loading latency is fully overlapped by computation, and the total latency corresponds to the accumulated computation time across all stages. Conversely, if $\Delta < 0$, the latency is dominated by the most time-consuming loading and computation stages. For the WS model, the latency is determined by identifying the kernel's critical path, as discussed in Sec. 4.4. The WS latency is intuitively calculated as the sum of the latencies of all stages along the critical path.

Using this model, we can quantitatively assess the overlapping efficiency of the FA3 kernel. The region-based profiler collects detailed performance data, allowing us to analyze

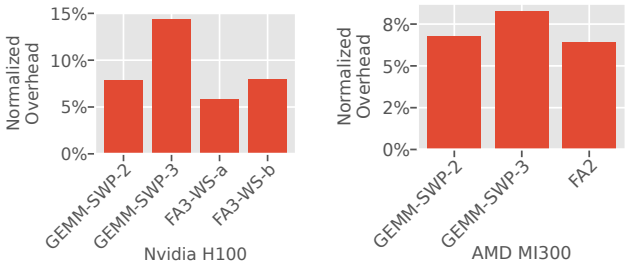

Figure 13: Normalized latency overhead

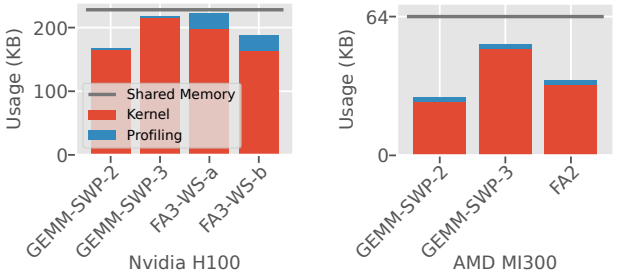

Figure 14: Memory usage

the current implementation and refine overlapping designs to minimize latency and improve resource utilization. For example, for an attention kernel with head dimension 128, head number 16, batch size 16, and sequence length 4096, the 2-stage SWP is calculated with a 467.07 TFLOPs and the vanilla Triton FA3 reaches a 526.97 TFLOPs. With the optimization passes incorporated, we can tune an FA3 kernel with improved overlapping, achieving 582.44 predicted TFLOPs.

6.2.3 Improved FA3 Evaluation

Combining the manual optimization passes with the profiling insights and performance model pass together, we can get an improved FA3 compiler pass optimization suite built upon Triton. Compared to the original execution dataflow of the vanilla Triton FA3, the optimized FA3 kernel achieves a 24.1% improvement as shown in Fig. 12. This shows the efficacy of the optimization insights discovered with the assistance of the performance tool. The improved Triton-FA3 kernel also outperforms the best manual FA3 kernel [41] by 7.6%. Particularly, without the assistance of the region-based timing tool, the vanilla Triton-FA3 kernel fails to achieve a competitive performance compared to the manual kernels. This suggests the immeasurable value of a fine-grained profiling tool benefiting the compiler passes and kernel optimization.

6.3 Profiling Overhead

We evaluate the profiling overhead of the proposed region-based timing tool in terms of both latency and memory consumption. Particular attention is given to shared memory usage, which is a critical bottleneck in the design of performance tools for GPU workloads. We benchmark SOTA GEMM operators with SWP designs divided into 2 or 3 stages, marked as GEMM-SWP-2/3, and WS FA3 operators with vanilla overlapping and the improved counterpart with the profiling insights, marked as FA3-WS-a/b.

Latency Overhead. We measure the end-to-end latency of the instrumented kernels and normalize the results to their original execution time. Fig. 13 illustrates the latency overhead across the evaluated benchmarks. For most cases, the overhead remains under 10%, ensuring that the proposed tool is practical for real-world scenarios without significantly impacting kernel performance. For the most complicated SWP GEMM kernel with three stages, we insert many records to cover its three stages. Even in this case, the overhead is kept within 15%. This minimal latency impact is crucial for enabling real-time profiling and maintaining production-level throughput during optimization workflows.

We hightlight that with the post-processing trace replay technique in Sec. 5.3 mitigating the interference of the profiling instructions, we can get relatively accurate profile results even if the overhead is extended. We have also introduced several memory management techniques like circular buffers, which together reduce the profiling overhead to approximately 8% in our evaluation. Moreover, ongoing enhancements, such as low-level instruction scheduling and clock offsetting, can further reduced the overhead.

Shared Memory Overhead. As detailed in Sec. 5.2, the proposed timing tool employs a circular buffer design to store recent profiling records within the limited shared memory available on GPUs. This approach ensures compatibility with diverse workloads, regardless of the size of the available shared memory, while also allowing flexible adaptation of the profiling life cycle.

Fig. 14 shows the shared memory usage across the benchmarked workloads. For this experiment, the circular buffer size was set to either maximize usable shared memory space or accommodate all profiling records for the workload. The results demonstrate that the tool effectively operates within the constraints of shared memory, even for industrial-grade kernels, without spilling profiling records to external memory.

For instance, in the most storage-intensive kernel, the SWP GEMM with 3 stages, there remains an unused shared memory space of 10.9 KB. With 4 profiled regions, the timing tool can track up to 16 iterations, providing sufficient and stable coverage to estimate the entire execution process. This efficient memory usage highlights the applicability of the tool for large-scale GPU workloads.

6.4 Low-level Deep-dive

To provide an empirical analysis of the optimization performance degradation introduced by KPerfIR, we examine its im-

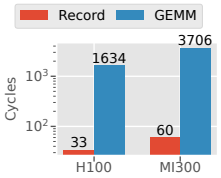

Figure 15: Cycle-level benchmarks

	GEMM	Theoretical	Actual
Active Cycles	199381	224981	229663
Relative Performance	0.89	1	1.02

Table 5: Performance degradation evaluation

pact at the low-level instruction level. Specifically, we identify the instrumented instructions generated by IR-level profiling and compare them with their vanilla counterparts to evaluate how profiling IR affects the compilation stack.

Cycle-level Overhead. At the GPU assembly code level, the SASS ISA, each KPerfIR record node is lowered to three instructions: a clock read instruction, an integer move instruction, and a predicated store instruction. These instructions collectively incur an average overhead of 33 cycles, as shown in Fig. 15. This latency represents the per-record profiling overhead observed in our sensitivity analysis. For loop-based timing, where profiling records are inserted into loop structures, five additional instructions are generated at the loop entry for index management. The instructions for each profiling record remain consistent at three, with their destination adjusted dynamically based on the loop iteration variable.

Optimization Degradation. One critical observation in our analysis is that profiling instrumentation can interfere with the compiler's low-level optimizations, such as instruction reordering and constant folding. Integrated profiling semantics at the IR level inherently trade some low-level control for improved tool portability and compatibility, as discussed in Sec. 4. This tradeoff introduces potential risks of unintended instruction reordering when profiling instructions interact with adjacent non-profiling instructions.

To study this impact, we modeled the theoretical execution time of the instrumented kernel as

$$T_{theoretical} = T_{vanilla} + N_{record} * Cycle_{record}. \quad (1)$$

The N_{record} is the number of instrumented records, and the cycles are measured as Fig. 15. Using this model, we compared the theoretical execution time with the actual performance of the instrumented workload to assess deviations caused by profiling instrumentation.

The results, summarized in Tbl. 5, show that the performance impact remains within 2%. This suggests that the profiling instrumentation at the compiler IR level introduces minimal overhead while maintaining compatibility with compiler optimizations. The findings highlight the practicality of the proposed approach, ensuring accurate profiling without significant performance degradation.

7 Discussions

7.1 Limitations

One limitation of our approach stems from restricted visibility into certain vendor-specific performance counters. Since KPerfIR inserts profiling instructions directly into the program to collect runtime information, the set of accessible metrics is constrained by the vendor's ISA. In contrast, vendor-provided tools such as NVIDIA's Nsight Compute (NCU) and AMD's ROCm Tools (e.g., ATT) have privileged access to undocumented performance registers not exposed to third-party developers. These proprietary counters can only be utilized through their official APIs or libraries. While our infrastructure may not achieve full parity with these tools in terms of raw counter access, our IR-level instrumentation enables unique insights into program behavior otherwise difficult to obtain with closed-source profilers.

7.2 Workload Generality

Beyond AI Workloads. While KPerfIR currently targets AI workloads through its integration with the Triton compiler, the core ideas behind our approach, namely a multi-level IR and transformation passes for performance tools, are broadly applicable. These techniques can generalize to other domains and compilers, such as those used in high-performance computing (HPC) [39] or scientific simulation [24].

Distributed Workloads. KPerfIR is also amenable to distributed GPU workloads [49, 50], which are typically structured as a series of kernels involving both computation and communication. For workloads that launch computation and communication kernels separately, KPerfIR already provides native support. For fused kernels, where computation and communication are fused within a single kernel [12, 37], KPerfIR can theoretically instrument and analyze them as well. However, full integration depends on ongoing upstream efforts to extend Triton's support for such fused distributed execution.

8 Conclusion

As AI compilers and GPU architectures continue to evolve, performance tooling must also advance to meet the growing demands of modern compilers. To address this need, we introduced KPerfIR, a novel compiler-centric profiling infrastructure built upon the Triton compiler. KPerfIR bridges the gap between compiler and profiler design, enabling the development of programmable, reusable tools and unlocking new possibilities for performance analysis and compiler optimizations. We envision KPerfIR as a foundation for an open, compiler-centric ecosystem, empowering the community to construct diverse and innovative performance tools that adapt to the dynamic needs of AI workloads.

A Artifact Appendix

Abstract

The KPerfIR is a performance tool infrastructure for the Triton [47] compiler and the results for the OSDI'25 submission are derived from some feature branches. While the core concept is stable, the implementation is still evolving and subject to change. A formal documentation can be found at https://triton-lang.org/main/dialects/ProtonOps.html.

Scope

We showcase the usability of the performance tool and the improvement results discussed in the paper by reproducing Fig. 11 and Fig. 12. Specifically, profiling the FA3 kernel with the region-based performance tool demonstrate the usage of the compiler-centric design. A comparison of the profile trace from the vanilla and improved FA3 kernels shows the methodology of intra-kernel region profiling. And the evaluation results shows the actual performance improvement.

Contents

We provide a Docker image that contains the Triton compiler and evaluation scripts for the artifact evaluation. Please follow the installation instructions in the following section to set up the environment. Within the Docker image, the contents are organized as follows:

```
workspace/
—— triton            % Triton compiler source code
—— tritonbench       % Triton FA3 benchmark suite
—— kperfir_artifact  % Other scripts and files
```

Hosting

This artifact is open sourced at https://github.com/ChandlerGuan/kperfir_artifact with the main branch and commit version e45891d.

Requirements

The Docker environment requires a Linux-based system with NVIDIA Container Toolkit installed. While the KPerfIR project is designed to be cross-platform, the artifact evaluation for the FA3 kernel requires a Nvidia H100 GPU.

Mirage: A Multi-Level Superoptimizer for Tensor Programs

Abstract

We introduce Mirage, the first multi-level superoptimizer for tensor programs. A key idea in Mirage is μGraphs, a uniform representation of tensor programs at the kernel, thread block, and thread levels of the GPU compute hierarchy. μGraphs enable Mirage to discover novel optimizations that combine algebraic transformations, schedule transformations, and generation of new custom kernels. To navigate the large search space, Mirage introduces a pruning technique based on abstraction that significantly reduces the search space and provides a certain optimality guarantee. To ensure that the optimized μGraph is equivalent to the input program, Mirage introduces a probabilistic equivalence verification procedure with strong theoretical guarantees. Our evaluation shows that Mirage significantly outperforms existing approaches even for DNNs that are widely used and heavily optimized. Mirage is publicly available at https://github.com/mirage-project/mirage.

1 Introduction

Enabling high-performance execution of deep neural networks (DNNs) on GPUs is critical for modern ML applications. Today's DNN frameworks generally specify DNN computation using tensor programs, which are directed acyclic graphs whose nodes and edges represent tensor algebra operators (e.g., matrix multiplication) and tensors (i.e., n-dimensional arrays) shared between operators.

To optimize an input tensor program, existing frameworks (e.g., PyTorch [34] and TensorFlow [9]) use manually designed rules to map the tensor program to expert-written GPU kernels. These approaches generally require extensive engineering efforts to design and implement optimization rules, and they may miss certain optimization opportunities. To address these challenges, recent work has introduced *automated* approaches that optimize tensor programs by searching over a comprehensive space of program transformations and applying them based on their performance on target GPUs. These approaches generally fall into two categories.

The first category of work, including Halide [35], TVM [13], and Ansor [51], is motivated by the idea of algorithm and schedule separation[1] introduced in Halide and optimizes the *schedule* of a tensor program while fixing the algorithm. For a given algorithm, these optimizers automatically generate performant kernels by searching for possible strategies to execute the kernel on the target hardware. However, due to the linear algebra nature of DNNs, a tensor program can be represented by a wide spectrum of mathematically equivalent algorithms. Existing schedule-based optimizers only consider kernels whose algorithms are manually specified by users, resulting in missed optimization opportunities.

The second category of work, including TASO, Grappler, Tensat, and PET, considers *algebraic transformations*, which exploit mathematical equivalence among different algorithms for a tensor program [3, 25, 46, 48]. Examples of algebraic transformations include (1) converting one linear algebra operator into another, such as transforming a convolution to a matrix multiplication; (2) fusing multiple operators to reduce memory access and kernel overhead; and (3) reorganizing operators based on commutativity, associativity, and distributivity. These optimizers perform algebraic transformations at the algorithm level and require programmers to manually specify the set of available operators and their implementations. They are thus limited by the performance of the provided kernels.

All existing automated optimization approaches, from both categories, still require programmers to manually specify a set of kernels (each defined by a tensor function), and then explore the search space of algebraic *or* schedule transformations. However, some advanced performance optimizations require coordinated transformations across the kernel, thread block, and thread levels of the GPU compute hierarchy, and involve introducing completely new kernel computations (e.g., a custom kernel that decomposes standard kernels and fuses only certain computations). Such optimizations are not included in the search space of existing automated methods and must still be implemented manually.

[1] In the schedule optimization literature, an algorithm describes what to compute in a kernel and a schedule specifies how to compute the kernel.

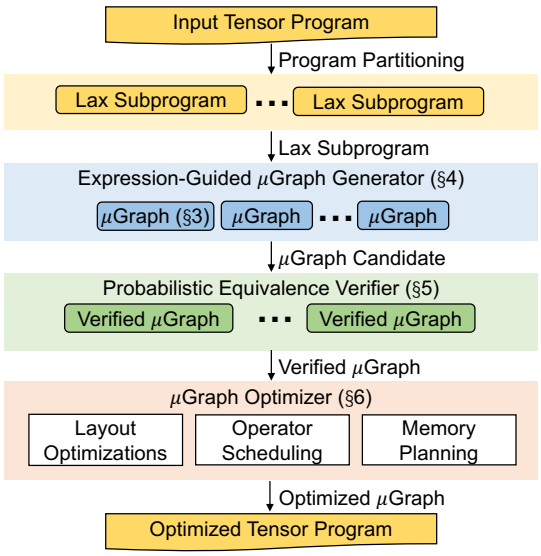

Figure 1: An overview of Mirage.

One such example is FlashAttention [17] (see §8.2 for details), which optimizes attention [47] on GPUs by reordering operators at the algorithm level (algebraic transformations), reorganizing the computation across GPU kernels (yielding new custom kernels), and adapting the parallelization strategy of each kernel to the GPU architecture (schedule transformations). The transformations required for this example cannot be automatically discovered by existing frameworks and must therefore be implemented manually. An implementation of FlashAttention in Triton [43], a widely used tensor program optimizer, contains more than 700 lines of code [8].

We present Mirage, the first *multi-level superoptimizer* for tensor programs. Mirage automatically discovers and verifies sophisticated optimizations of tensor programs that require joint optimization of algebraic transformations, schedule transformations, and the discovery of new custom kernels.

A key idea in Mirage is μGraphs, a *hierarchical graph representation* that specifies tensor programs across multiple levels of the GPU compute hierarchy. By uniformly treating the kernel, thread block, and thread levels, μGraphs can capture both algebraic and schedule transformations across these levels. Moreover, optimizing a μGraph can introduce new custom kernels, which go beyond both algebraic and schedule transformations. For example, Mirage automatically discovers the μGraphs representing FlashAttention [17] and its inference variant FlashDecoding [5] as well as other μGraphs that outperform these manually designed kernels by up to 2.2× for certain use cases. Most of these optimizations discovered by Mirage are outside the search space of existing methods.

Figure 1 shows an overview of Mirage. Mirage first splits an input tensor program into subprograms that fall into the restricted LAX fragment. The LAX fragment, formally defined in §5, includes multi-linear operators such as matrix multiplication and convolution, division (useful for normalizations), and limited exponentiation (useful for activations). Partitioning a tensor program into LAX subprograms reduces the optimization search space while preserving most optimization opportunities; it also enables Mirage's probabilistic equivalence verifier.

Expression-guided μGraph generator. For each LAX subprogram, Mirage's *expression-guided generator* exhaustively searches for possible μGraphs equivalent to it. A key challenge Mirage must address is its significantly larger search space compared to prior superoptimization techniques. For example, TASO [25] and PET [46] search only for tensor programs at the kernel level, using a fixed set of pre-defined kernels, while Mirage considers superoptimization across the kernel, thread block, and thread levels. To efficiently navigate this significantly larger search space, Mirage introduces a novel pruning technique based on *abstract expressions*, which greatly reduces the number of μGraphs Mirage must consider while providing a certain theoretical guarantee on the optimality of the discovered μGraphs. Mirage further reduces the search space by focusing the search on the kernel and block levels and using a rule-based approach for the thread level.

Probabilistic equivalence verifier. For a μGraph discovered by Mirage, verifying its functional equivalence with the input program introduces another challenge, since the input and output tensors of a program include up to many millions of elements. A key idea behind Mirage is *probabilistic equivalence verification*, which performs random tests over finite fields to check equivalence between μGraphs. While random tests typically provide limited correctness guarantees for general programs, Mirage leverages a novel theoretical result showing that the restrictions imposed by the LAX fragment ensure that, for LAX programs, random tests over finite fields offer strong correctness guarantees. Specifically, we show that a polynomial identity testing (PIT) algorithm [37, 54] can be generalized to LAX programs, yielding a randomized algorithm for LAX program equivalence that can be made arbitrarily precise. Mirage uses this randomized algorithm to (probabilistically) ensure that each optimized program is equivalent to the input program.

μGraph optimizer. For each verified μGraph, Mirage's *μGraph optimizer* maximizes its runtime performance by further considering potential tensor layouts, scheduling operator execution orders, and planning memory allocation at all of the kernel, thread block, and thread levels. Finally, Mirage returns an optimized tensor program based on the best discovered μGraph for each individual LAX subprogram.

Evaluation results. We evaluate Mirage on a variety of commonly used DNN benchmarks on NVIDIA A100 and H100 GPUs. Even for DNN benchmarks that are widely used

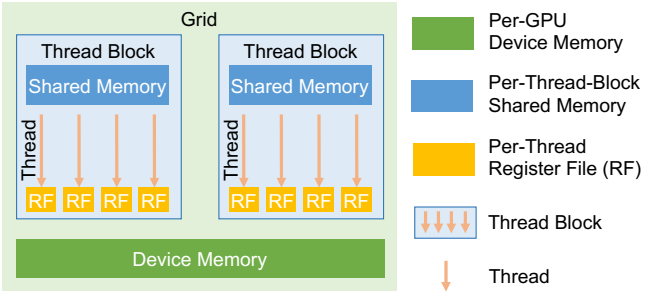

Figure 2: GPU compute and memory hierarchy.

and heavily optimized by existing systems, such as the group-query attention used in LLMs [41], Mirage still outperforms current approaches by up to 3.3× by exploiting subtle custom kernels and optimizations missing in existing systems.

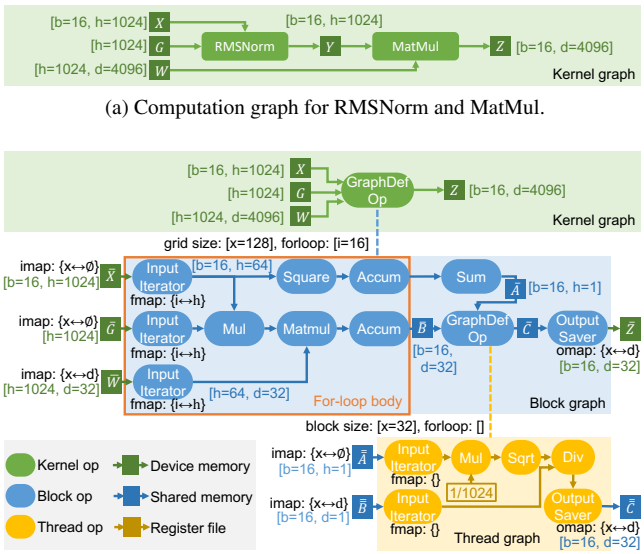
2 Multi-Level Graph Representation

Mirage uses a μGraph to specify the execution of a tensor program on GPUs. A μGraph contains hierarchical graphs at multiple levels to represent computation at the kernel, block, and thread levels[2]. This section first describes the GPU hierarchy and uses Figure 3 as a running example to introduce the key components of a μGraph.

GPU hierarchy. Figure 2 shows the hierarchy of today's GPUs. Computations on GPUs are organized as *kernels*, each of which is a function executed simultaneously on multiple GPU cores in a single-program-multiple-data (SPMD) fashion. A kernel includes a grid of *thread blocks*, each of which is executed on one GPU streaming multiprocessor and includes multiple *threads* to perform computation on individual data elements. Each thread is associated with a per-thread *register file*, and all threads within a thread block can access *shared memory* to enable collective operations. Finally, all inputs and outputs of a kernel are stored in GPU *device memory*.

Kernel graph. Each tensor program corresponds to one *kernel graph*, where each node represents a kernel running on an entire GPU, and each edge is a tensor shared between kernels. All tensors in a kernel graph are stored in GPU device memory since different kernels cannot share data in register files or shared memory. Each node in a kernel graph can be a *pre-defined* kernel operator supported by existing kernel libraries such as convolution by cuDNN [15] and matrix multiplication by cuBLAS [16]. In addition, to enable fine-grained inter-kernel optimizations such as kernel fusion, a node in a kernel graph can also be a *graph-defined* kernel operator, whose semantic and behavior are defined by a lower-level (i.e., block) graph. As an example, the kernel operator in Figure 3b is a graph-defined operator specified by a block graph.

[2]For simplicity, we use the term *block* to refer to a thread block of a CUDA kernel and *thread* to refer to a single CUDA thread.



(a) Computation graph for RMSNorm and MatMul.

(b) The best μGraph discovered by Mirage.

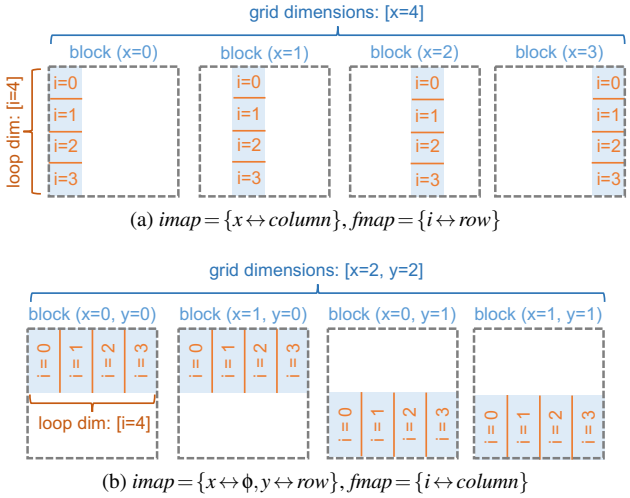
Figure 3: Figure 3a is the computation graph for RMSNorm and MatMul. Figure 3b shows the best μGraph discovered by Mirage for computing RMSNorm and MatMul, which fuses the computation in a single kernel to reduce device memory access and kernel launch overhead, outperforms existing approaches by 1.9×. Numbers in brackets indicate tensor shapes, and numbers in braces show the *imap*, *omap*, or *fmap* for the corresponding operators.

Block graph. A *block* graph specifies computation associated with a thread block[3], where each node denotes a *block operator* specifying computation within a block, and each edge (blue arrows in Figure 3b) is a tensor shared between block operators. Mirage stores all intermediate tensors within a block graph in GPU *shared memory* for two considerations. First, GPU shared memory offers much higher bandwidth than device memory, and this design allows Mirage to reduce device memory access by maximally saving intermediate results in shared memory. Second, for tensors whose sizes exceed shared memory capacity and must be stored in device memory, Mirage uses these tensors to split computation into multiple block graphs, each of which only contains tensors in shared memory. This separation does not introduce additional access to device memory.

Each block graph is also associated with properties specifying its execution, which we introduce below.

Grid dimensions. All blocks within a kernel are organized into a mesh with up to 3 dimensions, identified as x, y, and z. A

[3]In the CUDA programming model, a kernel's computation is defined as computations for independent thread blocks.



(a) $imap = \{x \leftrightarrow column\}, fmap = \{i \leftrightarrow row\}$

(b) $imap = \{x \leftrightarrow \phi, y \leftrightarrow row\}, fmap = \{i \leftrightarrow column\}$

Figure 4: Demonstrating how an input tensor is partitioned across blocks and for-loop iterations with *imap* and *fmap*.

block graph is associated with up to three *grid dimensions* that specify the number of blocks along the x, y, and z dimensions. The block graph in Figure 3b launches 128 blocks.

First, for each input tensor to a graph-defined kernel operator (e.g., X, G, and W in the kernel graph in Figure 3b), the associated block graph contains an *imap*, which specifies how the input tensor is partitioned into sub-tensors for individual blocks. For each grid dimension (i.e., x, y, or z), the *imap* maps it to either (1) a data dimension of the input tensor or (2) a special *replica* dimension ϕ. For (1), the mapped data dimension is *equally partitioned* across blocks along the grid dimension. For (2), the input tensor is *replicated* across these blocks. For example, the block graph in Figure 3b takes three inputs—$\overline{X}$, $\overline{G}$, and $\overline{W}$—representing the input tensors to each block. For $\overline{W}$, its $imap = \{x \leftrightarrow d\}$ indicates that the d dimension of tensor W is partitioned into 128 equally sized chunks. As a result, $\overline{W}$ has shape $[h = 1024, d = 32]$.

Second, for each output tensor of a block graph (e.g., $\overline{Z}$ in Figure 3b), the block graph includes an *omap*, which specifies how the outputs of all blocks are concatenated to construct the final output of the kernel operator. In an *omap*, each grid dimension must map to a data dimension of the output tensor, since different blocks must store disjoint tensors in device memory. For $\overline{Z}$ with shape $[b = 16, d = 32]$ in Figure 3b, its $omap = \{x \leftrightarrow d\}$ indicates that blocks with the same x index are concatenated along the d dimension, resulting in a tensor Z with shape $[b = 16, d = 4096]$.

For-loop body. To fit large input tensors in shared memory and to overlap data loading from device memory with computation, a block graph can include a *for-loop body*, which is executed multiple times to complete a kernel. Often, the for loop in a kernel is followed by some post-processing. For example, when computing an average value, the for loop would perform the summation of n values and the post-processing would divide by n. Mirage specifies the for-loop body of a block graph using *input iterators*, *for-loop accumulators*, and all operators in between, as shown in the orange box in Figure 3b). Each input tensor to a block graph first passes through an *input iterator*, which loads part of the tensor (e.g., $\overline{X}$, $\overline{G}$, and $\overline{W}$) from device memory into shared memory. Each input iterator is associated with an *fmap* to specify which part of the input tensor to load in each iteration. Formally, the *fmap* maps each for-loop dimension to either (1) a data dimension of the input tensor or (2) the replica dimension ϕ. Similar to *imap*, the tensor is equally partitioned along that dimension for (1) and replicated for (2). Figure 4 shows how an input matrix is partitioned across blocks and for-loop iterations using different *imap* and *fmap*.

Each block graph is also associated with a *for-loop dimension*, which determines how many iterations the for-loop body is executed to complete the kernel. In addition, Mirage uses *for-loop accumulators* (e.g., the two `Accum` operators in Figure 3b) to accumulate intermediate results computed in each iteration (using standard accumulators, e.g., summation and max) and store the accumulated results in shared memory. Once the for-loop body is completed, Mirage proceeds to execute the remaining operators outside the for-loop body directly on the accumulated results. An *output saver* then saves the final result from shared memory back to device memory.

Thread graph. A *thread graph* further reduces computation scope from a block to a single thread. Similar to a block graph, each thread graph is also associated with *block dimensions*, which specify the organization of threads within the block, and *for-loop dimensions*, which define the total number of iterations to finish the defined computation. Each thread graph includes *input iterators*, each of which loads an input tensor (e.g., $\overline{\overline{A}}$ and $\overline{\overline{B}}$ in Figure 3b) from shared memory into register files, and *output savers*, each of which stores an output tensor from register files back to shared memory (e.g., $\overline{\overline{C}}$). A thread graph is the lowest-level graph in a μGraph and contains only pre-defined thread operators.

Tensor layout. Each tensor in the kernel, block, or thread graph is associated with a *tensor layout* (omitted in Figure 3 for simplicity), specifying how the tensor is linearized in memory. Note that tensor layouts affect only the performance of a μGraph and have no impact on its output correctness.

Definition 2.1 (μGraph Validity)**.** A μGraph G is *valid* if: (1) for each kernel, block, and thread operator $o \in G$, its input and output tensors match the specification of o; (2) all tensors in each kernel, block, and thread graph can reside in GPU device memory, shared memory, and register file, respectively; and (3) for each block and thread graph with a for-loop body, any path from an input to an output passes through exactly one input-iterator, one for-loop accumulator, and one output saver.

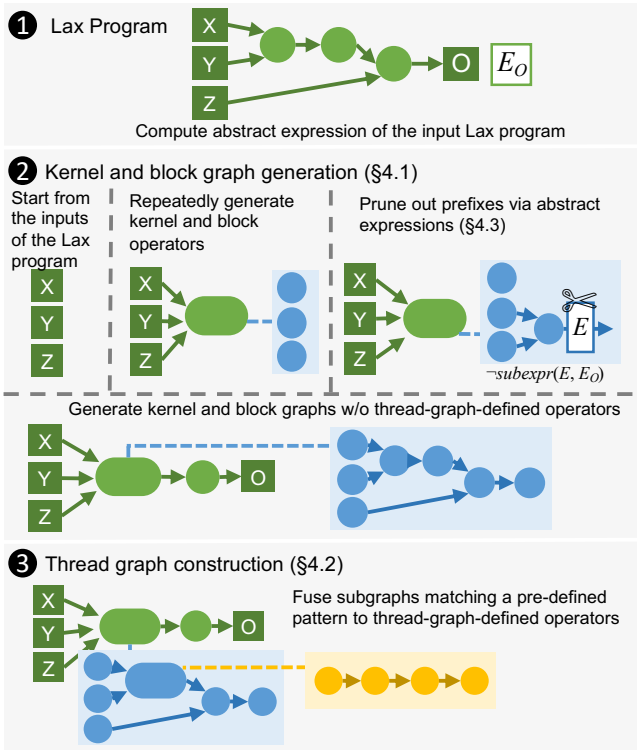


Figure 5: An overview of the μGraph generator.

Comparison with prior work. Prior work separately considers algebraic [25, 46] or schedule transformations [13, 31, 35], while μGraphs can represent both in a uniform way. Specifically, the grid and for-loop dimensions and their corresponding mappings (i.e., *imap*, *omap*, and *fmap*) to tensor dimensions constitute a comprehensive search space of possible schedules for graph-defined operators. The hierarchical graphs across the kernel, block, and thread levels allow Mirage to explore algebraic transformations at these levels.

3 Case Study: RMSNorm

In this section, we use root mean square layer normalization (RMSNorm) [50] as a case study to demonstrate the advantages of the μGraph representation and Mirage's superoptimization approach. RMSNorm is a widely used normalization technique in recent large language models [41]. Formally, RMSNorm takes two tensors, X and G, as inputs and normalizes their element-wise products according to the root mean square:

$$Y_{ij} = \frac{X_{ij}G_j}{\text{RMS}(X_i)}, \text{RMS}(X_i) = \sqrt{\frac{1}{d}\sum_{j=1}^{d} X_{ij}^2}, \quad (1)$$

where d is the hidden dimension size of X.

RMSNorm is often followed by a matrix multiplication (MatMul). Figure 3a shows the computation graph of an RMSNorm followed by a MatMul operator, where X is the input tensor, and G and W denote two weight tensors. Existing ML compilers generally launch two separate kernels for RMSNorm and MatMul computations, since both operations internally perform reductions across an input dimension, making it challenging to fuse their computations into a single kernel. This approach requires storing intermediate results (i.e., Y) in device memory since different kernels cannot share data in shared memory or register files.

Figure 3b shows the best μGraph automatically discovered by Mirage for computing RMSNorm and MatMul in a single kernel. The computation is fused in a single graph-defined kernel operator to avoid saving intermediate results (i.e., Y) in device memory and reduce kernel launch overheads.

We highlight the key differences between the μGraph discovered by Mirage and the original μGraph. These differences involve discovering new custom kernels and combining algebraic and schedule transformations, making it infeasible to discover the final μGraph by separately considering algebraic and schedule transformations. First, Mirage reorders MatMul and the division of RMSNorm by leveraging the commutativity of matrix multiplication and element-wise division (algebraic transformation). Second, Mirage performs the accumulation in the root mean square (i.e., $A_i = \sum_j X_{ij}^2$) and the accumulation in the matrix multiplication (i.e., $B_{ik} = \sum_j X_{ij}G_jW_{jk}$) in parallel (schedule transformation), avoiding writing the accumulation results to device memory. Next, Mirage instantiates a thread graph to perform a sequence of element-wise operators while maintaining all intermediate results in register files (schedule transformation). Finally, the best discovered μGraph uses a new custom kernel to fuse the computation of RMSNorm and MatMul, reducing device memory access and kernel launch overheads. This μGraph outperforms the hand-written kernels in existing systems by 1.5× and 1.9× on NVIDIA A100 and H100 GPUs respectively.

4 Expression-Guided μGraph Generator

This section introduces the Mirage μGraph generator, which automatically discovers potential μGraphs for an input tensor program. To generate μGraphs that capture optimizations at the kernel, block, and thread levels, Mirage must explore a significantly larger search space than existing superoptimizers, which only consider optimizations at the kernel level. Mirage employs two key techniques to address this challenge. First, based on the observation that optimizations at the kernel and block levels are substantially more critical to performance than optimizations at the thread level—since accessing device and shared memory is orders of magnitude more expensive than accessing register file—Mirage's μGraph generator employs a *hybrid approach*: it exhaustively considers all possible graphs up to a certain size at the kernel and block levels, and uses a rule-based strategy to construct graphs at the thread level. This approach reduces the search space while retaining

Algorithm 1 Mirage's hybrid μGraph generation algorithm.

Input: A LAX program with a computation graph G_{ref}
Output: A set of μGraphs $\mathcal{S}$

```
1:  E_O ← E(G_ref)

most performance-critical optimizations. Second, to further prune the search space, Mirage introduces a pruning technique based on an abstraction of μGraphs called *abstract expression*, which reduces the number of μGraphs Mirage must consider while providing a certain theoretical guarantee on the optimality of the discovered μGraphs. We introduce the hybrid μGraph generation algorithm in §4.1 and §4.2, and the expression-guided pruning techniques in §4.3.

4.1 Kernel and Block Graph Generation

Mirage generates kernel and block graphs incrementally and leverages several pruning techniques to reduce the search space, as shown in the second part of Figure 5. Specifically, Mirage maintains a *prefix* of a valid μGraph and iteratively extends it with new operators. For a graph $G=(V,E)$ we say that $G'=(V',E')$ is a *prefix* of G if it is a subgraph of G such that $\forall u \in V', \forall (v,u) \in E, v \in V'$.

To generate the next operator in the kernel graph, Mirage enumerates the kernel operator type t and the input tensor set I. If t represents the graph-defined operator type, Mirage generates the associated block graph that defines its kernel computation by (1) enumerating the grid and for-loop dimensions (introduced in §2), which enables Mirage to calculate the input tensor shapes of the block graph; and (2) performing a nested generation procedure similar to that used at the kernel level but without considering graph-defined operators. Line 6-16 and line 17-24 in Algorithm 1 show how Mirage generates kernel and block operators, respectively. Mirage checks tensor shape (line 28) and memory usage (line 29) before adding an operator, ensuring a valid prefix.

To ensure that identical μGraphs are generated only once, Mirage defines the *canonical form* of μGraphs. Given a μGraph G with its operators in topological order $o_1, \ldots, o_n$, the *index* of the j-th output of o_i is defined as a tuple (i, j). Each operator o_i in G is assigned a *rank* $(input_i, type_i)$, where $input_i$ is the list of input tensor indices of o_i, and $type_i$ is the operator type. A μGraph is in canonical form if its operators are ordered in increasing rank. Mirage generates only μGraphs in canonical form by requiring that operators be added in increasing order of rank (line 9 and 22). This approach does not prune out any valid solutions, since each μGraph can be transformed to canonical form by reordering the operators.

In addition, Mirage utilizes the *abstract expression* technique to prune out prefixes that do not satisfy certain constraints, which will be introduced in §4.3.

4.2 Thread Graph Construction

While a similar nested generation strategy can be applied to thread graphs, Mirage instead constructs them using a transformation-based approach (see the third panel of Figure 5 and lines 4–5 in Algorithm 1) to reduce the search space. Mirage applies operator fusion when constructing thread graphs, which reduces access to shared memory by reusing tensors in register file whenever possible. For example, Mirage fuses the three element-wise operators (`Mul`, `Sqrt`, and `Div`) in Figure 3b into a thread graph, avoiding saving intermediate results to shared memory and keeping the entire computation of these operators in register file. While our current implementation focuses on operator fusion, additional rule-based transformations can be used to construct thread graphs.

4.3 Pruning via Abstract Expressions

When searching the space of possible μGraphs, we aim to avoid μGraph prefixes whose intermediate results cannot contribute to the desired computation. For example, for the input program $X \cdot Z + Y \cdot Z$, we can prune a prefix that computes $X \cdot Y$, but we should not prune one that computes $X + Y$, as

Table 1: Operators supported by Mirage. The second column shows the graph levels supporting each operator (K, B and T denote kernel, block, and thread graphs, respectively). The last column defines the abstract expressions for the outputs of each operator, where E maps tensors to their abstract expressions.

μGraph Operator	Graph Level	Abstract Expression of Output Tensor
InIter	B	$\mathrm{E}(\mathrm{InIter}(X)) = \mathrm{E}(X)$
OutSaver	B	$\mathrm{E}(\mathrm{OutSaver}(X)) = \mathrm{E}(X)$
Matmul	K, B, T	$\mathrm{E}(\mathrm{Matmul}(X,Y)) = \mathsf{sum}(k, \mathsf{mul}(\mathrm{E}(X), \mathrm{E}(Y)))$[1]
Sum	K, B, T	$\mathrm{E}(\mathrm{Sum}(d_r, k_r, X)) = \mathsf{sum}(k_r, \mathrm{E}(X))$[2]
EwAdd	K, B, T	$\mathrm{E}(\mathrm{EwAdd}(X,Y)) = \mathsf{add}(\mathrm{E}(X), \mathrm{E}(Y))$
EwMul	K, B, T	$\mathrm{E}(\mathrm{EwMul}(X,Y)) = \mathsf{mul}(\mathrm{E}(X), \mathrm{E}(Y))$
EwDiv	K, B, T	$\mathrm{E}(\mathrm{EwDiv}(X,Y)) = \mathsf{div}(\mathrm{E}(X), \mathrm{E}(Y))$
EwExp	K, B, T	$\mathrm{E}(\mathrm{EwExp}(X)) = \mathsf{exp}(\mathrm{E}(X))$
Repeat	K, B	$\mathrm{E}(\mathrm{Repeat}(X)) = \mathrm{E}(X)$
Reshape	K, B	$\mathrm{E}(\mathrm{Reshape}(X)) = \mathrm{E}(X)$
Sqr	K, B	$\mathrm{E}(\mathrm{Sqr}(X)) = \mathsf{mul}(\mathrm{E}(X), \mathrm{E}(X))$
Sqrt	K, B	$\mathrm{E}(\mathrm{Sqrt}(X)) = \mathsf{sqrt}(\mathrm{E}(X))$
SiLU	K, B	$\mathrm{E}(\mathrm{SiLU}(X)) = \mathsf{silu}(\mathrm{E}(X))$
Accum	B	$\mathrm{E}(\mathrm{Accum}(X,m,i)) = \mathsf{sum}(i, \mathrm{E}(X))$ if $m = \phi$ else $\mathrm{E}(X)$ [3]

[1] k means the size of the last dimension of A, i.e., the reduction dimension. Matmul is performed on the inner most two dimensions and leading dimensions are batched.
[2] Sum along the dimension d_r for every k_r elements.
[3] Accumulate the results of i for-loop iterations along fmap m.

$(X+Y)\cdot Z$ is equivalent to the input program. However, how can we determine whether a prefix can contribute to a desired computation while searching for that computation? Below, we develop a pruning technique driven by this intuition that circumvents the "chicken and egg" problem via *abstraction*. We first present the abstraction—*abstract expressions*—and then explain how it is used for pruning. Finally, we offer a theoretical guarantee that, under certain conditions, this pruning does not exclude the optimal μGraph.

Abstract expressions. Recall that an edge in a μGraph corresponds to a tensor-valued function of the input tensors. Intuitively, abstract expressions abstract these functions by ignoring the differences between elements of the same input tensor. Formally, abstract expressions are first-order logic terms over the theory of integers and uninterpreted functions. In a μGraph, the abstract expression of each edge, denoted by $\mathrm{E}(\cdot)$, is defined in Table 1. When computing a μGraph's abstract expression, all graph-defined operators are "inlined". Specifically, the expressions computed for a graph-defined operator's inputs are passed into its lower-level graph, and the resulting output expressions of that lower-level graph become the output expressions of the graph-defined operator. Figure 6 shows the abstract expressions for a subgraph of attention.

While abstract expressions capture some information about the function computed at each edge, they also abstract away many details. For example, if X is a $k \times k$ matrix, summing over the rows and summing over the columns both yield the same abstract expression—$\mathsf{sum}(k, \mathrm{E}(X))$. But keeping k as part of the abstract expression is crucial for effective pruning.

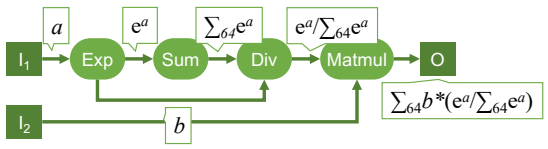

Figure 6: Illustration of abstract expressions. The abstract expressions of tensors are annotated on edges. A human-friendly notation is used here: e^a denotes $\mathsf{exp}(a)$, $\sum_k a$ denotes $\mathsf{sum}(k,a)$, a/b denotes $\mathsf{div}(a,b)$, and $a*b$ denotes $\mathsf{mul}(a,b)$. The tensors I_1, I_2 and O are all 64×64 matrices.

Abstract subexpression and pruning. We use abstract expressions to prune the search space of μGraphs by formalizing two relations over abstract expressions: equivalence and abstract subexpression. Specifically, we prune any μGraph prefix whose abstract expression is not a subexpression of some abstract expression equivalent to that of the input program. We formalize abstract expressions as uninterpreted functions in first-order logic over the theory of integer arithmetic and uninterpreted functions, and use an SMT solver to reason about them based on two sets of axioms in Table 2: A_{eq} and A_{sub}.

First, A_{eq} axiomatizes equivalence between abstract expressions. As will become clear below, these axioms need not be sound—it is not required that μGraphs with equivalent abstract expressions are functionally equivalent, since non-equivalent μGraphs can have the same abstract expression. Second, A_{sub} axiomatizes the subexpression relation between abstract expressions. A key property of A_{sub} is that whenever a μGraph G_1 is a prefix of G_2—meaning G_2 can be constructed by extending G_1 with additional operators—$\mathrm{E}(G_1)$ is an abstract subexpression of $\mathrm{E}(G_2)$; formally, $A_{\mathrm{sub}} \models \mathsf{subexpr}(\mathrm{E}(G_1), \mathrm{E}(G_2))$, where $\models$ denotes entailment modulo the theory of integer arithmetic and uninterpreted functions.

During the search, Algorithm 1 first computes the abstract expression of the input LAX program, denoted E_O, and prunes any μGraph prefix G if $A_{\mathrm{eq}} \cup A_{\mathrm{sub}} \not\models \mathsf{subexpr}(\mathrm{E}(G), E_O)$. That is, a graph is pruned if its abstract expression is not a subexpression of E_O. This check is performed using an SMT solver (Z3 [18]). As an optimization, the results of these checks are cached and reused, since Mirage may encounter multiple μGraphs with identical abstract expressions during the search.

Theoretical guarantee and the pruning-optimality tradeoff. Intuitively, our pruning would keep any prefix that can lead to a μGraph whose abstract expression is equivalent (according to A_{eq}) to that of the input LAX program. Formally:

Theorem 1 (Pruning via Abstract Expressions)**.** For an input μGraph G_0, and a μGraph G equivalent to G_0, if $A_{\mathrm{eq}} \models E(G_0) = E(G)$ then G will be generated by Algorithm 1.

Proof. By Tables 1 and 2, we show that for any operator op, if $Y = op(X_1, \ldots, X_n)$, then $A_{\mathrm{sub}} \models \mathsf{subexpr}(\mathrm{E}(X_i), \mathrm{E}(Y))$ for $1 \le i \le n$. That is, the abstract expression of each input to op

Table 2: Axiomatization of abstract expressions used for pruning. Mirage checks whether an abstract expression E_1 is a subexpression of E_2 by querying an SMT solver to check if $\mathsf{subexpr}(E_1, E_2)$ is entailed by these axioms. All variables in these axioms are universally quantified.

Abstract Expression Property	Comment
Equivalence Axioms A_{eq}

$\forall x,y,i.\ \mathsf{sum}(i,\mathsf{add}(x,y))=\mathsf{add}(\mathsf{sum}(i,x),\mathsf{sum}(i,y))$	associativity
$\forall x,y,i.\ \mathsf{sum}(i,\mathsf{mul}(x,y))=\mathsf{mul}(\mathsf{sum}(i,x),y)$	distributivity
$\forall x,y,i.\ \mathsf{sum}(i,\mathsf{div}(x,y))=\mathsf{div}(\mathsf{sum}(i,x),y)$	distributivity
$\forall x,y.\ \mathsf{mul}(\mathsf{exp}(x),\mathsf{exp}(y))=\mathsf{exp}(\mathsf{add}(x,y))$	distributivity
$\forall x,y.\ \mathsf{mul}(\mathsf{sqrt}(x),\mathsf{sqrt}(y))=\mathsf{sqrt}(\mathsf{mul}(x,y))$	distributivity
Subexpression Axioms A_{sub}	
$\forall x,y.\ \mathsf{subexpr}(x,\mathsf{add}(x,y))$	
$\forall x,y.\ \mathsf{subexpr}(x,\mathsf{mul}(x,y))$	
$\forall x,y.\ \mathsf{subexpr}(x,\mathsf{div}(x,y))$	
$\forall x,y.\ \mathsf{subexpr}(y,\mathsf{div}(x,y))$	
$\forall x.\ \mathsf{subexpr}(x,\mathsf{exp}(x))$	
$\forall x.\ \mathsf{subexpr}(x,\mathsf{sqrt}(x))$	
$\forall x.\ \mathsf{subexpr}(x,\mathsf{silu}(x))$	
$\forall x,i.\ \mathsf{subexpr}(x,\mathsf{sum}(i,x))$	
$\forall x.\ \mathsf{subexpr}(x,x)$	reflexivity
$\forall x,y,z.\ \mathsf{subexpr}(x,y)\wedge\mathsf{subexpr}(y,z)\rightarrow\mathsf{subexpr}(x,z)$	transitivity

is always a subexpression of *op*'s output. Given that A_{sub} includes reflexivity and transitivity axioms, it follows that for any G' that is a prefix of G, $A_{\text{sub}} \models \mathsf{subexpr}(\mathrm{E}(G'),\mathrm{E}(G))$. Together with the assumption that $A_{\text{eq}} \models E(G_0)=E(G)$, we have $A_{\text{eq}} \cup A_{\text{sub}} \models \mathsf{subexpr}(\mathrm{E}(G'),\mathrm{E}(G_0))$. Thus, no prefix of G will be pruned, and Mirage will generate G. □

The theorem highlights the role of abstract expressions in solving the "chicken and egg" problem outlined above. To decide if a prefix μGraph is useful, we reason about whether it is a prefix of a useful computation *in the abstract*. The choice of abstraction and the axioms A_{eq} represents a tradeoff between optimality and pruning. As Theorem 1 shows, we are only guaranteed to find the optimal μGraph whose abstract expression is equivalent to that of the input program under A_{eq}. Stronger axioms expand the set of μGraphs covered by the theorem but reduce pruning effectiveness, since more prefixes would pass the subexpression test. In particular, note that A_{eq} does not include cancellation rules (e.g., $\mathsf{div}(\mathsf{mul}(x,y),y)=y$). As a result, Mirage may miss some equivalent μGraphs. However, including such axioms would make everything a subexpression of everything, therefore nulling desired pruning. As our evaluation shows, the chosen A_{eq} yields a good balance between pruning and optimality.

5 Probabilistic Equivalence Verifier

Mirage's *probabilistic equivalence verifier* checks if a candidate μGraph is equivalent to the desired LAX program. The key idea is to evaluate both on *random inputs* in two finite fields. Using finite fields instead of floating point numbers not only avoids floating point errors but also provides a strong theoretical guarantee: the probability of accepting a non-equivalent μGraph can be made arbitrarily low.

For general programs, random testing can hardly provide any correctness guarantee. However, we show that for LAX programs (formally defined below), random testing offers a probabilistic correctness guarantee, and repeated tests can reduce the error probability to an arbitrarily small threshold.

Prior work [46] has applied a similar technique to check equivalence between tensor programs that contain only linear operators (e.g., matrix multiplication, convolution). We develop a random testing technique that also supports division and exponentiation, which are needed for many DNN optimizations (e.g., the RMSNorm example in §3).

Mirage verifies equivalence between LAX μGraphs (linear, division, and an exponentiation) defined below. We introduce the main theoretical results in §5.1 and present Mirage's verification methodology in §5.2.

Definition 5.1 (LAX μGraph)**.** A μGraph G is a LAX μGraph if (1) G contains only multi-linear operators[4], division, and exponentiation, and (2) every path from an input to an output in G includes at most one exponentiation.

5.1 Theoretical Foundations

Without loss of generality, we assume a LAX μGraph G takes n input tensors and produces one output tensor. Our theoretical results directly generalize to LAX μGraph with multiple outputs. Since each LAX μGraph includes linear operators, divisions, and at most one exponentiation along each path, the computation for each entry of the output tensor can be expressed in the following form (by using standard identities such as $\frac{\frac{a}{b}}{\frac{c}{d}}=\frac{ad}{bc}$, $\frac{a}{b}+\frac{c}{d}=\frac{ad+bc}{bd}$, $e^x e^y = e^{x+y}$):

$$\frac{\sum_{i=1}^{k} f_i \exp(g_i/h_i)}{\sum_{i=1}^{k'} f'_i \exp(g'_i/h'_i)} \tag{2}$$

where f_i, g_i, h_i, f'_j, g'_j and h'_j ($1 \le i \le k$, $1 \le j \le k'$) are polynomials over the entries of the input tensors.

The main theoretical result that underpins our randomized equivalence verification is the following theorem, which extends polynomial identity testing (PIT) [37, 54] on finite fields to LAX μGraphs. Note that the difference of two LAX

[4]Operator *op* with n inputs is multi-linear if *op* is linear to all inputs I_k:
(1) $\forall X,Y.op(I_1,...,I_{k-1},X,I_{k+1},...,I_n) + op(I_1,...,I_{k-1},Y,I_{k+1},...,I_n) = op(I_1,...,I_{k-1},X+Y,I_{k+1},...,I_n)$, and
(2) $\alpha \cdot op(I_1,...,I_{k-1},X,I_{k+1},...,I_n) = op(I_1,...,I_{k-1},\alpha\cdot X,I_{k+1},...,I_n)$.

Table 3: Arithmetic operations for random testing. Mirage selects two prime numbers p and q such that q divides $p-1$. x_p and x_q are values from the finite fields $\mathbb{Z}_p$ and $\mathbb{Z}_q$, respectively. The notation x^{-1} and $\sqrt{x}$ represents the multiplicative inverse and square root of x in the corresponding finite field. Specifically, $xx^{-1} \bmod p = 1$ and $\sqrt{x}\sqrt{x} \bmod p = x$.

Opt.	Opd. 1	Opd. 2	Output
Add.	(x_p, x_q)	(y_p, y_q)	$\big((x_p + y_p) \bmod p, (x_q + y_q) \bmod q\big)$
Sub.	(x_p, x_q)	(y_p, y_q)	$\big((x_p - y_p) \bmod p, (x_q - y_q) \bmod q\big)$
Mul.	(x_p, x_q)	(y_p, y_q)	$\big(x_p y_p \bmod p, x_q y_q \bmod q\big)$
Div.	(x_p, x_q)	(y_p, y_q)	$\big(x_p y_p^{-1} \bmod p, x_q y_q^{-1} \bmod q\big)$
Exp.	(x_p, x_q)	–	$\big(\omega^{x_q} \bmod p, -\big)$
Sqrt.	(x_p, x_q)	–	$\big(\sqrt{x_p}, \sqrt{x_q}\big)$

μGraphs is also of the form of Equation (2). Therefore, identity testing of two LAX μGraphs reduces to testing if an expression of that form is zero. Due to the presence of exponentiation, we use two finite fields instead of one.[5]

Theorem 2. Let P be a function of the form described in Equation (2), where $f_i, g_i, h_i, f_i', g_i', h_i'$ are non-zero polynomials of degree at most d with integer coefficients between $[-w, w]$. Let p, q be primes such that $q \mid p-1$ and $q > 2w$. Let $\mathcal{G}$ be the set of q-th roots of unity in $\mathbb{Z}_p$. If P is not a zero function, then [27]

$$\Pr_{(\vec{u},\vec{v},\omega) \leftarrow \mathbb{Z}_p^N \times \mathbb{Z}_q^N \times \mathcal{G}} \left[\frac{\sum_{i=1}^{k} f_i(\vec{u}) \omega^{g_i(\vec{v})/h_i(\vec{v})}}{\sum_{i=1}^{k'} f_i'(\vec{u}) \omega^{g_i'(\vec{v})/h_i'(\vec{v})}} \right] \leq 8dk^4/q + q^{-1/k^2}.$$

5.2 Random Tests over Finite Fields

Mirage leverages Theorem 2 to probabilistically verify the equivalence of two μGraphs by performing random testing over the finite fields $\mathbb{Z}_p$ and $\mathbb{Z}_q$ as defined in Theorem 2. To check the equivalence of two μGraphs, Mirage first generates input tensors, with each entry uniformly sampled from $\mathbb{Z}_p \times \mathbb{Z}_q$. Mirage also samples ω uniformly from the set of q-roots of unity in $\mathbb{Z}_p$, which is used for exponentiation. Mirage then evaluates the two μGraphs on these inputs using the operations defined in Table 3. As explained in §5.1, $\mathbb{Z}_p$ and $\mathbb{Z}_q$ are used for computations outside and inside the exponent, respectively. All operations except exponentiation are implemented via modular arithmetic in $\mathbb{Z}_p$ and $\mathbb{Z}_q$ independently. For exponentiation, Mirage uses the value x_q from $\mathbb{Z}_q$ and computes $\omega^{x_q} \bmod p$ to obtain a result in $\mathbb{Z}_p$.

Note that in a LAX μGraph, exponentiation is performed at most once along each path. Finally, Mirage checks whether the two μGraphs produce identical outputs. This process is repeated multiple times, and the two μGraphs are considered equivalent if they pass all random tests. The following theorem, which follows from Theorem 2, shows that this process can yield an arbitrarily low error rate.

Theorem 3. Equivalent μGraphs always pass μGraph verification. For two non-equivalent μGraphs and a given probability threshold $0 < \delta \leq 1$, the μGraphs pass all $\Omega(\frac{k^2}{\ln q} \cdot \ln \frac{1}{\delta})$ random tests with probability at most δ.

Numerical stability. While the theorem bridges finite fields and real-number computations, discrepancies can arise between real-number computations and floating-point operations, particularly involving overflow or underflow due to large intermediate values. Mirage employs floating-point tests to filter out μGraphs with significant numerical errors.

6 μGraph Optimizer

For each verified μGraph, Mirage's *μGraph optimizer* maximizes its performance by further performing *layout optimization*, *operator scheduling*, and *memory planning*, as shown in Figure 1. Mirage defers these μGraph optimizations until after verification for two reasons. First, these optimizations *do not* affect the correctness of the generated μGraphs; omitting them when generating μGraphs reduces the search space Mirage must consider, since μGraphs with the same graph topology but different choices of tensor layouts, operator orders, or memory allocation plans are considered identical by the μGraph generator. Second, applying these optimizations after verification also reduces the search space for these optimizations, since the μGraph optimizer only needs to optimize μGraphs that are functionally equivalent to the input.

Tensor layouts. The μGraph optimizer explores possible data layouts for all intermediate tensors at the kernel, block, and thread levels and chooses the best combinations to maximize performance. We formulate layout selection as a constrained optimization problem and solve it optimally using an integer linear programming (ILP) algorithm. Specifically, for each tensor t and each possible layout l for t, we introduce a boolean variable $B_{t,l}$ to indicate whether tensor t uses layout l. Operators at the kernel, block, and thread levels may impose various constraints on tensor layouts. For example, to use kernels from the cuBLAS library [16] for matrix multiplication, the innermost dimension of the two input tensors must be among the last two dimensions. These restrictions are converted into a series of linear constraints on $B_{t,l}$. Different tensor layouts may lead to varying performance. For example, some input tensor layouts support bulk copies from device to shared memory, while others do not. Mirage introduces a cost function to model the performance of each operator under different layout choices. Mirage uses an off-the-shelf ILP solver (i.e., Z3 [18]) to find an optimal layout strategy that satisfies all layout constraints while minimizing cost.

[5] We use two primes p and q for polynomial identity testing [37, 54] outside and inside the exponents, respectively. The condition q divides $p-1$ is to ensure the existence of q-th roots of unity in $\mathbb{Z}_p$.

Table 4: DNN benchmarks used in our evaluation.

Name	Description	Base Architecture
GQA	Group-query attention	LLaMA-3-70B [41]
QKNorm	QK normalization with attention	Chameleon-7B [40]
RMSNorm	RMS normalization with linear	LLaMA-2-7B [44]
LoRA	Low-rank adaptation	GPT-3-7B-LoRA [6]
GatedMLP	Gated multi-layer perceptron	Falcon-7B [10]
nTrans	Normalized Tarnsformer	nGPT-1B [28]

Operator scheduling. In a μGraph, there are multiple topological orders to execute operators, and different orders may yield different performance. For a given input μGraph, the μGraph optimizer identifies an efficient strategy to schedule operators by minimizing thread-level synchronization within each thread block (i.e., `__syncthreads()` in CUDA). To achieve this goal, Mirage labels each node with a *depth*, defined as the length of the longest path from any input operator to that node. Mirage uses a dynamic programming algorithm to compute the depth of each node and schedules all operators in ascending order of their depths. This approach minimizes the number of thread-level synchronizations required in the generated CUDA kernel, as Mirage only needs to insert synchronization points between operators with different depths.

Memory planning. A third class of post-verification optimizations is memory planning, which determines memory offsets for all intermediate tensors at the kernel, block, and thread levels. Mirage formulates memory planning as a *dynamic storage allocation* problem and exhaustively enumerates all possible allocation plans to discover an optimal strategy.

7 Implementation

Mirage is implemented in 30K lines of code in C++, CUDA, and Python. Kernel operators are implemented with the cuDNN and cuBLAS libraries [15, 16], and block and thread operators are implemented using cuTLASS [2] and CUDA PTX. For each input tensor program, Mirage automatically generates and verifies potential μGraphs. For each verified μGraph, Mirage produces CUDA source code for all custom kernels of the μGraph and compiles the code into binary using the CUDA compiler. This approach enables just-in-time (JIT) compilation and deployment for general tensor programs, and the generated kernels can be directly integrated into a PyTorch program with a few lines of code changes. Mirage's SMT and ILP solvers are implemented using Z3 4.12.6 [18].

Our implementation supports the operators listed in Table 1. Mirage can be extended to include new operators, such as variants of convolution or matrix multiplication, at the kernel, block, and/or thread levels. To support a new linear operator, Mirage requires (1) a float-pointing implementation of the operator at the kernel, block, and/or thread levels, which is used by the μGraph optimizer to generate CUDA kernels; (2) an implementation of the operator over modular arithmetic (see §5); and (3) an extension to the abstract expression axioms A_{eq} and A_{sub} for the operator (see §4.3).

To utilize Theorems 2 and 3, random tests should be performed with sufficiently large prime numbers p and q and iterated multiple times. Our current implementation uses the largest values of p and q whose product fits in 16-bit integers (i.e., $p=227, q=113$) to run these random tests on GPUs. We leverage Mirage's GPU optimizations–such as keeping intermediate results in shared memory–to accelerate the search procedure. We also perform a single random test without iterating it and compare all elements of the output tensors. We note that this equivalence verification procedure does not introduce false negatives. While it could, in theory, introduce false positives, we have not observed any in practice. For these reasons, we consider this procedure sufficient for the search process and plan to add a final verification step that provides the theoretical guarantees only for the best μGraph at the end of the optimization process.

Equivalence verification for non-LAX programs. While Mirage can generate μGraphs for arbitrary tensor programs, the probabilistic equivalence verifier is limited to LAX programs and does not support certain DNN operators such as ReLU [32]. As an alternative, we have developed a solver-based verifier for arbitrary tensor programs. The verifier relies on user-provided mathematical properties of individual operators (e.g., linearity, associativity, commutativity, and distributivity) defined in first-order logic and uses these properties to verify equivalence using an automated theorem prover. Compared to the probabilistic equivalence verifier, the solver-based verifier supports more general programs, while requiring additional manual effort to specify the properties of each new operator. A detailed discussion of the solver-based verifier is beyond the scope of this paper.

8 Evaluation

8.1 Experimental Setup

Since Mirage is a superoptimizer for LAX programs, we focus our evaluation on various DNN benchmarks commonly used in existing DNNs, each of which is a LAX program. These benchmarks provide the most fine-grained way to compare the performance of Mirage and existing systems. Table 4 shows the six benchmarks in our evaluation. GQA, RMSNorm, and GatedMLP are the main building blocks of large language models (LLMs). QKNorm introduces query-key normalization before attention to enhance model convergence [40]. LoRA enables low-rank adaptation for fine-tuning a DNN on different tasks. We use a context length of 8K for GQA and 4K for QKNorm, corresponding to the maximum supported by LLaMA-3-70B [41] and Chameleon-7B [40], respectively. In addition, we also evaluate how Mirage-generated kernels

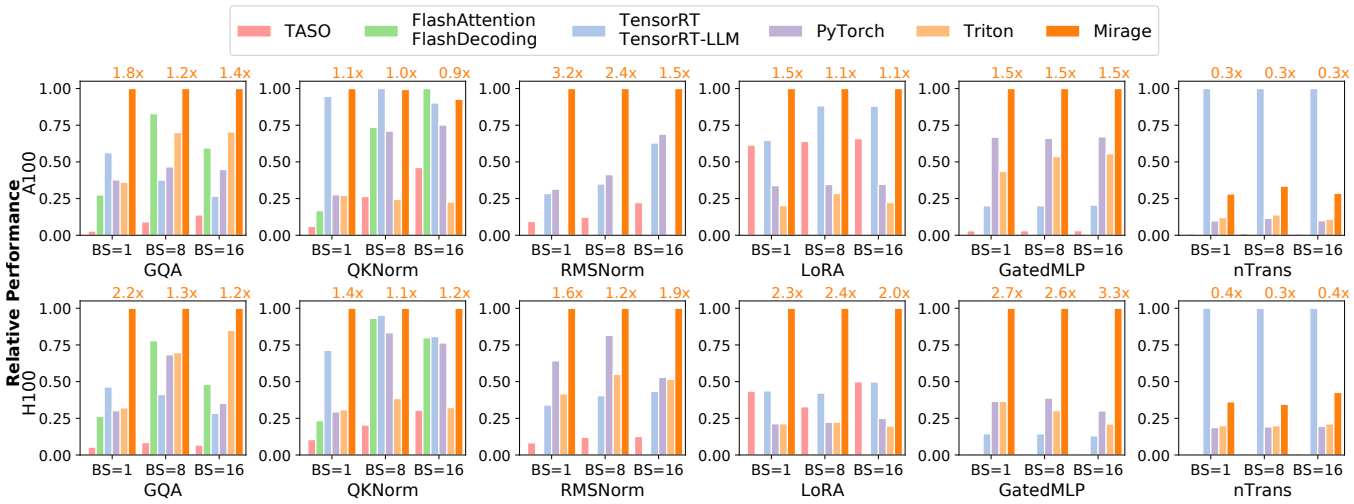

Figure 7: Comparing Mirage with existing systems for 6 benchmarks on an A100 and an H100 GPU. The performance of all systems are normalized by Mirage (higher is better). Numbers above the Mirage bars show the speedup over the best baselines.

improve the end-to-end performance of full DNNs, including Chameleon [40], nGPT [28], LLaMA-3 [41], and LoRA [22].

The experiments were conducted on NVIDIA A100 and H100 GPUs, each with 40GB of memory. All our benchmarks fit on a single GPU except GQA (used for LLaMA-2-70B), which is generally parallelized across four GPUs using tensor model parallelism [39]. Therefore, we evaluate GQA under this parallelism strategy, where the eight key-value heads are equally partitioned across four GPUs. Since the performance of Mirage and all baselines depends only on the shapes of the input tensors, we repeat each experiment 1,000 times using random inputs and report the average run time.

One of our benchmarks, LoRA, requires concatenation to express a common optimization: fusing two matrix multiplications via concatenation. To support this optimization in Mirage, we introduce a new linear operator that takes four inputs and computes $f(W,X,Y,Z)=(W\|X)\times(Y\|Z)$, where $\|$ is tensor concatenation. This operator is equivalent to computing $W\times Y+X\times Z$. We define the abstract expression associated with this operator as: $\mathrm{E}(f(W,X,Y,Z))=\mathsf{add}(\mathsf{sum}(k_1,\mathsf{mul}(\mathrm{E}(W),\mathrm{E}(Y))),\mathsf{sum}(k_2,\mathsf{mul}(\mathrm{E}(X),\mathrm{E}(Z))))$, where k_1 and k_2 are the last dimensions of W and X.

Unless otherwise stated, Mirage considers up to 5 operators in the kernel graph and up to 11 operators in each block graph.

8.2 Benchmark Results

Figure 7 compares the performance of Mirage with systems on six DNN benchmarks on NVIDIA A100 and H100 GPUs. All systems use half-precision floating points to run these DNN benchmarks. TASO [25] and PET [46] are DNN superoptimizers that automatically generate algebraic transformations at the kernel level. We report a combined TASO/PET baseline, as the latest TASO implementation includes PET's partially equivalent transformations as special substitutions. PyTorch [34] uses the highly optimized cuDNN and cuBLAS libraries [15, 16] to perform DNN operators on GPUs. For the PyTorch baseline, we enable `torch.compile` and use FlashAttention kernels to maximize performance. TensorRT and its LLM variant TensorRT-LLM include a set of manually designed and highly optimized kernels for common tensor operators such as attention [42]. FlashAttention and its inference variant FlashDecoding are manually written kernels for efficient attention [17, 21]. Finally, Triton is a schedule-based optimizer to generate high-performance kernels and has been adopted in production systems, outperforming other schedule-based approaches [43]. All baselines use CUDA Graphs to minimize kernel launch overhead.

Compared to the best existing approaches, Mirage improves the performance of these benchmarks by up to 3.3× by combing algebraic transformations, schedule transformations, and the generation of new custom kernels. §3 shows the best discovered μGraphs for RMSNorm. Next, we present a case study for the remaining benchmarks.

GQA. Group-query attention is the backbone of LLMs and has been heavily optimized by existing frameworks. For example, FlashAttention and FlashDecoding are expert-designed attention kernels and have been adopted in existing LLM inference systems [17]. Mirage discovers these expert-designed kernels as well as other μGraphs that outperform them by up to 2.2×. The speedup is achieved by two additional optimizations on top of existing hand-written kernels. First, current approaches rely on fixed heuristics to determine the grid dimensions for GQA, which are suboptimal in certain scenarios. For example, TensorRT-LLM launches the GQA kernel with grid dimensions of (8, 2, 1) and (8, 2, 8) when the batch sizes are 1 and 8, respectively. However, both configurations can-

(b) The best μGraph discovered by Mirage for QKNorm and attention.

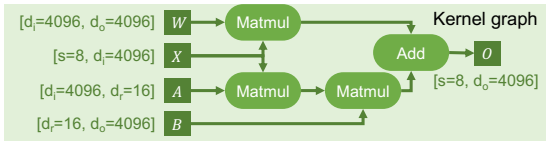
Figure 8: Comparing the μGraphs used by existing optimizers and Mirage for QKNorm and attention.

not fully utilize all SMs on A100 (108 SMs) and H100 (132 SMs) GPUs. In contrast, Mirage automatically searches for the best grid dimensions for each μGraph, resulting in full SM utilization. Further ablation study shows that the performance of the best μGraph discovered by Mirage degrades by 18% when using the same grid dimensions as TensorRT-LLM.

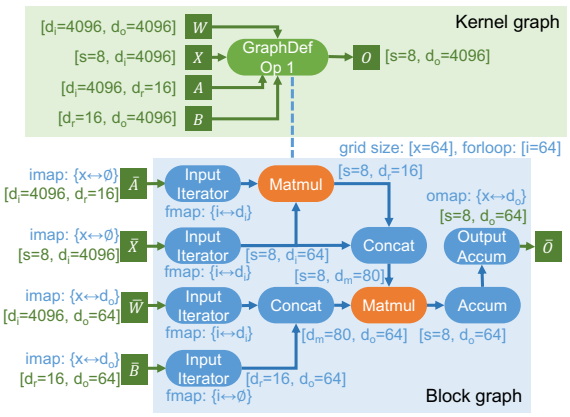
Second, existing approaches use fixed tensor dimensions to parallelize GQA across thread blocks. For example, FlashAttention [17] parallelizes attention across the *sample*, *head*, and *query sequence* dimensions, while FlashDecoding and TensorRT-LLM leverage the *sample*, *head*, and *key-value sequence* dimensions. Both strategies are efficient for conventional multi-head attention with many heads but suboptimal for GQA with fewer attention heads. In contrast, Mirage automatically selects the most efficient parallelization strategy by choosing among the sample, KV heads, query sequence, and key-value sequence dimensions. Moreover, Mirage generates different μGraphs tailored to different attention scenarios, reducing device memory access by up to 7× compared to the heuristics used in existing systems.

Implementing Mirage's μGraphs in existing systems is possible but requires extensive engineering effort to support different kernels for different scenarios. In contrast, Mirage automatically generates them and verify their correctness.

QKNorm. To reduce model divergence, several recent DNNs introduce query-key normalization (QKNorm) into the Transformer architecture [40]. QKNorm applies layer normalization to the query and key vectors before attention, as shown in Figure 8a. These additional normalization layers are not yet supported by existing attention implementations (e.g., FlashAttention and TensorRT-LLM) and require launching separate kernels for normalization and attention.



(a) The kernel graph for LoRA in existing systems.



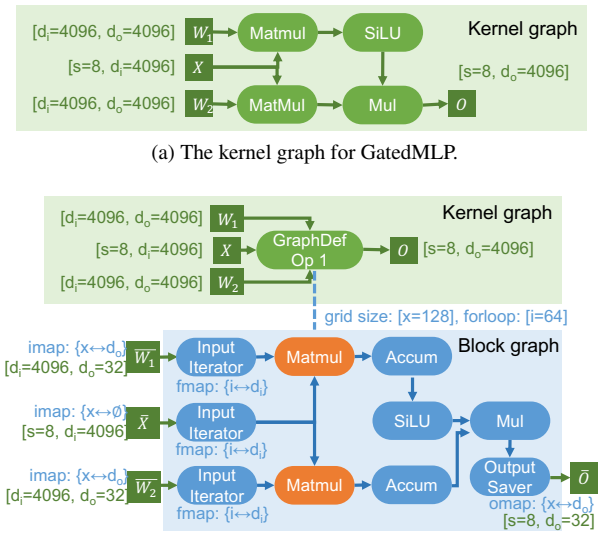
(b) The best μGraph discovered by Mirage for LoRA.

Figure 9: Comparing the tensor programs used by existing optimizers and by Mirage for LoRA: $O = W \times X + B \times A \times X$. Note that both matrices A and B are low-rank.

Mirage automatically discovers a μGraph that integrates QKNorm and attention computation into a custom kernel, as shown in Figure 8b. The μGraph reorganizes the attention computation to enable fusion with the two layer normalizations, which avoids writing intermediate results to GPU device memory and reduces the kernel execution time by up to 1.4×.

LoRA. Low-rank adaptation (LoRA) introduces a pair of low-rank adapters to the linear operators of a pre-trained DNN to improve its performance for downstream tasks. Existing tensor program optimizers launch separate kernels for the original linear operator and the two additional linear operators introduced by LoRA (Figure 9a), which introduces high kernel launch overheads since these LoRA operators involve minimal computation. Figure 9b shows the best μGraph discovered by Mirage for LoRA, which fuses the three `Matmul`s and the subsequent `Add` into a single kernel. Mirage reorganizes the computation into two block-level `Matmul`s by leveraging the following algebraic transformation: $W \times X + B \times A \times X = (W \| B) \times \big(X \| (A \times X)\big)$. The `Concat`s in Figure 9b do not involve any computation and are performed by updating tensor offsets in GPU shared memory. This μGraph reduces the execution cost of LoRA by 1.1-2.4×.

GatedMLP. Gated multi-layer perceptrons are commonly used in DNNs to capture non-linear representations. We use the GatedMLP configuration introduced in Falcon-7B [10], whose kernel graph is shown in Figure 10a. Existing tensor program optimizers generally fuse the two `Matmul`s in



(a) The kernel graph for GatedMLP.

(b) The best μGraph discovered by Mirage for GatedMLP.

Figure 10: Comparing the μGraphs used by existing optimizers and Mirage for GatedMLP.

a single kernel to reduce GPU device memory access, since the input tensor X only needs to be loaded once. However, this approach still requires launching multiple kernels and storing intermediate results—specifically, the output of the two `Matmul`s—in device memory, as the `SiLU` activation and elementwise multiplication are not fused with the `Matmul`s.

In contrast, the best μGraph discovered by Mirage (Figure 10b) performs the two `Matmul`s in parallel within the same block graph and fuses the remaining computation (i.e., `SiLU` and `Mul`) as post-processing steps within the same block graph. This approach yields 1.5× speedups on A100 GPUs and 2.7-3.3× speedups on H100 GPUs.

nTrans. To accelerate model training, nGPT introduces normalized Transformer, which normalizes all intermediate results in Transformer [28]. Formally, the computation is defined as $y = \texttt{Norm}(x + \alpha(\texttt{Norm}(h - x)))$, where `Norm` is a normalization layer, and x, h, and α are input tensors. Existing systems launch three separate kernels for nTrans, since it interleaves normalization and elementwise addition and multiplication. Mirage automatically discovers a μGraph that fuses the computation into a single kernel and stores all intermediate results in GPU shared memory. Mirage outperforms other baselines but is slower than TensorRT. This performance gap is because Mirage loads data from global memory to shared memory and writes it back for each tensor in graph-defined kernels. This design improves memory efficiency and enables asynchronous pipelines. However, for kernels with light computation, the overhead of these memory transfers can dominate the kernel runtime. To mitigate this overhead, we plan to extend Mirage to support bypassing shared memory during data loading, therefore avoiding unnecessary data movement.

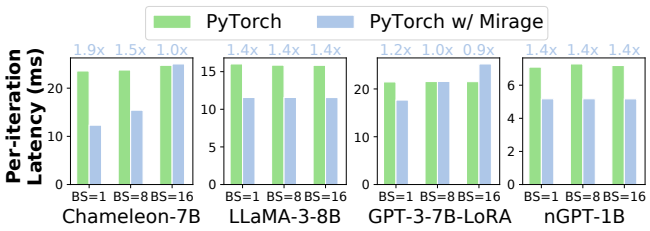


Figure 11: Comparing the end-to-end inference performance of PyTorch and PyTorch with Mirage-generated kernels.

Table 5: Ablation study on Mirage's techniques to accelerate μGraph generation. We evaluate the impact of multi-threading and abstract expressions on search time for RMSNorm.

Max # Ops in a Block Graph	Mirage	Mirage w/o Multithreading	Mirage w/o Abstract Expression
5	11 sec	58 sec	768 sec
6	16 sec	93 sec	19934 sec
7	22 sec	150 sec	> 10 h
8	24 sec	152 sec	> 10 h
9	26 sec	166 sec	> 10 h
10	26 sec	166 sec	> 10 h
11	28 sec	183 sec	> 10 h

8.3 End-to-end Results

In addition to the microbenchmark performance, we also evaluate how Mirage-generated kernels impact the end-to-end latency of commonly used DNNs. Mirage supports just-in-time compilation and deployment, and its generated kernels can be directly integrated into PyTorch programs. We compare PyTorch with its native handwritten CUDA kernels and PyTorch with Mirage-generated kernels on four DNN models. Figure 11 shows the results. Mirage reduces the end-to-end latency of these models by 0.9-1.9× by automatically generating highly optimized kernels. The improvement is achieved with a few lines of code changes to the PyTorch programs.

8.4 Search Time

In our evaluation, Mirage takes up to 4 hours to optimize a LAX program. This optimization is a one-time cost before deployment on the target hardware. This subsection provides detailed results and an ablation study of Mirage's search procedure, focusing on how its techniques enable the exploration of large μGraphs while maintaining low search time. In particular, we evaluate the impact of two techniques: pruning via abstract expressions (§4.3) and multi-threading. Table 5 reports the search times for RMSNorm as we vary the maximum number of operators allowed in a block graph.

Multi-threading significantly reduces the search time, while pruning via abstract expressions is crucial for the scalability of Mirage. Specifically, the pruning techniques allow Mirage to explore μGraphs whose block graphs can each have at most 11 operators, while disabling abstract expression pruning

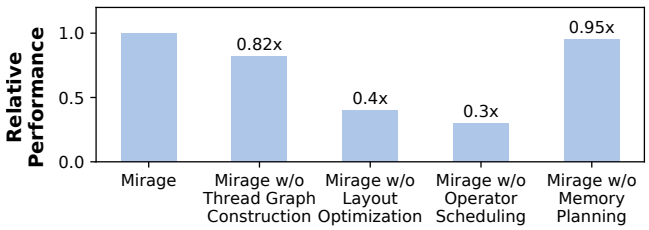

Figure 12: Ablation study on optimizations used in Mirage. We evaluate the performance degradation when disabling each optimization independently. The evaluation is performed on A100 for GQA with batch size 1.

restricts Mirage to handle block graphs with up to 6 operators within a 10-hour search window. Note that discovering the optimized μGraph for RMSNorm shown in Figure 3 requires exploring block graphs with 11 operators.

8.5 Ablation Study on Optimizations

We conduct an ablation study to evaluate the impact of thread graph construction and optimizations introduced in §6, including layout optimization, operator scheduling, and memory planning. Specifically, we measure the performance degradation of the best μGraph discovered by Mirage when each optimization is disabled independently. The study is conducted on an A100 using the GQA benchmark with a batch size of 1. The results, shown in Figure 12, indicate that disabling any individual optimization leads to a performance degradation ranging from 5% to 70%.

9 Related Work

Manually-designed kernels. Many existing frameworks, such as TensorFlow XLA [1, 9], PyTorch [34], and TensorRT [42], rely on GPU experts to manually design kernels for ML operators. Recently, significant engineering effort has been dedicated to hand-optimizing GPU kernels for commonly used DNNs, particularly foundation models [12]. For example, to accelerate attention computation [47], several specialized kernels have been developed based on FlashAttention [4,5,17,21]. Due to the increasing complexity of modern GPUs—such as tensor cores in A100s [29] and thread block clusters in H100s [7]—manually designed kernels may miss subtle optimizations that are hard to discover manually.

Superoptimization-based approaches. Superoptimization was originally introduced to find optimal instruction sequences [11, 30, 36]. Recent work has applied superoptimization techniques to tensor programs [23–26, 45, 46, 49, 52]. However, all these attempts only consider algebraic transformations at the kernel level and cannot discover more sophisticated optimizations that require jointly considering algebraic and schedule transformations at all of the kernel, block, and thread levels. Our evaluation shows that Mirage largely outperforms existing DNN superoptimizers, demonstrating the importance of multi-level joint optimization.

Schedule-based approaches. Recent work has introduced ML compilers that automatically optimize the execution schedule of kernel GPUs. Systems such as TVM [13, 14], Ansor [51], and Triton [43], along with others [19, 20, 53], build on the idea of algorithm-schedule separation introduced in Halide. They search for optimized schedules to execute a user-specified algorithm on GPUs. However, schedule-based approaches require users to explicitly specify the algorithm for each kernel, and their performance is limited to the quality of these provided algorithms.

Multi-level graph representations. Welder [38] and ASPEN [33] introduce multi-level tile graphs that share similarities with Mirage's μGraphs, as both representations follow the GPU hierarchy. However, prior work focuses on scheduling transformations, while Mirage extends beyond scheduling by also considering algebraic transformations and the discovery of new custom kernels. Most optimizations presented in this paper fall outside the scope of these prior approaches.

10 Conclusion

This paper proposes Mirage, the first multi-level superoptimizer for tensor programs. Mirage introduces a hierarchy graph representation to specify a tensor program at the kernel, thread block, and thread levels of the GPU execution hierarchy, and uses a novel pruning technique based on abstraction to significantly reduce the search space Mirage needs to consider while providing a certain optimality guarantee. Mirage outperforms existing tensor program optimizers by up to 3.3×, even for widely used and heavily optimized DNNs.

Acknowledgment

We would like to thank the anonymous reviewers and our shepherd, Stephanie Wang, for their valuable comments and suggestions. We thank Tianqi Chen, Phillip Gibbons, Bohan Hou, Muyan Hu, Jinchen Jiang, Xiaoyu Jiang, Ruihang Lai, Yu Zhou, and other CMU Catalyst members for their feedback on this work. Abstract

Heterogeneous deep learning systems (DLS) such as GPUs and ASICs have been widely deployed in industrial data centers, which requires to develop multiple low-level tensor programs for different platforms. An attractive solution to relieve the programming burden is to transcompile the legacy code of one platform to others. However, current transcompilation techniques struggle with either tremendous manual efforts or functional incorrectness, rendering "Write Once, Run Anywhere" of tensor programs an open question.

We propose a novel transcompiler, i.e., *QiMeng-Xpiler*, for automatically translating tensor programs across DLS via both large language models (LLMs) and symbolic program synthesis, i.e., neural-symbolic synthesis. The key insight is *leveraging the powerful code generation ability of LLM to make costly search-based symbolic synthesis computationally tractable*. Concretely, we propose multiple LLM-assisted compilation passes via pre-defined meta-prompts for program transformation. During each program transformation, efficient symbolic program synthesis is employed to repair incorrect code snippets with a limited scale. To attain high performance, we propose a hierarchical auto-tuning approach to systematically explore both the parameters and sequences of transformation passes. Experiments on 4 DLS with distinct programming interfaces, i.e., Intel DL Boost with VNNI, NVIDIA GPU with CUDA, AMD MI with HIP, and Cambricon MLU with BANG, demonstrate that *QiMeng-Xpiler* correctly translates different tensor programs at the accuracy of 95% on average.

1 Introduction

Due to the ever-increasing demand for computation from neural network workloads, various deep learning systems (DLS), e.g., NVIDIA GPU with Tensor Core [12], Google TPU [32], GraphCore IPU [9], and Cambricon MLU [3], have been deployed in data centers of cloud and internet service companies such as Microsoft [10], Google [6], and Amazon [4]. To fully exploit various DLS, it is required to develop multiple high-performance tensor programs, i.e., low-level implementations of tensor operators in deep learning, for different platforms, which are notoriously challenging because of the complicated architecture and programming models. Ideally, if we only need to write one copy of a program, and can run it on different platforms, that is, "Write Once, Run Anywhere", it is feasible to address the programming problem in data centers with heterogeneous DLS.

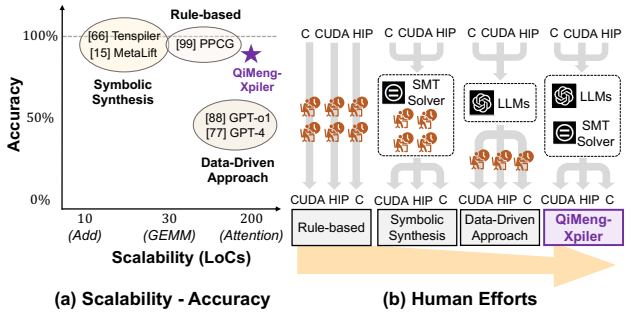

Figure 1: Comparing *QiMeng-Xpiler* to existing transcompilation techniques on (a) scalability-accuracy axis and (b) human efforts

One of the most attractive solutions to achieve "Write Once, Run Anywhere" on heterogeneous platforms is source-to-source compilation, i.e., transcompilation, which automatically compiles the code written with one high-level language to another. Existing transcompilation efforts fall into three categories, i.e., rule-based, symbolic synthesis, and data-driven approaches. The rule-based approaches require experts to manually define a set of transformation rules, typically applied to Abstract Syntax Tree (AST), between different programming languages, and then employ pattern matching to parse the input source programs [26, 31]. For example, a CUDA-to-FPGA translator, i.e., FCUDA, defines a set of transformation rules for data communication, compute optimization, and parallelism mapping [40]. The symbolic synthesis approaches generate semantic-preserving target code from either domain-specific languages [41] or input/output examples [52]. Since they typically rely on a costly search-based SMT (Sat-

*Yunji Chen (cyj@ict.ac.cn) is the corresponding author.

isfiability Modulo Theories) solver [37], it is hard to scale to large-size general-purpose programs. The data-driven approaches, which typically train neural networks from a large amount of source code for code generation, have emerged recently [16,44,53]. Notable examples include TransCoder [43], StarCoder [34], GPT-4 [15], and OpenAI-o1 [8] which automatically translate programs written in different high-level languages such as C++, Java, and Python.

However, the above transcompilation techniques are not applicable to DLS due to their complicated architecture and programming models. Regarding the rule-based approaches, the huge architectural discrepancy between different platforms makes it infeasible to manually define efficient transformation rules. Regarding the symbolic synthesis approaches, in addition to their limited scalability, it is infeasible to handle different parallel semantics, e.g., SIMT in CUDA C and SIMD in BANG C [2], for the SMT solver. Meanwhile, it also requires considerable manual efforts to accurately specify the input constraints for the SMT solver. Regarding the data-driven approaches, even with pre-trained large language models (LLMs), tensor program semantics cannot be fully preserved and thus the translation accuracy only achieves 29.6% [35], which requires considerable manual efforts for code correction. In summary, existing transcompilation techniques for tensor programs face challenges such as tremendous manual efforts, limited scalability, or functional incorrectness, as shown in Figure 1.

To automatically translate tensor programs across DLS with a correctness guarantee, we propose to exploit both the *flexibility of data-driven approaches*, specifically, via LLMs, and the *soundness of symbolic synthesis approaches*. However, the challenge of collaboration between LLM and symbolic synthesis is three-fold: (1) it is difficult to generate highly accurate code via LLM due to the scarcity of tensor programs, (2) it is non-trivial to determine which code snippets should be formally generated by search-based symbolic synthesis, in order to balance the computational costs and achieved accuracy, and (3) performance optimizations are hard to specify either with LLM prompts or synthesis specifications, making the performance of generated code significantly lags behind that of human experts.

1.1 Our Proposal

To address the above challenges, we propose to build a novel transcompiler, i.e., *QiMeng-Xpiler*, for translating tensor programs across DLS via both LLM (i.e., GPT-4 [20]) and search-based symbolic synthesis. The key of *QiMeng-Xpiler* is that *the program translation is automatically conducted as a series of LLM-assisted transformation passes, where incorrect code snippets are repaired by small-scale symbolic synthesis, and the optimal transformation passes are identified via hierarchical auto-tuning*. The advantages of proposed neural-symbolic synthesis are: (1) the entire transcompilation is decomposed into multiple transformation passes via a chain of LLM prompting, instead of a single prompt in traditional LLM-assisted code generation, to significantly improve the accuracy, (2) the problem size for symbolic synthesis is constrained to a limited scale so that the SMT solver can handle it efficiently, and (3) the performance optimization is achieved by exploring both the parameters and sequences of transformation passes.

Concretely, by considering the high parallelism, memory hierarchy, and specialized ISA of DLS, the proposed approach consists of three categories of transformation, i.e., *sequentialization/parallelization*, *memory conversion*, and *(de)tensorization*. Each transformation pass is first performed with LLM-based code transformation, then validated with unit-test, and finally repaired with an SMT-solver if necessary. Then, a hierarchical auto-tuning approach consisting of the *intra-pass* and *inter-pass* auto-tuning is conducted to improve the performance. The intra-pass auto-tuning uses brute-force search to find the optimal parameters (e.g., tiling sizes) for program transformation, and the inter-pass auto-tuning uses MCTS (Monte Carlo Tree Search) [19] to determine the optimal sequence of passes with maximized performance.

To demonstrate the generality of *QiMeng-Xpiler*, we conduct experiments on 4 different DLS with their interfaces, i.e., Intel DL Boost with VNNI intrinsics, NVIDIA GPU with CUDA C, AMD MI with HIP code, and Cambricon MLU with BANG C. Experimental results show that *QiMeng-Xpiler* correctly translates different programs at the accuracy of 95% on average, and the performance of translated programs achieves an average of 0.78× of vendor-provided manually-optimized libraries including cuDNN/cuBLAS [1,11] and oneDNN [14]. Moreover, the programming productivity of 2 representative DLS, i.e., NVIDIA GPU and MLU, is improved by up to 34.3× and 96.0×, respectively.

1.2 Key Contributions

To our best knowledge, this work is *the first to automatically translate tensor programs of deep learning systems with different programming models*. This paper makes the following contributions:

- **Neural-symbolic program synthesis**. We propose to use LLMs for generating high-level program sketches via pre-defined meta-prompts and repair the incorrect low-level details through SMT-based symbolic synthesis with limited scale, which achieves *automatic program translation with a correctness guarantee*.
- **Hierarchical performance auto-tuning**. We propose a hierarchical auto-tuning approach, where the *intra-pass* and *inter-pass* auto-tuning are used for exploring pass parameters and pass sequences, respectively, to maximize the performance of synthesized programs.
- **Extensive evaluation**. We conduct extensive evaluations on 4 different deep learning systems, and experimental

Table 1: Comparison of deep learning systems (Intel DL Boost, NVIDIA GPU, AMD MI, and Cambricon MLU) and their programming interfaces. The characteristics fall into three categories: Parallelism, Memory Hierarchy, and Specialized Intrinsics.

Platforms	Interfaces	Categories	Examples
Intel DL Boost	C with VNNI extensions	Specialized Intrinsic	`_mm_dpbusds_epi32(...)`, `_mm512_dpbusd_epi32(...)`
NVIDIA GPU with Tensor Core	CUDA C	Parallelism	`blockIdx`, `threadIdx`
		Memory Hierarchy	`registers`, `__shared__`, `__global__`
			`matrix_a`, `matrix_b`, and `accumulator` in Tensor Core fragments
		Specialized Intrinsics	`wmma::mma_sync(d, a, b, c)`
AMD MI with Matrix Core	HIP	Parallelism	`blockIdx`, `threadIdx`
		Memory Hierarchy	`registers`, `__shared__`, `__global__`
			`matrix_a`, `matrix_b`, and `accumulator` in Matrix Core fragments
		Specialized Intrinsics	`d = __builtin_amdgcn_mfma_f32_16x16x4f32(a, b, c, ...)`
Cambricon MLU	BANG C	Parallelism	`taskId` for task-level parallelism
			`clusterId`, `coreId` for multi-core parallelism
		Memory Hierarchy	`registers`, `__mlu_shared__`, `__mlu_device__`
			`__nram__`, `__wram__`
		Specialized Intrinsics	`__bang_mlp(...)`, `__bang_conv(...)`

results on accuracy, execution performance, and productivity improvement well demonstrate the effectiveness and efficiency of this work.

2 Background and Motivation

2.1 Background

Programming Deep Learning Systems. Deep learning systems (DLS) adopt different programming languages tailored to their hardware, such as CUDA C for NVIDIA GPU, HIP for AMD MI, BANG C for Cambricon MLU, and VNNI intrinsics for Intel DL Boost CPU. However, programming DLS poses substantial challenges due to their *inherent high parallelism*, *intricate memory hierarchies*, and *specialized instruction sets*. First, DLS typically follows parallel programming models, like SIMT or multi-core, diverging from conventional serial programming. This paradigm shift necessitates a deep understanding of task and data parallelism from programmers. Furthermore, DLS are designed with complex on-chip memory hierarchies to process diverse data types efficiently. For instance, Cambricon MLU uses separate neuron and weight storage for different memory types (i.e., NRAM and WRAM space), while NVIDIA GPU utilizes various memory spaces (e.g., local and shared memory) for multi-level dataflow. Such designs require programmers to explicitly manage complicated memory hierarchies. Additionally, to suit deep learning's computational demands, DLS often incorporate specialized instruction sets. Examples include Intel's DL Boost VNNI for specific operations and Cambricon's tensor intrinsics. These specialized intrinsics often come with intricate constraints, adding extra complexity to programming. Table 1 illustrates the stated programming difficulty for various DLS.

Search-based Program Synthesis. Researchers have studied how to use search-based program synthesis to transform legacy code to high-performance code with minimal manual efforts [17, 18, 30, 49]. The idea is to obtain programs that satisfy semantic correctness by searching through a predefined domain-specific language (DSL) or using an SMT solver for constraint solving. The main advantage of search-based program synthesis is to ensure the semantic equivalence between the original code and the translated code. However, these approaches always struggle with large search spaces, which means that they can only be applied to pre-defined DSL and thus cannot generate code for commodity deep learning systems. Additionally, they can only handle computational instructions and are unable to meet optimization requirements for hierarchical storage and parallel capabilities. Thus, the source-to-source translation across different deep learning systems remains an open problem.

LLM-assisted Program Generation. LLMs such as Codex [21] and StarCoder [34] are being increasingly used to assist in programming. They can generate programs based on problem descriptions and generate possible code snippets based on the provided code context, helping programmers write code quickly. They also allow programmers to describe problems in natural language without following specific programming language syntax. However, these LLMs have several limitations. Firstly, they lack a deep understanding of program semantics and cannot comprehend the intent of the code. This means that the generated code may be incorrect or incomplete, requiring further adjustment and optimization. Secondly, these models perform poorly in specific domains or complex problems, because it is typically difficult to obtain high-quality and diverse training data for these problems.

2.2 Motivation

To understand the design principle of *QiMeng-Xpiler*, we evaluate transcompilation of real-world tensor programs by state-of-the-art LLM (i.e., GPT-4) and program synthesis tools.

Taxonomy of the transcompilation errors. We first classi-

fied all errors introduced in the transcompilation process into 3 categories, each corresponding to specific characteristics of DLS mentioned above: (1) *Parallelism-related errors*, where the transcompilation fails to analyze the loop semantics and generates the incorrect loops or builtin variables of DLS, (2) *Memory-related errors*, where the transcompilation cannot deal with the intricate memory hierarchies for the DLS, resulting in incorrect memory declarations and usage, and (3) *Instruction-related errors*, which occur when the translated code utilizes incorrect instructions or parameters that cannot perform the same computation. Figure 2 illustrates examples of different errors when transcompiling from CUDA C to BANG C code by GPT-4. In Figure 2(a), LLM blindly reuses the GPU's parallel index (e.g., blockIdx.x * 1024 + threadIdx.x) on the MLU, ignoring the fact that the MLU's clusterId and coreId dimensions differ. Figure 2(b) fails to correctly place the B Tensor in the original GEMM operation into the required memory hierarchy, as `__bang_mlp` expects the B to be stored in WRAM, not NRAM. Figure 2(c) tends to replace the original SIMT-based scalar operations with SIMD-based tensorized instructions, but the parameter that indicates the tensor length should be 2309 rather than 1024.

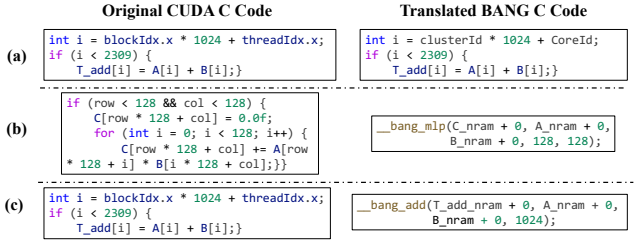

Figure 2: The unsuccessful transcompilation examples of GPT-4: (a) Parallelism-related. (b) Memory-related. (c) Instruction-related.

Based on the transcompilation error taxonomy, we examine the existing methods and draw the following observations.

Observation #1: *The single-step LLM-based transcompilation exhibits significant error rates across all three categories, posing challenges for accurately transcompiling programs across DLS.*

Table 2 presents the detailed results for transcompiling CUDA C code to BANG C for real-world operators (detailed in Sec.7) using GPT-4. Note that these categories are not mutually exclusive, which means a single program may trigger multiple types of errors. For the zero-shot, the compilation error rate was 100%, primarily because the LLM struggled with the *complex memory hierarchy* (100%) and *special instructions* (100%) due to its insufficient training on DLS-specific datasets. For the few-shot which provided several examples in prompts, although the translated code compiled successfully, it showed functional errors, particularly with parallelism (97.2%) and instruction-related issues (94.4%), resulting in an overall computation error rate of 92.3%. These findings highlight the limitations of single-step LLM-based transcompilations, even with the most advanced LLMs.

Observation #2: *Search-based program synthesis excels at optimizing loop bounds and indexing but struggles with high-level program sketches generation, while LLMs are proficient at generating high-level program sketches but prone to errors in low-level details such as loop bounds and indexing.*

Table 2: Breakdown of the unsuccessful transcompilations produced by GPT-4 based on outcome.(%)

Errors	Compilation			Total	Computation			Total
	Parallelism	Memory	Instruction		Parallelism	Memory	Instruction	
Zero-Shot	3	100	100	100	–	–	–	–
Few-Shot	2.3	27.1	76.5	49.4	97.2	2.8	94.4	92.3

Table 3: Taxonomy of the search-based program synthesis approach.

	Method	Inputs	Solving Time
High-level Program Sketchs	Verified Lifting (Tenspiler [42])	Custom IR	+++
Low-level Program Details	SMT Solver (Z3 [37])	SMT Query	+

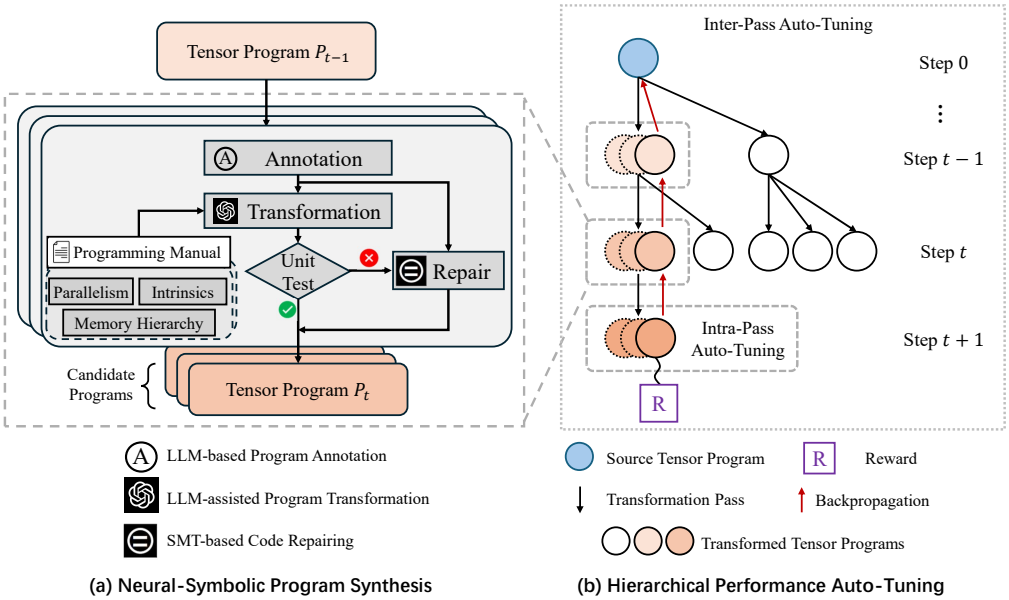
We analyze the strengths and limitations of search-based program synthesis and LLMs in tensor program transcompilation, highlighting their complementary roles. Search-based synthesis, as shown in Table 3, excels at synthesizing and verifying low-level details such as loop bounds and indexing, leveraging its ability to handle mathematical constraints. However, it struggles with generating high-level structures like control flow and efficiently utilizing the memory hierarchy and specialized intrinsics. In contrast, LLMs are highly effective at generating high-level program skeletons but prone to errors in low-level details, such as loop bounds and indexing. As illustrated in Figure 2(c), although the LLM correctly captures the semantics and utilizes the `__bang_add` intrinsic, it mistakenly sets the tensor length to 1024 instead of passing the actual scalar loop bound (i.e., 2309). By combining both approaches, LLMs generate the high-level program structure, while search-based synthesis refines the low-level details, leading to more accurate, efficient, and reliable program synthesis.

These observations motivate us to decompose the program translation process into a series of LLM-assisted transformations, where program synthesis tools can further enhance the correctness of transcompilation.

3 Overview

To automatically translate tensor programs across DLS with a correctness guarantee, as shown in Figure 3, *QiMeng-Xpiler* consists of two parts, i.e., *Neural-Symbolic Program Synthesis* and *Hierarchical Performance Auto-Tuning*.

Neural-Symbolic Program Synthesis. *QiMeng-Xpiler* first decomposes the entire transcompilation process into a series of LLM-assisted transformation passes. Among these, the 11 passes as listed in Table 4 can be categorized into 3 classes, i.e., (1)*sequentialization/parallelization*, (2)*memory conversion*, and (3)*(de)tensorization*. Specifically, the sequentialization/parallelization passes directly convert a parallel program into its sequential counterpart (e.g., from CUDA C to C) or vice versa, by appropriately mapping built-in parallel variables (e.g., `threadIdx.x` in CUDA C) to indexing vari-



(a) Neural-Symbolic Program Synthesis (b) Hierarchical Performance Auto-Tuning

Figure 3: The overview of *QiMeng-Xpiler*, a novel transcompiler for automatic transcompilation of tensor programs across different programming models. The transcompiler consists of two parts: (a) neural-symbolic program synthesis, which utilizes LLM to transform code and repair incorrect transformation through symbolic synthesis with limited scales, and (b) hierarchical performance auto-tuning, which systemically explores both the parameters and sequences of transformation passes.

Table 4: The transformation passes and their description.

	Name	Decription
(1)	Loop Recovery	Convert parallel variables to sequential for loops
	Loop Bind	Assign a sequential loop to parallel variables
	Loop Split	Divide a loop into several sub-loops
	Loop Fuse	Merge several loops into a hyper-loop
	Loop Reorder	Change the execution orders of loops
	Loop Expansion	Split a loop body into several loop bodies
	Loop Contraction	Merge the producer in the loop body of consumer
(2)	Cache	Adapt to the memory hierarchy for efficient load/store inputs/outputs
	Pipeline	Pipeline of data load/store and computation
(3)	Tensorize	Replace a specific loop body to leverage special intrinsics
	Detensorize	Restore a specific loop body from special intrinsics

ables. The memory conversion passes bridge the semantic gap between the memory hierarchies of different DLS by employing suitable strategies for data movement and access patterns. The (de)tensorization passes either convert sequential code into its parallel equivalent by invoking corresponding tensor intrinsics, automatically retrieved from the target system's programming manuals, or restore the original sequential code from the tensor intrinsics. Overall, these passes, each addressing a key characteristic of different DLS, i.e., parallelism, memory hierarchy, and specialized intrinsics, are sufficient to perform tensor program transcompilation across DLS.

To ensure both flexibility and correctness, each program transformation pass in *QiMeng-Xpiler* adopts a neural-symbolic approach, i.e., utilizing LLM to transform code and repair incorrect transformation through symbolic synthesis with limited scales. In each transformation pass, the LLM first generates transformed code, and this transformed code is then validated by unit tests; if it fails, it is repaired using small-scale SMT-based symbolic synthesis. We will detail this in Section 4.

Hierarchical Performance Auto-Tuning. To achieve automatic transcompilation and maximize the performance of transformed programs, *QiMeng-Xpiler* employs a hierarchical auto-tuning approach to systemically explore both the parameters (intra-pass auto-tuning) and sequences (inter-pass auto-tuning) of transformation passes. Specifically, the intra-pass auto-tuning utilizes brute-force search to identify the optimal parameters (e.g., tiling sizes) for program transformation. The inter-pass auto-tuning, on the other hand, leverages MCTS to automatically discover both functionally correct and optimal sequences of transformation passes for translating tensor programs across different DLS. Concretely, the MCTS in the inter-pass auto-tuning consists of four components: tensor programs, transformation pass, backpropagation, and reward. At each step $t-1$, the MCTS selects a candidate node (i.e., tensor program P_{t-1}) based on its score and expands the node by transforming it with an available transformation pass, resulting in tensor program P_t. Then, by executing P_t, a reward related to execution time is obtained. This reward is backpropagated to all ancestor nodes along the expansion path, updating their scores for the selection in the next step t. We will detail this in Section 5.

4 Neural-Symbolic Program Synthesis

QiMeng-Xpiler breaks down the traditional program transformation process into multiple transformation passes, with each pass covering a full workflow of neural-symbolic program synthesis containing program annotation, meta-prompts based transformation, bug localization, and SMT-based code repairing. The neural processes, program annotation, and meta-prompts based transformation, leverage the program-

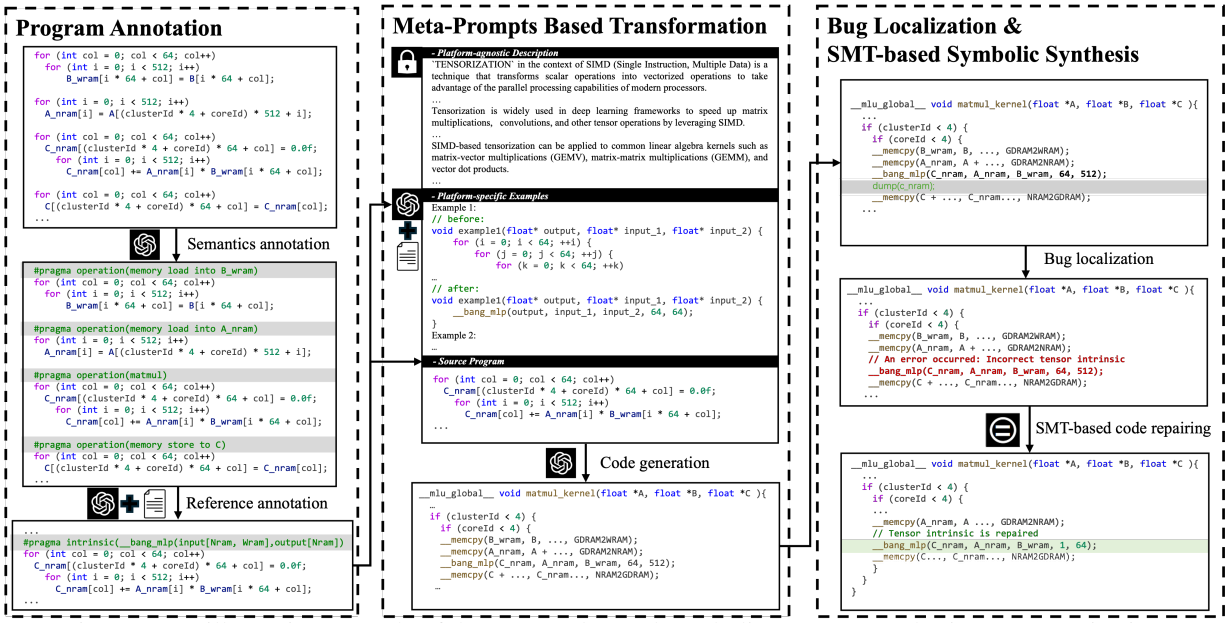


Figure 4: An illustrative example of the proposed neural-symbolic program synthesis on a tensorization case.

ming manual and the prior knowledge within the LLM to enhance the flexibility of program transformation, enabling *QiMeng-Xpiler* to handle larger-scale code compared to traditional methods. Meanwhile, the symbolic processes, bug localization, and SMT-based code repairing, ensure the correctness of the transformed program. These four processes are illustrated in Figure 4.

4.1 Program Annotation

For a specific transformation pass, the program annotation process marks code blocks with semantics related to the transformation pass, assisting in the subsequent program transformation process.

As shown in Algorithm 1, program annotation consists of two parts. The first part (lines 2-3) is semantics annotation which involves identifying computational operations with semantics (e.g., `operation(matmul)`). This part is performed by an LLM. The second part (lines 4-11) is reference annotation which involves performing an information retrieval in the programming manual based on each identified computational operation to obtain the corresponding target operation and parameters (e.g., `intrinsic(__bang_mlp(input[Nram, Wram], output[Nram])`). This part is first performed by a BM25 search engine [48] which can retrieve related information from the programming manual. Then, the retrieved information and the source program are sent to an LLM to annotate the operator with references.

Program annotation serves two main purposes. First, by identifying the computation operations in the source program, semantics annotation abstracts the platform-agnostic functional semantics of the source program instead of focusing on platform-specific details, which can help LLMs generate semantically correct programs in the subsequent LLM-assisted program transformation. Second, by applying reference annotation, the identified computational operations and their associated hardware characteristics (e.g., memory or computation shape constraints for special intrinsics) can be used in the subsequent meta-prompts based transformation process, aiding LLMs in generating more accurate programs.

Algorithm 1: Program Annotation Algorithm

```
   Input  : A source program P
   Output : An annotated program
1  Given: LLM, BM25 search engine (SE), programming manual M
   //Annotate program with identified computation
2  P_d ← LLM(P)
   //Get the list of computation information
3  L ← TraverseComputation(P_d)
4  for n in L do
       //Retrieve the programming manual of each
         computation
5      D ← SE(n, M)
       //Annotate program with memory spaces or tensor
         intrinsics
6      P_d ← LLM(P_d, D)
7  end
8  return P_d
```

4.2 Meta-Prompts based Transformation

Meta-prompts-based transformation uses LLMs to convert the source program into the target program with a correct program sketch. In this approach, meta-prompt is a high-level prompt template that can be adapted to different source programs based on the results of the previous program annotation process. The adapted prompt, along with the source program, is then provided as input to the LLMs. Each transformation pass has its own meta-prompt. Meta-prompts mainly consist of three parts: platform-agnostic description, platform-specific examples, and tuning knobs.

Platform-agnostic description. The platform-agnostic part describes the program's functionality and detailed constraints that must be considered during implementation. For example, in the case of Figure 4, the platform-agnostic part

refers to the functionality of the tensorization in the context of SIMD and the application scenarios like deep learning frameworks and common linear algebra kernels. This part of the prompt remains the same across different platforms.

Platform-specific examples. Although operators on different platforms share similar functional semantics, their implementation details, e.g., function names and parameters, can vary significantly. As a result, directly transforming programs across platforms with LLMs often leads to incorrect programs. To address this, we utilize the annotated source program and the LLM to search for platform-specific implementation examples in the target platform's programming manual that are functionally related to the source program. These examples are incorporated into the meta-prompt as the platform-specific component, bridging the gap between the high-level functional semantics of the operators and target platform. For instance, in Figure 4, the search results include an example of how to transcompile a `matmul` from C to BANG C.

Tuning knobs. The loop split pass and loop reorder pass require more constraints related to the target platform. This information is included in the meta-prompt optionally. For example, loop split needs to determine the loop split alignment size for the target platform and use this as the minimum unit to expand into a corresponding search space, which is then used for the auto-tuning of the generated program. Please refer to details in Section 5.

Based on the meta-prompt, the LLM can generate the transformed code with a generally correct program sketch but error-prone values. Then, we fix these buggy values with symbolic approaches, including bug localization and SMT-based code repairing, which will be introduced as follows.

4.3 Bug Localization

The feasibility of *QiMeng-Xpiler* relies on effectively reducing the code repair problem scale through precise bug localization during unit testing. The process begins by validating the transformed code against the provided unit tests. When a test failure occurs, Algorithm 2 is employed to systematically identify faulty code segments. The localization mechanism first traverses all buffers and applies binary search to pinpoint the initial faulty buffer. For each candidate buffer during the search, the algorithm identifies the corresponding pre-transformation buffer through name similarity matching, then compares the buffer values to determine the search direction. Value matches indicate downstream errors, prompting forward search, while mismatches suggest upstream errors, triggering backward tracing. This iterative process continues until the exact faulty buffer is identified, which subsequently helps determine the buggy code block. For the identified buggy code block, we perform further analysis by categorizing errors into two distinct types: index-related errors (such as inconsistent loop bounds, out-of-bounds accesses, or misaligned indices) and tensor instruction-related errors (including incorrect tensor intrinsic parameters or invalid instructions). Index-related errors are detected through control-flow graph (CFG) analysis, while tensor instruction-related errors are inferred when the CFG appears correct but tensor instructions are present. This localization approach is feasible because each transformation pass introduces only small-step changes while largely preserving the control flow and buffer structure, enabling effective comparative analysis as described.

Figure 4 demonstrates a bug localization example, where inserting a dump function after computing `C_nram` reveals a mismatch, while the input, i.e., `A_nram` and `B_wram` remain correct. This discrepancy confirms that the bug resides in the computation of `C_nram`. Since no control-flow changes are involved, the error is precisely attributed to the `bang_mlp` instruction.

Algorithm 2: Bug Localization Algorithm

Input : Source program S, Transcompiled program E

  return (N_e, T_{err})
end

4.4 SMT-based Code Repairing

Once the bug is located, *QiMeng-Xpiler* introduces SMT-based methods for code repairing. For index-related errors, *QiMeng-Xpiler* leverages an SMT solver to perform automatic repairs. As illustrated in Algorithm 3, *QiMeng-Xpiler* constructs symbolic constraints over loop bounds and buffer access indices, and encodes them as SMT queries. The SMT solver then searches for solutions that satisfy these constraints. Figure 5 presents examples of such constraints in two representative scenarios: in loop splitting, the solver guarantees that the transformed loops cover the same iteration space; in cache read insertion, it must align reused access indices. It is worth noting that when the loop nest is deep or the control flow is highly complex, the generated constraints can become too large to solve efficiently. For tensor instruction-related errors, *QiMeng-Xpiler* extracts the scalar computation logic and its corresponding semantics and passes them to Tenspiler [42], which automatically synthesizes semantically equivalent target code containing the appropriate tensor instruction.

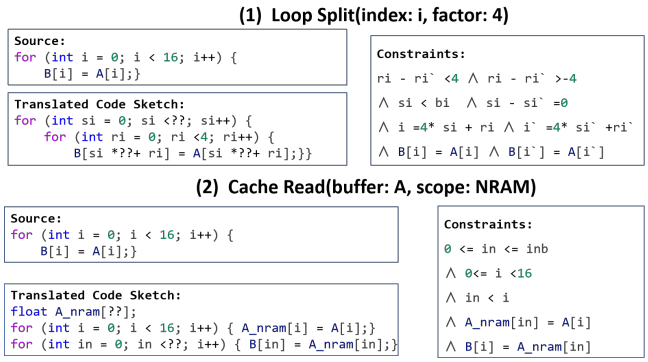

Figure 5: The SMT constraints for loop split and cache read.

By applying the above repair strategies, *QiMeng-Xpiler* effectively corrects LLM-generated programs and outputs the fixed version as the final result of a transformation pass.

Algorithm 3: SMT-based Code Repairing Algorithm

Input : A source program P, error program E
Output : A repaired program F
Given: Error code snippet S
$T_s \leftarrow \text{AST}(P)$; $S_s \leftarrow \text{extract}(T_s, S)$
$T_e \leftarrow \text{AST}(E)$; $S_e \leftarrow \text{extract}(T_e, S)$
//Generate the sketch according to transformation definition
$S_k \leftarrow \text{GenerateCodeSketch}(S_s, S_e)$
//Generate the smt query
$Q \leftarrow \text{CreateSMTQuery}(S_s, S_e)$
//Generate the verified code snippet
$R \leftarrow \text{SynthesisCode}(Q)$
$F \leftarrow \text{StitchBack}(P, R, S)$
return F

5 Hierarchical Performance Auto-Tuning

To fully automate code transcompilation and achieve higher performance, *QiMeng-Xpiler* employs a hierarchical auto-tuning approach, which effectively decouples high-level code structures from low-level details, enabling flexible enumeration of high-level program sketches (i.e., strategizing parallelization and thread bindings), as well as efficient sampling of low-level specifics (i.e., tiling size and loop orders). As a result, transcompilation exploration space can be formalized as follows:

$$S = \left\{ S^{(n)} \mid \begin{array}{l} S^{(t)} = \text{apply}(\text{apply}(S^{(t-1)}, d_t), k_t), \\ \forall d_t \in D_t, 1 \le i \le n, \\ \forall k_t \in K_t, 1 \le t \le n \end{array} \right\} \quad (1)$$

where s^0 denotes the source tensor program, and d_t represents a random selected pass from the pre-defined passes D_t, k_t represents a tuning option from the pre-defined tuning knobs K_t, and n is number of transformation. Thus, the size of the exploration space aligns with the number of pass sequences and tuning knobs. We have:

$$|S| = |D_1| \times |K_1| \times |D_2| \times |K_2| \times \ldots \times |D_n| \times |K_n| \quad (2)$$

To explore this huge search space, *QiMeng-Xpiler* puts forward a hierarchical performance auto-tuning consisting of two main components creatively: (1) **Intra-Pass Auto-Tuning**, which focuses on fine-tuning the performance of translated programs; and (2) **Inter-Pass Auto-Tuning with MCTS**, which is responsible for constructing a vast valid search space to identify the most optimal code transcompilation.

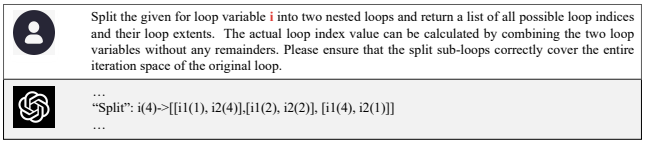

Figure 6: The auto-tuning prompt for loop split.

5.1 Intra-Pass Auto-Tuning

During the transformation process, passes such as `loop split` and `loop reorder` are tasked with making a series of critical decisions, including the split size and loop order, which significantly affect the performance of the resulting tensor program. To address these challenges, we consider implementing auto-tuning, an effective technique for automatically generating high-performance programs. Specifically, auto-tuning is implemented as a functional module that interacts with the aforementioned passes to create a search space consisting of multiple candidate programs. It then explores this space to identify the optimal program configuration.

Search space generation. The basis of intra-pass auto-tuning is to construct a search space with a large number of candidate programs, and our approach generates such space with the help of LLM and programming manuals. As shown in Figure 3, the auto-tuning module first interacts with the *loop split* to generate multiple programs with different adjustable parameters including: (1) the number of blocks for each logical loop, (2) the loop order after making decisions on (1). This is achieved by using specially designed meta-prompts as shown in Figure 6, which are then transferred to the prompts of the loop split and loop reorder pass. Then, the intra-pass auto-tuning module interacts with other passes to generate different program sketches, such as different loop binding strategies.

Search space exploration. Depending on the characteristics of the target code, e.g., in the case of BANG C language with larger instruction granularity resulting in a small search space, we directly employ a brute-force search approach for exploring the program with optimal performance. Actually, the size of the search space varies significantly for different DLS. Take the Matmul operation ($512 \times 512 \times 512$) as an example, on GPU the size of search space (K in Equation 1) is 150 while on MLU the size is only 10.

5.2 Inter-Pass Auto-Tuning with MCTS

We employs MCTS, which formulates the transcompilation as a Markov decision process where each intermediate program is represented as a state and the actions are the different passes that could be applied next. The reward is proportional to the execution time improvement, but any transformation that fails a unit test yields a reward of zero. The solution would be the actions that lead to the optimal pass sequence.

Reward function. To enhance the accuracy of the cost

model while minimizing additional overhead, we add real execution time measurements each time a new transformation pass is declared. While the program is not fully translated, MCTS runs in parallel with the current programs, records the best real throughput as the reward of the current transformation sequence and its corresponding program. At step t, the reward function is

$$T_{ti} = \begin{cases} T(p_{ti}), & \text{if } p_{ti} \\ 0, & \text{otherwise} \end{cases} \quad (3)$$

$$R_t = \max(T_{ti}) \quad (4)$$

where p_t denotes the transformed programs at iteration t, i is the index of transformed program within intra-pass auto-tuning search space, and T is the throughput of program.

Searching parameters setting. MCTS may fail to effectively reach a terminal node in a given iteration or even fail to generate the final transcompiled program. Therefore, to determine the appropriate maximum search depth(i.e., n in Equation 1) and the total number of simulations, we conducted design space exploration to balance search time and reward. Specifically, the maximum search depth of MCTS should exceed 11 passes, as all passes are crucial and may be repeated, with the number of simulations directly impacting both search time and reward. Ultimately, we selected $N = 13$ and 512 simulations for MCTS with early stopping mechanism, achieving competitive performance of the transcompiled program within a reasonable search time (e.g., hours).

6 Implementations

6.1 Implementation Details

QiMeng-Xpiler is implemented with $\sim 35k$ lines of Python code, encompassing the following core modules: LLM-based program annotation, LLM-assisted program transformation passes, an automated compilation, verification, and performance-benchmarking framework for bug localization, SMT-based code repair, an MCST search algorithm for inter-pass auto-tuning, and a search module for intra-pass auto-tuning. In addition, we constructed a test suite of $\sim 38k$ lines of CUDA C, HIP, C with VNNI, and BANG C kernel code, with 85.7% of the test cases sourced from TVM-generated kernels and the rest (e.g., *LLM* operation `Deformable Attention`, `Self Attention` and `RMSNorm` as listed in Table 6) sourced from open-source GitHub repositories, to comprehensively evaluate *QiMeng-Xpiler*'s transcompilation performance across multiple DLS.

6.2 Expanding to New DLS

QiMeng-Xpiler consists of two parts: *Neural-Symbolic Program Synthesis* and *Hierarchical Performance Auto-Tuning*. The latter maintains platform independence, enabling seamless expansion to new DLS without modification. The former currently implements 11 transformation passes, each pass consists of up to four processes: **Program Annotation**, **Meta-Prompts based Transformation**, **Bug Localization**, and **SMT-based Code Repairing**, as described in Section 4.

Table 5: Manual effort required for *QiMeng-Xpiler*.

Pass	Processes			
	Annotation	**Transformation**	**Bug Localization**	**Repair(SMT)**
Loop Recovery Loop Bind	–	Specify threads or cores if needed	Auto	Specify threads or cores if needed
Loop Split	–	Auto	Auto	Auto
Loop Fuse	–	Auto		
Loop Reorder	–	Auto		
Loop Expansion	–	Auto		
Loop Contraction	–	Auto		
Pipeline	–	Provide examples if needed		
Detensorize	–	Provide examples if needed		
Cache	Auto	Specify memory space if needed		
Tensorize	Auto	Provide examples if needed	Auto	Extend Tenspiler for new DLS

We report the manual effort required for each process when adapting *QiMeng-Xpiler* to a new DLS, shown in Table 5. In the table, entries marked with "Auto" indicate that the process is fully automated without requiring manual intervention, while "–" means the process does not apply to that particular pass. Concretely, the passes also fall into two categories: platform-agnostic passes and platform-specific passes. Platform-agnostic passes (i.e., Loop Split, Loop Fuse, Loop Reorder, Loop Expansion, and Loop Contraction) primarily operate on loop structures, do not depend on platform semantics, and can be applied across all target platforms using the same prompts and universal examples. Platform-specific passes like Loop Recovery, Loop Bind, Pipeline, Tensorize, Detensorize, and Cache, rely on the hardware characteristics of the target platform. Specifically, in cases where *QiMeng-Xpiler* cannot automatically reliably extract parameters from the DLS manual (i.e., parallel variables for Loop Recovery and Loop Bind, or the memory scope (e.g., local buffer) used for reads and writes in the Cache pass), users need to explicitly specify these details. For example, we manually specify the number of clusters and cores for MLU and define memory scopes across all platforms. For more complex transformations like Pipeline, Tensorize, and Detensorize, representative code examples are essential for improving transformation quality. While *QiMeng-Xpiler* attempts to automatically extract such examples from programming manuals, manual efforts become necessary when the available examples are insufficient or ineffective. For example, we provide Matrix Core samples for Tensorize on AMD MI. Furthermore, during *Tensorize* passes, LLMs may generate incorrect tensor instructions or parameters. We address this by employing Tenspiler [42] for automated tensorization repairing, thus its code generation backend requires extension when adapting to new DLS targets.

Note that this porting effort is only a one-time task with minimal overhead. For example, specifying the parallel vari-

ables and memory scope typically demands just a single additional line prompt. Similarly, extending Tenspiler for instructions like TensorCore, MatrixCore, or AVX-VNNI typically requires only a few lines of code. Once this setup is complete, *QiMeng-Xpiler* can fully support the new platform through its end-to-end fully automated transcompilation flow without requiring further user intervention.

7 Evaluation Methodology

Evaluated Platforms. We conduct experiments on 4 different DLS with distinct programming models as follows: 1) **Intel Gold 6348 CPU with VNNI Extension**, which utilizes a special instruction set for deep learning; 2) **NVIDIA A100 GPU with CUDA C**, which follows the SIMT programming model; 3) **AMD MI200 with HIP**, which provides an alternative to CUDA language; and 4) **Cambricon MLU with BANG C**, which follows SIMD programming model on a DSA.

Evaluated Benchmarks. We evaluate *QiMeng-Xpiler* on 21 widely-used deep learning operators (shown in Table 6), which can be grouped into 6 types of operations including *MatMul*, *Convolution*, *Activation*, *Pooling*, *Element-wise*, and *LLM* operation. Each operator is further evaluated by 8 typical shapes extracted from real network networks such as GPT [39], LLaMA-2 [47], DAT [54], BERT [25], ResNet [27], and MobileNet [28], VGG [45] and thus there are 168 test cases in total for evaluation. The test cases range from 7 to 214 lines of code and cover various types and shapes from real-world applications, which can comprehensively assess *QiMeng-Xpiler*'s capabilities.

Table 6: Evaluated Benchmark for *QiMeng-Xpiler*

Type	Operators	Lines of Code				Cases
		CUDA C	BANG C	Hip	C with VNNI	
MatMul	GEMM, GEMV Batch GEMM	26, 12 29	15, 11 16	25, 12 28	41, 34 47	24

Activation	ReLU, Softmax GeLU, Sigmoid	7, 24 7, 10	18, 18 29, 30	7, 24 7, 10	14, 28 14, 14	32
Elementwise	Add, Sign	20, 12	26, 29	18, 12	17, 14	16
Pooling	MaxPool, AvgPool MinPool, SumPool	25, 30 23, 29	25, 25 25, 25	25, 30 23, 29	31, 34 33, 30	32
LLM	LayerNorm Deformable Attention Self Attention, RMSNorm	42 139 54, 25	35 191 64, 18	42 139 54, 25	46 214 111, 18	32

Comparison Baselines. The comparison baselines for evaluations on accuracy include state-of-the-art LLM-based approaches and rule-based approaches. Regarding the LLM-based approaches, we select the **GPT-4 Zero-Shot**, **GPT-4 Few-Shot**, **OpenAI o1 Zero-Shot**, and **OpenAI o1 Few-Shot** as baselines for each transcompilation direction. Regarding the rule-based approaches, we compare *QiMeng-Xpiler* with two established approaches: **PPCG** [50] and **HIPIFY** [7]. PPCG utilizes polyhedral models for auto-parallelization from C to CUDA HIPIFY is a vendor-provided tool to migrate CUDA code to AMD HIP code. Note that rule-based approaches are not available for other transcompilation directions, primarily due to the complexity and significant human effort required in developing such tools. In contrast, search-based program synthesis methods struggle with the large search space and therefore are not suitable for direct transcompilation across different DLS. Furthermore, we evaluate execution performance by comparing the code generated by *QiMeng-Xpiler* with its manually optimized counterparts (e.g., PyTorch with backend libraries such as cuDNN/cuBLAS, CNNL, rocBLAS, and oneDNN). All experiments were conducted using PyTorch as the baseline framework. The corresponding backend libraries of Pytorch for each platform are listed in Table 7.

Table 7: The versions of the performance comparison baselines.

Baselines	Version	Description
PyTorch	v2.5	Deep Learning framework
cuDNN	v9.2.1	Backend library for NVIDIA GPU
CNNL	v2.0.3	Backend library for Cambricon MLU
OneDNN	v3.6	Backend library for Intel DL Boost
rocBLAS	v4.4.0	Backend library for AMD MI

Evaluation Metrics. We use three key metrics to evaluate the performance and accuracy of *QiMeng-Xpiler*: (1) **Compilation accuracy** is the ratio of programs that are correctly compiled. This metric gauges *QiMeng-Xpiler*'s ability to successfully pass compiler checks, reflecting its proficiency in processing source code to generate error-free programs. (2) **Computation accuracy** is introduced in this paper as a crucial metric that assesses the functional correctness of the translated code, deeming a generated code correct if it passes a set of unit tests. (3) **Execution performance** evaluates the performance of the translated code, highlighting the significance and practicality of the proposed method in real-world applications. In these metrics, we execute the translated code on real platforms and verify its correctness.

8 Experimental Results

8.1 Evaluations on Accuracy

We present the evaluations on compilation/computation accuracy in Table 8 and Table 9, where we compare *QiMeng-Xpiler* with state-of-the-art methods in different transcompilation directions. We conclude that **(1) *QiMeng-Xpiler* performs the best in all directions with close to 100% accuracy for compilation and 86.9% to 100% accuracy for computation.** This clearly indicates that *QiMeng-Xpiler* is capable of handling source-to-source code translation tasks on various DLS with minimal human efforts, bringing revolutionary advancements to the DLS programming domain. **(2) *QiMeng-Xpiler* performs better than the SOTA LLMs** (Table 8). While the SOTA LLMs have achieved high accuracy in some cases, their inherent uncertainty makes it impossible to guarantee 100% correctness. This limitation prevents them

Table 8: Experimental results on different transcompilation directions. (%)

Source	Method	Compilation Accuracy				Computation Accuracy

Table 9: Accuracy comparison to rule-based methods.(%)

Direction	Method	Compilation	Computation
CUDA C → HIP	Hipify	85.7	85.7
	QiMeng-Xpiler	100	100
C → CUDA C	PPCG	47.6	47.6
	QiMeng-Xpiler	100	98.2

from being reliably applied to transcompilers, which demand extremely high accuracy. In contrast, our approach combines LLM-assisted program transformation with SMT-based repairing, enabling automatic program translation with guaranteed correctness. **(3) *QiMeng-Xpiler* performs better than the SOTA rule-based methods** (Table 9). For C → CUDA C, *QiMeng-Xpiler* achieves 100% compilation and 98.2% computation accuracy which is ∼ 50% higher than PPCG. For the easier CUDA C → HIP task, *QiMeng-Xpiler* successfully converts and executes with 100% accuracy, outperforming HIPIFY, which achieves 85.7%. Also, this result shows that *QiMeng-Xpiler*'s flexibility across various DLS without much adaptation cost while rule-based methods cannot.

We conduct an ablation study to further analyze our neural-symbolic synthesis paradigm, shown in Table 8. Without the SMT solver, although *QiMeng-Xpiler* still achieves better accuracy than pure LLM-based methods, it cannot reach 100% accuracy (e.g., 52.4% computation accuracy in HIP → BANG C direction). This situation persists even after incorporating *QiMeng-Xpiler* with the SOTA LLM-based code generation method, Self-Debugging [22]. Due to transcompilers' high demand for accuracy, the methods that cannot achieve or close to 100% accuracy can be hardly applied in practice. In contrast, leveraging SMT-based code repairing can significantly improve the computation accuracy of program transcompilation, achieving a range of 86.9% to 100%. This underscores the necessity of the SMT solver or, more broadly, neural-symbolic synthesis for the transcompiler.

8.2 Evaluations on Execution Performance

We evaluate the performance on the four most common program transcompilation directions, i.e., C with VNNI → CUDA C, CUDA C → BANG C, CUDA C → HIP, and CUDA C → C with VNNI, in Figure 7. Note that we also show the functionally correct cases on each type of operator in the line chart and report the average performance across them. Results show that *QiMeng-Xpiler* achieves an average performance of 0.78× than its manually optimized counterparts across the four transcompilation directions and various operators. This performance gap stems from manually optimized operators can leverage highly specialized techniques tailored to specific hardware, such as handwritten assembly, deeply pipelined execution (e.g., 5-stage pipeline on MLU, multi-stage pipeline on GPU [29]), and aggressive loop unroll on CPU or GPU.

8.3 Case Study: Trancompilation from CUDA C to BANG C

We further demonstrate the superiority and effectiveness of *QiMeng-Xpiler* by comparing the transcompilation results of different methods in the CUDA C → Bang C transcompilation direction. This task is particularly challenging and representative because 1) it involves transcompiling between

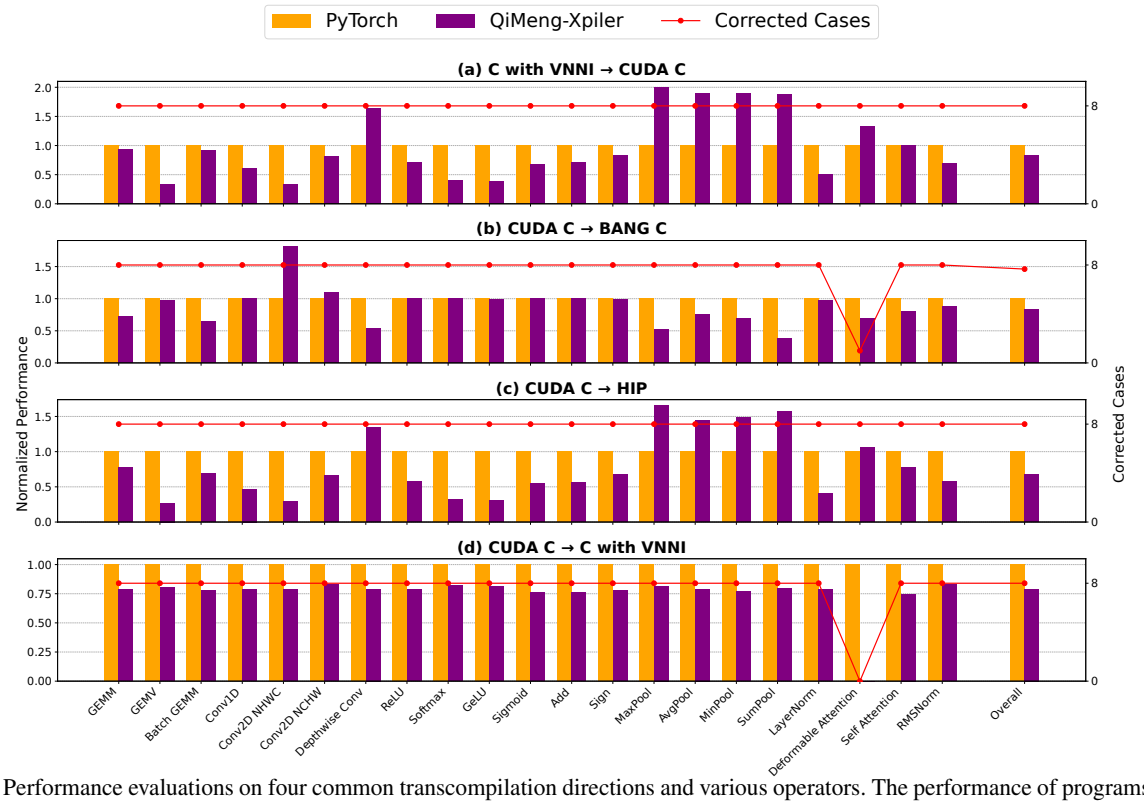

Figure 7: Performance evaluations on four common transcompilation directions and various operators. The performance of programs generated by *QiMeng-Xpiler* is compared to its manually optimized counterparts, PyTorch, with backend libraries such as cuDNN/cuBLAS, CNNL, rocBLAS, and oneDNN.

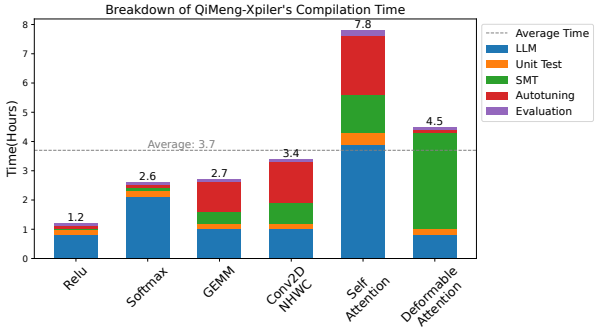

Figure 8: Breakdown of *QiMeng-Xpiler*'s compilation time.

two distinct programming models, namely translating from SIMT programs to SIMD programs, and 2) it targets an uncommon language, which has significantly less training data available for LLMs.

Overall, *QiMeng-Xpiler* achieves much more improvements in compilation/computation accuracy in CUDA C → BANG C compared to other transcompilation directions. While OpenAI o1 Zero-Shot shows excellent performance in some transcompilation directions, such as CUDA C → HIP, with compilation and computation accuracy of 85.7% and 82.7% respectively, its performance in CUDA → Bang translation is notably lacking, with results at 0%. This shortfall is primarily due to the aforementioned two challenges, which exceeds OpenAI o1 Zero-Shot's capabilities.

Although OpenAI o1 Few-Shot manages to boost compilation and computation accuracy substantially from 0% to 50.6% and 0% to 7.7%, respectively, by providing CUDA → Bang translations examples, there still exists a large room attaining the complete accuracy. In contrast, *QiMeng-Xpiler* w/o SMT achieves much higher compilation and computation accuracy of 82.7% and 54.2% correspondingly. This improvement stems from two key approaches adopted in *QiMeng-Xpiler* w/o SMT : 1) it gains a comprehensive understanding of the target language's keywords, syntax, and programming APIs by automatically annotating programs via document retrieval, thus compensating for the lack of domain-specific knowledge, and 2) whereas typical transcompilers attempt intricate inter-language translations in a single synthesis step, *QiMeng-Xpiler* w/o SMT splits the entire process into a series of LLM-based transformation passes. This enables *QiMeng-Xpiler* w/o SMT to effectively facilitate smooth translations between two substantially different source and target languages. Crucially, with the integration of SMT methods, *QiMeng-Xpiler* attains remarkable accuracy in the CUDA C → BANG C translation, achieving 100% in compilation and 91.7% in computation. This accuracy is largely due to *QiMeng-Xpiler*'s implementation of small-scale symbolic synthesis, which ensures the functional equivalence of each transformation pass guided by the LLM. In conclusion, our experiments prove that *QiMeng-Xpiler* successfully ac-

complishes transcompiler tasks across different DLS, even for a new and relatively uncommon DLS.

8.4 Compilation Time

Figure 8 shows the compilation time of 6 typical operators when translating from CUDA C to BANG C, which ranges from 1.2 to 7.8 hours, with 3.7 hours on average. We further analyze the breakdown of *QiMeng-Xpiler*'s compilation time and conclude that: 1) SMT is only triggered when the LLM fails to produce a correct translation, so for simpler programs, the proportion of time spent on SMT is smaller; 2) For matrix multiplication-like operators with a larger search space, the proportion of time spent on autotuning significantly increases; 3) Compilation time increases as the number of special intrinsics used in the program grows.

8.5 Productivity Improvement

We further evaluate how *QiMeng-Xpiler* improves programming productivity in real-world scenarios on 2 representative DLS, i.e., GPU and MLU. Specifically, we compare the development costs and performance achieved by manually implementing tensor programs versus those generated by *QiMeng-Xpiler* through automatic transcompilation, on the most challenging operator, Deformable Attention, with $\sim$ 200 LoCs.

We invited two CS master's students and two software engineers as junior and senior coders, respectively. Note that performance is normalized against the manually implemented programs by the senior coders. Table 10 shows that, programming productivity is improved by 34.3$\times$ for GPU and 96.0$\times$ for MLU via transcompiling legacy tensor program. Although *QiMeng-Xpiler* fails to automatically generate a functional-correct program for MLU, both junior and senior coders could debug the program with minimal effort, requiring an additional 3 hours and 0.5 hours, respectively.

Table 10: Productivity Improvement by *QiMeng-Xpiler*.

Deformable Attention ($\sim$ 200LoCs)		**CUDA C-> BANG C**		**C with VNNI -> CUDA C**	
		Costs	Performance	Costs	Performance
Senior Coder	Manual	$\sim$6 d	100%	$\sim$1 d	100%
	Ours	4.5 + 0.5 h	69.20%	2.1 h	132.50 %
	Time Saving	$\sim$28.8$\times$		$\sim$11.4$\times$	
Junior Coder	Manual	$\sim$30 d	49.85%	$\sim$3 d	75.76%
	Ours	4.5 + 3 h	65.17%	2.1 h	132.50 %
	Time Saving	$\sim$**96.0**$\times$		$\sim$**34.3**$\times$	

8.6 Case Study on FlashAttention

To evaluate *QiMeng-Xpiler*'s effectiveness on real-world, performance-critical kernels, we conducted a case study on FlashAttention (FA1) [24] and FlashAttention-2 (FA2) [23], a memory-efficient attention algorithm widely used in LLMs. Note that FlashAttention kernels require fine-grained parallelism and high-throughput shared memory access, capabilities that are not efficiently supported by CPUs. Table 11 shows the normalized performance of *QiMeng-Xpiler* on FA1 and FA2 compared to vendor-optimized implementations on different transcompilation directions. Results show that *QiMeng-Xpiler* achieves 0.61$\times$-0.81$\times$ the performance of its native implementations on all transcompilation directions, primarily due to its limited ability to match the intricate shared-memory tiling and data movement strategies employed in hand-optimized implementations.

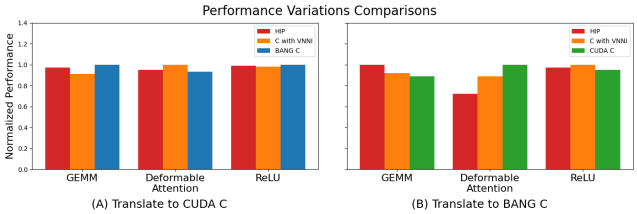

Figure 9: Normalized performance of `GEMM`, `Deformable Attention`, and `ReLU` across different trancompilation directions.

Table 11: Normalized performance of *QiMeng-Xpiler* on FA1 and FA2 compared to vendor optimized implementations. **Configuration:** Batch Size = 8, Number of Heads = 16, Head Dimension = 32, Sequence Length = 1024.

Source	**Operator**	**Target**		
		HIP	**BANG C**	**CUDA C**
HIP	FA1	–	0.74	0.71
	FA2	–	0.76	0.74
BANG C	FA1	0.77	–	0.75
	FA2	0.78	–	0.61
CUDA C	FA1	0.69	0.70	–
	FA2	0.81	0.63	–

8.7 Performance Variations Comparisons

In this experiment, we evaluate how *QiMeng-Xpiler*'s performance varies across different source platforms when targeting the same target platform. Figure 9 shows the normalized performance of three representative operators, `GEMM`, `Deformable Attention`, and `ReLU`, when transcompiled to CUDA C (left) and BANG C (right) from various source platforms. Results show that the transcompiled programs achieve comparable performance because *QiMeng-Xpiler* first converts all source programs into a unified intermediate representation (e.g., scalar C code), decoupling subsequent optimizations from source-specific tuning. The only exception is the transcompilation of Deformable Attention from HIP to BANG C, which achieves only 72% performance. This is mainly because a conditional statement in the HIP source code hinders optimization during conversion, preventing the generated BANG C program from being effectively optimized.

8.8 Failure Case

Since *QiMeng-Xpiler* cannot guarantee 100% correct translation in all cases, we analyzed the failure cases in depth and summarized key limitations as directions for future work.

Complex control flow. When the input program involves complex control structures like multiple nested loops and con-

ditionals, both LLMs and SMT tools struggle to capture the correct parallel semantics, resulting in translation or repair failures. For example, when transcompiling Deformable Attention from CUDA C to BANG C (as shown in Figure 10), the code snippet involves highly complex control flow. As a result, the neural component (i.e., LLMs) of *QiMeng-Xpiler* fails to generate the required SIMD intrinsics for BANG C, and the symbolic component (i.e., SMT solver) cannot infer the mathematical constraints needed for repair.

Difficult-to-understand computations. Although GPT-4 can recognize a wide range of scalar computations, it struggles to comprehend arbitrary special instructions, hindering its ability for accurate annotation.

To address these limitations, we plan to incorporate more advanced LLMs and SMT techniques, which are expected to significantly enhance *QiMeng-Xpiler*'s capability in handling complex, real-world deep learning kernels.

```
for (int32_t i_m_5 = 0; i_m_5 < 8; ++i_m_5) {
  if ((((((int32_t *)xy_rounded)[(i_m_5 + 8)] < 0) || (((int32_t *)height_width)[0] <= ((int32_t *)xy_rounded)[(i_m_5 + 8)])) ||
    ((((int32_t *)xy_rounded)[(i_m_5 + 24)] < 0)) || (((int32_t *)height_width)[1] <= ((int32_t *)xy_rounded)[(i_m_5 + 24)]))) {
    for (int32_t i_d_7 = 0; i_d_7 < 512; ++i_d_7) {
      ((float *)corner_values)[(((i_m_5 * 512) + i_d_7) + 12288)] = 0.000000e+00f;
    }
  }
}
```

9 Related Work

Rule-based approaches. These methods focus on transcompiling source programs to target languages using expert-defined rules [5, 7, 13, 50]. For instance, C2Rust [13] and CxGo [5] translate C code to Rust and Go, respectively, while HIPIFY [7] converts CUDA to HIP. PPCG [50] extracts the polyhedral model from the source program, applies predefined rules for scheduling and parallelization, and generates code from the transformed model. These approaches are labor-intensive, relying on manual rules that require extensive knowledge of both the source and target languages, limiting their applicability to specific platforms. Moreover, they often struggle with irregular code structures, reducing their robustness and general applicability.

Data-driven approaches. Data-driven methods, which train neural networks using supervised or unsupervised corpora, have gained prominence following the success of Neural Machine Translation (NMT). Tools like TransCoder [43] use sequence-to-sequence models for translating between C++, Java, and Python. More recent works leverage LLMs (e.g., CodeX [21], StarCoder [34], CodeGen [38], CodeT5 [51], CodeGeeX [55], LLaMA [47], Gemini [46], GPT-4 [15], and OpenAI o1 [8]) for program translation, achieving superior performance. However, while these methods reduce human effort, they often fail to guarantee the functional correctness of the translated code, especially across different DLS.

Symbolic synthesis approaches. Symbolic synthesis approaches generate semantically equivalent code from input-output pairs or formal semantic specifications. For example, C2TACO [36] uses a guided enumerative synthesizer and automatically generated I/O examples to translate C tensor code into the TACO DSL [33]. Recent methods like MetaLift [18] and Tenspiler [42] adopt a more extensible approach by first converting the source program into a unified intermediate representation (IR) and then synthesizing target programs in the same IR domain. These approaches reduce the need for manual transformation rules and are effective for small-scale projects. However, they rely on expensive search-based SMT solvers, which makes them less scalable for larger, real-world applications. Additionally, methods like MetaLift and Tenspiler require users to manually define the semantics of the target language using the specification IR, which is both challenging and error-prone.

In summary, existing approaches either demand significant manual effort, suffer from functional correctness issues, or have limited scalability, making them ineffective for automatically translating programs across DLS with different programming models. In contrast, *QiMeng-Xpiler* is the first work to tackle this challenge by proposing a novel neural-symbolic synthesis framework, where translation is performed through a series of LLM-assisted transformations, with functional equivalence ensured for each transformation via small-scale symbolic synthesis.

10 Conclusion

We propose a neural-symbolic synthesis approach, *QiMeng-Xpiler*, for automatically translating tensor programs across heterogeneous DLS with different programming models. *QiMeng-Xpiler* conducts the program translation as a series of LLM-assisted transformation passes, where incorrect code snippets are repaired by small-scale symbolic synthesis. In addition to ensuring functional correctness, *QiMeng-Xpiler* also employs hierarchical auto-tuning to improve the performance of translated programs. Experimental results on 4 different DLS demonstrate that *QiMeng-Xpiler* correctly translates different tensor programs at the accuracy of 95% on average, and the performance of the translated program achieves an average of 0.78× of vendor-provided manually-optimized libraries. Moreover, the programming productivity of DLS is improved by up to 96.0×.

WaferLLM: Large Language Model Inference at Wafer Scale

Congjie He[1] Yeqi Huang[1] Pei Mu[1] Ziming Miao[2] Jilong Xue[2] Lingxiao Ma[2] Fan Yang[2] Luo Mai[1]

[1]*University of Edinburgh* [2]*Microsoft Research*

Abstract

Emerging AI accelerators increasingly adopt wafer-scale manufacturing technologies, integrating hundreds of thousands of AI cores in a mesh architecture with large distributed on-chip memory (tens of GB in total) and ultra-high on-chip memory bandwidth (tens of PB/s). However, current LLM inference systems, optimized for shared memory architectures like GPUs, fail to exploit these accelerators fully.

We introduce WaferLLM, the first wafer-scale LLM inference system. WaferLLM is guided by a novel PLMR model (pronounced as "Plummer") that captures the unique hardware characteristics of wafer-scale architectures. Leveraging this model, WaferLLM pioneers wafer-scale LLM parallelism, optimizing the utilization of hundreds of thousands of on-chip cores. It also introduces MeshGEMM and MeshGEMV, the first GEMM and GEMV implementations designed to scale effectively on wafer-scale accelerators.

Evaluations show that WaferLLM achieves up to 200× higher accelerator utilization than state-of-the-art methods. Leveraging a wafer-scale accelerator (Cerebras WSE2), WaferLLM delivers GEMV operations 606× faster and 16× more energy-efficient than on an NVIDIA A100 GPU. For full LLM inference, WaferLLM achieves 10-20× speedups over A100 GPU clusters running SGLang and vLLM. These advantages are expected to grow as wafer-scale AI models, software, and hardware continue to mature. WaferLLM is open-sourced at https://github.com/MeshInfra/WaferLLM.

1 Introduction

Large Language Model (LLM) inference is a rapidly growing workload. It has two phases [15]: (i) the *prefill phase*, which processes input tokens (the prompt) and spends most of its cycles on General Matrix Multiply (GEMM); and (ii) the *decode phase*, which generates tokens one by one in an autoregressive manner, primarily performing General Matrix-Vector Product (GEMV). Decode requires repeatedly loading the entire LLM model into on-chip memory, with GEMV dominating its cycles. Since LLMs generate many tokens, especially in the test-time scaling scenario, such as the OpenAI-o1/o3 [16, 33] and DeepSeek-R1 [13], inference is constrained by GEMV latency, making it inherently memory-bandwidth-bound.

To address memory bandwidth bottlenecks, AI accelerators are increasingly adopting system-on-wafer integration [21]. This approach scales chip area to a full wafer, up to 100× larger than a typical GPU die, enabling significantly more on-chip cores, memory, and bandwidth. Examples include Cerebras WSE [24] and upcoming Tesla Dojo [41]. The Cerebras WSE-2, for instance, integrates 850,000 cores with 40GB of on-chip memory, 1,000× more than GPUs, and provides 22PB/s memory bandwidth, 7,000× higher than GPUs. TSMC anticipates widespread adoption of system-on-wafer integration, citing advantages in performance, energy-efficient die-to-die communication, and cost reduction. IEEE similarly forecasts a surge in wafer-scale computing by 2027 [21]. Wafer-scale accelerators are already seeing real-world deployment, particularly in model serving. In February 2025, Mixtral and Perplexity adopted wafer-scale chips, achieving cost parity with GPUs in terms of tokens per dollar [40, 44]. G42 now operates data centers fully outfitted with wafer-scale accelerators, and Cerebras has secured major commercial contracts [39].

Unlocking the potential of wafer-scale accelerators is challenging because current LLM systems rely on *shared memory architectures* typical of GPUs and TPUs. Wafer-scale accelerators, however, adopt *network-on-chip* (NoC) designs that interconnect millions of cores with local memory in a *massive-scale, mesh-based memory architecture*. This architecture far exceeds the scale of on-chip crossbars (e.g., one-hop NUMA such as GraphCore IPU), multi-socket NUMA [2], and high-density AI clusters (hundreds of GPUs per pod) [17]. Without fully addressing this fundamental shift in memory architecture, directly applying designs from state-of-the-art systems like T10 [25] and Ladder [45] to wafer-scale devices often results in extremely poor performance.

To address these challenges, we propose a *device model* that captures the critical hardware properties of wafer-scale accelerators, highlighting key differences from shared-memory devices. This model enables us to evaluate current LLM inference design principles, identify non-compliant areas, and pinpoint where new approaches are required. Guided by this model, we can achieve an ambitious system design: *running complete LLM inference on a single chip*, minimizing costly off-chip communication and maximizing on-chip memory bandwidth utilization.

The above idea motivates WaferLLM, the first wafer-scale LLM inference system, yielding several contributions:

(1) Device model for wafer-scale accelerators. We propose

the PLMR model[1], which captures the key hardware properties of wafer-scale accelerators: (i) Massive **P**arallel cores (P): Millions of cores can be integrated on a large wafer, requiring systems to effectively partition LLMs and their operations. (ii) Highly non-uniform memory access **L**atency (L): Inter-core data access exhibits significant variation, with latency differences up to 1,000×, necessitating the system to mitigate this. (iii) Constrained per-core local **M**emory (M): Each core has limited memory (tens of KBs to several MBs), requiring efficient memory usage. (iv) Limited hardware-assisted **R**outing (R): The NoC routing hardware is constrained by the area size per core and can only support a limited number of routing paths, e.g., less than 2^5 on Cerebras WSE-2.

(2) Wafer-scale LLM parallelism. We propose an effective, PLMR-compliant LLM parallelism policy for wafer-scale accelerators. In the prefill phase, we design fine-grained partitioning to achieve million-core parallelism. For the decode phase, where tensor dimensions are insufficient for partitioning, we design fine-grained replication to enable parallelism with minimal communication costs. As a result, WaferLLM achieves larger-scale and finer-grained parallelism (satisfying P in PLMR) than GPU-based approaches. Additionally, we replace conventional GPU-based GEMM and GEMV operators with new algorithm designed for the PLMR model (satisfying L, M, and R) and propose tensor placement strategies that eliminate matrix transpositions, which are costly with a mesh NoC (satisfying L).

We also designed a scalable KV-cache management method for wafer-scale devices. This approach features a novel KV cache shift method to ensure balanced core usage (satisfying P and M), avoiding skewed utilization of cores caused by KV cache concatenation methods common on GPUs.

(3) Wafer-scale GEMM. We propose MeshGEMM, a scalable GEMM algorithm for wafer-scale devices, accelerating the prefill phase. Unlike conventional distributed GEMM algorithms, MeshGEMM achieves full PLMR compliance by leveraging two key operations: *cyclic shifting* and *interleaving*. Cyclic shifting ensures algorithm correctness while maintaining bounded usage of local memory (satisfying M). The interleaving operation minimizes communication latency in the mesh NoC, effectively reducing the overhead of highly non-uniform memory latency (satisfying L) and routing resources (satisfying R).

(4) Wafer-scale GEMV. We propose MeshGEMV, a scalable GEMV algorithm for wafer-scale devices, accelerating the decode phase. Unlike existing GEMV implementations, MeshGEMV uses a novel *K-tree allreduce* algorithm to aggregate local GEMV results across massive cores. This algorithm ensures routing resource usage meets the hardware's limitation (satisfying R) and reduces communication latency (satisfying L).

[1]PLMR model can be pronounced as "Plummer"

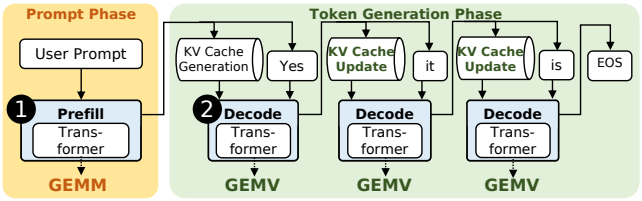

Figure 1: Key components in LLM inference

We implemented WaferLLM on the Cerebras WSE engine using approximately 7,000 lines of CSL (a C-like programming language) for LLM parallelism, MeshGEMM, and MeshGEMV, and 2,000 lines of Python for loading LLM checkpoints, launching inference, and execution parallelism policy.

We conducted end-to-end LLM inference experiments with various models, including full LLaMA3-8B and LLaMA2-13B, as well as subsets of layers of CodeLLaMA-34B, and QWen2-72B. By combining wafer-scale LLM parallelism, GEMM and GEMV, WaferLLM outperforms state-of-the-art (SOTA) systems: (i) 100-200× faster than T10 [25], the SOTA system for massive cores with a distributed on-chip memory architecture, and (ii) 200-400× faster than Ladder [45], the SOTA system for shared-memory architectures.

Micro-benchmarks further show that MeshGEMM is 2-3× faster than SUMMA [42], the default optimized GEMM for Cerebras WSE, and Cannon [6], the SOTA GEMM for supercomputers with large-scale mesh architectures. MeshGEMV achieves 4-8× speedups over Cerebras's optimized GEMV, and 606× than a single A100 GPU. Additionally, WaferLLM 's cache shift method is up to 400× more scalable than the KV cache SOTA on GPUs, such as PagedAttention [20].

Combined, WaferLLM (on Cerebras WSE-2) outperforms SGLang (on single A100) by 30-40×. Compared to the optimal performance of SGLang on A100 multi-GPUs connected with NVLink and RDMA, WaferLLM delivers a 10-20× faster end-to-end speed and is 2.5× more energy-efficient. The reduced gains from GEMV to LLM are due to current limitations in software, hardware, and existing LLM model designs. We anticipate stronger performance as wafer-scale AI computing matures and these limitations are addressed.

2 Background and Motivation

2.1 LLM inference and its key constraint

An LLM inference system typically performs auto-regressive token-by-token generation, as illustrated in Figure 1. The model comprises multiple transformer layers, dominated by self-attention and feedforward blocks. Inference operates in two phases: prefill and decode. The total cycles of the prefill phase are dominated by GEMM operations (shown by ❶). While the total cycles of the decode phase are dominated by

	System-on-Die	System-on-Wafer
Area (mm^2)	Up to 858	Up to 73062
# Transistors (TSMC n3)	~1s Tillion	~10s Trillion
# Cores	1,000s-10,000s	100,000s-1,000,000s
On-Chip Memory	10s-100s MB	~10s GB
Memory Bandwidth	1s TB/s	~10s PBs/s
Attached HBM	~10s-100s GB	10s TB (via TSMC SoW) [21]
Die-to-Die Bandwidth (TB/s)	~1s-10s (via off-chip)	~10s-100s (via on-chip)
Die-to-Die Latency (ns)	~100s (via off-chip)	~1s (via on-chip)
Die-to-Die Power (pJ/bit)	~10s (via off-chip)	~0.1s (via on-chip)

Table 1: System-on-Die vs. System-on-Wafer

GEMV operations (shown by ❷).

LLM inference is memory bandwidth-bound. Model weights (10-1,000 GB) are fetched repeatedly from external memory during inference, as GPUs typically have only 100 MB of on-chip memory. For per request, generating thousands of tokens per second demands hundreds of TB/s bandwidth, far exceeding the capabilities of HBM (high bandwidth memory) on current GPUs.

While tensor parallelism across GPUs can increase bandwidth, mitigating communication bottlenecks in a large GPU cluster remains challenging. Also, adding GPUs improves throughput for concurrent queries but does not reduce time per output token (TPOT), as each query is still memory bandwidth-limited.

2.2 Reasons for wafer-scale accelerators

To increase memory bandwidth, accelerator designers are increasingly adopting system-on-wafer integration [21] for several reasons:

Performance advantages. System-on-wafer technology allows trillions of transistors to be integrated into a single wafer-scale chip, up to 100× more than a typical GPU die, shown in Table 1. This enables millions of AI-optimized cores, providing tens of GBs of on-chip memory and up to tens of PB/s memory bandwidth, 1,000× higher than a standard GPU's several TB/s. Future wafer-scale chips can also attach 40-80× more HBM chips to their edge compared to a standard die [21].

Integration efficiency. System-on-wafer excels at integrating massive parallel cores, with wafer-based die-to-die connections offering up to 10× more bandwidth per unit area, 100-300× latency benefit, and nearly 100× better power efficiency per bit than conventional PCB-based chip-to-chip interconnection [24] (e.g., NVIDIA NVLink, PCIe), shown in Table 1. As noted earlier, LLM inference is primarily constrained by memory bandwidth due to intensive data access. In distributed settings, inter-chip communication overhead from remote memory access, especially during decode-phase GEMV, limits scalability. Thus, system-on-wafer integration offers lower-latency and high-bandwidth interconnects and improved efficiency over conventional chip-to-chip links.

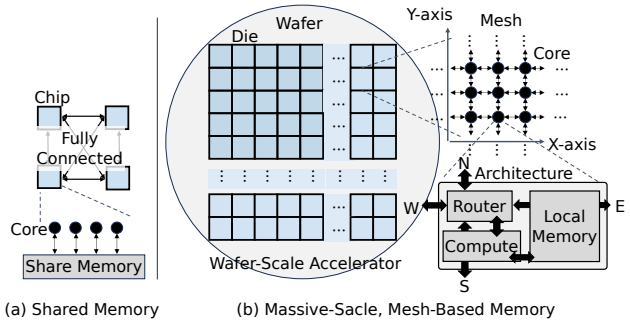

Figure 2: Massive-scale mesh-based memory architecture

Lower cost. Wafer-scale integration can lower the manufacturing cost, since a significant fraction of the cost of fabrication (typically 30-50%) is related to testing and packaging the individual chips [48]. Additionally, wafer-scale integration has made notable progress in yield improvement. Companies such as TSMC are also developing techniques to integrate fully tested dies on a single wafer, further enhancing yield.

2.3 Challenges for wafer-scale LLM inference

The key challenge in leveraging wafer-scale accelerators for LLM inference is their shift to a distributed, non-uniform memory architecture on a single chip. Current LLM systems are optimized for shared memory (single chip) or fully connected architectures (e.g., GPU pods), as shown in Figure 2(a). However, as on-chip memory size grows, these architectures face exponential manufacturing costs and performance degradation, driving the need for a distributed on-chip architecture.

AI accelerator designers predominantly use a **mesh-like network-on-chip (NoC)** to connect **massive cores** (ranging from hundreds of thousands to millions), as shown in Figure 2(b). The mesh topology is favored for its efficiency in core arrangement, enabling effective cooling [29], power delivery [19], and cost-efficient wiring [38, 46], with each core communicating only with nearby neighbors, as shown in Figure 2(b). Alternative topologies, such as 3D torus or tree structures, are impractical due to high on-chip wiring costs. Therefore, wafer-scale chip makers such as Cerebras WSE [24] and Tesla Dojo [41] adopt massive-scale mesh architectures. Even non-wafer-scale accelerators such as Meta MTIA [30], Tenstorrent [18], and others [4, 31] use mesh to scale cores on a chip.

The massive-scale mesh architecture presents challenges for several LLM operations due to their high data movement demands: (i) managing LLM models and KV cache, (ii) GEMM operations during the prefill phase, and (iii) GEMV operations during the decode phase. Other operations, such as element-wise computations such as dot-product and activation functions, require no data movement and naturally benefit from parallelism. Operations needing allreduce, such as RMSNorm and Softmax, can leverage GEMV solutions.

3 Device Model for Wafer-Scale Accelerators

3.1 The PLMR model

We develop the PLMR model to capture the unique hardware properties of wafer-scale accelerators and to motivate system requirements needed for utilizing this emerging hardware.

(1) **Massive Parallelism (P)**: A wafer-scale accelerator can accommodate millions of parallel cores, compared to thousands in GPUs. Each core features a local hardware pipeline that overlaps data ingress, egress, computation, and memory access at the cycle level. This requires the computation to be partitioned at a massive scale and a fine-grained schedule to overlap computation, memory access, and NoC communication.

(2) **Highly non-uniform memory access Latency (L)**: Accessing memory across cores in a mesh incurs highly non-uniform latency. In a mesh with $N_w \times N_h$ cores, organized as a rectangle, the maximum number of NoC hops between two cores is $N_w + N_h$, and the worst-case memory access latency is given by $\alpha(N_w + N_h) + \beta r$, where $r < N_w + N_h$ denotes the number of routing stages along the communication path. Here, α denotes the per-hop transmission latency, the cost incurred when a message is directly forwarded at a core according to the router hardware's pre-configured rules, increasing with hops. β represents the per-routing latency, the overhead when a message is involved in header parsing and rewriting by software at a core when forwarding [27]. Typically, $\alpha < \beta$. In a mesh with a million cores, the maximum number of hops and routing can reach up to several thousand, resulting in up to a thousand times latency gap between local and remote memory access. Consequently, minimizing long-range communication is critical for performance.

(3) **Constrained per-core local Memory (M)**: Each core has a small local memory (tens of KBs to several MBs), as performance and energy efficiency decline with larger capacities [47]. As a result, computation data must be explicitly partitioned into fine-grained chunks to fully fit within the constraints of each core's local memory.

(4) **Constrained Routing resources (R)**: Wafer-scale accelerators integrating millions of cores impose strict constraints on each core's routing circuit complexity or routing table size. For example, on the Cerebras WSE-2, each core can recognize only message headers with a 5-bit address code. Consequently, each core can support at most 2^5 distinct routing paths, and the software system must carefully plan these paths. For long-distance remote communication, a pair of cores can consume routing resources to establish a direct routing path, incurring only α latency. However, if the number of routing paths exceeds hardware limits, messages must be relayed through multiple intermediate cores, introducing additional β latency.

We expect these properties to remain relevant, as they are rooted in the fundamental characteristics of hardware and its manufacturing process. The PLMR model applies to both current (Cerebras WSE) and future (Tesla Dojo) wafer-scale devices. Even some non-wafer-scale devices with mesh-based NoC architectures, such as Tenstorrent Blackhole [18], can be represented by PLMR with adjusted parameters for parallelism (P), the size of the mesh (L), or relaxed constraints on local memory (M) and routing resources (R).

3.2 Limitations of state-of-the-art approaches

Leveraging the PLMR model, we analyze why existing AI systems fail to fully utilize wafer-scale accelerators. To run an LLM on a wafer-scale accelerator, we generally have two choices: (i) abstract the distributed local memory in each core as a shared memory and directly access data placed in a remote core through NoC; and (ii) explicitly partition computation into distributed cores and use message passing to exchange necessary data. We analyze two types of representative systems: LLM runtime or DNN compilers for shared memory architecture such as GPUs, e.g., Ladder [45]; and the SOTA compiler for distributed on-chip memory architectures, e.g., T10 [25] for GraphCore IPU.

Shared-memory system. A shared-memory-based DNN compiler such as Ladder usually assumes a uniform memory access pattern within the underlying memory hierarchy, which cannot tolerate the thousands of times latency variance in wafer-scale accelerators when accessing data from remote memory (failing in L). Moreover, these compilers [10, 28, 37, 45, 51, 54, 57] often focus primarily on partitioning computation, with less emphasis on optimizing data partitioning. This approach can easily lead to significant data duplication and violate the memory constraint requirements (failing in M). Finally, these compilers are unaware of the communication distance of each core, poorly addressing the constraint of routing resources.

Distributed-memory system. The T10 system [25] is designed for AI accelerators with an on-chip crossbar, which ensures a constant latency of memory access to any other cores on the same chip. T10 handles small local memory and balances communication loads, addressing memory constraints (M) and routing resource limitations (R). However, on a PLMR device, it fails to account for varying memory access latency (failing in L) and scales to thousands, not millions, of cores (failing in P).

4 Wafer-Scale LLM Parallelism

We present wafer-scale LLM parallelism, featuring new designs across prefill, decode, and KV cache management.

4.1 Prefill parallelism

The parallelism for LLM prefill must ensure compliance with the PLMR model. Key challenges include: (i) Handling multiple large matrices during prefill, requiring effective dimension

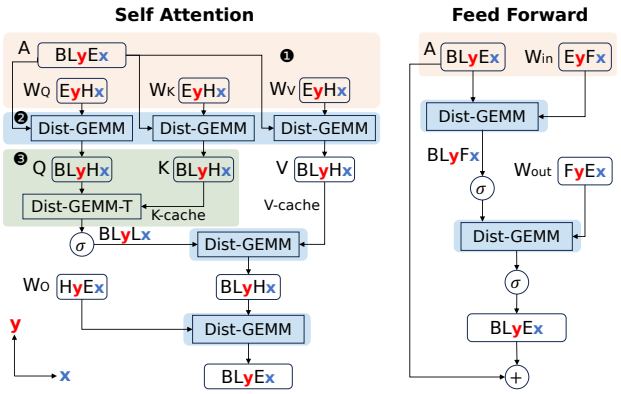

Figure 3: Prefill parallelism plan. E_xF_y represents a matrix of shape EF, where the E dimension is partitioned along the x-axis of cores, and F along the y-axis of cores on a mesh.

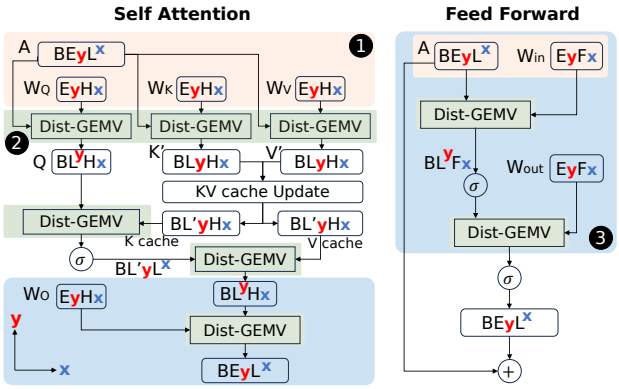

Figure 4: Decode parallelism plan. E^yF_x indicates the E dimension is replicated along the y-axis, and F is partitioned along the x-axis.

partitioning to achieve million-core parallelism (P); (ii) Optimizing GEMM operations, which involve further partitioning and overlapping computation and communication, to minimize long-range communication latency (L), respect local memory constraints (M), and account for limited routing resources (R); and (iii) Handling matrix transposes, which are costly on a mesh NoC (L) but often required for sequential GEMM operations.

Designing fine-grained partitioning for million-core parallelism. To achieve high chip utilization, we propose partitioning two dimensions of the input activation and weight matrices along both the X- and Y-axes of cores. This approach enables finer-grained, million-scale parallelism compared to existing methods [12,15,32,35], which typically partition only the embedding dimension, resulting in insufficient parallelism on PLMR devices.

We illustrate this partitioning using self-attention and feed-forward, as shown in Figure 3. For this discussion, we define the following annotations: the input activation A and weight W are multi-dimensional tensors during the prefill process. B represents the batch size, L the sequence dimension [2], E the embedding dimension, H the head dimension, and F the hidden dimension in the feedforward block. As shown by ❶, the partitioning layout of A is represented as BL_yE_x, where the L dimension is partitioned along the Y-axis of cores, and the E dimension along the X-axis of cores. Similarly, all weight matrices (W_Q, W_K, W_V, W_{in}, and W_{out}) are partitioned across both dimensions.

Designing PLMR-compliant distributed GEMM. We propose replacing conventional GEMM operators, which are designed for shared memory architectures, with a newly designed PLMR-compliant distributed GEMM during the prefill phase (as shown in ❷ of Figure 3). Unlike TPU and GPU systems that primarily rely on allgather operations for GEMM, PLMR-compliant distributed GEMM algorithms achieve high NoC bandwidth utilization while respecting local memory and routing constraints, ensuring compliance with the L, M, and R properties. This PLMR-compliant distributed GEMM is fully described in Section 5.

Using transposed distributed GEMM to avoid matrix transpose. We propose a transpose-free parallelism plan for prefill to avoid matrix transpose, a common operation in LLM systems designed for shared memory architectures. The L property in PLMR highlights that matrix transposition is particularly costly on a wafer-scale device. It requires a core on one corner of the mesh to send data to the opposite diagonal corner, creating a long-range communication path.

Our transpose-free parallelism plan leverages transposed distributed GEMM (denoted as dist-GEMM-T) [11, 42] to compute $Q@K^T$ during LLM prefill, as shown by ❸ in Figure 3. Specifically, the intermediate Q and K tensors, generated by multiplying X with W_Q and W_K, require transposing K before proceeding with dist-GEMM operations due to the on-chip partition shape.

4.2 Decode parallelism

The parallelism strategy for LLM decode must address its memory-bandwidth-intensive nature, presenting several challenges: (i) Decode uses smaller matrices than prefill due to limited input sequences and batch sizes, requiring careful parallelization when dimensions are insufficient for partitioning; (ii) The phase heavily relies on GEMV operations, which are less compute-intensive than GEMM, resulting in short computation phases with limited overlap with communication, making GEMV vulnerable to long-range communication latency on a mesh NoC (L) and requiring adherence to local memory and routing constraints (M and R); and (iii) Sequential GEMV operations introduce costly matrix transpose on a NoC, risking violation of the L property.

Designing fine-grained replication to enable parallelism at minimal communication cost. When tensor dimensions are insufficient to achieve the high parallelism required for decode, we propose fine-grained replication of tensors in LLMs,

[2] L: sequence dimension; L: memory access latency in PLMR.

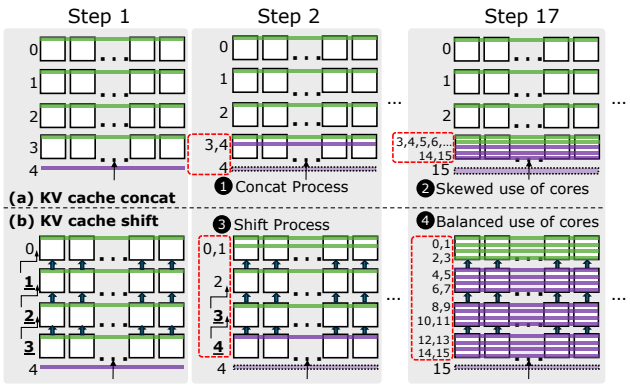

Figure 5: KV cache concatenation vs. KV cache shift

specifically replicating the sequence dimension, where the sequence length equals the prompt length during prefill phase and equals 1 during the decode phase. This approach offers two key advantages: (i) it improves parallelism and ensures balanced loads across all cores, and (ii) it avoids additional communication operations such as allreduce across all cores. As shown by ❶ in Figure 4, the E dimension is partitioned along the y-axis, and the L dimension is replicated along the x-axis, represented as BE_yL^x. Weight matrices W are partitioned across both dimensions, consistent with the prefill phase.

Our fine-grained replication differs from recent work on long-context/sequence inference systems [49, 55], which selectively replicate certain dimensions during the prefill phase rather than the decode phase.

Designing PLMR-compliant distributed GEMV. We found that existing GEMV implementations fail to fully comply with PLMR requirements due to long-range communication and excessive routing resource consumption at each core. To address this, we propose a PLMR-compliant distributed GEMV, utilizing this new implementation throughout the decode phase (as detailed in ❷ of Figure 4). A comprehensive description of this GEMV design is provided in Section 6.

Pre-optimizing model weight placement to avoid matrix transpose. To avoid matrix transpose during decode, we pre-optimize the model weight layout for decode, particularly for the distributed GEMV operation, to eliminate matrix transpose. While this introduces re-placement overhead between prefill and decode phases, the overhead is far smaller than that of sequential matrix transpose during token generation.

Figure 4 illustrates this proposal, detailed in ❸. Specifically, we optimize the placement of weights such as W_O and W_{out} for distributed GEMV in decode, differing from their layout in the prefill phase. This approach also removes transpose operations in calculating $Q@K^T$ during decode self-attention.

4.3 Shift-based KV cache management

KV cache management on PLMR devices is challenging as it requires storing large data across distributed cores while adhering to local memory constraints (M) and distributing KV cache computations to achieve high parallelism (P). To address these, we have the following insights:

Existing concatenate-based management causes skewed core utilization. Current KV cache management methods primarily concatenate the most recently generated KV vectors to the existing cache. Though efficient in shared memory architectures, this concatenate operation leads to highly skewed core utilization on PLMR devices, as shown in ❶ of Figure 5, where only the core in a row is responsible for storing and computing over the generated KV vector. After several token generation steps, this only core quickly becomes the bottleneck, as depicted in ❷ of Figure 5, causing skewed memory usage and violating the M in PLMR. Moreover, the imbalanced KV cache distribution across cores results in inefficient parallelism, violating the P property.

Proposing shift-based management for balanced core utilization. We propose a shift-based KV cache management strategy that evenly distributes cache data across all cores. Instead of concatenating new KV cache vectors at the end, this method performs a balancing shift operation, where each row transfers the oldest KV cache data to the row above, as shown in ❸ of Figure 5. When new KV data arrives, each core checks its local capacity against its neighbors. If equal, upward shifts are triggered, with each row receiving data from below and passing some to the row above. As illustrated in ❹, this ensures even KV cache distribution across all cores.

The upward shifts utilize NoC links in parallel, maintaining high performance and satisfying the P property. The physical placement of KV cache aligns with logical continuity and only involves data movement between the adjacent cores, adhering to the L property. This method also fully resolves the M violation issue observed in the last row of cores with the concatenate-based approach.

4.4 Implementation details

We outline several implementation details below:

Prefill and decode transition. Prefill and decode require distinct strategies. To handle the transition efficiently, we reshuffle KV cache and weights through the fast NoC, which often provides 100s Pbits/s aggregated bandwidth, completing instantly without relying on slower off-chip memory.

Parallelism configuration. WaferLLM uses offline autotuning to select core counts for each model, optimizing latency based on model size, input/output length, memory per core, and prefill/decode phases. It chooses different core counts for each phase, with fast dynamic remapping enabled by high NoC bandwidth. For models with variable input/output lengths, average values are used to maintain near-peak performance. Autotuning runs separately per model to adapt to specific needs.

Variations of self-attention. WaferLLM supports variations of Self-Attention, including Grouped Query Attention [3], Multihead Attention [43], and Multi-query Attention [5].

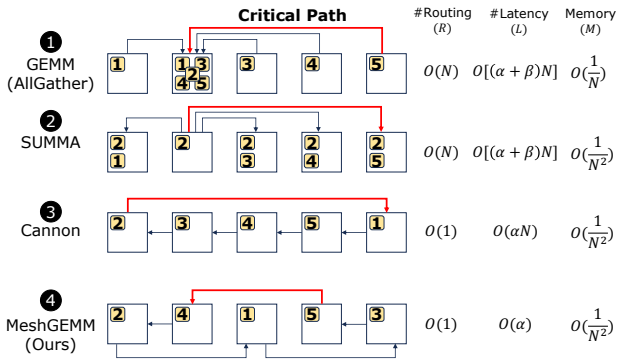

Figure 6: PLMR compliance in distributed GEMM

These differ by performing dist-GEMM, dist-GEMV and dist-GEMM-T locally after grouping by head dimensions.

5 Wafer-Scale GEMM

In this section, we introduce MeshGEMM, a scalable distributed GEMM for massive-scale, mesh architectures.

5.1 PLMR compliance in distributed GEMM

To identify a scalable distributed GEMM for PLMR devices, we define the following metrics: (i) *Routing paths per core*: The number of routing paths per core, with fewer paths ensuring compliance with the R property. (ii) *Latency of critical path*: Maximal latency among all communication paths in each step to transmit submatrix (as the red lines in Figure 6), with less latency adhering to the L property. (iii) *Memory per core*: The memory required per core, with lower usage ensuring the M property.

We analyze current distributed GEMM methods and show how MeshGEMM meets these metrics:

(1) **GEMM via Allgather** is commonly used in GPU and TPU pods for distributed GEMM [32, 35, 56]. Its critical communication path in each step is one core gathering data from the farthest cores, shown as the red line in Figure 6 ❶, and N steps to complete the allgather. Each core creates N routing paths to neighbors in its row and column (violating R). The constraint of R necessitates step-by-step submatrix transmission via intermediate cores, introducing a communication latency of $O[(\alpha+\beta)N]$ along the critical path (violating L), and each core uses $O(1/N)$ memory due to inflated working buffers (violating M).

(2) **SUMMA** is Cerebras' default choice for distributed GEMM on its wafer-scale engine [7]. Its critical communication path in each step is where one core broadcasts data to the farthest core along the column or row, shown by the red line in ❷ of Figure 6. Same to the allgather communication in ❶, each core creates N routing paths (violating R) and spans the critical path with $O[(\alpha+\beta)N]$ latency (violating L) in each step. While SUMMA improves memory usage compared to allgather, requiring only a working set equal to the size of locally partitioned submatrices, it still doubles the peak memory usage.

(3) **Cannon** is mesh-optimized choice for distributed GEMM [6], popular in supercomputers and distributed cluster. Its critical communication path in each step is the head cores send data to the tail cores shown in ❸ of Figure 6. Each intermediate core communicates with two neighbours in a 2D torus and passes through the submatrix from head to tail, which only needs $O(1)$ communication paths and optimal memory usage of $O(1/N^2)$.
Notably, Cannon involves only a constant number of routing paths per core, allowing static routing rules to be assigned for both neighbor communication and the critical path. At each step, submatrices can pass directly from the head to the tail core through intermediate cores, unlike GEMM via allgather or SUMMA, which require step-by-step message transmission. As a result, the critical path incurs only per-hop latency α, without additional per-routing overhead β. However, since the critical path spans N hops, it still incurs $O(\alpha N)$ latency, shown as the red line in ❸, violating the L.

(4) **MeshGEMM (Ours)** is a distributed GEMM which complies with the PLMR model. The critical communication path in each step, which we named as two-hop transmission, is shown as the red line in ❹ of Figure 6, which is significantly shorter than the others. Each core communicates with two two-hop away neighbors(proven in later sections to be scalable for larger-sized mesh architectures), and passes through a one-hop neighbor's communication. This design achieves $O(1)$ communication paths per core needed and optimal memory usage of $O(1/N^2)$, similar to Cannon. Crucially, it bounds the critical path to constantly 2 hops with $O(\alpha)$ complexity, making it uniquely capable of addressing the L property.

5.2 Design intuitions and scalability analysis

Our design involves two phases: (i) We ensure algorithm correctness using a cyclic shifting process for GEMM, and (ii) then use interleaving to bound the critical path latency to a constant. Based on the cyclic shifting and interleaving, we get the **two-hop transmission** communication path, and we prove that it, on this cycle, is the minimal distance required to satisfy the L property.

Cyclic shifting. Cyclic shifting enables MeshGEMM to satisfy the M and R properties by limiting communication to two neighbors and minimizing memory usage. It ensures correct GEMM results, following reasoning similar to Cannon [6]. As illustrated in ❸ of Figure 6, a logical circle of 5 cores is flattened into the physical communication mapping, with a critical path from head core to tail core.

Interleaving. For the flattened communication plan, we would like to minimize the length of the critical path further, thus satisfying the L property. Our key intuition here is

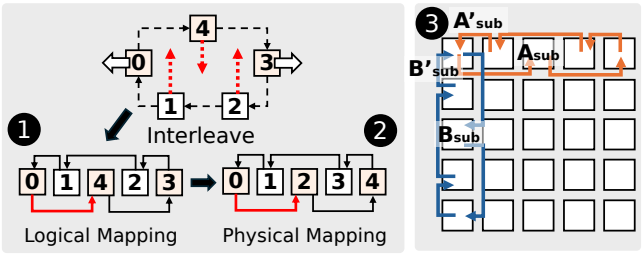

Figure 7: Design intuitions and scalability analysis.

Algorithm 1: INTERLEAVE

Input: index, N
Output: send_index, recv_index

```
if index mod 2 == 0 then
    recv_index = Max (index - 2, 0);
    send_index = Min (index + 2, N - 1);
else
    recv_index = Min (index + 2, N - 1);
    send_index = Max (index - 2, 0);
if index == 0 then recv_index = 1;
if index == N - 1 then
    if N mod 2 == 0 then recv_index = N - 2;
    else send_index = N - 2;
Return send_index, recv_index;
```

to introduce an INTERLEAVE operation to find the mapping relationship from logical to physical, defined in Algorithm 1. As shown by ❶ of Figure 7, MeshGEMM first insert core 1 in between core 0 and 4 and core 2 in between core 4 and 3 to form a logical mapping, and then call the INTERLEAVE operation to get the send to and receive from neighbours' index, resulting in a permutated, equivalent communication plan as shown by ❷ in Figure 7. For example, there are 5 cores total (N=5), so physical core 2 (index=2) sends data to physical core 4 (send_index=4) and receives from physical core 0 (recv_index=0). Figures 6 and 7 illustrate the case with 5 cores as an example, while Algorithm 1 demonstrates that the two-hop communication pattern in MeshGEMM generalizes to mesh architectures of arbitrary size with $N \geq 3$.

Scalability analysis. We can prove that the two-hop distance created by INTERLEAVE cannot be further reduced. The proof relies on the fundamental properties of sequential arrangements: if we attempt to create a circular sequence where each number differs from its neighbors by exactly one hop, we encounter a mathematical impossibility. This can be understood by visualizing the numbers as points on a line - while adjacent numbers can be connected, the endpoints of the sequence cannot simultaneously maintain single-hop differences with their neighbors while forming a circle.

Note that our discussion, based on a 1D array, naturally extends to a 2D mesh, as the 1D array corresponds to the mesh's X-axis and Y-axis due to their symmetry.

5.3 The MeshGEMM algorithm

We outline the key steps of MeshGEMM below:

(1) **Initialization:** Consider $C = A \times B$. MeshGEMM will partition A and B into tiles A_{sub} and B_{sub} along two dimensions, forming $N \times N$ tiles, which are distributed across the cores. Each core receives one tile of A_{sub} and one of B_{sub}. MeshGEMM will then use INTERLEAVE to initialize the neighbors' positions for each core.

(2) **Alignment:** Each core will then align with neighbors to align the input submatrices in a way that ensures every core in the distributed system begins with the appropriate operands for the matrix multiplication process.

(3) **Compute-shift loop:** Each core operates with a compute-shift loop involving N steps of communication and computation. In each step, every core computes the partial sum of its corresponding $C_{sub} = A_{sub} \times B_{sub} + C_{sub}$. Meanwhile, shift A_{sub} along the X-axis and B_{sub} along the Y-axis to get new A'_{sub} and B'_{sub} for the next step computation as ❸ we shown in Figure 7. After N steps, the accumulated C_{sub} is returned.

5.4 Implementation details

Handling non-square mesh. For a non-square mesh $N_h \times N_w$ ($N_h \neq N_w$), the A and B matrices can be logically partitioned into $N_{lcm} \times N_{lcm}$ cores, where N_{lcm} is the least common multiple of N_h and N_w.

Transposed distributed GEMM. The above algorithm can be applied to the computation of $C = A \times B^T$, the dist-GEMM-T in Figure 3 to avoid transposing B on mesh. It does not require alignment before computation and only necessitates N steps of two-hop compute-shift for the right matrix B along the Y-axis. After each shift step, each core computes $C_{\text{sub}} = A_{\text{sub}} \times B_{\text{sub}}$, followed by a ReduceAdd of C_{sub} along the X-axis. After N steps, the final matrix C is obtained.

6 Wafer-Scale GEMV

In this section, we describe MeshGEMV, a scalable GEMV algorithm for PLMR devices.

6.1 PLMR compliance in distributed GEMV

The completion time of a distributed GEMV is primarily determined by an element-wise computation to generate a partial sum result at each core and then an allreduce operation that aggregates partial results from all selected cores and then sends the aggregated results back to all cores for the continuous GEMV. As the analysis in GEMM, in wafer-scale GEMV, we also define the following metrics: (i) *Routing paths per core*: The number of routing paths per core, with fewer paths ensuring compliance with the R property (ii) *Latency of critical*

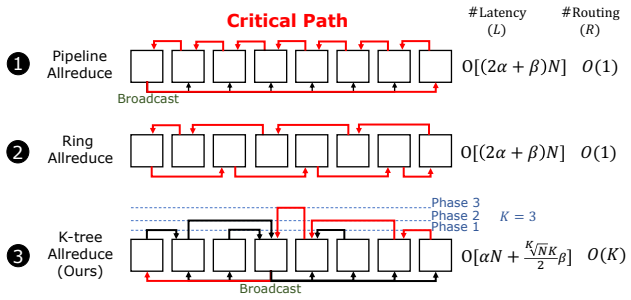

Figure 8: PLMR compliance in distributed GEMV

path: Maximal latency of the whole allreduce communication, mainly determined by the time from when the partial sum is sent from the farthest core to when the aggregated sum is received by the farthest core.

We analyze current distributed GEMV methods and show how MeshGEMV meets these metrics:

(1) **GEMV with pipeline allreduce** is commonly used in TPU pod systems [35] and as the default in Cerebras demo [9]. As illustrated by the red line in the Figure 8 ❶, the critical path of the pipelined all-reduce starts from the farthest core, where partial sums are reduced step-by-step toward the root core, and the aggregated result is then broadcast from root to all cores. While this approach ensures that the routing path per core remains within the R constraint, $O(1)$ per-core routing resource usage, it incurs a total of $2N$ hops and N routing stages, violating the L property.

(2) **GEMV with ring allreduce** is commonly used in GPU pod systems, where it is the default configuration, especially for a large amount of data [27]. As shown by ❷ in Figure 8, the critical path of ring allreduce involves each partial sum traversing all cores in the ring. Similar to pipelined allreduce, this approach maintains $O(1)$ routing paths per core, but incurs a communication latency of $O[(2\alpha+\beta)N]$, thus violating the latency constraint L defined in PLMR.

(3) **GEMV with K-tree allreduce (Ours)**. As analyzed above for pipelined and ring allreduce, the sequential execution of reduce-add operations leads to N routing stages along the critical path. In contrast, K-tree allreduce organizes the reduce-add path as a balanced K-tree, enabling K phases grouped parallel reductions with $O(\sqrt[K]{N})$ cores per group and reducing the critical path to only $\frac{K\sqrt[K]{N}K}{2}$ times routing and N hops. However, this comes at the cost of requiring $O(K)$ routing paths per core.

6.2 The MeshGEMV algorithm

We will outline the key steps of MeshGEMM below:

(1) **Initialization:** Consider $C = A \times B$ and A is a vector. MeshGEMV will partition B into tiles B_{sub} along two dimensions, forming $N \times N$ tiles and distributed across the cores. For A, MeshGEMV will partition it along the vector length, forming N tiles distributed on one axis and replica A on another axis. Each core receives one tile of A_{sub} and one of B_{sub}. Then we determine which cores form a group to obtain aggregated results in each phase based on the K-tree.

(2) **Parallel computation:** In this stage, each core performs a local GEMV $A_{\text{sub}} \times B_{\text{sub}}$ to obtain C_{sub} partial sum.

(3) **Aggregation:** The aggregation step primarily involves using the K-tree allreduce we design. The key steps are as follows: (i) In the 1st-phase, each group performs group reduction and obtains the partial sum of C_{sub} at the root core of each group. (ii) In the kth-phase, the results from the $(k-1)$ th-phase are reduced to the root cores of each group in the kth-phase. After K times repeating, C can be obtained by concatenating the C_{sub} from all K-tree root cores. (iii) Optionally, a broadcast operation from the root core of the K-tree may follow, depending on whether continuous GEMV is required.

Scalability Analysis. As shown in ❸ of Figure 8, this method scales efficiently with parallelism and meets the L property by selecting an appropriate K. It requires $K+1$ paths at the tree root core but allows flexible adjustment of K to address R based on hardware limitations. Compared to pipeline and ring all-reduce, K-tree all-reduce essentially builds pass-through paths between distant cores by consuming routing resources, thereby reducing routing latency.

However, a larger K is not always better, as it depends on N and R constraints. Additionally, larger K increases routing complexity and overhead. Considering these factors, we have chosen $K = 2$ for our current implementation, evaluated in the following sections.

7 Evaluation

We extensively evaluated WaferLLM against various state-of-the-art methods and systems. Our results show that:

(1) WaferLLM achieves orders of magnitude speedup over T10 and Ladder in LLM inference (§7.1);

(2) WaferLLM's MeshGEMM and MeshGEMV perform and scale strongly over the state-of-the-art (§7.2);

(3) WaferLLM's shift-based KV cache management enables over 360-385× more token capacity (§7.4);

(4) WaferLLM on Cerebras WSE-2 achieves 10-20× e2e speedup compared to the optimal performance of SGLang on A100 GPUs-cluster, and about 30-40× speedup compared to a single A100 GPU. WaferLLM also achieves approximately 2.5× better energy efficiency (§7.1,§7.5).

Experiment setup. We evaluate WaferLLM on a server with Cerebras WSE-2. WSE-2 has 850,000 Cores, each with a Compute Engine (CE) operating at a maximum of 1.1 GHz. Each clock cycle can fetch two 32-bit operands from SRAM, perform a multiply-accumulate operation, and then write back

to SRAM. Each core also has a fabric router that can send or receive 32-bit messages from neighbouring cores with a single clock cycle. Additionally, each core contains 48KB of SRAM, with the chip totalling 40GB of aggregated SRAM [24].

We compare WaferLLM with two DNN compilers: (i)T10 [25], the state-of-the-art compiler for AI accelerators with inter-core connections and distributed on-chip memory, and (ii)Ladder [45], the state-of-the-art compiler for shared memory architectures. For T10, we implemented it on WSE-2, treating each core as part of a distributed memory system interconnected by a crossbar, despite the actual mesh topology. T10 maps data to core IDs and fetches data from local SRAM as required. For Ladder, we treated the distributed memory architecture of the chip, interconnected by mesh, as unified memory, requiring collective communication over the NoC to access data.

We use the Nvidia A100 for GPU comparison experiments, which shares the same 7nm process as the WSE-2 for fairness. The experiments utilize up to 16 GPUs across two nodes (2×8 configuration). Within a single node, the eight A100 GPUs are interconnected via NVLink, while inter-node communication is handled through a high-performance InfiniBand (IB) network. We use SGLang [53], one of the highest-performing LLM inference systems for GPU-based experiments.

Experiment metric. To evaluate the maximum per-request throughput performance of LLM inference systems on different hardware, we define Throughput per Request (TPR) as a key metric. TPR is derived from the more widely used Time per Output Token (TPOT), with TPR $= \frac{1}{\text{TPOT}}$.

LLM models. Our evaluation includes various representative LLMs of different sizes and architectures. Specifically, LLaMA3-8B and LLaMA2-13B are widely used open-source LLMs, with LLaMA3 using group-query attention instead of multi-head attention to reduce KV cache usage. For LLaMA2-13B, we modified the model to remove the 4K context length limitation to evaluate system performance across different input and output lengths. Additionally, due to the tensor parallelism constraints, the number of attention heads of a model must be divisible by the number of GPUs used. We did not conduct the multi-GPU experiment of LLaMA-2 on a 16-GPU cluster. CodeLLaMA-34B is a specialized LLM for coding tasks, while QWen2-72B, another popular LLM, is renowned for its high model quality.

7.1 LLM inference

We first report the end-to-end performance of WaferLLM compared to T10 and Ladder on WSE-2 and SGLang on the A100 GPU cluster. Then we further analyze the performance to provide deeper insights by breaking down the execution into prefill and decode phases.

End-to-end throughput. Table 2 shows the inference TPR

[3] No 2×8 GPUs, due to model architecture and tensor parallelism.

Model	Device		Input/Output Seqence Length			
			2048/128	4096/128	2048/2048	4096/4096
LLaMA3-8B	WSE-2	WaferLLM	764.4	604.4	2370.3	2459.0
		T10	4.6	4.5	58.3	94.6
		Ladder	1.2	1.1	7.4	8.7
	A100 GPU (SGLang)	1	34.8	31.1	36.5	78.4
		8	117.2	109.0	128.4	256.1
		2×8	73.7	70.2	79.3	162.5
LLaMA2-13B	WSE-2	WaferLLM	473.9	414	1690.3	1826.0
		T10	2.6	2.5	35.0	58.3
		Ladder	0.7	0.7	4.9	6.1
	A100 GPU (SGLang)[3]	1	20.4	17.1	21.1	47.9
		8	79.6	70.5	86.9	172.4

Table 2: End-to-end LLM inference TPR

of LLaMA3-8B and LLaMA2-13B on WSE-2 and A100 with different input and output sequence lengths. Here, the end-to-end throughput is calculated as the total number of tokens generated during the decode phase divided by the total time spent in the prefill and decode phases. WaferLLM uses core configurations optimized for the best performance with each model. In LLaMA3-8B, we use 660×660 cores for prefill and 360×360 for decode. In LLaMA2-13B, we use 750×750 cores for prefill and 375×375 for decode. CodeLLaMA-34B and QWen2-72B are not included due to the memory constraint of a single WSE-2 chip.

Compared to T10, WaferLLM achieves 160× speedup on average, up to 180×, for short sequence generation tasks such as 4096 and 2048 input context lengths with 128 tokens output. For longer tasks, with input context lengths of 4096 and 2048 tokens and output lengths of 4096 and 2048 tokens, WaferLLM achieves 36× on average and up to 48×. Although T10 designs the compute-shift model that considers the memory constraints (M) and routing resource limits (R) of a PLMR device, it does not account for the cores interconnected by a mesh NoC. Thus, failing to address varying hop distances (L) and scale to millions of cores (P), highlighting the need for new system designs in massive-scale NUMA architectures.

Compared to Ladder, WaferLLM achieves 625× speedup on average, up 677×, for short sequence generation tasks such as 4096 and 2048 input context lengths with 128 tokens output. For longer sequence generation tasks, with input context lengths of 4096 and 2048 tokens and output lengths of 4096 and 2048 tokens, WaferLLM achieves 312× on average and up to 342×. That is because Ladder is designed for shared memory architecture and does not consider the characteristics of the PLMR device, resulting in failure in partitioning LLMs across millions of cores (P), incurring costly long-range NoC communication (L), failure in handling local memory constraints (M) and limited routing resources (R).

Prefill throughput. Table 3 shows the prefill performance for an input sequence length of 4096, using core configurations from 480×480 to 720×720. For CodeLLaMA-34B and QWen2-72B, which exceed the memory capacity of WSE-2 and a single A100, we evaluate a subset of layers and scale the results proportionally due to their uniform layer structure.

WaferLLM achieves significant speedups over T10 and

	Ladder	3.2	3.3	3.4			

Table 4: Decode Throughput per Request (TPR)

Ladder by effectively addressing all PLMR properties, an average speedup of 160× (up to 178×) over T10 and 270-450× over Ladder. As discussed in Section §2, GEMM is the primary bottleneck, and MeshGEMM substantially enhances WaferLLM's prefill performance, analyzed in detail in Section §7.2.

Additionally, WaferLLM scales throughput with increasing cores across all models. For instance, WaferLLM achieves a 1.6× scaleup on QWen2-72B and a 1.4× scaleup on LLaMA3-8B when scaling from 480×480 to 720×720 cores. In contrast, T10 and Ladder fail to scale effectively, with throughput even declining as more cores are added. This is mainly because T10 and Ladder do not account for the spatial locality characteristic (L) of highly uniformly distributed memory, which can lead to frequent long-distance data reads across cores and increased communication overhead.

Decode throughput. Table 4 shows decode throughput for core configurations from 420×420 to 660×660. For CodeLLaMA-34B and QWen2-72B decode benchmark on WSE-2 and single A100, we evaluate a subset of layers and scale the results.

By addressing all PLMR properties, WaferLLM achieves an average speedup of 5.7× (up to 6.5×) over T10 and 217× (up to 260×) over Ladder.

Compared to the 160× speedup WaferLLM achieves over T10 during prefill, it offers only about a 6.5× speedup during decode. However, WaferLLM maintains a consistent 200-500× advantage over Ladder in both prefill and decode stages. This is mainly because prefill involves dist-GEMM computations, which require each data element to traverse cores along the same row or column sequentially. In contrast, the dist-GEMV allreduce operation in decode only requires traversal across cores in the same row or column, without enforcing a

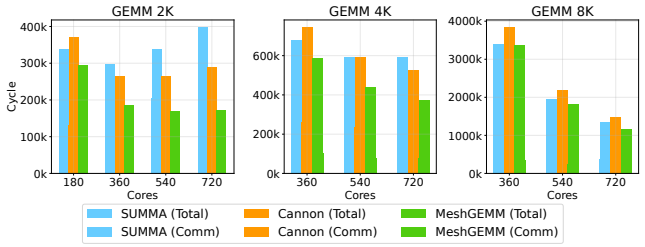

Figure 9: MeshGEMM vs. SUMMA & Cannon

strict access order. While T10's compute-shift paradigm does not consider the spatial locality of cores on a mesh NoC, it still accounts for distributed memory, which allows performance gains when memory (communication) accesses are order-independent. In contrast, Ladder is entirely designed for a shared memory architecture, leading to severe communication overhead regardless of whether memory access order is required.

Comparison with SGLang. As shown in Table 2,3 and 4, WaferLLM demonstrates clear advantages over SGLang + A100 GPU clusters in prefill, decode tasks, and also the end-to-end performance across models ranging from 8B to 72B. More detailed comparisons with GPUs are discussed in Section §7.5.

It is worth noting that T10 and Ladder fail to leverage the powerful hardware capabilities of the WSE-2 when compared to SGLang. For example, in prefill tasks and for Ladder in decode tasks, their performance is even worse than that of SGLang running on a single A100. This highlights that designing high-performance systems and algorithms on wafer-scale chips must carefully consider the PLMR model; otherwise, not only will the massive compute potential of the chip go underutilized, but performance may even degrade due to the highly uniform distributed memory resulting from the large-scale mesh NoC.

7.2 MeshGEMM

We compare MeshGEMM with Cannon [6] and SUMMA [42] on WSE-2 across different core scales and matrix sizes.

Scaling core count. Figure 9 shows that across matrices of different sizes, MeshGEMM can achieve the lowest latency than SUMMA and Cannon by scaling up the number of cores. Compared to the pipeline broadcast in SUMMA and head-to-tail transmission in Cannon, interleave transmission in MeshGEMM can minimize per-step communication overhead and, as much as possible, overlap communication with computation during large-scale fine-grained parallel execution. It demonstrates stronger scalability, maintaining over 70% computational efficiency even near the hardware limit. In contrast, SUMMA and Cannon exhibit poor scalability, with computational efficiency falling below 50% with 720×720 cores, primarily due to the communication overhead in SUMMA and Cannon, increasing with the parallelism scale.

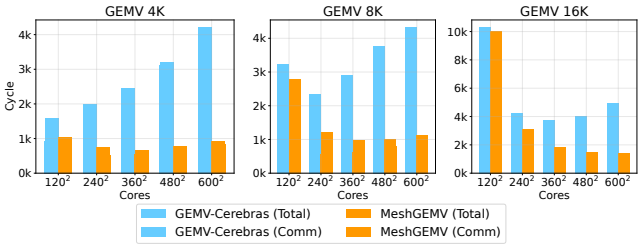

Figure 10: MeshGEMV vs. GEMV-Cerebras

Additionally, increasing the number of cores does not always bring performance gains, especially for small matrix GEMM tasks. For example, in GEMM 2K, when scaling from 360×360 to 720×720 cores, the end-to-end latency of SUMMA and Cannon increases instead of decreasing. This is because the per-core computation cost drops sublinearly as cores increase beyond a threshold (due to fixed overheads like function calls and logic checks). At the same time, communication overhead grows linearly, as seen from the shaded areas in Figure 9, leading to worse overall performance. In contrast, MeshGEMM only shows a slight communication overhead increase at 720×720 cores and maintains stable end-to-end latency. This is because its interleave communication bounds the per-step communication cost to a constant, independent of core count (the total communication overhead grows only because the number of steps increases in all dist-GEMM algorithms). Thus, MeshGEMM can achieve a better overlapping between communication and computation even under large-scale fine-grained parallelism (each core is only responsible for a small amount of data).

Scaling matrix size. We also evaluate MeshGEMM with larger matrix sizes, transforming GEMM into a more computationally intensive operation. At large scales, though the cost of communication becomes less significant, MeshGEMM maintains its scalability and outperforms SUMMA and Cannon by a wide margin, reducing total cycles by around 17%.

An interesting observation in Figure 9 is that for GEMM 8K, communication cycles decrease as core count increases. This occurs because when processing large data volumes, communication is bandwidth-bound rather than latency-bound. Increasing the number of cores not only boosts aggregate compute power to reduce computation overhead but also increases aggregate bandwidth to lower overall communication cost.

7.3 MeshGEMV

We evaluate MeshGEMV and the default GEMV implementation on Cerebras (pipeline allreduce) across various core scales and matrix shapes.

Communication latency bottleneck. Figure 10 shows that communication becomes the primary bottleneck for dist-GEMV computations on WSE-2, especially when the parallelism scale is large relative to the computation per core, where communication overhead can dominate 90% of the total. However, MeshGEMV significantly reduces communication overhead compared to the Cerebras baseline GEMV, achieving about 4.6× higher end-to-end performance. This is because large-scale dist-GEMV requires long-distance allreduce communication, and MeshGEMV uses K-tree Allreduce to maximize parallelism in the allreduce process, minimizing communication and computation costs along the critical path.

Model	LLaMA3-8B	LLaMA2-13B
Concat-based (PagedAttention)	382	16
Shift-based (WaferLLM)	137548	6168

Table 5: Maximum decode output length

GEMV	[1,16K]×[16K,16K]			[1,32K]×[32K,32K]		
TP in SGLang(A100)	1 GPU	8 GPUs	2×8 GPUs	1 GPU	8 GPUs	2×8 GPUs
Time (ms)	0.336	0.253	0.340	1.231	0.341	0.339
MeshGEMV (WSE-2) Time (ms)	0.0012			0.00203		
A100/WSE-2 Energy Ratio	**7.47**	**44.97**	**120.88**	**16.17**	**35.83**	**71.25**

Table 6: Comparing MeshGEMV (WSE-2) with TP in SGLang(A100) of GEMV latency and energy.

Scaling core count and matrix size. We also evaluate MeshGEMV with larger matrix sizes. For GEMV 8K and 16K compared to 2K, the baseline shows a trend that the end-to-end overhead first decreases and then increases. The initial decrease comes from increased core count, where the higher aggregate compute power and bandwidth reduce computation and communication costs. However, as the core count grows, the communication latency of allreduce eventually overtakes computation and bandwidth as the dominant bottleneck. In contrast, MeshGEMV's inflection point appears later, which means that for the same data size, MeshGEMV's communication overhead grows much more slowly with increasing core count compared to the baseline, demonstrating better scalability. This enables more flexible on-chip mapping policies, such as using more cores to store additional LLM parameters to meet memory limitations (M) without introducing significant extra overhead.

7.4 Shift-based KV cache management

We also compare the shift-based KV cache management with the concat-based KV cache management in PagedAttention. We evaluate KV cache capacity on LLaMA3-8B and LLaMA2-13B using the same settings as the end-to-end inference evaluation in Section §7.1. Table 5 shows that WaferLLM's shift-based KV cache management supports 360× and 385× more tokens than the concat-based method for LLaMA3-8B and LLaMA2-13B, respectively. This improvement results from balanced core utilization and the resolution of skewed data issues achieved by the shift-based approach.

7.5 Comparison with GPUs

We compare WaferLLM against the state-of-the-art LLM inference system on GPUs using Cerebras WSE-2 and NVIDIA

Prefill (4K CTX)	LLaMA3-8B			LLaMA2-13B	
SGLang(A100) TPR	1 GPU	8 GPUs	2×8 GPUs	1 GPU	8 GPUs
	13988	17361	13994	7805	12287
WaferLLM WSE-2 TPR	27686			17498	
A100/WSE-2 Energy Ratio	**0.05**	**0.34**	**0.84**	**0.06**	**0.30**

Table 7: Comparing WaferLLM (WSE-2) with SGLang(A100) in prefill throughput and energy.

SGLang(A100) TPR	1 GPU	8 GPUs	2×8 GPUs	1 GPU	8 GPUs
	78	260	164	48	175
WaferLLM WSE-2 TPR	2700			2039	
A100/WSE-2 Energy Ratio	**0.92**	**2.22**	**7.02**	**1.13**	**2.49**

Table 8: Comparing WaferLLM (WSE-2) with SGLang(A100) in decode throughput and energy.

A100. To compare against the H100 fairly, we would need access to the WSE-3, which is a 5nm manufacturer but unavailable to us.

GEMV. We compared MeshGEMV with the GEMV parallelization strategy that follows SGLang's [53] multi-GPU tensor parallelism, while the computation on each GPU is accelerated using the cuBLAS library. Shown by Table 6, compared to a single A100 GPU, MeshGEMV outperforms by 280-606× with different matrix sizes, showcasing the advantages of providing substantial memory bandwidth through wafer-scale devices. This also translates to 7.5-16× greater energy efficiency, reflecting the benefits of wafer-based connections (connecting on-chip memory) over PCB-based ones (connecting off-chip HBM) in GPUs.

Distributed GEMV on multi-GPUs shows limited scalability: a single A100 yields the highest energy efficiency per FLOP, and performance improves only 1.32× from one to eight GPUs, then degrades at sixteen. This inefficiency stems from memory intensity and communication overhead over NVLink and IB. In contrast, MeshGEMV exploits WSE-2's low-latency NoC to scale across hundreds of thousands of cores, achieving 166-210× higher performance and 45-70× better energy efficiency at peak compared to the best GPU cluster results. Moreover, GEMV exhibits similar performance for 16K and 32K tasks on two machines with 16 GPUs, mainly because communication overhead dominates the computation in distributed GEMV across two nodes.

Despite these advantages, MeshGEMV does not achieve the theoretical 7,000× improvement. Profiling identifies three contributing factors: (i) WSE-2 cores, still in their second generation, cannot fully overlap memory access and computation; (ii) edge cores are underutilized; and (iii) NoC long-range communication overhead persists, despite MeshGEMV mitigating it effectively. We anticipate these gaps will continue to narrow as wafer-scale accelerators mature.

LLM inference. The maximum TPR achievable on GPU clusters is significantly lower than on WSE-2. We compare WaferLLM with SGLang on an A100 multi-GPUs cluster and find that WaferLLM delivers a 6-20× higher TPR across a range of input/output lengths and model sizes from 8B to 72B, with the gap widening for longer outputs and larger models (Table 2). As shown in Tables 7 and 8, scaling SGLang from 1 to 8 GPUs yields only 1.2-1.6× prefill and 3.3-3.6× decode speedups, far below ideal linear scaling. Performance further degrades when scaling to 16 GPUs, due to inter-node communication bottlenecks. As a result, peak TPR for dense models is typically reached within a single 8-GPU node, where WaferLLM still outperforms SGLang up to 20×. For use cases demanding high per-request throughput, wafer-scale accelerators are substantially more capable than conventional xPU-based systems.

In terms of energy efficiency, though a WSE-2 chip has 47× the area and 37× the power and cost of an A100, WaferLLM still achieves a 2-2.5× energy efficiency advantage at SGLang's optimal multi-GPU result, owing to GPUs' nonlinear scaling on decode. This advantage is especially valuable for long-output scenarios like test-time scaling, where serving cost is critical. However, compared to GEMV, WaferLLM's decode energy efficiency advantage is reduced due to: (i) limited local SRAM (48KB) on WSE-2 cores, which hinders efficient tensor parallelism and necessitates pipeline parallelism, causing up to 5× underutilization; and (ii) GPU-optimized LLaMA models with narrow layers that constrain layer placement and worsen utilization on WSE-2.

8 Implementation Detail and Future Direction

We discuss the current limitations of WaferLLM and wafer-scale accelerators and envision their future solutions:

Hardware architecture. The performance of WaferLLM is currently constrained by execution bubbles caused by the need for pipeline parallelism. Increasing a core's local memory by 5-6× could eliminate the need for pipeline parallelism, enabling full tensor parallelism, as on vLLM and SGLang. Wafer-scale chip designers are already moving in this direction. Cerebras WSE-3 retains the same NoC configuration but improves per-core efficiency and local memory, while Tesla's Dojo incorporates 1MB of per-core memory.

Memory-to-Compute Ratio. LLM decoding demands a near 1:1 memory-to-compute ratio. However, GPUs like A100 have limited on-chip SRAM, forcing frequent off-chip memory access and yielding a poor ratio of 1:312 (FP16). Multi-GPU setups exacerbate this due to heavy inter-GPU communication. In contrast, Cerebras WSE-2 maps most model weights onto on-chip memory via a low-latency NoC, achieving near-ideal locality and approaching a 1:1 ratio. To fully realize this balance on mesh-based NoCs, adherence to the PLMR model is essential, enabling WaferLLM to outperform GPU-based systems by orders of magnitude in TPR.

Handle reliability issues. Currently, Cerebras WSE-2/3 handles faults by hardware, only exposing healthy cores (organized in a mesh) to software, with no explicit handling required at the software level. Moreover, redundant cores and

links are built in at fabrication, and the on-chip SoC dynamically remaps and reroutes around defects at runtime, ensuring minimal performance impact at a low redundancy cost. Meanwhile, wafer-scale chip makers recently reported a 93% functional wafer area, higher than 70–80% in commercial GPUs [8], due to the smaller area per core design. Over two years of WSE-2 deployment, we have observed high reliability, confirming the effectiveness of these fault-tolerance mechanisms in real-world use.

Various model architecture. WaferLLM is also beneficial for MoE as it shares key operators with dense LLMs, including MeshGEMM, MeshGEMV, and shift-based KV cache management. The main difference is the all-to-all communication between attention and expert layers, which we implement using WSE-2's NoC multi-cast operations. Further optimizations for sparse models, such as offloading and sparse attention, are among our future research.

Beyond Cerebras WSE. While evaluated on Cerebras WSE, the PLMR model generalizes to emerging mesh-like architectures such as Tesla Dojo, which also feature hundreds of thousands of cores with local memory and constrained NoC routing. Variants like 2D torus or hybrid mesh-switch topologies also conform to PLMR. Our design for MeshGEMM and MeshGEMV targets worst-case 2D mesh and remains competitive across such platforms. Beyond on-chip meshes, chip-to-chip mesh interconnects, as seen in Tenstorrent's core- and card-level meshes, also align well with PLMR. Looking ahead, advancements in wafer-scale integration, such as TSMC's projected 40× density increase by 2027, further reinforce the long-term applicability of our approach.

9 Related Work

Deep learning frameworks and compilers. Current deep learning frameworks and compilers, such as PyTorch, TensorFlow, and XLA [1, 10, 28, 34, 36, 37, 45, 51, 54, 57], are designed for shared memory architectures and use a tile-based "load-compute-store" computation model. While effective for shared memory, this model ignores the unique characteristics of PLMR devices, making it inefficient for wafer-scale AI chips. LLM frameworks such as vLLM and TensorRT-LLM [20, 56] have emerged to support modern LLMs but rely on frameworks and compilers designed for shared memory architectures (e.g., PyTorch [34]), inheriting similar limitations on wafer-scale chips.

Distributed GPU and TPU systems. The on-chip distributed memory architecture could theoretically be treated as a distributed LLM system, as studied in prior works [20, 23, 35, 49, 52, 56]. However, such systems, designed for GPU and TPU pods (up to thousands of nodes), rely on more capable routers and lack local memory constraints, making them misaligned with the PLMR model. These approaches are complementary to our focus on on-chip scaling.

Systolic array. Systolic array architectures [22], used in AI accelerators such as Amazon Trainium and Google TPU, focus on the design of small cores rather than larger wafer-scale accelerators. With limited processing elements (usually up to hundreds) in a core, they are not PLMR devices but complement WaferLLM. For example, a Cerebras WSE core could employ a systolic array to accelerate local GEMM operations.

Dataflow architectures. Prior research has explored computation on dataflow architectures that account for inter-core connections. TENET [26] maps computation spatially and temporally to connected cores in a dataflow pattern. DISTAL [50] enables scheduling over distributed clusters using a dataflow approach. SambaNova [14] combines model and pipeline parallelism for DNN execution. However, none of these works scale computation to wafer-scale chips.

Wafer-scale allreduce. Recent research [27] has investigated wafer-scale allreduce, but a single allreduce cannot fully parallelize GEMV or support full LLM inference as achieved by WaferLLM. Additionally, this prior work is a specific instance of the K-tree allreduce proposed in WaferLLM.

10 Conclusion

We envision this paper as a foundational step in exploring the potential of wafer-scale computing for LLMs. The simple yet effective PLMR model has revealed significant opportunities, guiding the development of the first wafer-scale LLM parallelism solution and scalable GEMM and GEMV algorithms for wafer-scale accelerators. Despite the limitations of the current software stack for wafer-scale devices, our approach achieves orders-of-magnitude improvements in both performance and energy efficiency. We hope this work inspires greater focus on wafer-scale computing and advances the path toward a more sustainable future for AI.

11 Acknowledgments

We sincerely thank our shepherd, Marco Canini, and the OSDI reviewers for their insightful feedback that greatly improved this paper. We are also grateful to Yuqing Xia (Microsoft) for her valuable input during the development of this work.

We acknowledge the hardware resources provided by the Edinburgh International Data Facility (EIDF) and the Edinburgh Parallel Computing Centre (EPCC), particularly their support in granting access to the Cerebras WSE systems. We thank Nick Johnson for coordinating access and Mark Parsons for supporting the hardware acquisition and our project.

Finally, we appreciate the generous assistance of Leighton Wilson and Mathias Jacquelin from Cerebras for their patience and detailed responses to our many questions regarding CSL and the Cerebras WSE.

BLITZSCALE: Fast and Live Large Model Autoscaling with $O(1)$ Host Caching

Dingyan Zhang, Haotian Wang†, Yang Liu†, Xingda Wei✉[1], Yizhou Shan[2], and Rong Chen, Haibo Chen[1]

[1]Institute of Parallel and Distributed Systems, Shanghai Jiao Tong University [2]Huawei Cloud

Abstract

Model autoscaling is the key mechanism to achieve serverless model-as-a-service, but it faces a fundamental trade-off between scaling speed and storage/memory usage to cache parameters, and cannot meet frequent scaling requirements across multiple hosts. The key problem is that data plane performance is slow, and scaled instances remain stopped while parameters are loading.

In this paper, we first show that the data plane can be made *fast* with no or $O(1)$ caching by loading parameters through the compute network between GPUs because: (1) its speed is comparable to host cache and is underutilized, and (2) scaling multiple instances requires no or $O(1)$ caching with network-optimized multicast. Second, autoscaling can be made *live* by breaking the scaling abstraction for inference from a coarse-grained instance-level to a fine-grained layer-level. This allows us to offload the layer computation from the overloaded serving instances to the scaled ones without waiting for the parameters to be fully loaded.

Under real-world workloads, our system BLITZSCALE achieves up to 94 % lower tail latency reductions compared to state-of-the-art autoscaling system (ServerlessLLM), and it reduces the GPU time used for serving by 49 % when compared with serving systems that do not support autoscaling like DistServe and vLLM with the same service-level-agreement.

1 Introduction

Recent years have seen rapid growth in applications powered by deep learning models like large language models (LLMs) [13, 53, 34, 54, 61]. Due to the huge computation requirements, these models are typically served in model-serving-as-a-service systems (MAAS) [63, 11, 23, 76, 20, 10, 29], which manage a cluster of accelerators (e.g., GPUs) and provision an appropriate number of serving *instances* containing GPUs to each model deployed.

An MAAS system has two design objectives: *maximizing goodput*—the number of requests that meet the service level objective (SLO), and *minimizing instances provisioned* to each model to improve hardware utilization. Achieving both is challenging due to the unpredictable short-term fluctuations in a model's instance demands, (5 × required within 2 seconds), because the request arrival rate bursts at seconds-level [45, 80], where the memory usage of each request is also unpredictable due to the auto-regressive nature of LLMs [45, 80, 29] (see also Figure 1 and §2.2).

Model autoscaling is a promising solution [76, 11, 29, 3]. With autoscaling, a MAAS system only provisions the average number of instances required over the long term for each served model, which remains relatively stable [71]. This improves utilization. Upon bursts, the system automatically scales new instances, avoiding SLO violations due to request queueing caused by insufficient instances provisioned.

Autoscaling speed is critical in minimizing SLO violations because the queued requests are not served until the instances are scaled. For instance, the inference time of a Llama3-8B is 80-900 ms on commodity GPU (A800), while users expect a tight response time (< 1 second) for scenarios like chatbot [12, 81, 33]. Meeting such tight SLO requires less than 500 ms scaling time, but achieving this is challenging especially for LLMs with 10-400 GB parameters. The key reason is the **slow data plane** of autoscaling—the process of loading the model parameters to instances' GPUs. While high bandwidth SSDs are utilized in current work [29], the speed provided by SSDs of GPU servers (2-10 Gbps per GPU [35, 9, 27]) is still far from ideal. For instance, loading Llama3-8 B to a GPU takes 12.8 seconds with 10 Gbps SSD. Another factor obstructing fast scaling is that existing scaling methods are **stop-the-world**: the scaled instances cannot serve requests until all parameters are loaded. This implies that autoscaling is directly bottlenecked by the data plane.

To mitigate the above issues, state-of-the-art systems like ServerlessLLM further adopt a multi-tiered caching system by caching model parameters in the host (CPU) DRAM to accelerate the data plane [36, 41]. Under cache hit, they can leverage the fast CPU-GPU link (e.g., 256 Gbps PCIe) to load parameters. However, achieving a high hit rate is unfeasible: ServerlessLLM reports a hit rate of 40–75 %, which is confirmed by us (see §3). The root cause is that a MAAS typically hosts many models, thus achieving a 100 % cache hit requires caching all these models on the DRAM of each host, clearly impractical. Vendors typically host many models because there are hundreds of popular open-source model families designed for different purposes [28]. Meanwhile, each model family has different scales for balancing the serving cost and accuracy [4]. Finally, developers can upload their customized fine-tuned models based on open-source models [10].

To achieve fast model scaling without relying on cache hit, we make the following two key contributions:

1. Data plane made fast with $O(1)$ or no caching with

†These authors contributed equally to this work.

✉Xingda Wei is the corresponding author (wxdwfc@sjtu.edu.cn).

compute network multicast. First, a MAAS is backed by fast GPU-GPU/CPU compute fabrics [50], which are 100–400 Gbps RDMA and even 16 Tbps NVLink [35, 9, 27]—much faster than SSD and comparable (or even faster than) CPU-GPU PCIe. The compute fabric is used for data transfer during serving and we found it largely under-utilized, i.e., up to 7.4 % of total bandwidth even in network-heavy workloads like serving LLMs with prefill and decode disaggregation [55, 81, 38, 19, 75] (§3). Thus, we can borrow such fast links for accelerating the data plane of autoscaling.

Second, network-based data plane requires no or minimal caching to achieve fast scaling. Specifically, if a model is already deployed on some instances, we can directly multicast the parameters from deployed instances through the network, eliminating the need for caching. Such multicast is extremely efficient because a serial forwarding multicast [66] can load bulk data (e.g., model parameters), regardless of the number of receivers. Even if no instance is deployed, multicast can be done with $O(1)$ host caching by simply broadcasting the parameters from the host with the cached model. This $O(1)$ caching per-model allows us to avoid all cache misses since the aggregated host memory of all machines is sufficient to cache all models served by a MAAS.

Although fast networking can significantly accelerate the data plane with minimal caching, a stop-the-world loading remains a bottleneck in cases when the networking is not fast enough. For example, to achieve at most 40 % SLO violations when serving a BurstGPT workload with Qwen2.5-72B, the system needs to achieve a tight 500 ms stop time. Achieving so requires 576 Gbps per-GPU[1] parameter transfer bandwidth, far exceeding the available bandwidth of typical compute network setups (e.g., 200 Gbps per-GPU) and even when caching at the host (256 Gbps PCIe). Thus, we argue that an ideal parameter loading should be *live*: before the data loading finishes, the scaled instance should be able to serve requests.

2. Data plane made live with fine-grained scaling abstraction and cooperative execution. Model scaling cannot be live using traditional on-demand data loading techniques commonly found in serverless computing [74, 69, 39] or inference loading overlap in PipeSwitch [15] (§4), because an instance can only emit results once all the parameters are loaded. This stop is rooted in the coarse-grained scaling abstraction of existing systems: they can only scale and serve at the instance level. To realize live scaling, our key insight is that *models can be served in a fine-grained, layer-by-layer manner*. With this fine-grained layer-wise scaling, we can offload part of the layer's computation from overloaded instances to scaled instances with cooperative execution, thus improving the overall serving throughput even before the scaled instance has loaded all the parameters.

Challenges and solutions. First, utilizing network-based multicast is non-trivial in our setup. Though the mechanism of multicast is simple, i.e., simply forwarding parameters between instances with the network, the challenges lie in generating the multicast plan, i.e., determining how the data flows between instances. First, we need to quickly generate an efficient plan online on diverse network topologies since our sources and destinations are dynamically determined, but generating an optimal plan is NP-hard on heterogeneous networks in serving clusters [18]. Second, we need to avoid network interference between the scaling and serving, otherwise, we observed a 1.5 × longer scale time and 50% degraded tail TBT (§4). Current solutions [22, 19, 32] mainly target offline scenarios like training, so they can tolerate long plan generation time and don't need to consider interference from serving workloads. To address the issue, we propose a model-aware multicast planner, which leverages the key features of compute network and the static data flow in model serving to quickly generate a near-optimal, interference-free multicast plan for scaling (§5.1).

Second, it is challenging to schedule how requests are executed between deployed and live scaling instances, i.e., which instance executes which layers. The challenge lies in the fact that the serving capability of the scaling instances is limited—it can only execute layers with parameters loaded, and this capability is dynamically changing. A naive best-effort scaling that executes as many layers as possible cannot balance the load because at the beginning of autoscaling, the new instances can only execute few layers, with requests still queued at the overloaded instances. A better solution is to adjust the load holistically by considering future incoming layers, and we realize this with a ZigZag pipeline scheduling and achieve 50% tail latency reduction under bursty workloads (§5.2).

Demonstration with BLITZSCALE. We built BLITZSCALE, an MAAS system with the fastest autoscaling speed with $O(1)$ caching. We adopted a global parameter pool to cache the model parameters across all the machines, and integrated the aforementioned interference-free multicast plan for scaling and efficient ZigZag scheduling-based live scheduling. To show the effectiveness of BLITZSCALE, we evaluated BLITZSCALE by running real-world traces (i.e., BurstGPT [71], AzureCode and AzureConv [14]) across a variety of recent models with different sizes and architectures, including Llama3-8B, Mistral-24B, and Qwen2.5-72B. First, BLITZSCALE has 47–75 % shorter time-to-first token, and has up to 94 % shorter time-between-tokens than the state-of-the-art work (ServerlessLLM [29]). Second, compared to serving systems without autoscaling support, i.e., vLLM [44] and DistServe [81], BLITZSCALE reduces the GPU used for serving a single model by 49 % with no SLO violations compared to an over-provisioning setup that provisions the GPUs based on the maximum request rate. BLITZSCALE is open-sourced at https://github.com/blitz-serving/blitz-scale.

[1] 72 B model requires at least four GPUs per-instance for serving.

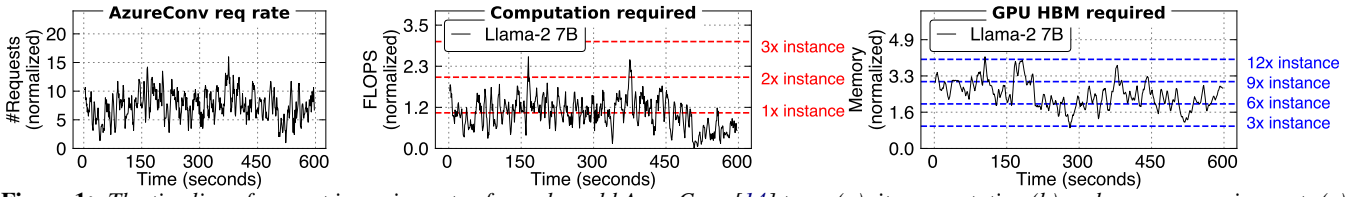

Figure 1: *The timeline of request incoming rate of a real-world AzureConv [14] trace (a), its computation (b) and memory requirements (c) when serving this workload without SLO violation.*

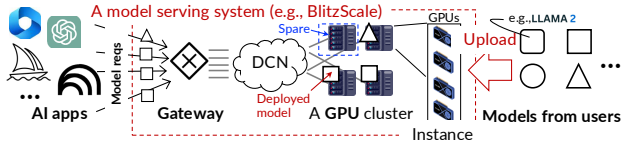

Figure 2: *An illustration of Model as a Service (*MAAS*) system. DCN states for data center network.*

2 Background: MAAS and Autoscaling

2.1 System setup: model-serving-as-a-service (MAAS)

MAAS system setup and the serving instance. BLITZSCALE targets a MAAS scenario [63, 11, 23, 76, 20, 10, 29]: the cloud allows the users to deploy their model serving on its managed hardware, and only charges users based on the number of requests processed within SLO [10, 20]. The model can be popular open-source models like Qwen [4] or customized models uploaded by the users. Thanks to the above pricing strategy, the cloud can dynamically adjust hardware resources to a specific model to maximize its hardware utilization. Figure 2 shows a typical deployment of a MAAS system. For each user-deployed model, the system dynamically allocates the required hardware resources (GPUs) to serve the inference requests of the model. Note that due to the diversity of AI applications, there would be hundreds or even thousands of models served simultaneously by a MAAS system [21].

In this paper, we use *instance* to denote a set of GPUs storing a complete copy of a model parameter for serving this model. An instance can have a single GPU or multiple GPUs when the parameter is large and sharded across them, e.g., with tensor parallelism [47]. Because each instance has a maximal serving throughput, the cloud can deploy multiply instances of the same model by provisioning multiple sets of GPUs, where the number of instances is dynamically scaled based on the incoming request rate. BLITZSCALE supports autoscaling with all existing model serving methods at the instance level.

Serving within an instance: non-LLM & LLM. Each serving instance processes requests in the following workflow: it queries the model in a layer-by-layer computation paradigm (see Figure 9 (a)) and gets the final results. For simple models like vision models, the model is queried once with the input data (image). On the other hand, for large language models (LLMs) [65], the request queries the model multiple times: the model is first queried with input text (prompt) to produce a result (token). This first query is typically termed *prefill*. The token is then used to generate subsequent tokens iteratively until the model returns an end-of-sequence token. The auto-regressive phase is termed *decode*.

We note two important features of LLMs. First, the performance for prefill and decode is measured separately. Prefill is evaluated with the time-to-first-token (TTFT) while decode is evaluated using time-between-tokens (TBT). Second, the LLM query is stateful: the intermediate results—usually termed as *KVCache*—are cached in GPU memory during the auto-regressive phase of a request for acceleration.

Serving across instances: prefill and decode (PD) disaggregated LLM serving. Observing the different computing paradigms of prefill and decode, recent works propose separating the instances for prefill and decode (PD disaggregation) when processing serving requests [55, 81, 38]. Specifically, for each request, one instance processes the prefill phase (prefill instance) and another instance (decode instance) processes the decode phase. This paradigm requires excessive data movement between the two instances because the prefill instance needs to transfer the KVCache to the decode instance. BLITZSCALE works for both PD disaggregated and non-disaggregated LLM serving.

2.2 Dynamic hardware demands when serving a model

Determining the hardware requirements, i.e., the right number of instances for serving a model is challenging because the hardware demands are unpredictable and fluctuating. First, the incoming request rate for a serving workload fluctuates over time and is hard to predict [29, 59, 80]. Figure 1 (a) presents the number of requests sent to a single model service over time from a real-world trace—BurstGPT [71]: the incoming inference requests increase 5 × within 2 seconds with no predictable trend. Since the FLOPS of an instance is fixed, the unpredictable rate causes the computation requirement—FLOPS required to finish the pending requests within SLO—unpredictable. Figure 1 (b) confirms this by measuring the requirement of the prefill instances when serving the BurstGPT with Llama2-7B.

Second, serving modern models like LLM has non-trivial and unpredictable memory requirements. As shown in Figure 1 (c), the KVCache usage of the decode instances is multiple times larger than the memory capacity of a single instance and fluctuates over time (3–12 ×) when serving the BurstGPT workload with Llama2-7B. The root cause is that the KVCache of requests must be stationary in GPU memory during the decode phase. The KVCache of requests are large,

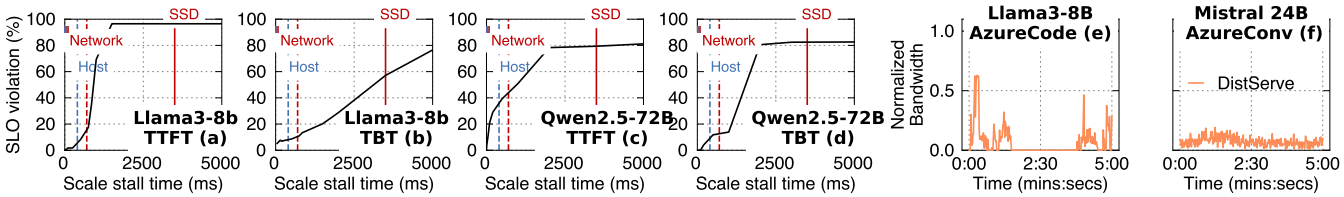

Figure 3: *A characterization of SLO attainment for different inference cases (a)–(d) with varied duration of autoscaling stops on BurstGPT [71]. (e) and (f): an analysis of compute network usage in serving workloads. The evaluation setup is in §6.*

e.g., 190–760 GB for Llama2-7B to serve BurstGPT, and the stay time is unpredictable due to the auto-regressive nature of LLMs. To avoid performance losses when out of memory, a MaaS system must provision sufficient instances to hold KVCache from ongoing requests, so the number of instances required by a model also unpredictably fluctuates.

2.3 Model autoscaling for handling dynamic demands

Model autoscaling, which dynamically deploys[2] serving instances on spare GPUs to scale up the serving capability, is a promising solution to handle fluctuated and unpredictable computation and memory demands [29, 76, 11]. The rationale is that though a single model's workload is unpredictable, the aggregated workloads of all models served by a platform are relatively stable [80]. Thus, when the load of a specific model service increases, we are able to find spare GPUs from other models to scale up the serving capability of this model.

Autoscaling an instance requires two basic steps: (1) initialize a proper execution context, e.g., create CUDA contexts (control plane) and (2) load the model parameters to the GPUs' memory (data plane). We focus on (2) because (1) can be minimized with recent advances in GPU startup methods like checkpoint and restore [40, 79] and our Rust/C++-based serving platform (see also §6.3). For (2), the state-of-the-art system—ServerlessLLM [29] optimizes the data plane with SSD-optimized parameter loading. Unfortunately, it does not account for the scaling speed required by models. Our measurements in the next section show that SSD-based scaling significantly lags behind applications' requirements.

3 Characterizing Scaling Requirements and Compute Network between Instances

Model autoscaling requires fast data plane. If the data plane speed is not fast enough, during burst period, the requests still violate the SLO due to increased queueing time. Specifically, SLO defines the tolerable end-to-end latency measured from the time a request is sent to the system to the time the inference response is returned. Thus, the latency includes the queueing delays waiting for the scaled instance to be ready for inference.

To characterize how different scaling speeds affect SLO attainments, we implemented a simulator on DistServe [81] that provisions models to all GPUs and applies manual delays based on the simulated speed for modeling different scaling speeds. We set TTFT and TBT SLO based on inference speed of different models following prior works [81]. Specifically, we use 450 ms and 150 ms for Llama3-8B model, and 1250 ms and 200 ms for Qwen2.5-72B model with tensor parallelism degree of 4. §6 describes the detailed evaluation setup.

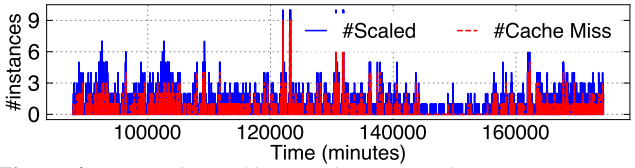

Figure 4: *An analysis of host cache misses when running ServerlessLLM [29] on BurstGPT [71].*

Figure 3 (a)–(d) shows the results: We can see that for a 72 B model, maintaining SLO violations below 60 % requires a minimum per-instance scaling speed of 220 Gbps per-GPU[3], which is only achievable when the model parameters are loaded from the host memory. The scaling time requirement correlates directly with inference time—our evaluated workload (BurstGPT [71]) has an average TTFT of 771 ms (with queueing time). Thus, to achieve 1250 ms SLO for all requests, the scale time must be below 500 ms, so a 576 Gbps per-GPU network speed is required (measured by dividing the parameter size by the scale time). This far exceeds what vendor-provided per-GPU SSDs bandwidth can deliver (2–10 Gbps per-GPU [35, 9, 27], detailed in §A.2).

Loading model parameters from host memory is not effective due to misses. While caching the parameters on the host CPU memory can meet the scaling speed requirement for some setups (e.g., 8 B, 24 B) with the fast host-GPU interconnects (256 Gbps PCIe 4.0), cache misses are common in real-world traces, because the scarce host memory cannot support the caching all models deployed on the MaaS. Figure 4 presents the number of instances scaled and cache misses encountered in the BurstGPT workload using ServerlessLLM [29]. Following its setup, we set a 5-minute keep-alive interval for caching models at the host. The miss rates range from 20–46%, depending on the time, which aligns with the numbers reported in ServerlessLLM's paper (25–60%). Interestingly, many misses occur when scaling multiple instances, because involving more hosts increases the

[2] It also stops a serving instance to scale down. Since scaling down is simpler, we omit its details for brevity.

[3] 72 B model uses four GPUs per-instance.

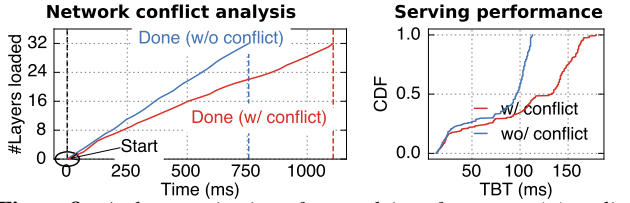

Figure 8: *A characterization of network interference on (a) scaling speed and (b) serving performance.*

probability of scaling a model on a host without the cached parameters. Therefore, we still need accelerating scaling speed when the model parameters are not cached at the host.

Opportunity: fast and underutilized compute network. First, compute networks between GPUs (and CPUs) have comparable or even faster speeds than host-to-GPU link. As shown in Figure 5, the inter-GPU network (RDMA) operates at 200 Gbps, which is close to the host-to-GPU PCIe speed (256 Gbps). With NVLink, the speed is much faster. More importantly, these networks are underutilized during serving. Figure 3 (e) and (f) measure the peak network usage of DistServe [81], a PD disaggregated serving system that heavily utilizes the network due to KVCache transfers. To measure peak usage, we provisioned all the GPUs for serving, and evaluate a workload with the maximal request rate that our clusters can serve. Even under peak load, more than 40% of the network capacity is free, opening up the opportunity to use the compute network for the scaling data plane.

4 System Overview of BLITZSCALE

BLITZSCALE scales models through the compute network to accelerate scaling even under cache misses on the host. We achieve this by first managing model parameters—scattered across GPUs behind serving instances (for deployed models) and CPUs (cached at the host)—through a global parameter manager. The manager maintains a mapping between models and their sources. With the manager, we can quickly read parameters from these sources with the fast RDMA or NVLink. Besides, we also offload computation from overloaded instances to instances with partially loaded parameters to achieve live scaling.

System architecture and workflow. Figure 6 shows our system architecture. Like prior work [56, 29, 62], we have a load monitor (①) tracking the serving load for each model service, and deciding whether to scale and how many new instances are required (§5.3). On each machine, we further adopt off-the-shelf GPU kernels FlashInfer [1] to query the model efficiently. The key differences are twofold. First, our scale planner (②) will derive a scaling plan that guides how to load parameters onto the scaled instances (§5.1) with compute network efficiently. The planner consults the global parameter manager (③) to identify the sources of model parameters. In our example, the new instance can load the parameters of model □ from the GPU0 on host N $(N, 0)$, or from host 2's CPU memory $(2, _)$. Second, during scaling, our live execution (exe.) scheduler (④) will redirect requests between instances to fully utilize the scaled instances even before the parameters are fully loaded (§5.2).

Challenges and approaches. Despite leveraging fast networking, making autoscaling fast and live needs to address the following challenges.

C#1. Online interference-free scale plan generation. Generating the scale plan is similar to generating a *multicast* plan [18, 22, 32, 16, 17], i.e., how to quickly distribute data (parameters) from some sources to targets. There are two additional requirements for autoscaling. First, the plan must be generated online on dynamically changing sources and targets, but optimal plan generation is NP-hard [18] on a heterogeneous network. Second, the plan needs to eliminate interference between loading and the serving workload. Figure 7 shows an example when a model is served via PD disaggregation. In PD disaggregation serving workload KVCache is migrated from prefill to decode instances (a), and this migration overhead can be hidden [55]. However, sup-

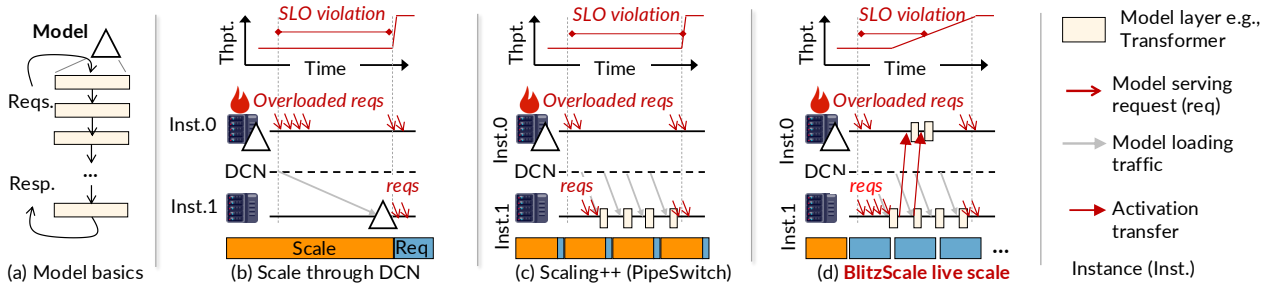

Figure 9: *(a) An overview of how model executes requests. (b) An illustration of naive model scale through DCN. (c) An illustration of an optimized scaling method with overlapped execution [15], but it still cannot be live. (d) How* BLITZSCALE *scales models lively.*

pose we want to scale a prefill instance: if we naively select a prefill instance as the source (b), the scaling will compete the network bandwidth with the serving workload, leading to 1.5 × longer scale time as well as 50% tail TBT increase due to the amplified KVCache migration overhead (Figure 8 (b)).

To this end, we design a serving-guided greedy plan generation method based on three observations (§5.1). First, the network heterogeneity mainly comes from NVLink, whose speed is extremely fast, i.e., it can broadcast a Llama3 8B to 8 GPUs within 120 ms. Thus, we can abstract instances linked with NVLink as a logical instance group to eliminate NVLink from the network topology. Second, loading parameters from the network is bandwidth-intensive, so we can greedily construct serial forwarding chains [66] for multicast, which is optimal in the common case. Finally, the network (RDMA) between GPU servers is bi-directional [72, 52], meaning that the network flows of incast and outcast don't interfere (c). Thus, we can leverage this feature to avoid interference by removing flows in the same direction on the same network link during plan generation. For example, we can load the parameters from the decode instance to the prefill instance (see Figure 7 (d)).

C#2. Realizing live autoscale. Live autoscaling—allowing the scaled instance to increase system throughput before all parameters are fully loaded—is necessary because SLO violations can still happen (Figure 3 (c)) even with fast networking. It is challenging to achieve this in existing systems. For example, PipeSwitch [15] and DeepPlan [42] leverage the layer-by-layer execution nature of models to perform inference: As shown in Figure 9 (c), once the first layer is loaded on inst.1, they redirect the overloaded requests to it for execution. Meanwhile, inst.1 will load subsequent layers concurrently. However, such overlapping is not live because, until all the layers are loaded, inst.1 still cannot finish requests to increase the system throughput.

To this end, we propose a novel cooperative execution scheme for live autoscaling. The key observation is that though the scaled instance alone cannot finish the requests until all layers are loaded, it can alleviate the load of the overloaded instance with its loaded layers, thus improving the serving throughput. Figure 9 (d) illustrates this. When inst.0 becomes overloaded and inst.1 is under scaling, after inst.1 has loaded the first layer, we redirect all requests from inst.0 to inst.1 for execution. Once inst.1 completes the first layer's execution, it forwards the activation back to inst.0 to process the remaining layers, and the system throughput increases with reduced queued latencies, as queued requests are processed faster. To see why the throughput increases, consider serving a 7-layer model. inst.0 alone will have a throughput of 1/7. With our live scaling, after loading one layer on inst.1, inst.0 only needs to execute 6 layers, so its throughput increases to 1/6. The throughput continues to improve as more layers are loaded, reaching the peak (doubled) after half of the layers have been loaded—half of the scaling time. §5.2 describes our ZigZag scheduling for coordinating overloaded and new instances during live autoscaling to achieve optimal performance for live autoscaling.

5 Detailed Design and Implementation

5.1 Online network-based scale plan generation

When the planner is notified to scale the parameters onto n new GPUs, it will get s sources from the parameter pool, find t spare GPUs as target and generate a plan on how to send parameters from s sources to a subset of n GPUs in t targets. There are three metrics to minimize for the generation: (1) the scale time, (2) the plan generation time, and (3) the interference with serving workloads.

Modeling the network between GPUs. Effectively generating a plan requires a model of the network between sources and targets, which is non-trivial due to the complexity of the network topology in serving clusters. Our model assumes a

Input: D_{src}, source GPUs; D_{tgt} target GPUs; n: number of GPUs to scale;
BW_i: return the scale out network bandwidth of GPU i;
L_i: return the leaf switch ID of GPU i;
$Scale_i$: the scaleup domain ID of GPU i.
Output: **Plan**, a graph indicating how the parameters are loaded.

```
1  D_src = D_src.prune().group_by(L_i).sorted_by(sum([BW_i])).flatten()
2  D_tgt = D_tgt.group_by(Scale_i).sorted_by(sum([BW_i]))
                ▸ sort D_tgt according to the order of Leaf ID in D_src
          .groupby(L_i).sortby(D_src.index(L_i).min()).flatten()
3  m = 0; Plan = ∅
4  While not D_tgt.empty() and m < n:
   |  ▸ G_tgt: targets group connected by the scale up network
   |    L_tgt: the leaf switch of these targets.
5  |  G_tgt, L_tgt = D_tgt.pop_front()
6  |  If D_src.filter(= L_tgt).sum([BW_i]) ≥ G_tgt.sum([BW_i])
   |  |  ▸ sources within the leaf have sufficient bandwidth for loading
7  |  |  D_tmp = D_src.truncate(= L_tgt); D_src ++ D_tmp
8  |  G_src = D_src.truncate(sum([BW_i]) ≥ G_tgt.sum([BW_i]))
9  |  Plan = Plan ++ (G_src, G_tgt); m = m + |G_tgt|
10 |  D_src = G_tgt ++ D_src
11 return Plan
```

Notation:

- **++** ▸ join 2 data collections, e.g., [x, y] ++ [z, w] = [x, y, z, w]
- **[Func]$_i$** ▸ apply **Func** to all elements of a data collection, e.g., G.sum([BW$_i$]) is the summation of bandwidth of all elements in G
- **Iter. index(value)** ▸ locations where a unique value first occurs in **Iter**
- **Iter.truncate(predicate)** ▸ pop front until the first remaining element satisfies predicate
- **Iter.truncate(flatMap, predicate)** ▸ pop front and apply flatMap onto the popped elements until the result satisfies predicate

Figure 11: *The pseudocode of the plan generation algorithm.*

simplified scale-up and scale-out network hybrid networking, widely adopted for GPU clusters [25, 70, 50]. Figure 10 (a) illustrates the modelling.

First, we model the GPUs connected via fast scale-up networking like NVLink as groups of GPUs. Such GPUs have ultra-high interconnect bandwidth (1,600-3,600 Gbps) so scaling within a group has negligible overhead. On the other hand, GPUs connected via slower scale-out networking like RDMA are more difficult to model due to a hierarchical structure. To this end, we adopted a simple leaf-to-spine model that covers widely deployed topologies including Clos and Rail-optimized [70] with different subscription ratios: each GPU (i) has a BW_i bandwidth connected to a leaf switch (LeafID), where GPUs within the same leaf switch have a full-mesh connection, i.e., the bandwidth between GPUs (i) and (j) is $\min(\mathrm{BW}_i, \mathrm{BW}_j)$ with full bandwidth. Second, leaf switches are connected to spine switches, with inter-leaf bandwidth equal to or smaller than the intra-leaf bandwidth. For simplicity, we don't model the spine network and rely on upper-tier protocols like Virtual Link Trunking (VLT [30]) and Equal-Cost Multi-Path (ECMP [37]). to support efficient inter-leaf networking.

Multicast-chain-based greedily plan generation. To quickly generate the plan online, we use a three-step greedy

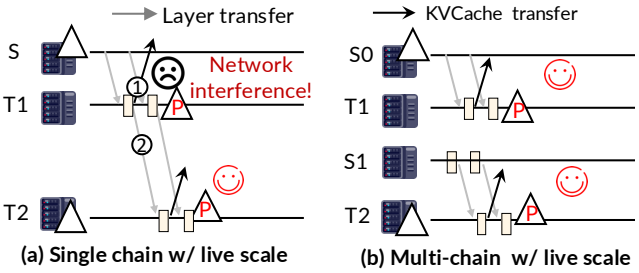

Figure 12: *An illustration of why multiple chains are better especially under live scaling.*

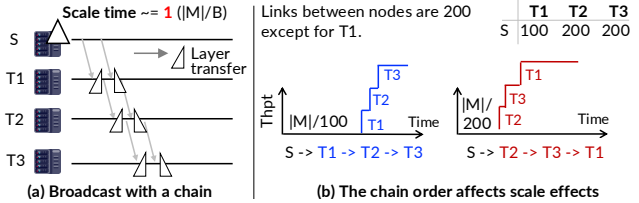

Figure 13: *An illustration of (a) why chain is friendly to broadcast with huge bandwidth requirement and (b) why we chooses a specific chain order. $|M|$ is the model size and B is the slowest network bandwidth between nodes in a chain.*

algorithm as shown in Algorithm 11. First, we prune the sources to avoid any interference with serving workloads (Line 1). Second, we group targets connected with scale-up networking like NVLink as a group (Line 2) such that we can leverage the NVLink broadcast to efficiently realize parallel sharded parameter transfer, see Figure 14 and described below. Finally, we form multiple serial broadcast chains (Line 3–10) to generate the plan.

Specifically, a serial broadcast chain is formed by a set of source and target nodes, i.e., $S \rightarrow T_1 \rightarrow T_2 \rightarrow ... \rightarrow T_n$. Note that a node in a chain may have multiple GPUs. Such a chain has a nice property that it is optimal in bandwidth-intensive transfer like model scaling, because the overall transmission time is irrespective of the instances scaled with such a chain. As shown in Figure 13 (a), when T1 receives the first layer, T1 immediately forwards it to T2. Meanwhile, S will continue to send the second layer to T1, so the time of sending the first and second layer is overlapped.

While a serial chain is sufficient for efficient parameter broadcasting for nodes that are connected with the same bandwidth links, multiple chains are necessary in a leaf-spine network where inter-leaf bandwidth may vary and in our live scale setup. This is because (1) multi-chain avoids relatively slow inter-leaf communications if each leaf switch has sources and targets (Line 6–7), and (2) it enables more interference-free live scaling especially in PD disaggregation setting. Figure 12 illustrates the latter: suppose we want to scale up two prefill instances in a live manner, the KVCache will be transferred to the decode instances once prefill is done. With a single chain, only $T2$ can join the live scale without network interference, because at $T1$, the KVCache transfer (①) interferes with the parameter forward traffic (②). With

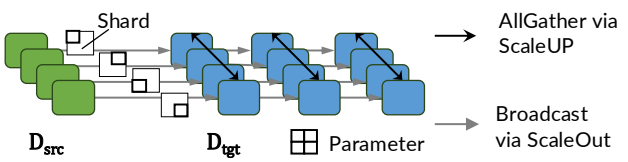

Figure 14: *An illustration shareded parameter transfer with scale up network.*

two chains backed by two parameter sources (b), both $T1$ and $T2$ can live scale without interference.

Note that the order of nodes in the chain is important: we chose a decreasing order with respect to the aggregated link speed between nodes (Line 2, 5). This is because sending to nodes with higher bandwidth achieves a faster increase in the serving throughput. As shown in Figure 13 (b): suppose the source (S) sends parameters to $T2$ twice as fast as $T1$. A chain order of $S \rightarrow T2 \rightarrow T1$ is better than $S \rightarrow T1 \rightarrow T2$ because the downtime of $T2$ is only half. Note that the source can be a group of GPUs because GPUs typically have dedicated network cards in our setup.

Optimization: parallel sharded parameter transfer from multiple sources. For a broadcast chain where the source and target contain GPUs with duplicated parameters, we further leverage the scale-up network to parallelize a transfer link. Figure 14 shows a concrete example. Suppose the source and target nodes have four GPUs each. For such a transfer, each source GPU only needs to forward 1/4 of the sharded parameters to each target GPU, where the target GPUs can use NVLink-based AllGather to get the full parameters. This reduces the scaling time to 1/4 as the NVLink AllGather time is negligible.

5.2 Efficient live autoscaling with ZigZag scheduling

Selecting instances for live scaling. After getting the chains from Algorithm 11, we select instances to participate in live autoscaling based on the following criteria: (1) the necessity of live autoscaling, i.e., when a stop-the-world scaling will cause SLO violation and (2) the presence of overloaded instance that can cooperate. Both are readily available: (1) we can profile the relationship between load speed and SLO violation in Figure 3 for the judgement and (2) autoscaling is typically triggered when the system is overloaded. Thus, for each overloaded instance, we will identify an instance in the chain that satisfies (1), typically the tail instances in the chains as it has the slowest link.

Live autoscale protocol with paired instances. Suppose we have selected a new instance (inst.1) to offload computations from an overloaded instance (inst.0). To begin live autoscaling, we use a three-step transition protocol: (1) Once inst.1 starts loading parameters, we redirect all queued and new requests from inst.0 to it for execution. The redirection time is negligible because the request payloads are much smaller than the model. (2) After the first layer is loaded on inst.1,

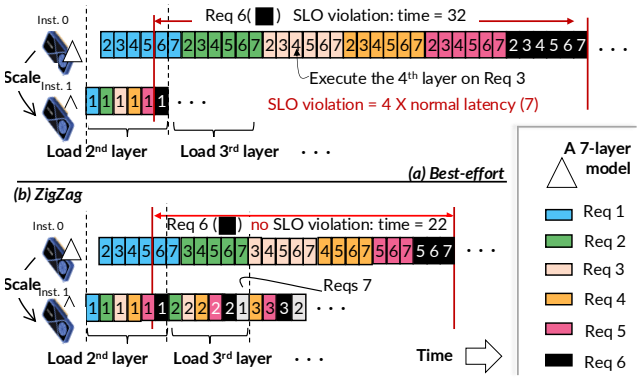

Figure 15: *An illustration of the necessity of ZigZag scheduling. Note that the execution starts when the first layer has been loaded to instance 1 (inst.1). Our example assumes the time of loading a layer can perform 6-layer computations.*

it begins executing the first layer of all requests. Note that during the loading of the first layer, inst.0 remains active by processing its pending requests. Finally, when the model has completed loading on inst.1 (3), requests will be re-distributed evenly between both instances.

The scheduling problem. A key issue to address in the above (3) is how to best utilize inst.1 to maximize the goodput during live autoscaling. Specifically, we should decide a pipeline configuration for each request batch, i.e., how many layers to execute on inst.1 and inst.0, respectively. One naive policy is best-effort: for each batch, we execute as many layers as possible on inst.1 (not exceeding half) and execute the rest on inst.0. While it adapts configurations with model loading, we found it is suboptimal because inst.1 has limited serving capacity during initial loading, so most requests are still queued at inst.0, causing SLO violations. Figure 15 (a) shows a concrete example of a 7-layer model executed with the best-effort scheduling. The load time of one layer can do 6-layer computations, a common setup (e.g., Llama2-7B model with a moderate batch size of 2000 prefill tokens under 200 Gbps RDMA network). Thus, before the second layer has been loaded to inst.1, the current request batches (req 1–6) can only use a $(1, 6)$ pipeline configuration. However, request 6 will suffer from SLO violation due to waiting for requests 1–5 to be completed on inst.0, as their execution time has reduced a little due to the imbalanced loads.

The ZigZag scheduling. To address this issue, our observation is that by delaying request scheduling on inst.0, inst.1 will have more layers coming, opening opportunities to balance the workload between instances. Figure 15 (b) shows this: After requests 2–5 have been executed on inst.1, we delay their execution on inst.0 and wait for the second layer to come. This allows us to adopt a more aggressive pipeline configuration $(2, 5)$ for them. Note that the delay won't waste GPU because we can schedule pending requests (e.g., 6). After the second layer has been loaded, inst.1 can come back (thus, in a ZigZag way) to execute the second layer of re-

quests 2–5. Thus, the second layer execution of requests 3–6 is overlapped with the execution of layers 3–6 for request 2. Thanks to this overlap, the overall inference time of request 7 decreases from 32 to 22, now within the SLO.

The above ZigZag scheduling can be formulated as follows. Assuming a first-come-first-serve (FCFS) scheduling policy, the de facto for serving [44, 75, 77]. For ease of presentation, we first assume non-LLM and then extend to LLM in §5.4. The scheduling has two parts:

(1) Pipeline configuration. Given N request batches with equal execution time, we first determine the pipeline configuration $(\mathrm{T}_i, \mathrm{S}_i)$ for them, where T_i and S_i are the number of layers to be executed on the target and source GPU for request i, respectively. The goal is to minimize the average latency, which can be formulated with the following Integer Linear Program (ILP):

$$\text{Latency}_{\text{avg}} = (\sum_{req=1}^{N}\sum_{i=1}^{req}\mathrm{S}_i)/N$$

To see why such a formula holds, consider the example in Figure 15 (b). Each request's latency is the time the source instance finishes its part of the computation, which includes its own execution time and the sum of its previous requests' time (queueing time). We only need to consider previous requests because they are executed in a FIFO order. In our example, request 3's latency is 17 (12 for requests 1 and 2's execution and 5 for its own). For non-LLM, the execution time of each layer is the same if the batch size is the same. Note that we omit the activation transfer latency since it is negligible.

The problem has the following constraints:

$$\begin{aligned}
\min\quad & \text{Latency}_{\text{avg}} \\
\text{s.t.}\quad & \mathrm{S}_i + \mathrm{T}_i = L, \quad \forall i \quad \text{Pipeline limit } \textbf{(C1)}, \\
& \sum_{j=1}^{i}\mathrm{T}_j \le \sum_{j=1}^{i-1}\mathrm{S}_j, \forall i > 1 \quad \text{Pipeline dependency } \textbf{(C2)}, \\
& \text{Time}_l * \mathrm{T}_i \le \sum_{j=1}^{i-1}\mathrm{T}_j + (N-i+1)\times(\mathrm{T}_i - 1), \\
& \forall i > 1 \quad \text{Load limit } \textbf{(C3)}
\end{aligned} \tag{1}$$

C1 ensures that the pipeline should be fully executed. **C2** states pipeline dependency: when the source instance executes request i's S_i layers, the target instance must finish the execution of T_i. The start execution time of request i on the source is $\sum_j^{i-1}\mathrm{S}_j$. The finish time of i on the target instance is $\sum_j^{i-1}\mathrm{T}_j + \mathrm{T}_i$, which simplifies to $\sum_j^{i}\mathrm{T}_j$. Finally, **C3** ensures that once the target instance request's i's T_i layers, all these layers must be loaded, where Time_l is the time to load one layer normalized to the execution time of one layer in pipeline. The term $(N-i+1)\times(\mathrm{T}_i-1)$ indicates that the load time can be overlapped with executing of the succeeding requests of i.

Input: **Q**: an atomic distributed priority queue that stores the requests to be scheduled. The priority is defined as follows: for **req i** and **req j**, the **P(i) > P(j)** if and only if **i < j** and **i** have loaded layers unexecuted. The subscription (e.g., **i**) indicates the request's arrival time.

At New Instance (target instance)

```
0  spawn(update_Q_when_layers_come) ▸ Run in the background
1  while execute under live:
2  |   q = Q.get_front()
3  |   forward_one_layer(q)
```

At Old Instance (source instance)

```
4  while execute under live:
   |   ▸ Pull the pending requests with
5  |   If q, activation = pull_the_earlist_request(Q):
6  |   |   forward_all(q, activation)
```

Figure 16: *The pseudocode of the ILP-free ZigZag scheduling.*

While solving this ILP is NP-hard, it remains manageable (less than 40 ms to solve for Llama3-8B) because models typically have only a few dozen layers. Additionally, we only need to configure the pipeline for the batches of requests executed during parameter loading, which is a dozen of so in practice. Nevertheless, to further eliminate the solving time for models with more layers (e.g., 80 layers for Qwen-72B), we also derived an ILP-free method that we described below.

(2) Scheduling requests in an ILP-free ZigZag way. Specifically, we found that by delaying sending the requests on the source instance and letting the target instance execute the requests once it is free, we can achieve ZigZag scheduling without solving the ILP. Figure 16 shows the pseudocode of how we schedule the requests on both instances. The new instance maintains a priority queue (that can be pulled by the source instance via RPC) for all requests, where the priority is defined by (1) the FCFS order and (2) requests with next-to-execute layer loaded coming first. Once the new instance has executed one layer (Line 3), we keep the executed request in the queue so it can be scheduled back once more layers are loaded. The requests are scheduled on the source instance only if it is not overloaded, i.e., has no pending requests (Line 5). Thus, if the source instance is busy, the request will still be executed on the target instance.

5.3 Global parameter pool and scaling policy

Global parameter pool and local memory cache. Our global parameter pool tracks the locations of the model parameters across deployed GPUs and host CPUs with local memory cache. To ensure at least one copy of the model parameters is available in the memory of GPU or host at the cluster scale, during system initialization, we distribute one copy of the model's parameters evenly to the CPU hosts and track their locations at a centralized manager. When a model is deployed to or reclaimed from a GPU, we further update the locations in the manager, and reclaim/reload cached copies on the host cache.

Scaling policy. Our paper focuses on the autoscaling mechanism, which is orthogonal to the autoscaling policies, includ-

ing collecting workload metrics with workload monitoring and determining how many new instances to scale based on these metrics. Our current implementation follows prior works [62, 2] that first records the serving loads with tokens per second and KVCache usage globally.

For scaling up, when the average monitored load surpasses a pre-defined upper bound, we allocate sufficient instances to meet that demand. The upper bound can be derived by profiling the average serving load per-instance offline. We leave a more detailed explanation in another paper. For scaling down, we follow previous works'[56, 29] timeout-based policy: when the average monitored load falls below a lower bound in a time window, we shut down some instances and revoke all GPUs assigned to them. Given BLITZSCALE's rapid autoscaling capabilities, we adopt an extremely short sub-second level timeout.

5.4 Specializations and optimizations for LLM

While most techniques described above work for all models following a layer-by-layer architecture, the unique characteristics of LLMs especially for LLMs served with PD disaggregation require several specializations and optimizations.

Retrofitted live pipeline scheduling formulation. Our formulas and constraints described in §5.2 cannot be directly applied to LLMs because the prefill and decode time of a layer is approximately linear to the total batched token size [55, 75]. For prefill-only live scheduling, e.g., autoscaling a prefill instance in PD disaggregation, we fix the formulation by adding a regulation parameter for each request batch by profiling its execution time with the counts, similar to a priori work [75]. A more tricky case involves handling decoding, e.g., when scaling instances that combine prefill and decode, or scaling a decode instance in PD disaggregation. The complexity arises because decode batch size changes dynamically due to its auto-regressive nature. Fortunately, our ILP-free scheduling method can also work for decoding.

Supporting PD colocation. We seamlessly support PD colocation since a PD-colocated instance is a normal model instance. Meanwhile, our ILP-free ZigZag scheduling also applies to pipelined execution under PD colocation [5].

Live scaling decode instances in PD disaggregation. Live scaling a decode instance in PD disaggregation without interference is impossible due to the incast bandwidth contention of both parameter loading and KVCache transfer. Thus, we leverage the fact that the prefill and decode instances share the same model parameters, so we can live scale a decode instance by first mutating some prefill instances to decode instances, while concurrently live scaling the prefill instances to compensate for the prefill throughput.

Optimized scaling policy for PD disaggregation. Prescaling instances can hide the cost of scaling, but a too-early scaling wastes GPU resources. In PD disaggregation, we found we can pre-scale decode instance at zero cost, because the need for scaling decode instances can be evidenced by the requirement for scaling prefill instances. Specifically, once we found a significant requirement for scaling prefill instances, we will simultaneously scale decode instances. This effectively hides the scaling cost of decode instances, and is even effective for other systems like ServerlessLLM [29], see §6.1.

	Cluster A (m x g)	**Cluster B** (m x g)
GPU	A800 80 GB (4x8)	A100 80 GB (2x8)
GPU-GPU (intra)	1.6 Tbps NVLink	256 Gbps PCIe
GPU-GPU (inter)	100 Gbps RDMA	100 Gbps RDMA
Host-GPU	128 Gbps PCIe	128 Gbps PCIe
SSD-GPU	10 Gbps	10 Gbps

Table 1: *Evaluation clusters. m is the number of hosts and g is the number of GPUs per host.*

6 Evaluation

System implementation. BLITZSCALE is a MAAS system capable of serving both traditional models and LLMs with 24,000 lines of Rust and C++ code. It builds upon widely applied LLM optimizations like PD disaggregation and continuous batching. We leverage existing highly-optimized serving system components (with no autoscaling support) wherever possible. For instance, all our GPU kernels for LLM come from FlashInfer [1]. We choose a native-language-based framework implementations because we found it is challenging to implement fine-grained scheduling in Python. §A provides more implementation details.

Testbed. Our evaluations are conducted on two testbeds listed in Table 1. Cluster A can serve larger models (e.g., 72 B) with tensor parallelism [44] thanks to the NVLink while cluster B is more suitable for serving single-GPU models.

Evaluated traces and models. Because the scaling requirements are closely related to the incoming request rates, we chose three typical real-world traces: BurstGPT [71], AzureCode and AzureConv, both from Azure [55]. The detailed trace shapes are shown in the first column in Figure 17. Since the traces are collected from clusters with different serving capabilities, we follow the standard approach [46, 8, 36] to scale the traces to fit our clusters. Specifically, we scale the trace with temporal pattern preserved using TraceUpscaler [57], and the scaled average request rate is half of the maximum serving capacity of our cluster.

For models, we focus on evaluating LLMs because other non-LLMs are much smaller and trivially scale efficiently with BLITZSCALE. Specifically, we choose Llama3-8B, Mistral-24B and Qwen2.5-72B, all are popular LLM models with high accuracy. Since BLITZSCALE is only sensitive to the model size, we may omit the detailed model family name and only uses their sizes in the following description for simplicity. For small model (8B), it only needs one GPU

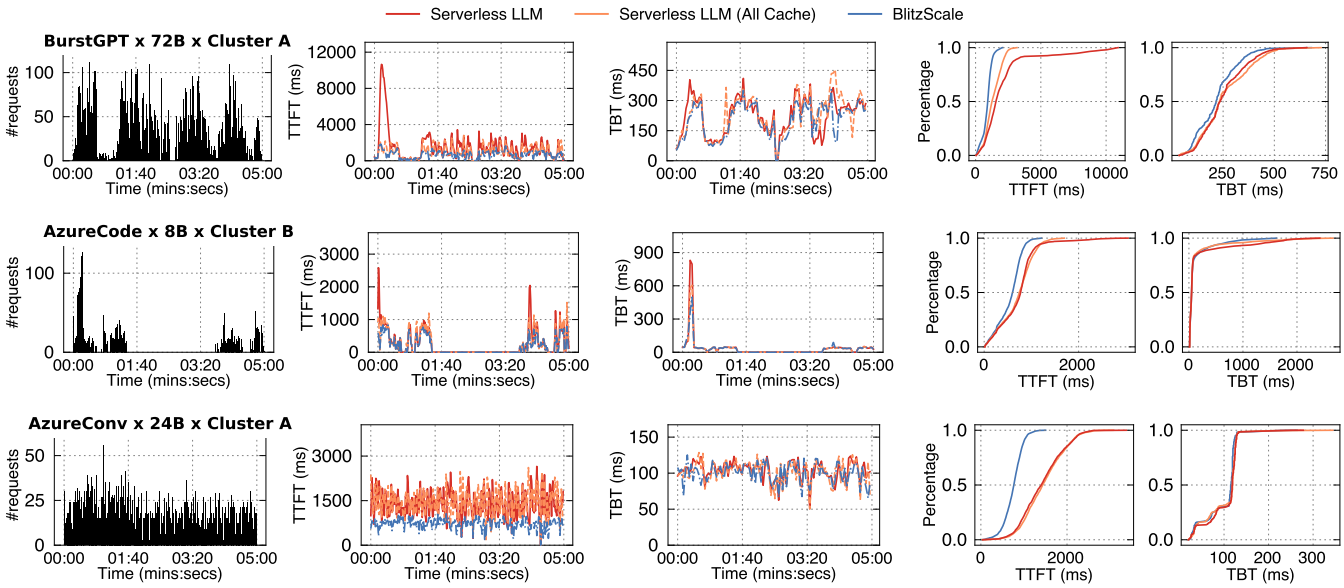

Figure 17: *End-to-end performance comparison between* BLITZSCALE *and ServerlessLLM on various workloads, models and clusters.*

per instance while for 72 B models the minimal number of GPUs used by one instance is 4.

Comparing targets. Without explicit mention, we compare BLITZSCALE with the following baselines:

1. ***ServerlessLLM (S-LLM)*** ***[29]*** is the state-of-the-art MAAS with a focus on accelerating autoscaling speed. It utilizes host memory to cache recently loaded models with a time-to-live eviction policy. Under cache misses, it loads parameters from SSD with SSD bandwidth fully utilized.
2. ***ServerlessLLM optimal (AllCache)*** is the autoscaling speed optimal version of ServerlessLLM that always loads the parameters from the host cache.
3. ***DistServe*** [81] is the state-of-the-art LLM serving system without autoscaling support. It leverages PD disaggregation. We chose it because autoscaling is more challenging in PD disaggregation due to the complexity of multiple instances scaling (prefill and decode) and the need to avoid scaling interference. We compare with other common PD colocation systems like vLLM [44] in §6.4.

For a fair comparison, we adopted the same scaling policy for both BLITZSCALE and variants of S-LLM.

6.1 Autoscaling performance under real-world traces

Due to space limitations, for each model, we choose one trace on one of the clusters to evaluate the performance. Figure 17 presents the end-to-end performance when serving with a prefill and decode disaggregation setup where the instances for different phases are scaled independently. The first column shows the request rate of the trace, the second and third columns show the mean TTFT and TBT, respectively, where each point is the average latency measured during a small time window (1s), and the final two columns present the cumulative distribution function (CDF) of the TTFT and TBT during the evaluation period, respectively. We focus on comparing with S-LLM and AllCache in this section and leave the comparison with DistServe in the next section, as it does not support autoscaling.

Overall performance. First, we can see that BLITZSCALE has the lowest TTFT and TBT in all workloads thanks to the fast autoscaling speed. Specifically, on BurstGPT, the TTFT is 75.5 % and 21.1 % shorter than S-LLM and AllCache, respectively, and the TBT is 7.4 % and 5.1 % shorter, respectively. Nevertheless, the degrees of improvement are different across metrics due to the unique characteristics of the prefill and decode phases. Meanwhile, the behaviors of systems, especially S-LLM, are different across workloads due to the different request arrival patterns (see the first column). We elaborate on the differences in the following.

TTFT vs. TBT. BLITZSCALE is more effective in reducing the TTFT than TBT on all workloads. This is due to two reasons. First, the decode instance can be pre-scaled thanks to our optimized policy (§5.4), which we apply to all baselines. Specifically, when the prefill throughput increases, BLITZSCALE (and its baselines) will simultaneously scale the decode instances, yet no more decode instances are needed at the scale time. Thus, the scaling time is overlapped with the prefill time, which hides some scaling overheads. Second, decode scales less than prefill because as long as there is sufficient memory on the decode instances, all systems can handle decoding with a slightly increased TBT due to no queueing. Since all models adopt modern LLM optimization group query attention [6] with low memory footprint, decoding instances are more sufficient than prefill instances. Nevertheless, BLITZSCALE still achieves a 5.1–7.4 %, 88.3–

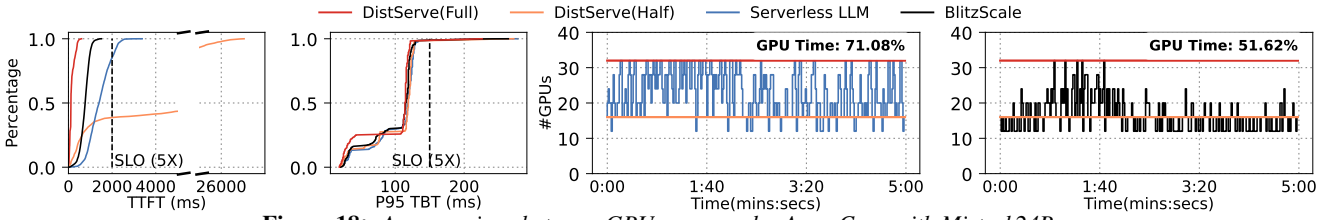

Figure 18: *A comparison between GPU usage under AzureConv with Mistral 24B.*

94.1 % and 0.7–1.8 % shorter TBT than S-LLM and AllCache on three workloads, respectively.

Comparisons between different workloads results. BLITZSCALE always outperforms AllCache thanks to fast network-based autoscaling as well as live scaling, but S-LLM has different behaviors compared to AllCache in these workloads. On BurstGPT, S-LLM first has a sharp TTFT spike at the first burst (time 0:05), while it is close to AllCache in future bursts, because future bursts can benefit from host cache. In comparison, on AzureCode, S-LLM has spikes under both bursts (time 0:05 and time 03:25), because the gap between two bursts makes the host cache evicted due to a time-to-live policy. Finally, on AzureConv, since the bursts continuously arrive, S-LLM always hits the host cache, so the performance—see the CDF graphs—is similar to AllCache.

6.2 Performance and resource usage

Comparison with non-autoscaling systems. We first compare BLITZSCALE with DistServe. Since DistServe does not support autoscaling, its performance is highly dependent on the number of provisioned instances. Therefore, we evaluate two setups: DistServe (full) uses all GPUs in our cluster and represents an optimal performance at the cost of GPU waste. On the other hand, DistServe (half) uses GPUs with the average number of instances required to handle all the workloads within the evaluation period. For simplicity, we only present the results on AzureConv on 24B models, the overall trends are similar. We have carefully calibrated DistServe's performance, such that when autoscaling is disabled in BLITZSCALE, DistServe has the same performance as BLITZSCALE in all setups.

The first two columns of Figure 18 present the latency results. First, it can be observed that DistServe (full) has the best performance, because the GPU is over-provisioned so it doesn't suffer from queueing or scaling overhead. Nevertheless, BLITZSCALE still achieves the same service level objective (SLO) as DistServe (full) while S-LLM incurs 18.7 % SLO violations. We follow the traditional 5 × SLO [81] since all our workloads (chat and code generation) are latency-sensitive. Specifically, if a request's end-to-end (TTFT or TBT) latency is exceeds 5 × the average latency, it violates the SLO. Finally, DistServe (half) has the poorest performance: on average, BLITZSCALE has a 95.8 % and 1 % shorter TTFT and TBT than DistServe (half). BLITZSCALE achieves this by using the same GPU time for serving this model as DistServe

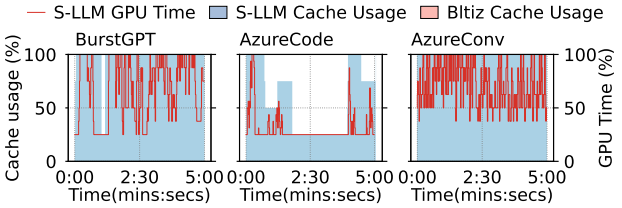

Figure 19: *A comparison of host cache usage on S-LLM and* BLITZSCALE *under the evaluated workloads.*

(half), and this time is 50 % smaller than DistServe (full), which we elaborate next.

GPU time used. The last two columns of Figure 18 show the GPU time used by S-LLM and BLITZSCALE, respectively. For S-LLM and BLITZSCALE, we collected the aggregated GPU usage at each time point for both prefill and decode instances, and the overall time is calculated by integrating the area under the curve. For variants of DistServe, their GPU time is constant across the evaluation period. We can see that BLITZSCALE has 19.46 % lower GPU time than S-LLM thanks to the fast autoscaling capability: with low scaling speed, there would be more queued requests, so the system would trigger more scaling operations that use more GPU time. This is unnecessary with BLITZSCALE. Even with less GPU time used, BLITZSCALE has a 48.1 % and 1.8 % shorter TTFT and TBT than S-LLM, respectively.

Host cache usage. Compared to ServerlessLLM, BLITZSCALE also consumes less host memory for parameter caching. Figure 19 reports the host memory usage for different systems. We omit AllCache and DistServe, as AllCache always fully replicates parameters to all hosts while DistServe does not need caching. We normalize the host cache usage as different workloads use different clusters. The results deliver two messages. First, BLITZSCALE only needs minimal host caching (less than one) to achieve fast autoscaling: this is as expected by our design because we prefer to load parameters from GPUs of instances that serve the model, and even when no serving instance is available, we only need one host copy due to the network-based multicast. Second, the memory usage of ServerlessLLM is proportional to the number of hosts involved in the serving, so a model can quickly "pollute" the host cache. This is non-optimal for an MAAS system because it can simultaneously serve many models while the host cache is limited.

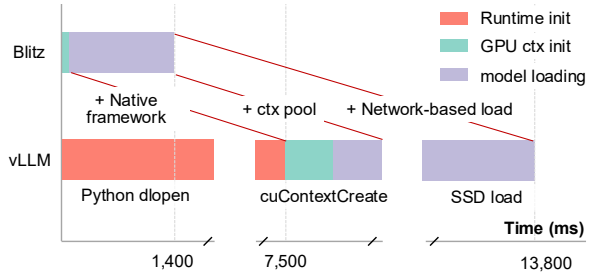

Figure 23: *A comparison of init time of* BLITZSCALE *and vLLM*

6.3 Detailed performance analysis

A detailed look at the live scale. Figure 21 shows a throughput timeline when using BLITZSCALE and AllCache to scale six 24 B prefill instances. BLITZSCALE utilizes two broadcast chains (each involving 3 instances), while the end instances involve a live autoscale. The start instances are the decode instances. For AllCache, it directly loads the parameters from the host memory of the scaled instances. We can see that first, even with a few loaded layers (e.g., at time 500 ms), BLITZSCALE can gradually emit tokens as a result of live execution. Second, BLITZSCALE can scale faster even compared with AllCache, thanks to our NVLink-based fused link transmission protocol: it can finish scaling in 1,200 ms while AllCache takes about 2,000 ms.

Ablation study. Figure 20 conducts an ablation study on the effectiveness of our proposed techniques. We measured the effectiveness by incrementally enabling different techniques and reporting the results on the three workloads: "+Network" leverages fast computing network instead of SSD for autoscaling, "+Multicast (fast)" further applies our optimized parameter broadcast protocol described in §5.1, while "+ZigZag (live)" enables live autoscaling of §5.2.

First, we can see that all techniques are effective in improving the end-to-end serving performance, but the degrees differ across workloads. First, "+Network" improves the scaling performance in all workloads thanks to the higher bandwidth for the autoscaling data plane. Second, "+Multicast (fast)" is effective in AzureCode and AzureConv, but it is less effective in BurstGPT due to the limitations of our cluster (up to 8 instances can be scaled on 72 B model), so there are no cases to simultaneously scale multiple instances, which is the targeted case for this technique. Live autoscaling is mostly effective in AzureCode because it is evaluated on a cluster with slow networking (Cluster B). Finally, our techniques are not such effective on decoding because decode instances are sufficient in most cases, which we have discussed in §6.1. One exception is AzureCode: in this workload, the prefill throughput increases slower than others (see the first column of Figure 17), so the decode instances are triggered later. As a result, the slow scale of ServerlessLLM's SSD cannot be hidden, making a faster scaling more beneficial.

Network usage. Figure 22 shows the network usage of BLITZSCALE and S-LLM: we can see that though BLITZSCALE leverages compute network for autoscaling and the scale frequency is high (see the last column of Figure 18), the additional network usage is negligible.

Control plane vs. data plane of model autoscaling. Figure 23 compares the control plane and data plane overhead during model autoscaling with vLLM. We can see that with proper optimizations, the control plane overhead is negligible.

6.4 Performance under LLM PD colocation

Finally, Figure 24 compares the performance of BLITZSCALE and vLLM where the serving is conducted in PD colocation on BurstGPT workloads with Llama2-7B model. The general trend is similar to PD disaggregation: BLITZSCALE has comparable performance with over-provisioned vLLM, while compared with an average provisioning, BLITZSCALE has a 0.24× shorter P99 TTFT. Interestingly, we found BLITZSCALE has even shorter tail TTFT compared with over-provisioned vLLM, because our scheduling framework is optimized for cluster serving.

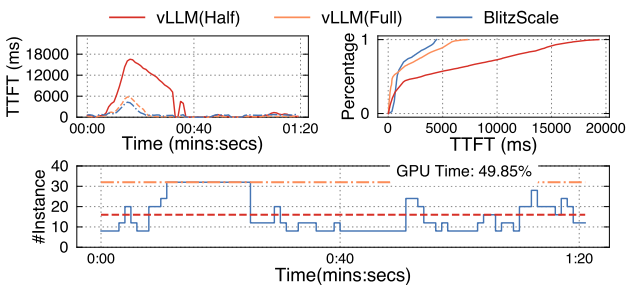

Figure 24: *A comparison of* BLITZSCALE *and vLLM on the BurstGPT workload.*

7 Related work

Optimizing model serving without autoscaling. Serving models at scale is non-trivial. A significant body of research focuses on how to efficiently utilize GPUs to accelerate model serving [81, 75, 44, 45, 77, 55, 31, 68], e.g., Orca [77] proposes iterative-scheduling and selective batching. AlphaServe [45] employs pipeline parallelism to better handle load spikes, but it cannot adjust pipeline instances dynamically. These systems assume running on a fixed pool of GPUs, and we have shown the necessity of dynamically adjusting pool size and how to achieve so efficiently with BLITZSCALE. BLITZSCALE complements these single-instance model serving systems with fast autoscaling mechanisms: we build upon them for fast model serving on a single instance, and additionally provide ultra-fast scaling when the system needs to change the number of serving instances.

Dynamic scaling serving instances. Dynamically scaling serving instances is challenging, mainly because the size of model weights is huge and still increasing, so loading them to the accelerators (data plane) is time-consuming. Some existing works accelerate the loading [15, 41, 46, 62]: For example, both PipeSwitch [15] and DeepPlan [41] leverage the layer-by-layer character of models to overlap the inference and parameter loading to hide the loading cost. They only focus on host-to-device loading and such overlap is not live especially when the models are large. SpotServe [46] and Llumnix [62] realize live migration but migration cannot fully unleash the computing capabilities of both instances. BLITZSCALE provides a new mechanism to scale serving instances lively during parameter loading, resulting in throughput increase even with unfinished loading, which we have shown critical in reducing latencies under bursty workloads.

A concurrent work λScale [78] also focuses on using network to accelerate model autoscaling. The key difference is that λScale scatters the parameters scaling on multiple instances to reduce the time for scaling at the cost of decreased serving throughput, while BLITZSCALE seamlessly scales full parameters on all instances with a similar speed, yet does not sacrifice the throughput thanks to our multicast-chain-based scaling. Moreover, during scaling BLITZSCALE has a gradually increasing throughput thanks to our live scaling while λScale is still a stop-the-world approach.

Accelerating coldstart in serverless computing. Accelerating model scaling builds upon coldstart acceleration in serverless computing [51, 7, 60, 26, 64, 58, 67], which focuses on starting general-purpose computing instances like containers. We built upon these works, e.g., for accelerating container startup time, yet designed efficient network-based live autoscale tailored for model scaling with the domain-specific knowledge of model serving.

8 Conclusion and Future Work

Autoscaling is the key to achieving both high goodput and hardware utilization in model as a service systems, but the performance overhead introduced by current slow and stop-the-world autoscaling significantly limits its effectiveness. In this paper, we first show that the data plane of model autoscaling can be made fast with less than $O(1)$ caching by leveraging network-based model-aware multicast. We next show that the data plane can be made live through model-aware remote execution. Equipped with these two techniques, our system BLITZSCALE has at most 94.1 % better performance and 19.46 % better resource utilization compared to state-of-the-art serving systems with and without autoscaling, respectively. We believe our work demonstrates the potential and practicability of autoscaling-empowered model as a service systems.

While fast and live autoscaling of BLITZSCALE takes a key step toward modern elastic serving systems, several challenges remain. First, during our investigations, we found scaling policies—determining when and how to scale—may also impact system efficiency. The policy depends heavily on workload characteristics, which we leave as future work. Second, BLITZSCALE currently focuses on instance-level scaling, whereas modern models can scale by changing the parallel configuration within an instance, e.g., scaling experts in mixture-of-experts (MoE) models. While BLITZSCALE in principle works for such a setup, we leave the detailed exploration in the future work.

Acknowledgment

We would like to thank OSDI reviewers and our shepherd for their insightful feedback. We sincerely thank Qinwei Yang, Xinhao Luo, and Mingcong Han for giving us feedback on GPU communication library, kernel, driver and runtime. We also thank Xiating Xie, Chenhan Wang and Sundi Guan for refining the presentation of this paper. We thank Alibaba Tongyi Lab for providing the testbed during the early stage of this work. Table 2: *A survey of* MAAS *hardware configurations from GPU vendors.*

A Appendix

A.1 Notable implementation details

Network library We implement a communication library that abstracts both NVLink and RDMA to holistically transfer parameters, similar to DeepEP [24]. During our implementation, we found establishing communication group between machines is slow (e.g., 100 ms) when using off-the-shelf group communicators (e.g., NCCL [49]), which significantly limit the effectiveness of network-based scaling. Fortunately, we found that our plan only requires P2P communication between each pair of nodes. Therefore, we pre-create a connection pool that supports full-mesh connections on each. While the compute network (RDMA) has potential scalability issue [43], it only occurs when transferring small payloads and can be addressed using advanced RDMA transport like DCT [73].

Native serving engine with CUDA context pool. Before execution, a CUDA context with loaded kernels (cuModule) must be created on GPU. Creating such a CUDA context takes about 500 ms, and is non-negligible in serving instance autoscaling. To mitigate such an overhead, BLITZSCALE preserves a small CUDA context pool with pre-loaded kernels and transfers parameters to GPU within one of the existing CUDA contexts, similar to an existing work [40]. Furthermore, BLITZSCALE is built using C++ and native CUDA APIs, eliminating the overhead of initializing PyTorch (e.g. `dlopen`).

Fault tolerance. When machine failures occur, we will autoscale new instances using our scaling mechanism. One problem is that cached parameters on the failed machine are lost, so we need to redistribute these parameters to other machines to maintain our global parameter pool invariant. For other components in the system like scheduler or monitor failures, we follow the same procedure in existing work for recovery [56, 29].

A.2 Hardware configurations for MAAS

Table 2 lists the hardware configurations backed by typical MAAS systems.

Bayesian Code Diffusion for Efficient Automatic Deep Learning Program Optimization

Isu Jeong Seulki Lee

Ulsan National Institute of Science and Technology (UNIST)

Abstract

We introduce Bayesian code diffusion, a new deep learning program optimization strategy devised to accelerate the auto-tuning process of deep learning compilers. Using the concepts of *prior* and *posterior* distributions in the Bayesian framework and reformulating them in the context of deep learning program optimization, the proposed approach efficiently searches for optimal program code in a significantly reduced search space through an iterative diffusion of program code. To further enhance the efficiency of program optimization, we propose pre-training and fine-tuning for the cost model, which improves both the model's predictive accuracy and training efficiency. We implement Bayesian code diffusion in Ansor and evaluate its performance on a wide range of deep learning models on both CPUs and GPUs. Existing approaches struggle to reliably generate high-performing deep learning programs, i.e. achieving low program execution latency, across various configurations, including diverse deep learning model architectures and hardware platforms (CPU and GPU). In contrast, Bayesian code diffusion reduces the end-to-end compilation (optimization) time required to generate the equivalent program execution latency in various configurations, i.e., achieving up to 3.31× optimization speedup. This substantial improvement demonstrates that Bayesian code diffusion performs efficient and principled deep learning program optimization across a wide range of deep learning models, operators, and hardware (CPU and GPU).

1 Introduction

High-performance deep learning (tensor) programs are essential for constructing efficient deep learning systems. To achieve this, deep learning compilers, such as TVM [6], Glow [34], nGraph [10] and XLA [23], have been developed to generate deep learning programs optimized for various hardware architectures, such as CPUs, GPUs, and others. Without relying on hardware vendor-specific libraries, e.g., BLAS [22], Intel MKL [19], Nvidia cuBLAS [29], and cuDNN [30], they perform program optimizations by exploring the search space constructed from pre-defined rules and patterns, such as templates [6]. The search space is navigated by tuning its associated parameters, minimizing manual effort.

However, these deep learning compilers often result in suboptimal program performance, resulting in increased program execution latency. To generate improved deep learning (tensor) programs, the concept of auto-tuning [7] has been proposed, where a set of parameters that define the program codes are automatically searched and optimized. Notably, Ansor [47] constructs an expanded search space for each subgraph of the deep learning model through sketch generation, followed by random initialization and evolutionary search [41]. Although such auto-tuning techniques can identify deep learning programs that achieve lower execution latencies, extensive program exploration in an expanded search space often leads to increased program optimization time.

The increased optimization time observed in auto-tuning approaches highlights three opportunities for improvement. First, each subgraph is assigned an independent search space with a distinct set of optimizations, despite potential overlaps between them, which may be redundant. These redundancies present opportunities for improvement through reuse or shared optimization across subgraphs. Second, many existing auto-tuning methods [7, 47] perform a large number of random searches to identify optimal program codes, which can be time-consuming and cause inefficiencies in program optimization, despite the opportunity to start from better initial points. Lastly, the cost model used to predict the expected performance of the generated program, i.e., program execution latency, is trained without a learning strategy, presenting an opportunity to improve both predictive accuracy and learning efficiency through more principled training strategies. Although various approaches [12, 14, 26] have been proposed to exploit these opportunities, each has limited effectiveness in fully resolving these issues and presents its own set of limitations, as summarized in Tab. 1.

In this paper, we introduce the concept of Bayesian code diffusion and demonstrate its implementation, which enhances

Table 1: The comparison of state-of-the-art auto-tuning methods for deep learning (tensor) program optimization relative to Ansor [47] shows that the proposed Bayesian code diffusion enhances all features.

the efficiency of auto-tuning for optimizing deep learning (tensor) programs. We reformulate the problem of deep learning program optimization based on the Bayesian framework [27] and present an efficient solution for addressing it. Specifically, we leverage the concept of *prior*, represented by well-optimized program code for a specific subgraph, and propagate its parameter to a *posterior* subgraph—another similar subgraph to be optimized—to facilitate an efficient search for optimal programs in the program parameter space. Inspired by the observation that deep learning models often share similar subgraphs in their architectures, we iteratively transform the *posterior* program within the highly-likely parameter spaces close to the *prior*'s parameter distribution through the process we term *code diffusion*. This process enables an efficient and principled optimization of program parameters, in contrast to existing auto-tuning methods [7, 47] applying random search in an expansive program parameter space.

We also propose a cost model learning strategy (i.e., pre-training and fine-tuning) that adjusts the optimization order of program subgraphs to improve the convergence and predictive accuracy of the cost model. Auto-tuning generates a large number of program candidates, but measuring their latency on hardware is costly. To reduce this overhead, a cost model is trained during program compilation (optimization) to estimate the program latency based on a small subset of hardware measurements, following an online learning approach. However, existing approaches, such as round-robin or gradient-based sampling [47], yield overly diverse data samples, hindering the cost model's ability to generalize. In contrast, the proposed pre-training and fine-tuning strategy guides the cost model through a more structured data sequence, improving both learning efficiency and prediction quality. Initially, the cost model is trained using a set of *prior* program codes across subgraph clusters in a random order —we refer to as *pre-training*— to enhance its generalization capacity by learning diverse data generated through hardware measurements of heterogeneous *prior* subgraphs. Then, the cost model is trained with specific and homogeneous data generated by each cluster of similar subgraphs one by one —we refer to as *fine-tuning*— to improve its predictions on each subgraph cluster, on top of the generalization ability obtained during pre-training.

We implement the proposed Bayesian code diffusion on Ansor [47], demonstrating that it can be seamlessly and easily integrated into existing auto-tuning frameworks with minimal modification and effort. We conduct extensive experiments across a wide range of deep learning models, such as ResNet [16] and BERT [11]. The experimental results show that Bayesian code diffusion accelerates the end-to-end compilation (optimization) time of deep learning models by up to 3.31× while producing programs with execution latencies up to 1.13× faster than those generated by state-of-the-art auto-tuning methods [47]. The reduced compilation time is achieved by effective program sharing, efficient and principled program search, and online optimization on both CPU and GPU, without compromising on program execution latency. In contrast, previous methods are often limited by inefficient program search capabilities [26, 47], or constrained hardware compatibility (CPU/GPU) [3, 12, 46], or limited support for operators [46]. Some also rely on pre-compiled programs [14] or offline-trained cost models [35].

2 Background and Opportunities

2.1 Deep Learning Compilers and Auto-Tuning

Deep Learning Compilers. To accelerate deep learning workloads on target hardware architectures, specialized hardware vendor libraries, such as BLAS [22], Intel MLK [19], Nvidia cuBLAS [29], and cuDNN [30], have been widely used to generate efficient deep learning programs. However, developing these hardware-dependent libraries requires significant time and resources, making it difficult to keep up with the rapid emergence of state-of-the-art deep learning models and new hardware platforms. Intermediate Representation (IR)-based deep learning compilers [6] try to tackle this problem by being designed to operate across various hardware architectures without being constrained by hardware dependencies, alleviating the burden of manual optimization. These deep learning compilers, such as TVM [6], Glow [34], nGraph [10] and XLA [23], take deep learning workloads as input and apply a range of optimizations at both high-level and low-level IR to generate efficient deep learning program code without relying on hardware vendor libraries.

Auto-Tuning. Auto-tuning [7, 47] is a technique that automates the hardware-specific optimizations of the low-level IR lowered from the high-level IR graph—e.g., Relay IR [33] in TVM and HLO IR [15] in XLA— of the deep learning model. In the backend of the compiler, it sketches for optimal program parameters, such as loop tile size, from a vast set of candidates to ensure that the final program code performs best on the target hardware. For example, to explore efficient code implementation for the given tensor operations, AutoTVM [7] builds the search space of the parameters based on manually defined templates which demand considerable time and effort in their design. Consequently, the search space becomes dependent on manually predefined templates, which restricts the search scope and range. To solve this problem, Ansor [47] automatically constructs the search space through program sampling and fine-tuning stages, finding optimal program code without being restricted by limited templates.

Fig. 1 illustrates the auto-tuning process of Ansor [47]. Ansor first constructs the search space by generating a set of optimization rules, named sketch, for each subgraph. It then selects a subgraph and performs random initialization for the parameters of optimization rules belonging to the sketch, followed by iterative fine-tuning to optimize the parameters of these rules and generate executable complete program code. Among the resulting candidates, only those predicted by the cost model to have low latency are retained and evaluated on the target hardware. The cost model is trained with these evaluation results from scratch in an online learning paradigm. This process is repeated until the time budget is exhausted.

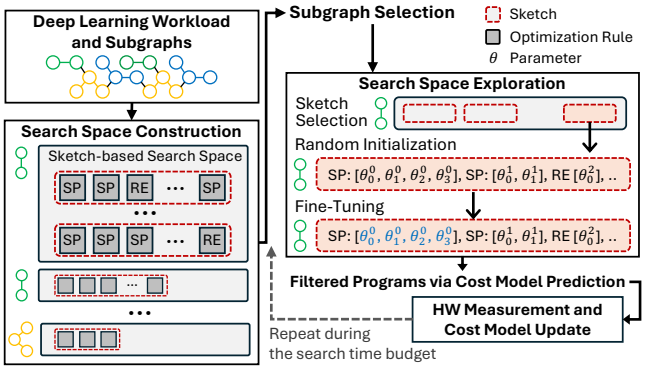

Figure 1: An overview of auto-tuning process in Ansor [47]. The details of the optimization rule, SP (Split-Step), and its parameters θ (integers) are described in Sec. 4.3.

2.2 Opportunities of Auto-Tuning

Although Ansor [47] automates finding optimal hardware-specific program code through program sampling and fine-tuning, it presents several opportunities, as described below.

Opportunity 1: Ignored Subgraph Similarity. In auto-tuning, the computation graph (i.e., high-level IR) is divided into subgraphs that can be optimized via pattern mapping or specific logic. Ansor [47] constructs the search space for each subgraph by recursively applying predefined optimization rules, such as reordering, multi-level tiling, and node fusion. Since this set of rules, named sketch, lacks specific parameters that define tile sizes and loop annotations, they must be determined by tuning (optimizing) parameters to generate executable programs. However, each parameter is determined independently through random initialization to produce executable program code. As a result, the optimal program parameters identified by one subgraph are not shared with others, even though there is potential for reuse when subgraphs exhibit similarities.

To reuse optimized program code, TransferTuning [14] adapts parameters previously optimized for a different deep learning model and transforms them to fit the recipient subgraph of the target deep learning model. However, this approach requires a pre-compiled deep learning program that closely resembles the recipient deep learning program, which limits its usability and applicability in practice. Although DietCode [46] creates a unified search space for microkernel operations and collectively optimizes them, it supports only a limited set of operators (e.g., dense and batch matmul), requiring the development of each individual operation and restricting implementations to only GPUs.

Opportunity 2: Randomized Fine-Tuning Initialization. To fine-tune program codes, Ansor [47] begins with a set of candidate complete programs, known as schedules, obtained through a combination of sketch generation and random parameter initilization. These initial programs are then iteratively fine-tuned with search algorithms, such as evolutionary operations [41], to produce new programs that can achieve improved performance, typically lower program execution latency. However, since these initial candidate programs are generated randomly, a large number of fine-tuning iterations is typically required to identify the optimal program code.

To reduce extensive random sampling and fine-tuning, SelectiveTuning [3] selects a subgraph in the high-level IR and optimizes its parameters through sufficient searches. The optimized parameters are then adapted to other subgraphs of similar structure through a one-time transformation based on predefined rules. While this approach can reduce random search iterations, relying on a one-shot single transformation without sufficient fine-tuning often results in suboptimal program performance, thus limiting its overall effectiveness.

Opportunity 3: Learning Strategy of Cost Models. Auto-tuners employ a cost model [47] that predicts the expected performance of the generated programs (i.e., execution latency) to select ones anticipated to perform better than others. The cost model is trained from scratch during compilation using hardware measurements in an online learning setting. Since optimization depends on the cost model, both the quality and quantity of the training data are critical for effective auto-tuning. In general, the training set is derived from programs executed using the round-robin and gradient with respect to program latency, without considering similarities, resulting in

the cost model being trained on overly broad and diverse data. If so, it must make predictions on a wide range of diverse programs, which may result in suboptimal prediction accuracy. Moreover, the diversity of data can prolong the training time, leading to unreliable predictions until the model convergence. Additionally, if there exist similar programs, they tend to produce similar data samples, causing the model to learn redundant and ineffective samples. This not only fails to enhance the model's learning performance but also wastes time and resources [26, 32, 42].

To accelerate convergence and improve prediction performance of the cost model, FamilySeer [26] groups similar subgraphs and trains a separate cost model for each group. Although this approach can reduce program search time by using a dedicated cost model for each group, the limited range and diversity of training datasets can often result in suboptimal programs, as each group is likely to generate only similar program samples. Moreover, it does not reuse optimized parameters across subgraphs, resulting in inefficient search.

3 Methodological Idea

To take advantage of the aforementioned opportunities of auto-tuning in deep learning compilers, we propose Bayesian code diffusion, of which the key idea is illustrated in Fig. 2.

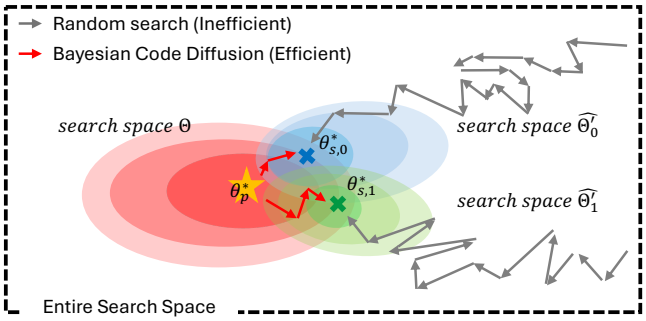

Figure 2: The concept of Bayesian code diffusion: a sufficiently optimized *prior* parameter of one subgraph (θ^*_p) is propagated to similar subgraphs (*posteriors*). Then, *posterior* parameters ($\theta^*_{s,\{0,1\}}$) are derived and refined from the *prior* for each subgraph via code diffusion using a Bayesian formulation, enabling efficient deep learning program optimization.

It first selects a *prior* subgraph and performs a sufficient search to find its optimal program parameters. These optimized parameters are then propagated to structurally similar subgraphs, referred to as *posterior* subgraphs, from a Bayesian perspective. The initial search space of each *posterior* subgraph is restricted to that of the *prior* subgraph, and optimization is performed in the vicinity of the *prior*'s optimal parameters through *prior* propagation. Then these parameters are fine-tuned by adding some noise to find the optimal configuration for the *posterior* subgraph. This process is referred to as *code diffusion*. Repeating this code diffusion process enables the effective propagation of the most promising area of the search space among similar subgraphs, effectively reducing fine-tuning iterations. Also, in this process, the cost model undergoes pre-training using *prior* subgraphs and is subsequently fine-tuned on *posterior* subgraphs, allowing it to learn efficiently and effectively. The following subsection presents the hypothetical formulation of Bayesian code diffusion (Sec. 3.1) and empirical findings that support the idea and validity (Sec. 3.2).

3.1 Theoretical Formulation

Prior Parameters. Bayesian code diffusion first begins by clustering subgraphs of the deep learning model according to their similarities and selecting one of them as the *prior* subgraph $\mathcal{G}_p$ for each cluster. Given $\mathcal{G}_p$, the optimization task is to find the optimal parameter θ^*_p generating optimal program code for $\mathcal{G}_p$. If we employ the Bayesian formulation to this, with an abuse of notations, the optimization task can be expressed as maximizing the following conditional likelihood.

$$\theta^*_p = \underset{\theta_p}{\operatorname{argmax}} f_{\min}(c(\theta_p) \mid \theta_p) \tag{1}$$

Here, $c(\theta)$ is the program code defined by the parameter θ, and $f_{\min}(c(\theta))$ is defined as the hypothetical probability density regarding whether the execution latency of $c(\theta)$ is the minimal or not among all $\theta \in \Theta$ explored so far, as follows:

$$f_{\min}(c(\theta)) = \begin{cases} 1 & \text{if } l(c(\theta)) < l(c(\theta')) \ \forall\ \theta' \in \Theta \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

where $l(c(\theta))$ is the execution latency of $c(\theta)$, and Θ is the total set of schedules explored so far. Now assume a subgraph $\mathcal{G}_s$, presumed to be similar to $\mathcal{G}_p$, is given, and the task is to find its optimal parameter θ^*_s. In principle, the optimal program code $c(\theta^*_s)$, which yields the minimum latency for $\mathcal{G}_s$, can be found if all possible parameters $\theta \in \hat{\Theta}$ are explored. This can be expressed as a hypothetical marginal distribution over all possible $\theta \in \hat{\Theta}$, which is given by:

$$f_{\min}(c(\theta^*_s)) = \sum_{\theta \in \hat{\Theta}} f_{\min}(c(\theta) \mid \theta) f(\theta) \tag{3}$$

In Ansor [47], the search space $\hat{\Theta}$ is defined by a sketch—a sequence of optimization rules—and consists of all possible parameter combinations for those rules, defined as $\hat{\Theta} = \prod_{i=0}^{K} \theta_i$, where K is the number of rules belonging in the sketch. However, due to the vastness of $\hat{\Theta}$, exhaustively exploring all configurations $\theta \in \hat{\Theta}$ is infeasible, necessitating the derivation of a feasible yet effective subspace $\hat{\Theta}' \subseteq \hat{\Theta}$.

Prior Propagation. To reduce $\hat{\Theta}$ into a feasible yet effective search space $\hat{\Theta}'$, we take θ^*_p, optimized for the *prior* subgraph $\mathcal{G}_p$ in Eq. (1), as the *prior* parameter for $\mathcal{G}_s$ by setting $\hat{\Theta}' = \{\theta^*_p\}$. Specifically, we may regard θ^*_p as the mode of the hypothetical Gaussian distribution for θ_p, i.e.,

$f(\theta_p) = \mathcal{N}(\theta_p^*, \sigma_p^2)$ with the mean θ_p^* and variance σ_p^2. Based on our observations that θ_p^* and θ_s^* are likely to be close in the search space, i.e., $\theta_p^* \simeq \theta_s^*$ as $\mathcal{G}_p \simeq \mathcal{G}_s$, we also assume the hypothetical distribution of θ_s is also likely to be close to that of θ_p, and thus take $f(\theta_p) = \mathcal{N}(\theta_p^*, \sigma_p^2)$ as the hypothetical *prior* distribution of θ_s as $f(\theta_s) = \mathcal{N}(\theta_p^*, \sigma_s^2)$. From this, we can avoid computing the intractable marginal in Eq. (3) over all possible $\theta \in \hat{\Theta}$, but instead evaluate the following hypothetical *posterior* as a joint distribution:

$$\theta_s^* = \underset{\theta_s \in \hat{\Theta}'}{\operatorname{argmax}}\, f_{\min}(c(\theta_s), \theta_s) = \underset{\theta_s \in \hat{\Theta}'}{\operatorname{argmax}}\, f_{\min}(c(\theta_s) \mid \theta_s) f(\theta_s) \quad (4)$$

where $\hat{\Theta}' = \{\theta_p^*\}$ for the beginning. To identify θ_s^*, we evaluate the hypothetical maximum joint probability in Eq. (4), as $f_{\min}(c(\theta_s^*))$ always returns one by definition as in Eq. (2), and it does not provide the confidence that θ_s^* found so far is indeed the true optimum. However, when multiplied with $f(\theta_s)$, $f_{\min}(c(\theta_s) \mid \theta_s) f(\theta_s)$ can quantify the confidence that the found θ_s^* is the true optimal parameters, i.e., the lower the value, the more likely that θ_s^* is the true optimum.

Code (Parameter) Diffusion. After the *prior* propagation, the search space for $\mathcal{G}_s$ is defined as $\hat{\Theta}' = \{\theta_p^*\}$, where θ_p^* is considered the initial candidate for the optimal parameter for $\mathcal{G}_s$, i.e., $\theta_s^{(0)} = \theta_p^*$, and Eq. (4) is evaluated with it. to find an improved θ_s^*, we apply code diffusion to θ_p^*, which hypothetically generates the next *posterior* candidate $\theta_s^{(1)}$ from θ_p^*, and subsequently the program code $c(\theta_s^{(1)})$. At the tth optimization iteration, the *posterior* parameter $\theta_s^{(t)}$ is obtained by hypothetically diffusing θ_p^* as follows:

$$\theta_s^{(t)} = \sqrt{1 - \sigma_{s,t}^2}\,\theta_p^* + \sqrt{\sigma_{s,t}^2}\,\varepsilon \quad (5)$$

where $\varepsilon \sim \mathcal{N}(0, \mathbf{I})$, and $\sigma_{s,t}^2 < 1$ is the variance of the diffusion for $\theta_s^{(t)}$. The newly diffused parameter $\theta_s^{(t)}$ is then appended to the search space as $\hat{\Theta}' = \{\theta_s^{(0)}, \theta_s^{(1)}, \ldots, \theta_s^{(t-1)}\} \cup \{\theta_s^{(t)}\}$ and evaluated using Eq. (4). If $\theta_s^{(t)}$ yields the maximum value for Eq. (4), it is deemed the optimal, i.e., $\theta_s^* = \theta_s^{(t)}$. By repeating code diffusion, $\theta_s^{(t)}$ gradually difusses from θ_p^*, expanding the search space from the *prior* distribution $f(\theta_p)$, in contrast to many existing approaches [3, 14] that operate within a fixed search space. By searching for θ_s^* starting from the mode of the *prior* distribution θ_p^* and iteratively diffusing θ_s around it, θ_s^* can be efficiently found within highly likely search spaces.

3.2 Empirical Support

The concept Bayesian code diffusion is based on the following empirical findings, which form the basis of its core principles.

Commonalities in Incomplete Programs (Sketches). Table 2 presents a list of subgraphs of BERT [11], indicating that five out of eight subgraphs share the same incomplete programs, i.e., the sets of optimization rules (sketches) S_0 based on the similarity of their operations when utilizing Ansor [47]. Nevertheless, even though some subgraphs exhibit identical forms of sketches, independent program optimization tasks and distinct search spaces are assigned for each subgraph. This arises from potential differences in their details, e.g., tensor dimensions, resulting in a redundant and inefficient search process. Given that many deep learning models exhibit repetitive operations in their network architectures, there exists a potential for the proposed *prior* propagation, contingent upon the subgraphs sharing the same sketches from which program code parameters can be effectively diffused.

Subgraph	Subgraph Description	Sketches
$\mathcal{G}_0$	batch_matmul_3	S_0
$\mathcal{G}_1$	variance	S_1
$\mathcal{G}_2$	batch_matmul_1	S_0
$\mathcal{G}_3$	softmax_broadcast_to	S_2
$\mathcal{G}_4$	batch_matmul	S_0
$\mathcal{G}_5$	batch_matmul_4	S_0
$\mathcal{G}_6$	batch_matmul_2	S_0
$\mathcal{G}_7$	mean	S_3

Table 2: (Left) The subgraphs in BERT [11] and their sketches obtained by applying Ansor [47], where subgraphs $\mathcal{G}_{0,2,4,5,6}$ produce the same sketches $S_0 = \{s_0^0, s_1^0, s_2^0\}$.

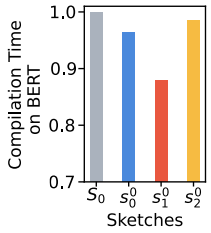

Figure 3: (Right) The compilation time of the subgraphs $\mathcal{G}_{0,2,4,5,6}$ taken by Ansor [47] on the operation `batch_matmul` in BERT [11] using the sketches S_0 and each sketch $s_i^0 \in S_0$ on a GPU. Here, '1.0 (gray)' denotes the time required when using all sketches $S_0 = \{s_0^0, s_1^0, s_2^0\}$.

Sketch-based Optimization. Figure 3 illustrates an example in which a set of subgraphs deriving the same sketches $S_0 = \{s_0^0, s_1^0, s_2^0\}$, i.e., $\{\mathcal{G}_0, \mathcal{G}_2, \mathcal{G}_4, \mathcal{G}_5, \mathcal{G}_6\}$, can be effectively optimized from the single sketch, s_1^0. The bars in the figure present the optimization (compilation) time required to achieve the same program latency when using only a single sketch ($s_i^0 \in S_0$), compared to using all sketches (S_0). It is observable that rather than exhaustively exploring the parameter search space of all sketches, it is more efficient to focus on a single sketch. Thus, if one of the subgraphs sharing the same sketches identifies the optimal parameters for one of them, the others can also derive optimized parameters from the same sketch with reduced search time. This indicates that the parameter search space can be effectively reduced by optimizing a common single sketch among similar subgraphs.

Parameter Distances. Fig. 4 (left) shows the distances between the optimized configuration, i.e., sketches and their parameters, for the subgraphs that have the same incomplete programs (sketches). It is compared with the distances between the configuration for subgraphs that have different sketches (right). The figure shows that the distances within the identical sketches cluster are significantly closer compared to those across the sketches cluster. This suggests that it is more likely to identify the optimal configuration by starting from one of the optimal parameters for the same sketch and taking it as a *prior* to explore in its vicinity through code diffusion.

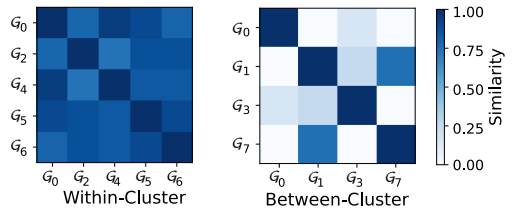

Figure 4: The cosine similarities between configurations optimized by Ansor [47]. The subgraphs $\{\mathcal{G}_0, \mathcal{G}_2, \mathcal{G}_4, \mathcal{G}_5, \mathcal{G}_6\}$ are optimized from the same sketch, while $\{\mathcal{G}_0, \mathcal{G}_1, \mathcal{G}_3, \mathcal{G}_7\}$ have different sketches. The darker, the higher similarity. The details of distance measurement is in Fig. 10.

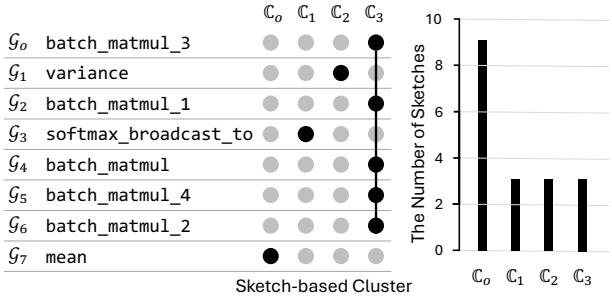

Figure 5: An example of sketch clustering applied to BERT [11], comprising four clusters: $\mathbb{C}_0$, $\mathbb{C}_1$, $\mathbb{C}_2$, and $\mathbb{C}_3$. Subgraphs within the same cluster are linked by vertical lines. As shown in Fig. 3, subgraphs with identical *sketches* are grouped into the same cluster. The figure on the right shows the number of *sketches* for each cluster. For example, $\mathbb{C}_3$ consists of subgraphs that have *sketches* $S_0 = \{s_0^0, s_0^1, s_0^2\}$.

4 Implementation

We describe how Bayesian code diffusion (Sec. 3.1) is implemented within deep learning compilers, based on Ansor [47]. The overall procedure of Bayesian code diffusion is summarized in Alg. 1, and an example is illustrated in Fig. 6.

4.1 Sketch-based Subgraph Clustering

The first step of Bayesian code diffusion is to cluster a set of subgraphs into distinct groups. Existing approaches, such as Nimble [21], SelectiveTuning [3], and FamilySeer [26], group subgraphs based on their operations, which do not necessarily produce identical sketches due to variations such as tensor dimensions. Since different sketches correspond to distinct optimization spaces and configurations, the optimal program code may vary accordingly, thus increasing the search space to explore. For this reason, we cluster subgraphs based on their sketches to enhance both the likelihood of discovering effective prior program parameter θ_p^* and the efficiency of code diffusion, motivated by the observations provided in Sec. 3.2. The search space of *posterior* subgraphs is initialized to the parameter search space for a sketch where θ_p^* is observed, thereby reducing the overall search space efficiently. As shown in Fig. 3, sketch-based optimization not only simplifies the optimization scopes and processes but also reduces the search space, as the proposed code diffusion occurs solely within the parameters, without involving optimization rules. This approach enables parameters to evolve efficiently during code diffusion, facilitating the automatic discovery of optimal parameters. Fig. 5 shows an example of sketch-based subgraph clustering. Nonetheless, Bayesian code diffusion can also be applied to operation-based clustering [3].

Algorithm 1 Bayesian code diffusion. $\theta^{*,i}$ denotes the optimal parameter for subgraph $\mathcal{G}^i$, and $\mathcal{B}$ indicates the time budget. Hyper-parameters ε_e and ε_m define the number of iterations for fine-tuning and hardware measurement, respectively.

Input: Subgraphs $G = [\mathcal{G}^0, \cdots, \mathcal{G}^n]$
Output: Optimal parameters θ^* for G
BayesianCodeDiffusion begin
  $[G^1, \cdots, G^m] \leftarrow$ `SketchBasedClustering`(G)
  for *each cluster* $G^i \in [G^1, \cdots, G^m]$ **do**
    $G_{\text{prior}} \leftarrow G_{\text{prior}} \cup \{\mathcal{G}^i_{\text{prior}} \mid \mathcal{G}^i_{\text{prior}} \in G^i\}$ [Eq. 6, 7]
    $G_{\text{posterior}} \leftarrow G_{\text{posterior}} \cup \{\mathcal{G}^{i,j} \in G^i \mid \mathcal{G}^{i,j} \neq \mathcal{G}^i_{\text{prior}}\}$
    for $\mathcal{G}^i_{prior} \in G_{prior}$ **do**
      `PriorOptimization`$(\mathcal{G}^i_{\text{prior}}, \varepsilon_e, \varepsilon_m)$
    end
    for $\mathcal{G}^{i,j} \in G_{posterior}$ **do**
      `CodeDiffusion`$(\mathcal{G}^{i,j}, \theta^{*,i}, \frac{\varepsilon_e}{2}, \frac{\varepsilon_m}{2})$
    end
  end
  while $\mathcal{B} > 0$ **do**
    $\mathcal{G}^{i,j} \leftarrow$ `GradientBasedSelection`(G)
    `CodeDiffusion`$(\mathcal{G}^{i,j}, \theta^{*,i}, \frac{\varepsilon_e}{2}, \frac{\varepsilon_m}{2})$
  end
end
`PriorOptimization`$(\mathcal{G}, \varepsilon_e, \varepsilon_m)$ **begin**
  $S \leftarrow$ `SketchGeneration`$(\mathcal{G})$
  `RandomInitialization`$(\mathcal{G})$
  `FineTuning`$(\mathcal{G}, \varepsilon_e)$
  $\mathcal{B} \leftarrow \mathcal{B} - \varepsilon_m$
end
`CodeDiffusion`$(\mathcal{G}, \theta^*, \varepsilon_e, \varepsilon_m)$ **begin**
  $S \leftarrow$ `SketchGeneration`$(\mathcal{G})$
  $S \leftarrow \{s \in S \mid s$ is *sketch* for $\theta^*\}$
  `PriorPropagation`$(\mathcal{G})$ [Fig. 8, Eq. 8, 9]
  `FineTuning`$(\mathcal{G}, \varepsilon_e)$
  $\mathcal{B} \leftarrow \mathcal{B} - \varepsilon_m$
end

4.2 Prior Selection and Optimization

The second step of Bayesian code diffusion is to select a *prior* subgraph $\mathcal{G}_p$ in each cluster and optimize it. Since subgraphs in the same cluster share structurally identical operations but differ in their tensor dimensions, we evaluate their similarity based on these tensor dimensions among them. For example, the subgraphs $\mathcal{G}_{0,2,4,5,6}$ in Fig. 3 all perform the same operation, `batch_matmul`, yet exhibit variations in their tensor dimensions. Then, the *prior* subgraph $\mathcal{G}_p$ is selected such that its tensor dimensions are closest to those of all the other

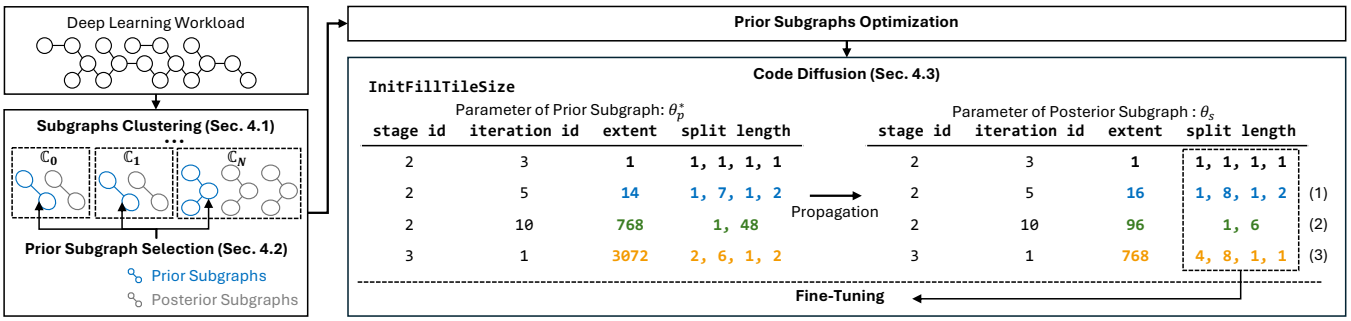

Figure 6: Given a set of subgraphs from a deep learning model, they are first clustered according to their sketches derived by Ansor [47]. Within each subgraph cluster, a prior subgraph is selected and optimized. Subsequently, the remaining subgraphs are optimized through prior parameter propagation, followed by iterative code diffusion using the Bayesian implementation.

Table 3: The examples of parameter initialization rules for program sampling used in Ansor [47] for both CPU and GPU.

subgraphs in the cluster while maintaining distinction from the subgraphs in different subgraph clusters. It is based on the assumption that the subgraph with tensor dimensions most similar to those of all other subgraphs is expected to enhance the effectiveness of code diffusion for the *posterior* subgraphs (Sec. 3.2), which also improves the code compatibility.

Given a set of N subgraphs $G = \{\mathcal{G}^0, \mathcal{G}^1, \cdots, \mathcal{G}^N\}$ in a subgraph cluster, each subgraph $\mathcal{G}^n$ consists of an operator sequence $o^n = [o_0^n, o_1^n, \cdots, o_K^n]$ with their tensor dimensions $[\mathbf{i}_0^n, \mathbf{i}_1^n, \cdots, \mathbf{i}_J^n]$. To compose the tensor dimension vector $\mathbf{i}^n$ for o^n, $[\mathbf{i}_0^n, \mathbf{i}_1^n, \cdots, \mathbf{i}_J^n]$ is concatenated as $\mathbf{i}^n = \text{concat}(\mathbf{i}_0^n, \mathbf{i}_1^n, \cdots, \mathbf{i}_J^n)$. Then, cosine similarities between all pairs of $\mathbf{i}^p$ and $\mathbf{i}^q$ are computed to construct the similarity matrix $\mathbf{S} \in \mathbb{R}^{N \times N}$, where the (p,q)th element $s_{p,q}$ is defined as:

$$s_{p,q} = [\mathbf{i}^p \cdot \mathbf{i}^q \;/\; \|\mathbf{i}^p\| \cdot \|\mathbf{i}^q\|] \;\; \forall \;\; 1 \le p,q \le N. \tag{6}$$

Given the similarity matrix $\mathbf{S}$, the *prior* subgraph $\mathcal{G}_p$ is chosen to maximize the average similarity of tensor dimensions across the elements of each row of $\mathbf{S}$, which is given by:

$$\underset{1 \le p \le N}{\text{argmax}} \frac{1}{N} \sum_{q=1}^{N} s_{p,q} \;\; \forall \;\; s_{p,q} \in \mathbf{S} \tag{7}$$

For example, consider three simple subgraphs, $\{\mathcal{G}_0, \mathcal{G}_1, \mathcal{G}_2\}$. The operation in $\mathcal{G}_0$ is $[[1,1]] + [[2,2]]$, whereas in $\mathcal{G}_1$, it is $[[1,1],[2,2]] + [[3,3],[4,4]]$. Additionally, the operation in $\mathcal{G}_2$ is defined as $[[1,1,1],[2,2,2]] + [[3,3,3],[4,4,4]]$. Although these subgraphs are structurally identical, i.e., execute same operation, `add`, they differ in their tensor dimensions, i.e., the tensor in $\mathcal{G}_0$ has dimension $(1,2,1,2)$, in $\mathcal{G}_1$ dimension $(2,2,2,2)$, and in $\mathcal{G}_2$ dimension $(2,3,2,3)$. Given tensor dimension similarities defined as $Sim(\mathcal{G}_0, \mathcal{G}_1) = 0.95, Sim(\mathcal{G}_1, \mathcal{G}_2) = 0.98, Sim(\mathcal{G}_2, \mathcal{G}_3) = 0.99$. We select $\mathcal{G}_2$ as the *prior* subgraph due to its higher overall similarity to other subgraphs within the cluster.

In this way, $\mathcal{G}_p$ becomes the subgraph exhibiting the highest similarity with the other subgraphs in terms of tensor dimensions. Once $\mathcal{G}_p$ is chosen, the optimal parameter θ_p^* is explored within the search space corresponding to $\mathcal{G}_p$ by evaluating Eq. (1) through random search, with θ_p sampled from a uniform distribution. This exploration is repeated in proportion to the size of the cluster, i.e., the number of subgraphs $|\mathcal{G}|$. During this process, the cost model is trained using diverse data samples generated by various *prior* subgraphs with differing configurations within each cluster, improving its potential generalization ability across clusters. We refer to this training phase as pre-training.

4.3 Code Diffusion for Posterior Optimization

The final step of Bayesian code diffusion is to propagate the *prior* parameters to the other subgraphs in the same cluster and apply code diffusion by iteratively searching for the optimal *posterior* parameters for each subgraph alongside the *prior* parameter distribution. In auto-tuning frameworks like Ansor [47], which comprises random parameter initialization and fine-tuning, code diffusion is applied to random parameter initialization, subsequently facilitating the efficient fine-tuning of sampled programs. Given a sketch, the parameter initialization rules, shown in Tab. 3, are applied for program sampling, performing optimization tasks such as tiling, parallelization, and vectorization. In existing methods [47], the parameters governing these rules are typically searched randomly, causing inefficiency in optimization, which can be accelerated by diffusing the *prior* parameter. Here, we describe how code diffusion is applied to `InitFillTileSize` in Ansor [47], which works on both CPU and GPU. The implementations for other rules are similar and thus omitted. The role of `InitFillTileSize` is to initialize the parameters of the split-step optimization rule (SP), which divides a loop (iterator) into two or more nested loops. It assigns tile sizes

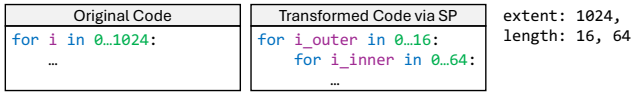

Figure 7: An example code transformation using the split-step (SP) with `extent=1024` and `length=[16,64]`.

based on two parameters, i.e., `extent` and `length`, to fit the extent of each loop axis, as illustrated in Fig. 7. The `extent` refers to the length of the axis to split and `length` denotes the multiple split factors. Given `extent`, code diffusion searches for the optimal parameters for `length` by diffusing the *prior* parameter θ_p^* to the *posterior* parameter θ_s, as shown in Fig. 6.

Although the optimization task for each subgraph executes the split-step at the same stage and iteration, the `length` of the loops to be split differ among subgraphs, which complicates the application of the *prior* parameters. To enable code diffusion across loops of varying `length`, we devise three mechanisms of code diffusion, which implement Eq. (5) in Sec. 3.1 without knowing the exact true probability distribution $f(\theta_s) = \mathcal{N}(\theta_p^*, \sigma_s^2)$.

First, if the `extent` of the split-step of the *prior* subgraph $\mathcal{G}_p$ matches that of the *posterior* subgraph $\mathcal{G}_s$, the same `length` of θ_p^* is applied to θ_s. Conversely, if the `extent` differ, the `length` in the *prior* parameter θ_p^* is diffused to θ_s such that θ_s is closest to the `length` of θ_p^* among all `length` derivable from the `extent` of θ_s. In particular, by using the rule that `length` consists of a set of divisors of the `extent`, we choose the divisor of the `extent` of θ_s closest to `length` of θ_p^*. Let e_p and e_s be the `extent` of $\mathcal{G}_p$ and $\mathcal{G}_s$, respectively, and the `length` of e_p is given as $\mathbf{l_s} = \{l_p^0, \cdots, l_p^n\}$. Then, the `length` $\bar{\mathbf{l}}_s$ of the *posterior* parameter θ_s is diffused as:

$$\bar{\mathbf{l}}_s = \{\bar{l}_s^i \in \mathbf{l}_s \mid \forall l_p^j \in \mathbf{l}_p, l_s^i = \min|l_p^j - l_s^i|\} \quad \text{where } \mathbf{l}_s = \{l_s^i \in \mathbb{Z}^+ \mid l_s^i \text{ divides } e_s\}. \tag{8}$$

For example, the `length` $\mathbf{l}_p$ of θ_p^*:$[1,7,1,2]$ is diffused to the $\bar{\mathbf{l}}_s$ of θ_s:$[1,8,1,2]$, as shown (1) in Fig. 6. The blue box in Fig. 8 shows the code implementation for this case.

Second, the `length` $\bar{\mathbf{l}}_s$ of θ_s is diffused based on the ratio of the `extent` and `length` of θ_p^*, as follows:

$$\bar{\mathbf{l}}_s = \{\bar{l}_s^i \in \mathbf{l}_s \mid l_s^i = \min|l_s^i - \hat{l}_s^i|, \hat{l}_s^i = \left\lfloor l_p^i \cdot \frac{e_s}{e_p} \right\rfloor \forall\, l_p^i \in \mathbf{l}_p\} \tag{9}$$

which corresponds to the green box in Fig. 8. For instance, $\mathbf{l}_p$ of θ_p^*:$[1,48]$ is diffused to θ_s:$[1,6]$, as shown (2) in Fig. 6. This ensures that the `length` of θ_s is proportionally aligned with that of θ_p^*, thus diffusing them in close proximity to the hypothetical *prior* parameter distribution $f(\theta_p)$.

Lastly, to ensure diversity in search spaces, the `length` of θ_s is generated randomly, without code diffusion, as shown in the yellow box in Fig. 8 with an example given (3) in Fig. 6. Given that θ_s^* can be possibly far from θ_p^*, this diversification process should be considered in optimization.

```
InitFillTileSize::Apply(search_policy, state){
  _extent = prior ->extent;
  _legnths = prior ->lengths;

  if (_extent == extent){ lengths = _lengths}
  else {
    random_choice = random_device();
    if (random_choice == 0){
      if (extent % mul(_lengths) == 0){
        lengths = _lengths;
      } else {
        divisors_of_extent = calculate_divisors(_extent);
        lengths = map_lengths_to_cloest_divisors(_lengths);
      }          Reuse Prior θ*p or diffuse θ*p to θs (closest to θ*p)
    }

    else if (random_choice == 1){
      divisors_of_extent = calculate_divisors(_extent);
      lengths = map_lengths_to_cloest_divisors(
      _lengths*(_extent/extent));
    }      Reuse Prior θ*p or diffuse θ*p to θs (based on the extent)

    else if (random_choice == 2){

}}
```

Figure 8: The implementation of for `InitFillTileSize` in Ansor [47], showing three cases of code diffusion for posterior optimization (i.e., blue, green, and yellow boxes).

Among these three code diffusion methods, one of them is randomly chosen for the *posterior* subgraph optimization at every t-th search iteration. From this, the *posterior* parameter is diffused to $\{\bar{\mathbf{l}}_s\} \in \theta_s^{(t)}$ and then appended to the search space as $\hat{\Theta}' = \{\theta_s^{(0)}, \theta_s^{(1)}, \ldots, \theta_s^{(t-1)}\} \cup \{\theta_s^{(t)}\}$. In this way, $f(\theta_s) = \mathcal{N}(\theta_p^*, \sigma_s^2)$ can be effectively implemented, allowing for identifying θ_s^* that maximizes Eq. (4) and quantifying the confidence whether θ_s^* is the true optimal parameter or not, i.e., the lower the value of $f_{\min}(p(\theta_s) \mid \theta_s) f(\theta_s)$, the higher it is likely to be true optimal. Fig. 9 shows an example of the *posterior* program $c(\theta_s^*)$ optimized from the *prior* program $c(\theta_p^*)$ through code diffusion.

$c(\theta_s^*)$

Figure 9: An example of the posterior program code $c(\theta_s^*)$ (right) diffused from the prior program code $c(\theta_p^*)$ (left).

The true distribution $f(\theta_s)$ described in Sec. 3.1 is challenging to obtain directly within the program parameter space. However, it can be estimated by evaluating the distance between the mode (mean) of the *prior* distribution, θ_p^*, and the *prior* parameter θ_s. Fig. 10 illustrates the schedule encoding process used for distance measurement. The schedule comprises optimization rules (represented as text) and their corresponding parameters (represented as a list of numbers) [47]. Due to the combination of text and parameters existing within a dynamic range—caused by differences in the type and number of optimization rules across sketches—directly comparing

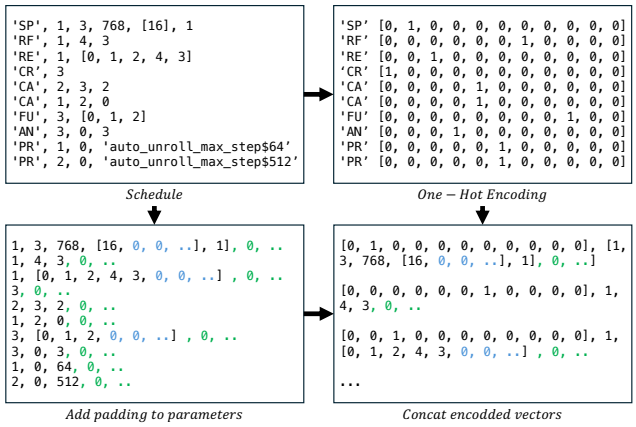

Figure 10: The process of converting a schedule [47] into a vector representation for measuring distances between schedules: the blue and green text indicate padding applied to standardize the vector's shape.

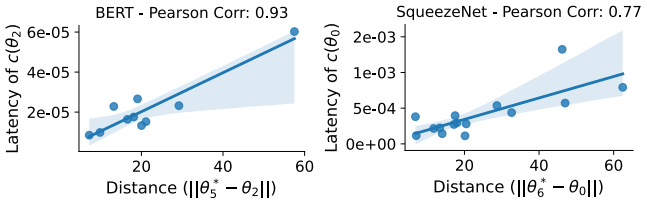

Figure 11: The latencies (ms) of the generated programs measured on CPU over the norm distance between optimal parameter θ^* and the parameter θ of another subgraph in Ansor [47] for BERT [11] (left) and SqueezeNet [18] (right).

distances or similarities between schedules becomes complex. Consequently, encoding these schedules as vectors is necessary. Here, a total of 11 optimization rules are employed, including SP (split-step), FU (fuse), among others [47]. The textual representations of these rules are converted into a one-hot vector of length 11. Subsequently, the corresponding parameters are zero-padded to transform the varying lists of numbers into a static length for uniformity. In Fig. 10, blue text denotes zero padding applied to specific parameters within identical rules, while green text represents zero padding applied to parameters across different rules. Finally, the one-hot and padded vectors are concatenated to form a unified representation. Figure 11 shows the correlation between the distance between the optimal parameter θ_a^* and θ_b of the other subgraph and the latency. This figure demonstrates that the program latency $l(c(\theta_b))$ decreases as the distance between θ_b and θ_a^* diminishes, indicating that a more optimal program can be discovered when θ_b is diffused from θ_a^*.

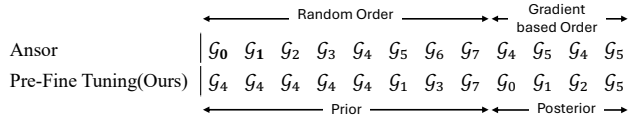

Figure 12: The optimization sequence of BERT [11] subgraphs of Ansor [47] and Bayesian code diffusion (Pre-Fine Tuning), which trains the cost model with datasets generated in different orders, with subgraphs optimized by Ansor.

5 Cost Model of Bayesian Code Diffusion

In auto-tuning, the cost model is essential for evaluating candidate programs by filtering out inefficient ones. Surviving candidates are executed on hardware, generating execution results used to refine the model's prediction accuracy. By continuously learning from online execution results, the cost model gradually improves its predictive performance from scratch within the online learning paradigm With an accurate cost model, program execution can be selectively guided, substantially reducing the need for exhaustive hardware measurements and accelerating the compilation time. For example, Tenset [48] has demonstrated that a cost model pre-trained on a large-scale dataset can accelerate search time.

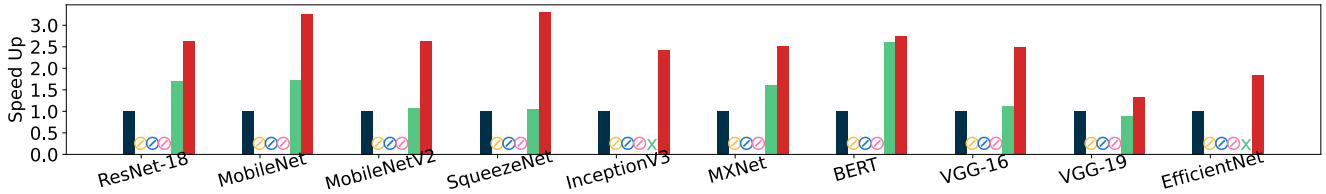
Two studies highlight the importance of the cost model from different perspectives. When the training data for the cost model is biased by the search method, the stability of its predictive accuracy can deteriorate [28], while FamilySeer [26] deliberately biases the data by grouping subgraphs and training a dedicated cost model for each group, allowing faster convergence and program selection. They show that prediction performance and learning efficiency can be improved depending on the learning strategy and cost model.

In optimizing process of *prior* and *posterior* subgraphs, the cost model of Bayesian code diffusion leverages strengths of the two approaches. First, during the optimization of *prior* subgraphs within each cluster, the cost model is trained using the execution data from *prior* programs across diverse clusters. We refer to this process as pre-training. Then, by tuning the *posterior* subgraphs, the cost model is further refined with execution data from *posterior* programs similar to their corresponding *prior* programs. We refer to this process as fine-tuning. This learning strategy enables the cost model to converge quickly while minimizing data bias.

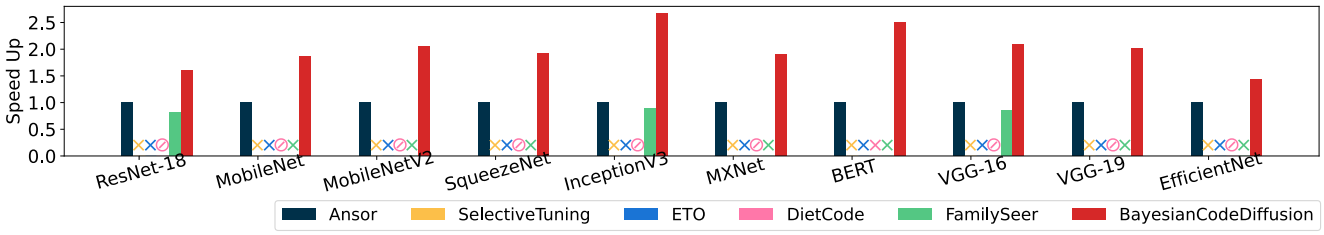
Importantly, we do not modify the cost model architecture or input features and use XGBoost [4] as the cost model, following Ansor [47]. Instead, we adjust the sequence in which execution (training) data is generated. Fig. 12 depicts subgraph optimization sequences of Ansor [47] and Bayesian code diffusion, generating data in different orders for cost model training. As shown in Fig. 5, for the clusters $\mathbb{C}_0, \mathbb{C}_1, \mathbb{C}_2$ and $\mathbb{C}_3$, *prior* subgraphs are selected as $\mathcal{G}_7, \mathcal{G}_3, \mathcal{G}_1$ and $\mathcal{G}_4$, respectively. Bayesian code diffusion optimizes each *prior* in proportion to the size of the cluster it belongs to, assigning greater importance to larger clusters. This contrasts with Ansor's cost model training sequence, which begins with a round-robin over randomly ordered subgraphs and then proceeds with a gradient-based selection strategy.

6 Experiments

We implement the proposed Bayesian code diffusion on Ansor [47] (`tvm@a340dbe`), which is available at GitHub



(a) Compilation (optimization) speedup on CPU (Intel Core i9-11900K)



(b) Compilation (optimization) speedup on GPU (Nvidia A6000)

Figure 13: The compilation (optimization) time speedup in generating deep learning programs with execution latencies equivalent to the best latencies achieved by Ansor [47], normalized to a baseline of 1.0 (the blue bars). The symbol '×' indicates that the corresponding method fails to generate a program with latency equivalent to Ansor's best, while '⊘' denotes that the corresponding method is not applicable to the target deep learning model or hardware (CPU/GPU).

repository[1], providing the detailed procedures. We evaluate it on an Intel Core i9-11900K@3.50GHz CPU and Nvidia A6000 GPU with a wide range of deep learning models, i.e., ResNet-18 [16], VGG-{16,19} [38], BERT [11], MobileNet [17], MobileNet-V2 [36], SqueezeNet-V1.1 [18], Inception-V3 [39], MXNet [5], and EfficientNet [40].

6.1 End-to-end Model Compilation

Fig. 13 presents the end-to-end optimization (compilation) speedup achieved by Bayesian code diffusion in generating deep learning programs with execution latencies equivalent to the best-latency programs produced by Ansor [47] on both CPU and GPU. The results are compared with alternative approaches, i.e., Ansor [47], FamilySeer [26], DietCode [46], ETO [12], and SelectiveTuing [3]. On the CPU, the proposed Bayesian code diffusion outperforms Ansor [47] by an average of 2.52× speedup (arithmetic mean) and other methods by an average of 1.95× speedup, with a maximum speedup of up to 3.31×. Similarly, on the GPU, Bayesian code diffusion outperforms all other methods by an average of 2.00×, with a maximum speedup of up to 2.79×. The result also shows that previous methods are either (1) unable to generate programs with the equivalent execution latencies, such as ETO [12] and FamilySeer [26], which are marked as × in Fig. 13 or (2) inapplicable to specific subgraphs (operators) or hardware platforms (CPU or GPU), such as DietCode [46], ETO [12], and SelectiveTuing [3] marked as ⊘. In particular, DietCode [46] is designed with GPU architectural features, such as thread blocks, and thus is limited to supporting only GPUs and a subset of operators, rather than the full range of operators and CPUs. Notably, DietCode does not implement the support for convolutional operations, and consequently, it is only evaluated on BERT. Similarly, ETO [12] is also tailored for GPU architectures, and SelectiveTuning [3] has demonstrated effectiveness only on GPUs, with no reported evaluation conducted on CPUs. Unlike these existing methods, which lack applicability, compatibility, optimality, and hardware independence, the proposed Bayesian code diffusion consistently generates programs with the minimum optimization times across various models and hardware (both CPU and GPU), enabling reliable, versatile, and efficient deep learning program optimization.

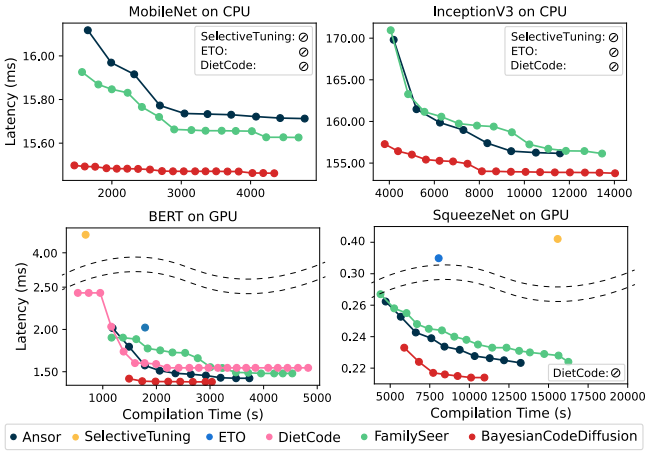


Figure 14: The execution latencies (ms) of the generated programs over compilation (optimization) time (s). The methods that are not applicable either to the target deep learning models or hardware (CPU/GPU) are indicated by the symbol '⊘'.

tion (optimization) time on both CPU and GPU. It shows that Bayesian code diffusion provides enhanced performance in both program latency and compilation time when compared to alternative methods. For example, it provides optimization (compilation) speedups of 3.25× for MobileNet on CPU, 2.28× for InceptionV3 on CPU, 2.50× for BERT on GPU, and 1.91× for SqueezeNet on GPU, while generating programs whose execution latencies are consistently lower than those of other methods throughout the entire optimization. This is because Bayesian code diffusion and existing approaches, such as Ansor [47], explore the search space with distinct strategies. Notably, Bayesian code diffusion explicitly targets narrowed and more probable subsets of the search space. Although other approaches could find programs with comparable execution latencies to Bayesian code diffusion by continuously exploring the large entire search space, they would come at the cost of significantly increased time. As a result, Bayesian code diffusion can efficiently constrain and explore the search space, and identifies lower-latency programs more effectively compared to alternative methods, under the same time budget.

Tab. 4 summarizes the program latency speedup achieved by Bayesian code diffusion at the first iteration (i.e., first-diffused latency) and the last iteration of code diffusion (i.e., last diffused latency), respectively, in comparison with alternative methods. Following Ansor [47], Bayesian code diffusion allocates the total search time budget by dividing it among the subgraphs. After each subgraph is optimized through the pre-fine tuning process described in Sec. 5, the remaining time budget is used to further optimize the subgraphs in a gradient-based order [47]. We define the first-diffused latency as the program latency measured when all subgraphs have been tuned at least once. The last-diffused latency refers to the program latency obtained after fully utilizing the entire time budget to optimize all subgraphs. The first-diffused latency is compared against the program latency obtained when all subgraphs are tuned by each method. In contrast, the last-diffused latency is compared against the program latency achieved after each method has exhausted its entire search time budget. At the outset (Tab. 4, left of the slash), it begins from first diffused programs exhibiting the lowest latency across all cases, for instance 1.65× latency speedup for MXNet on GPU, compared to other approaches that either fail to generate programs with equivalent latencies or require significantly more time to achieve them. After full iterations of Bayesian code diffusion (Tab. 4, right of the slash), Bayesian code diffusion produces last diffused programs with the lowest program latency among all methods, e.g., 1.13× speedup for VGG-19 on GPU, while significantly reducing optimization time at the same time, as presented in Fig. 13. These results suggest that a series of mechanisms of Bayesian code diffusion, i.e., *prior* optimization, and code diffusion for *posterior* program generation, brings consistent improvements in both program compilation (optimization) time and the execution latency of the generated program.

6.2 Subgraph Cluster Optimization

Tab. 5 lists a set of operator sequences of several subgraph clusters in some deep learning models, and Fig. 15 presents their optimization speedup using Bayesian code diffusion, compared with Ansor [47]. As illustrated in the figure, the proposed Bayesian code diffusion optimizes deep learning operators to achieve latencies equivalent to Ansor's best results, with an average optimization speedup of 2.11×. Fig. 16 shows the optimization efficiency of Bayesian code diffusion on several subgraph clusters (i.e., clusters A, B, C, and D) over the optimization time, indicating that it generates programs with lower execution latency using reduced subgraph compilation (optimization) time compared to that of Ansor.

Table 5: A set of operation sequences in subgraphs.

Idx	Operator Sequence	Model	HW
A	conv2d_add_nn_relu	MobileNet	CPU
B	conv2d_NCHWc_add_add_nn_relu	MXNet	CPU
C	conv2d_NCHWc_add_nn_relu	InceptionV3	CPU
D	conv2d_add_nn_relu	SqueezeNet	GPU

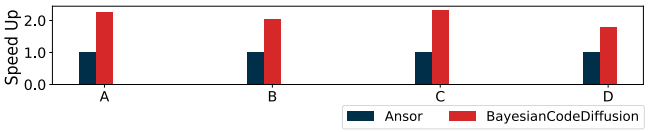

Figure 15: The optimization speedups on subgraph clusters in Tab. 5, compared against Ansor [47].

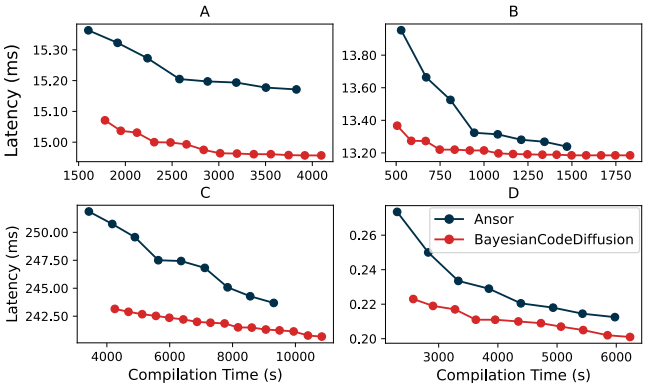

Figure 16: The latencies of the generated programs (ms) over the subgraph cluster compilation (optimization) time (s).

6.3 Cost Model

Fig. 17 plots the program execution latency over the compilation (optimization) time, comparing the proposed pre-training strategy and fine-tuning with Ansor [47] that does not apply it. The sequences of subgraph optimization for both cases are illustrated in Fig. 12, which generates training data samples in different orders for training the cost model. To evaluate the cost model as an independent variable, we optimize the programs using Ansor without using code diffusion in both experiments. The cost model is then trained on data samples produced in different orders. As shown in the figure, the proposed pre-training and fine-tuning method reduces compilation time by producing programs with lower latencies, without requiring any modifications to the cost model. This result suggests that the effectiveness of the cost model can be enhanced by first improving its generalization ability with various datasets and subsequently learning and making predictions on specific subgraph clusters. We expect further improvements could be achievable by incorporating advancements in enhancing the learning capacity and prediction accuracy of the cost model [2, 35, 44] into the proposed Bayesian code diffusion. We leave this exploration for future work.

6.4 Subgraph Sparsity

The performance of Bayesian code diffusion can be influenced by the degree of similarity among subgraphs of models.

In particular, if each subgraph generates a distinct sketch, it leads to an excessively large number of small clusters. As a result, the selected *prior* subgraph receives fewer tuning opportunities, and fewer *posterior* subgraphs can benefit from *prior* propagation, possibly reducing its effectiveness. Additionally, high operator diversity can negatively affect the cost

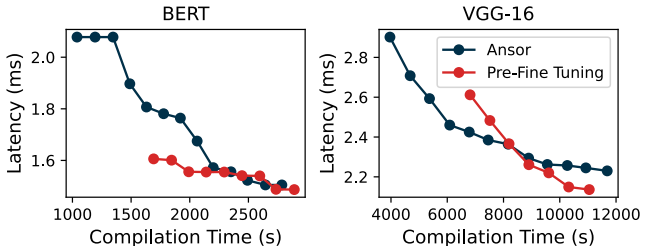

Figure 17: The latency (ms) of generated programs for BERT [11] and VGG-16 [38] over the compilation (optimization) time (s), under different training orders of the cost model as illustrated in Fig. 12.

Table 6: A comparison between sketch sparsity ($\mathbb{S}_S$), operator sparsity ($\mathbb{S}_O$), and program optimization speedup.

Network	$\mathbb{S}_O$	CPU		GPU	
		$\mathbb{S}_S$	SpeedUp	$\mathbb{S}_S$	SpeedUp
ResNet-18	0.83	0.83	2.63	0.83	1.60
MobileNet	0.14	0.57	3.25	0.14	1.85
MobileNetV2	0.44	0.76	2.62	0.71	2.05
SqueezeNet	0.22	0.43	3.30	0.22	1.92
InceptionV3	0.22	0.53	2.42	0.22	2.67
MXNet	0.62	0.86	2.51	0.62	1.91
BERT	0.38	0.50	2.75	0.50	2.50
VGG-16	0.40	0.93	2.48	0.87	2.08
VGG-19	0.40	0.93	1.33	0.87	2.01
EfficientNet	0.66	0.88	1.85	0.88	1.43

model's pre-training and fine-tuning strategies. Even when sketches differ, subgraphs that share the same operator tend to produce similar program data. Consequently, fine-tuning results from one cluster can positively influence others that, despite having different sketches, share the same operator. However, when operator diversity is high, such cross-cluster generalization becomes limited, reducing the effectiveness of the cost model's learning strategy.

To quantify the diversity of sketch generation and operator across subgraphs, we define sketch sparsity and operator sparsity as shown in Eq. (10), where G_{all} is the total number of subgraphs, $\max(|G_S^i|)$ is the number of subgraphs that belong to the largest cluster obtained via sketch-based clustering, and $\max(|G_O^i|)$ is the number of subgraphs containing the most frequent operator in the model. A higher sparsity value indicates lower subgraph similarity. Tab. 6 compares sketch sparsity, operator sparsity, and optimization speedup of Bayesian code diffusion in Fig. 13 across different models.

$$\mathbb{S}_S = 1 - \max(|G_S^i|)/G_{\text{all}},\ \mathbb{S}_O = 1 - \max(|G_O^i|)/G_{\text{all}} \quad (10)$$

Fig. 18 presents the Pearson correlation [13] between subgraph sparsity (i.e., sketch sparsity and operator sparsity) and average program optimization speedup on various models on CPU and GPU. Overall, the sketch sparsity shows a stronger correlation with optimization speedup on CPU, while operator sparsity is more strongly correlated on GPU. This indicates that *prior* propagation has a large impact on compilation time on CPU, whereas pre-training and fine-tuning strategy in cost model are more impactful on GPU.

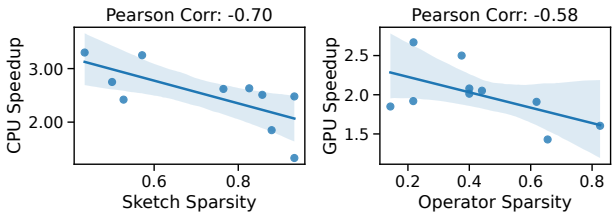

Figure 18: The Pearson correlation [13] between subgraph sparsity and speedup on CPU and GPU. On CPUs, speedup is correlated more strongly with sketch sparsity, whereas on GPUs, it is more closely associated with operator sparsity.

6.5 Prior Selection

We evaluate the *prior* selection described in Sec. 4.2. Specifically, we compare the program execution latency of the first diffused code in Bayesian code diffusion; the *prior* subgraph is selected based on either high or low similarity to other subgraphs in the same cluster. Fig. 19 presents the mean latency of l_h and l_l across various models in Fig. 13, where l_h and l_l represent the program execution latency of the first diffused code obtained by selecting *prior* subgraphs with high and low similarity, respectively. In general, selecting a *prior* subgraph with high similarity enables Bayesian code diffusion to find lower-latency programs across both CPU and GPU. On average, the normalized latency l_h/l_l is 0.99 on CPU and 0.91 on GPU, indicating consistent performance improvement of high-similarity *prior* subgraph over low-similarity *prior* subgraph. Therefore, Bayesian code diffusion tends to be more effective when selecting the subgraph with the highest similarity to others as the *prior* subgraph within the cluster.

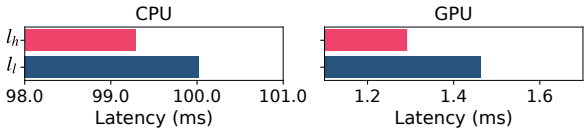

Figure 19: A comparison of l_h and l_l on CPU and GPU, where l_h and l_l denote the program execution latency of the first diffused code optimized using high- and low-similarity *prior* subgraphs, respectively. The bar lengths indicate the mean value of execution latencies of various deep learning models.

7 Discussions and Limitations

From Hypothetical Concept to Implementation. Applying the proposed concept of Bayesian code diffusion to the deep learning program optimization problem requires several considerations and presents some complexities in implementation. For instance, the true prior distribution $f(\theta_p) = \mathcal{N}(\theta_p^*, \sigma_p^2)$ is unknown and must be effectively approximated to conduct precise code diffusion for the *posterior* optimization. Although the optimal *prior* parameter θ_p^* is empirically estimated in our implementation by allocating a large search time budget proportional to the cluster size for sufficient search, there is no guarantee that the identified θ_p^* is truly optimal. While Eq. (4) in Sec. 3.1 provides a confidence measurement on the *posterior* optimal parameter θ_s^*, a similar quantity needs to be devised for the optimal *prior* parameter θ_p^* to improve the overall performance of subsequent code diffusion. Furthermore, implementing code diffusion for the *posterior* program optimization may not be straightforward in practical implementations. In this work, we demonstrate a concrete implementation of code diffusion for Ansor [47]; however, different deep learning compilers or optimization mechanisms may require modifications of the code diffusion approach, distinct from the approach presented here. We will investigate to bridge the gap between the hypothetical concept of Bayesian code diffusion and its practical implementations, aiming to develop a generalized solution that can address or mitigate these implementation challenges.

Prior Selection. Selecting the optimal *prior* subgraph within a subgraph cluster during online program optimization is a challenging task. That is because the *prior* subgraph capable of generating the optimal programs can only be identified after the full compilation (optimization) of the target deep learning model. In this work, we estimate the most suitable *prior* during the optimization process by measuring the tensor shape distances between subgraphs in a cluster in an online manner. Although this approach results in substantial improvements in both optimization time and program execution latency, we have observed that superior *prior* subgraphs exist in certain cases, which could further enhance program optimization performance. We will study alternative approaches that can more accurately select the *prior* subgraph to facilitate enhanced code diffusion for the *posterior* parameter optimization.

Cost Model. While Bayesian code diffusion proposes and employs pre-training and fine-tuning of the cost model, which enhances the program optimization performance, additional improvements could be achieved by enhancing the cost model itself. For instance, in this work, the cost model or learning algorithm is utilized as presented in Ansor [47] without modification. However, more advanced cost models, such as neural network-based approaches [44], could be employed to enhance the model prediction accuracy. Regarding learning strategies, active learning [2], which selects and focuses on learning from data examples expected to contribute to model performance, can be used to enhance both prediction accuracy and training efficiency. Additionally, we can leverage a large pre-collected dataset as pre-training data in an offline manner [35], followed by fine-tuning the cost model in an online context. Therefore, it is worth investigating how improvements to the cost model, including modeling methods and learning strategies, affect the performance of the proposed Bayesian code diffusion in a synergistic manner. However, we generally conjecture that improvements to the cost model could help further enhance program optimization, as these mechanisms are orthogonal to one another.

Applicability to Other Deep Learning Compilers. The core idea behind Bayesian code diffusion is that structurally

similar subgraphs can share optimization patterns, enabling more efficient program tuning. This insight can extend beyond Ansor [47], to other deep learning program optimization frameworks such as MetaSchedule [37] and TASO [20], expanding its applicability. MetaSchedule [37], a stochastic search framework, probabilistically samples transformation rule parameters. Bayesian code diffusion can be integrated into MetaSchedule, where *posterior* program distributions follow *prior* distributions, or their parameters are diffused from *prior* programs. For TASO [20], a superoptimizer based on graph substitutions performs graph transformations independently by generating and comparing candidates. While TASO does not exploit subgraph similarity, its search space can be reduced by identifying and matching common subpatterns.

8 Related Work

Subgraph Similarity. Similar to Bayesian code diffusion, some existing works group subgraphs. TransferTuning [14] transfers an optimized schedule from one model to another running on CPU based on model similarity. However, it requires a pre-optimized schedule of a separate model, which differs from the proposed approach not requiring it. Instead, the *prior* is propagated in an online manner within the same model, which is applicable to both CPU and GPU. FamilySeer [26] groups subgraphs with identical operator sequences and assigns a cost model to each. However, the narrow dataset generated by a single group often leads to suboptimal program performance. The proposed approach addresses this by pre-training and fine-tuning the cost model, accelerating program optimization while ensuring optimal performance. The proposed approach can also be applied to reduce search spaces in dynamic tensor program optimizations, e.g., Nimble [21] and DietCode [46], which construct a shape-generic search space. SelectiveTuning [3] also clusters subgraphs and transfers schedules from representative subgraph to others. In contrast to this method, which provides suboptimal performance as it modifies the transferred schedule only once using pre-defined rules, the proposed approach employs iterative and adaptive code diffusion, producing optimal programs.

Efficient Search Space Exploration. Many studies try to facilitate efficient exploration of program search spaces. Being orthogonal to the proposed Bayesian code diffusion, they can be applied to further accelerate optimization in the reduced search space derived from the *prior* programs. For example, Chameleon [1] explores search spaces using reinforcement learning, and ALT [42] minimizes hardware measurements while exploring optimal compile time with active learning. Dynamic gradient descent search [24] improves the performance of the program by replacing traditional random sampling. Some works aim to address the inefficiencies of auto-schedulers. DynaTune [45] efficiently allocates time resources to optimization tasks, and AdaTune [25] reduces the hardware measurements needed to stabilize the performance of the program. However, these approaches do not utilize similarity between subgraphs, missing opportunities for more efficient exploration and program reuse. Thus, Bayesian code diffusion can complement them. Thus, integrating Bayesian code diffusion can reduce redundant searches by reducing exploration spaces, improving exploration efficiency, reducing hardware measurements, and enhancing cost model accuracy, leading to more effective deep learning program optimization.

Cost Model. Cost models are typically trained online during compilation using data generated via hardware measurements [6, 47]. BALTO [2] reduces training data through diversity-based active learning, and TLP [44] uses a neural network and extracts features from primitives to ensure portability across various hardware and efficiently explore programs with limited data. In contrast, offline learning utilizes a pre-trained cost model using pre-collected data to reduce compile time. This includes approaches such as Tenset [48] and One-shot tuner [35] that train a neural network cost predictor offline. Although offline learning reduces compile time, it requires a substantial amount of data to train the model, which may not be available for heterogeneous hardware. This contrasts with the proposed approach for online training. In this work, we introduce the concept of online pre-training of the cost model using the *prior* s of different clusters, which is fine-tuned on cluster-specific data, one at a time. It enables the model to ensure generalizability while improving the predictions for each cluster, without modifying the cost model.

Large Language Models. Advances in large language models (LLMs) have prompted their adoption in code generation tasks [8, 9, 43]. In particular, TLM [43] proposes a tensor language model for deep learning program optimization and departs from traditional program sampling methods by reconstructing the search space through a generative compiler based on LLMs. However, this approach requires extensive computational resources due to the pre-training of huge models like GPT-2 [31] with large-scale datasets. Additionally, this offline learning paradigm struggles with heterogeneous hardware, differing fundamentally from the online learning approach adopted in Bayesian code diffusion.

9 Conclusion

We introduce Bayesian code diffusion, which enhances the auto-tuning efficiency for deep learning (tensor) programs by reformulating optimization as a distribution-based problem using Bayesian principles. By diffusing well-optimized program code as a *prior* across similar subgraphs, it enables an efficient search for optimal parameters for *posterior* programs compared to random search methods. Additionally, pre-training and fine-tuning the cost model improves prediction accuracy. Implemented on Ansor, the proposed Bayesian code diffusion accelerates compilation times and reduces the program latency for deep learning models on both CPUs and GPUs, outperforming state-of-the-art auto-tuning methods.

Training with Confidence: Catching Silent Errors in Deep Learning Training with Automated Proactive Checks

Yuxuan Jiang Ziming Zhou Boyu Xu Beijie Liu Runhui Xu Peng Huang

University of Michigan

Abstract

Training deep learning (DL) models is a complex process, making it prone to silent errors that are challenging to detect and diagnose. This paper presents TRAINCHECK, a framework that takes a proactive checking approach to address silent training errors. TRAINCHECK automatically infers invariants tailored for DL training. It uses these invariants to proactively detect silent errors during the training process while providing debugging help. To evaluate TRAINCHECK, we reproduce 20 *real-world* silent training errors with diverse root causes. TRAINCHECK successfully detects 18 errors within a single training iteration. It also uncovers 6 unknown bugs in popular training libraries that lead to silent errors.

1 Introduction

Training deep learning (DL) models has become integral for many application domains [8, 17, 24]. DL training, however, is a complex process involving multiple steps and layers of components such as user code, compiler, training framework, optimization libraries, drivers, and distributed systems. Moreover, these components undergo frequent updates [9, 13] due to the rapid pace of DL research. Consequently, training jobs are prone to errors from various sources [51].

To make matters worse, while some errors cause immediate job failures and are relatively easy to identify (*e.g.*, GPU out of memory or illegal argument exceptions), many others are *silent or latent*. Such errors do not cause obvious training disruptions but eventually produce suboptimal/incorrect models or cause noticeable failures much later.

Figure 1 shows a *real-world* silent training error in HuggingFace's training of BLOOM-176B [4]. DeepSpeed's `BF16Optimizer` was used in this training task, which had a logic bug in gradient clipping. This bug did not trigger any exception but caused parts of the model to diverge silently across GPUs, a problem that went undetected for 10 days.

Detecting such silent errors is inherently difficult due to the lack of clear signals. When they are detected, substantial training resources have been wasted. The problem is further compounded by the trend of training large models using massive resources. Moreover, during diagnosis, developers are often left in the dark and have to take a trial-and-error approach [53], such as tweaking hyperparameters and rerunning the task while the real root causes are elsewhere, which is tedious and

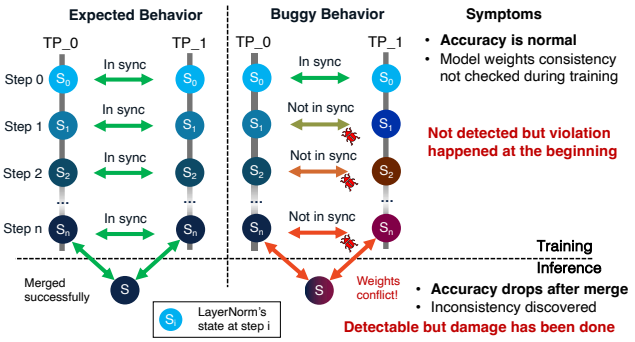

Figure 1: Silent error in BLOOM-176B training.

time-consuming. Indeed, developers have expressed frustration with diagnosing these silent errors [7, 20, 37, 38, 46, 47].

Current practices rely on high-level model evaluation signals such as loss, accuracy, and gradient norms [1, 5]. While these signals provide useful information about overall training progress, they are not designed for error detection. They are often noisy and evaluated only periodically, leading to missed or delayed detection. Even when anomalies are observed, they provide little diagnostic value for identifying the root cause. The aforementioned BLOOM-176B training error, for example, did not manifest as abnormal loss or accuracy, and it took developers 12 days to diagnose and resolve the problem [4, 6]. A few static solutions exist to detect certain errors with specific root causes, such as tensor shape mismatches [22], but they fail to cover many other types of silent training errors.

Our insight is that a fundamental reason behind the challenges is the lack of *proactive checks* to continuously validate a training task. We call such checks, *training invariants*, which are rules that should hold throughout the training. Violation of a training invariant indicates potential errors. The concept of invariants is not new and has been widely studied in traditional software. However, existing tools such as Daikon [16] focus on low-level variable relationships (e.g., `var1 > var2`) and fail to capture the high-level semantics of silent errors in DL training, making them ill-suited for this domain.

Based on this insight, we design an end-to-end framework, TRAINCHECK, that enhances a DL training job with training invariants to proactively detect a wide variety of silent errors. Compared to generic high-level signals, the training invariants TRAINCHECK introduces can more accurately and quickly detect anomalies. Upon detection, TRAINCHECK provides debugging information indicated through the violated

invariant and relevant traces. Compared to static approaches, TRAINCHECK can provide stronger assurance. Its checks capture misbehavior caused by various root causes. It operates continuously with a running training task, enabling the detection of real errors in deployment, which may only occur under specific datasets, environments, or scales.

In designing TRAINCHECK, we aim to explore two key research questions. First, *what kind of training invariants are effective* to address silent training errors? We initially hypothesized that, due to the stochastic nature of DL training, the invariants would need to encode probabilistic predicates, which can be complex and unstable. Our further investigation leads to the insight that, by properly choosing the level of behavior to observe, a training invariant can be made simpler and more precise. Non-determinism is an artifact of checking at too high of a level. The invariants should operate at a level below model evaluation signals, but not as low as traditional software invariants. In the BLOOM-176B example, an effective training invariant is roughly: the weights of certain layers should stay consistent across tensor parallelism (TP) ranks. We thus focus on such rule-level training invariants.

Second, *how can we automatically obtain and check training invariants*? The above invariant description is informal. The actual invariant must be concrete and detailed enough to be directly *checkable* for a specific training task. It is impractical to ask developers to manually write and maintain such invariants. Deep learning frameworks and training practices evolve rapidly, introducing new APIs, model architectures, and algorithms that make handwritten invariants difficult to catch up. Moreover, invariants must match precisely with the actual implementation, not just high-level intent.

Automated inference is needed, but this is challenging. For example, to infer the above invariant, we need to collect information about each worker's role (*e.g.*, TP rank), tensor properties (replicated or partitioned), and observed values. The conditions under which this invariant applies are subtle: it only holds in distributed training when using tensor parallelism and LayerNorm, and only for weights *replicated* across TP ranks. This makes identifying the correct *precondition* critical—for example, the tensor must have `tensor_model_parallel=False`. These kinds of invariants go beyond what traditional invariant inference tools like Daikon [16] are designed to handle.

TRAINCHECK is designed to address these unique challenges and automatically infer concrete, checkable training invariants for assorted DL training tasks written on top of popular frameworks such as PyTorch [2] and DeepSpeed [40]. TRAINCHECK first instruments a given DL training program to collect traces. To achieve high usability and low overhead, we take a monkey-patching approach to dynamically inject the instrumentation code for framework API invocations and a proxy-based approach to intercept state updates.

To infer invariants from the collected traces, TRAINCHECK defines a set of generic relation templates. It uses an efficient algorithm that generates hypotheses based on a relation template and validates the hypotheses in the traces to generate invariants. TRAINCHECK further designs an algorithm to deduce the precondition, if any, for each invariant.

To use the inferred invariants for detecting silent training errors in a specific training pipeline, TRAINCHECK selectively instruments the pipeline for only information relevant to the invariants. A verifier continuously validates the traces from the instrumented training task to check violations.

Unlike traditional invariant inference tools that operate within a single program, a unique feature of TRAINCHECK is its ability to generate invariants *transferable* across different training programs and even different libraries. This makes TRAINCHECK broadly applicable and adaptable. Consequently, we can leverage high-quality DL training pipelines, such as those found in tutorials and example repositories, *e.g.*, PyTorch examples [35], to infer the invariants and apply them to other training programs. This helps with both improving invariant accuracy and aggregating effective invariants.

For evaluation, we collect and reproduce 20 *real-world* silent training errors with diverse root causes. TRAINCHECK detects 18 cases within a single training iteration while providing debugging hints. TRAINCHECK additionally uncovers 6 previously unknown errors, all of which have been confirmed with 3 being fixed. We also share our experiences applying TRAINCHECK to various DL training scenarios and highlight challenges and opportunities in this domain. TRAINCHECK is open sourced at https://github.com/OrderLab/TrainCheck.

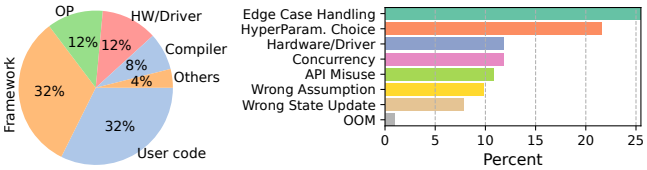
The contributions of this paper are as follows:

- We investigate the notorious yet under-explored problem of silent errors in DL training and conduct an empirical study to shed light on their characteristics.
- We propose an approach that uses training invariants to proactively validate DL training and catch silent errors.
- We design and implement TRAINCHECK, which, to the best of our knowledge, is the first framework that automatically infers and checks invariants tailored for DL training tasks.
- We evaluate TRAINCHECK in detecting real-world silent training errors and exposing unknown errors.

2 Silent Errors in DL Training

To gain a deeper understanding of silent training errors, we conduct an empirical study on *real-world* errors that DL practitioners encountered. We aim to provide insights regarding their root causes, impact, and current detection methods.

Methodology To ensure the study is representative, we inspect diverse sources: (1) GitHub issues from popular libraries such as PyTorch [36] and DeepSpeed [12], (2) discussion forums such as StackOverflow [41] and the PyTorch forums [34], and (3) papers and blog posts from DL practitioners [6,52]. For GitHub, we search closed issues labeled or containing the keywords "correctness" or "silent". For discussion forums, we search for posts with "silent" or "bug" in the title or description. We also examine DL training papers and blog posts from large organizations such as HuggingFace [4],



(a) Location. (b) Type.

Figure 2: Root cause locations and types of the studied errors.

Bloomberg [45], and Meta [14, 52], particularly those discussing widely deployed LLMs like Llama3 [14], OPT [52], and BLOOM [4]. These sources often describe errors arising in industrial-scale training pipelines. Many of the candidate reports from GitHub and user forums are incomplete or poorly understood, as silent errors are often difficult to diagnose. We carefully inspect each case and curate a set of high-quality instances that are well-documented, diagnosed with clear root causes, likely reproducible, and impactful.

In total, we collect 88 silent errors with known root causes. Among the sources, 70 are GitHub repository issues, 16 from discussion forums such as StackOverflow and the official PyTorch Forums, and 2 from industrial reports [4, 52].

2.1 Analyses and Observations

Diverse Root Causes The studied errors are caused by defects in a wide range of components involved in DL training, including user code, framework, compiler, mathematical operators for different hardware or from optimization libraries, and underlying system components such as driver or hardware.

Figure 2a shows the distribution of the locations of the root causes. The majority of the errors are caused by user code (32%) and framework (32%), followed by mathematical operations (12%), hardware (12%), compiler (8%), and other factors (4%). User code may contain missing or incorrect API calls or poorly chosen hyperparameters. Frameworks may have bugs in their Python components, often involving high-level algorithm logic. Mathematical operations such as matrix multiplication can produce inaccurate results. Hardware failures are usually caused by driver or device faults that lead to communication errors or memory corruption. Compiler failures occur when Torch Dynamo, PyTorch's JIT compiler, is unable to compile the pipeline correctly.

Figure 2b shows the root cause types for the studied cases. For user-code-induced silent errors, we identify two primary categories: (1) *Incorrect Implementation* and (2) *Inappropriate Design Choices*. The first includes incorrect, missing, or inconsistent API calls or parameter updates. For example, one error is caused by a missing `zero_grad()` inside the training loop, resulting in noisy gradients; another stems from initializing the optimizer before model transformations, leaving the optimizer with incorrect parameters to update. The second category involves flawed design choices, such as selecting an unsuitable loss function, setting an overly aggressive dropout rate, or using a problematic data processing pipeline. While individual components may appear correct, their interaction often leads to numerical instability or divergence. For instance, BLOOM developers encountered repeated loss explosions when training with the float16 data type, which was mitigated by switching to bfloat16 and applying gradient clipping.

Iter	Type	Loss Diff	PPL Diff	Diff (Loss/PPL)
2000	Valid	+1.14%	+1.43%	+0.014 / +0.050
2000	Test	+2.74%	+3.30%	+0.032 / +0.107
4000	Valid	+3.05%	+3.36%	+0.033 / +0.099
4000	Test	+4.67%	+4.79%	+0.047 / +0.131

Table 1: Reproducing DeepSpeed-1801 (the root cause of BLOOM-176B silent training error) in a small transformer-based language model. Due to resource constraints, we trained for only 2000 and 4000 iterations. However, the impact of the error—observed as differences in loss and perplexity due to weight merging—is already noticeable and increases with the number of training iterations.

Severe Consequences The impact of silent errors can be enormous. DL training tasks are often run on many GPUs for a long time. This is the case for the motivating example in Figure 1, which is a large-scale training task that involves 384 A100 GPUs for 3.5 months. Discovering errors late in the training result in significant waste of expensive resources.

The majority of the studied errors result in either suboptimal or incorrect models. In the former case, users may choose to accept the degraded outcome to avoid paying the expensive retraining cost, but must live with lower model performance. In the latter case, rerunning the job leads to a significant waste of costly training resources. Many errors also introduce severe performance impacts. For example, in PyTorch-Forum-84911, the data processing code in the user program mistakenly resizes the input images to 1024×1024 instead of the expected 224×224, significantly increasing per-iteration training time. Moreover, due to their silent nature, the effects of these errors often persist and accumulate over time.

Challenging Detection and Diagnosis Unlike other DL training failures that trigger explicit exceptions (*e.g.*, Illegal Argument) or terminate jobs, silent training errors are challenging to detect. In many of our studied errors, although the root cause is triggered early on, the error remains undetected for a long time. Developers currently mainly rely on high-level model evaluation metrics such as loss or accuracy. However, silent errors often do not cause immediate anomalies in such evaluation metrics. For example, in PyTorch-Forum-84911, the loss and accuracy metrics are still changing over time. For large-scale training jobs, it can take hours or even days for a silent error to show obvious signs of anomalies in these metrics. Moreover, these metrics can be highly noisy in real-world training tasks. Using them for detection can easily create false alarms. When a silent error causes a performance impact, it can also be difficult for developers to tell whether or not the long training iteration is expected. Even after the error is detected, developers often have no clear clues of the root cause. The diagnosis process is onerous and often based on

ad-hoc trial-and-error changes (e.g., to hyperparameters) and rerunning the training job to check if the error is fixed, leading to both developer productivity loss and wasted resources.

2.2 Case Studies

We describe two representative cases from our study.

BLOOM-176B training (DeepSpeed-1801) This is the example described in § 1, which occurred in HuggingFace's training of BLOOM-176B in 2022 [4]. Due to the large model size, 3D parallelism [31] was used to partition the model across multiple GPUs and nodes. Conceptually, tensor parallelism partitions the model by splitting individual layers into multiple GPUs. Thus the same layer on different GPUs is not the same. However, in implementation, due to the communication cost, certain layers that do not impose a memory bottleneck are not partitioned. In the Megatron-style tensor parallelism [31], LayerNorm layers are not partitioned as their size is small (<1% of the model weights) compared to the other layers, like attention layers. Thus, optimizers must be aware of this partition scheme, carefully distinguish between different kinds of layers, and perform updates accordingly. This leads to complex logic in the optimizer.

In this specific training task, DeepSpeed's BF16Optimizer was used. It had a bug that causes the gradient clipping to be enabled on only the first GPU on layers that are not partitioned. This caused the LayerNorm layers' weights to silently diverge, as these layers were updated with different gradients.

This bug neither triggers exceptions nor immediately affects loss or accuracy. Only when the model partitions across GPU need to be merged into one checkpoint file will users realize that the model has diverged. This happens in two scenarios: (1) when training completes, and the model needs to be served or further fine-tuned; (2) during training, there is a need to change the parallelism configuration, e.g., due to failure of a GPU. The developers of BLOOM-176B were lucky enough to catch this error before the model was served in production or further fine-tuned while investigating another error. The detection took 10 days, and it required 9 additional days to merge the weights and mitigate the impact of divergence.

We conduct an experiment to further confirm the impact of this error on a small scale. Specifically, we train a small transformer-based language model using the CodeParrot clean dataset [10], with 4 tensor parallel (TP) ranks and 2 data parallel (DP) ranks. The results are shown in Table 1.

At the initial steps (2000 and 4000) iterations, the loss and the perplexity of the model on the validation and test set are both noticeably affected by merging the weights, and the difference increases with the number of training iterations.

PyTorch-115607 Another interesting case is PyTorch-115607. It showcases situations when a silent training error can be detected, but the diagnosis is frustrating. `torch.dynamo` [2] is a new feature in PyTorch that provides a Just-In-Time (JIT) compiler for unmodified PyTorch programs. It transparently swaps bytecode to be executed with a more optimized version and thus can speed up the training process. It uses guards to ensure that when certain conditions change (e.g., the shape of a tensor changes), the bytecode is recompiled to reflect the changes. Ideally, every critical variable that can affect training should be guarded. However, in this case, a guard is missing, which causes the model to not update if a developer decides to only do a forward pass without a backward pass in a certain iteration. This error can be detected since the entire model is not updating. However, diagnosing it can be problematic: if the training program does not dump per-iteration loss and accuracy, the developer would have no idea where the model stopped updating.

2.3 Implications

Our study underscores the significant challenges posed by silent errors in DL training. It also reveals implications for designing solutions to address such errors.

Manual methods for detecting and diagnosing silent errors are time-consuming, ineffective, and impractical, given the scale and complexity of the DL training system stack. Automated approaches are essential to reduce the burden on developers while improving the reliability of training pipelines.

Monitoring high-level signals such as loss and accuracy is insufficient. These metrics are often noisy and periodic, leading to missed or delayed detection. They are also prone to false alarms because it is difficult to distinguish between expected fluctuations and true anomalies. Moreover, they provide few clues for debugging. Fundamentally, they are not designed for error detection. A true detection solution is required and needs to operate at a deeper level than such signals.

The diverse locations and root causes of silent errors call for systematic approaches. While point solutions, such as using differential testing [27, 33] to find bugs in DL compilers and frameworks, have been proposed, they offer only limited help in addressing the broad categories of silent errors.

Eliminating all bugs statically is ideal, but it is nearly impossible due to the complexities involved in DL training. Many bugs tend to only trigger in a specific environment, dataset, or scale. Continuous monitoring of a DL training task provides a safety net to detect silent errors at runtime.

3 System Design

Motivated by our study, we design TRAINCHECK, a framework that takes a proactive validation approach to quickly and reliably detect silent DL training errors with a wide variety of root causes, while providing diagnosis clues.

The designs of TRAINCHECK are guided by two key insights we have from analyzing real-world cases. First, while the symptoms of silent training errors take time to become visible and often appear non-deterministic in generic, high-level signals such as loss, the root causes of many errors are triggered early on and detectable through specific, lower-level checks. Second, seemingly unrelated DL training programs

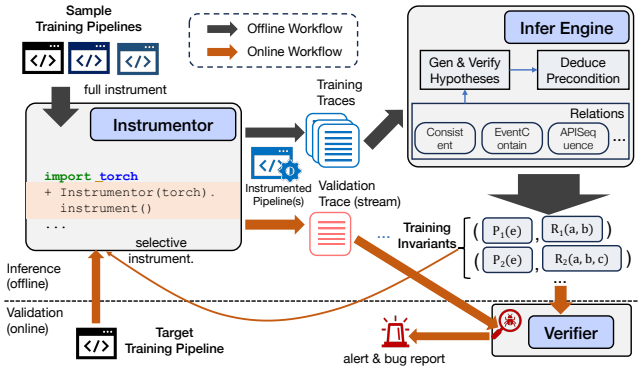


Figure 3: Workflow of TRAINCHECK.

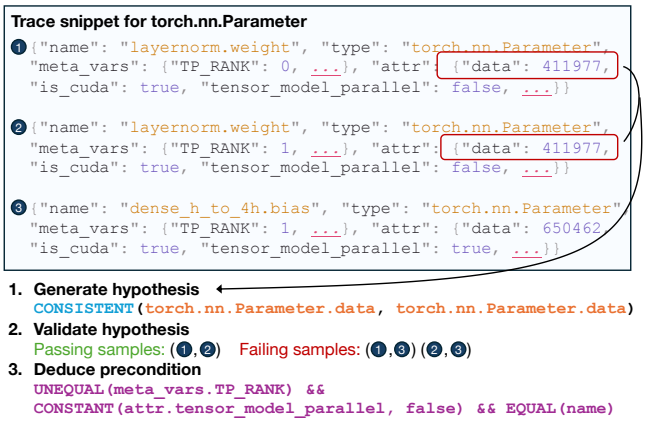

Figure 4: The invariant with preconditions TRAINCHECK infers for Bloom-176B error (§ 2.2), and the simplified trace it emits and uses.

can share similar correctness properties due to the heavy reliance on external libraries and similar training methods.

Based on these insights, TRAINCHECK introduces the notion of *training invariants*, which are rules that should hold during training, *e.g.*, the model weights should stay consistent across distributed workers. These rules capture the semantics and correctness properties specific to a training task. Interestingly, we observe that a training invariant often only applies under specific conditions, *e.g.*, to particular layers or parallelism settings, *i.e.*, they have *preconditions*. TRAINCHECK automatically infers training invariants as well as their preconditions and enforces them to detect silent errors.

Scope. Silent errors in DL training span a broad spectrum, ranging from correctness violations such as buggy API implementations to optimization-sensitive issues like hyperparameter choices. This work specifically focuses on correctness violations, which directly affect the integrity and correctness of training outcomes, and are often high-impact and actionable, yet remain largely overlooked by existing tools. Within this scope, TRAINCHECK aims to provide early and accurate *detection* of silent training errors before they silently propagate and accumulate. While its detection results can offer useful diagnosis hints to developers, providing systematic debugging support for precisely identifying root causes deserves dedicated investigation in future work.

3.1 Overview

Figure 3 shows the workflow of TRAINCHECK, which operates in two phases. In the offline phase, it automatically infers a set of training invariants from high-quality training pipelines. In the online phase, these invariants are deployed to a given training job to check for violations during training. TRAINCHECK reports invariant violations with contextual information to assist confirmation and investigation.

TRAINCHECK comprises three major components: (1) Instrumentor, which dynamically instruments DL training programs to collect runtime traces with low overhead; (2) Infer Engine, which analyzes these traces to infer training invariants and their preconditions automatically; and (3) Verifier, which continuously validates a training task against the invariants. When Instrumentor is used in the online stage, it performs selective instrumentation relevant to the inferred invariants.

Relation	Description
$Consistent(V_a, V_b)$	V_a and V_b should have the same values, while the values may change
$EventContain(E_a, E_b)$	E_b must happen in the duration of E_a
$APISequence(I_a, I_b, \ldots)$	I_a, I_b, ... must all occur and in the specified order
$APIArg(I_a, is_distinct)$	Ensures argument consistency or distinction in all calls to I_a
$APIOutput(I_a, bound_type)$	The output of I_a must meet certain attribute constraints

Table 2: Sample relations TRAINCHECK defines and supports.

In this section, we focus on Infer Engine. § 4 will describe the design of Instrumentor. Figure 4 shows a simplified example of the concrete training invariant with preconditions TRAINCHECK infers for the Bloom-176B training error.

3.2 Invariant Representation

TRAINCHECK focuses on capturing semantic rules related to DL training. Such rules can be expressed as logical relations involving key variables (e.g., model weights), and events (e.g., API invocations). Infer Engine defines a generic *relation interface* from which the specific relations can be implemented. An invariant is a relation instantiated with concrete variables and APIs that must satisfy the specified relationship.

Through analyzing silent training errors in practice, we identify and provide a set of representative relations often violated in these silent errors. Table 2 lists five relations TRAINCHECK supports. For example,

- **Consistent** relation establishes that two attributes of different variables should be equal despite how the value changes. This is effective for distributed training, where the model layers can be partitioned or duplicated across workers, and for model architectures that use shared parameters.
- **EventContain** relation establishes that when an API is invoked, a specified child event, such as another API call or a variable state change, occurs within that invocation. For example, calling `Optimizer.step` should always contain updates to the model parameters and the corresponding opera-

tions that perform those updates. This relation is effective for catching misconfigurations or unexpected arguments that otherwise lead to silent control-flow deviations.

- **APISequence** relation establishes (1) the group of APIs that should be called together and (2) the order in which they should be called. Users often forget to call certain APIs or call them in the wrong order, which can lead to silent errors. For example, in a few rookie mistakes collected from StackOverflow, users forgot to call `Optimizer.zero_grad` before `loss.backward`, leading to training instability.

These relations are deterministic and encode strict semantics, enabling precise and timely detection of silent errors. Besides the built-in relations, TRAINCHECK is extensible, so developers can easily add new relations into the framework.

Invariant inference in TRAINCHECK begins by instantiating each relation with concrete *descriptors*. A descriptor is a predicate that selects which trace records or events an invariant should examine. API descriptors specify the API's name and, optionally, the expected arguments or return values. Variable descriptors specify a variable's type and attribute name, along with an optional expected value or value change.

3.3 Trace Representation

TRAINCHECK collects execution traces from a DL training program by instrumenting it to emit relevant runtime information. A raw trace consists of a sequence of records capturing API entry and exit points, as well as variable states. Each trace record is annotated with a timestamp and thread ID. TRAINCHECK further extracts high-level *events* from raw trace records to represent semantically meaningful behaviors. For example, an *APICallEvent* represents a complete API invocation, aggregating its entry and exit records along with derived attributes such as execution duration and nested events. These high-level events form the foundation for invariant inference by providing structure to raw trace data.

TRAINCHECK additionally introduces **meta variables**, contextual attributes for a trace record. These include properties such as the training iteration number, distributed training ranks, and active context managers. Users can also define custom meta variables, such as pipeline stage (*e.g.*, initialization, training, or evaluation). These meta variables are essential for precondition inference (§ 3.5), enabling TRAINCHECK to generate invariants that are both precise and interpretable.

3.4 Invariant Inference

TRAINCHECK takes a hypothesis-based approach to infer training invariants from traces. As summarized in Algorithm 1, the inference workflow contains three main steps. (1) **Hypothesis generation**: The engine scans through all traces to instantiate a relation with potential concrete descriptors. (2) **Hypothesis validation**: For each hypothetical invariant, TRAINCHECK validates it against the trace and records entities that match the descriptors as passing/failing examples based on whether the relationship holds. (3) **Precondition deduction**: Try to deduce the distinction between passing/-failing examples. Such distinction, if found, will be used as the precondition for the property, and if not found, the hypothetical property is invalidated and dumped.

Algorithm 1: Invariant Inference

```
Input: traces, relation_pool
Output: all_invariants
all_invariants ← [];
foreach relation ∈ relation_pool do
    hypotheses ← [];
    foreach trace ∈ traces do
        hypotheses.extend(relation.GEN_HYPOS(trace));
    foreach hypo ∈ hypotheses do
        foreach trace ∈ traces do
            relation.COLLECT_EXAMPLES(trace, hypo);
    foreach hypo ∈ hypotheses do
        preconditions ← INFER_PRECONDITION(hypo);
        if preconditions ≠ null then
            hypo.invariant.preconditions ← preconditions;
            all_invariants.append(hypo.invariant);
return all_invariants;
```

Algorithm 2: Hypothesis Generation for `Consistent`

```
Input: trace
Output: Generated hypotheses
variables ← trace.get_all_variables();
foreach (var_1, var_2) ∈ Combinations(variables, 2) do
    foreach (attr_1, attr_2) ∈
      CartesianProduct(var_1.attrs, var_2.attrs) do
        if exists_value_match(attr_1.states, attr_2.states)
            hypo ←
              NEW_HYPO(relation ← ConsistentRelation,
                entities ← [VarDesc(var_1.type, attr_1.name),
                VarDesc(var_2.type, attr_2.name)]);
            yield hypo;
```

Each relation type implements the methods to generate and validate hypotheses for that relation. These methods are invoked in the generic inference loop. For the motivating example, the `Consistent` relation can be instantiated with two `torch.nn.Parameter` object's `data` attribute (Figure 4). Algorithm 2 shows how the hypotheses are generated for this relation. The other relations' hypotheses generation and validation are defined in a similar vein.

3.5 Preconditions

Semantics in deep learning are often context-sensitive and can only be applied to a specific subset of the training pipeline. For example, the parameter consistency invariant in distributed training should only be checked for the same model layer across workers within the same training iteration and only for the parameters replicated instead of partitioned across workers. For another example, the output tensor dtype usually depends on the input tensor dtype, but when an autocast context manager is active, the output tensor dtype should be the

autocast dtype instead of the input dtype.

TRAINCHECK thus defines *preconditions* for a training invariant. Preconditions provide various benefits: (1) confidence in the invariant's accuracy, (2) reduction in false positives, (3) debugging, as when the invariant is violated, the precondition can help explain which part of the pipeline is causing the error, and (4) reduced overhead by only performing the applicable checks. In addition, preconditions enable **transferable invariants**, as they provide a very clear context of when the invariant should be applied and thus can be applied to other pipelines that share the same context.

3.6 Deducing Preconditions

We design an algorithm to deduce the weakest yet safe preconditions for each invariant. A precondition is considered *safe* if it provides a clean separation: evaluating to `true` for *all* passing examples and `false` for *all* failing examples.

A precondition consists of one or more *conditions* (predicates) that compare a field's values across all trace records of a given example. TRAINCHECK supports four types: `CONSTANT`, where the field's value is identical in every record and must match a specific required value; `CONSISTENT`, where the field's value is identical in every record without a specific value constraint; `UNEQUAL`, where the field takes different values across records; and `EXIST`, where the field appears in every record.

The deduction algorithm first scans through the passing examples and produces conditions for each example. It then forms a *candidate precondition* by using the conditions found. For each example, the algorithm finds the conditions satisfied in all trace records of that example. The candidate precondition is then formed by taking the conjunction of the conditions satisfied in all passing examples. This conjunction is verified against the failing examples to see whether the precondition is safe; if so, the algorithm returns that precondition.

By restricting the candidate precondition to a conjunction of conditions that hold in all passing examples, the algorithm implicitly assumes the invariant applies to only a single scenario, which is often not the case. For instance, the parameter consistency invariant holds both across (1) data-parallel workers and (2) LayerNorm parameters on tensor-parallel workers.When the initial candidate precondition is unsafe, the algorithm attempts to split the passing examples into subgroups based on remaining non-overlapping conditions and performs inference on each subgroup. If no further splitting is possible, the algorithm terminates and reports an inference failure. If the preconditions inferred from these subgroups are safe and collectively cover all passing examples, they are combined disjunctively to form the final precondition.

Prune Irrelevant Conditions Numerous conditions can be inferred from the trace, but not all are relevant to the invariant. For example, in the parameter consistency invariant for distributed training, it is likely that all the parameters have the same `is_cuda` attribute. TRAINCHECK prunes irrelevant conditions during the safety verification process by removing conditions not violated in any failing examples. These conditions evaluate to true in all examples and are not discriminative. This approach is simple yet effective in removing a good amount of noisy conditions unrelated to the invariant.

A more complex situation is when the irrelevant condition is an artifact of the invariant handled by the current algorithm. For example, all consistent model weights will also have the same gradient values to maintain consistency. However, using consistent gradient values as a condition for the parameter consistency invariant is not a good idea because, while safe, it is too shallow and prevents the algorithm from going deeper to find the multiple scenarios that the invariant holds. To fix this problem, we allow each relation to encode rules on what conditions should be avoided in the precondition inference process. For example, a `Consistent` invariant, if about attributes of type `torch.Tensor`, cannot use any other attributes of type `torch.Tensor` as a condition. Alternatively, static analysis can help determine correlated fields and remove them from the precondition inference process, but its complexity and overhead may not be justified by the benefits.

Example In the simplified example presented in Figure 4, there is one passing example and two failing examples. Each example contains two trace records of `torch.nn.Parameter` objects. The algorithm first generates the candidate precondition by finding the conditions that hold in the positive example, which is `CONSTANT(tensor_model_parallel, False) && CONSTANT(is_cuda, True) && UNEQUAL(meta_vars.TP_RANK)`

Verifying the conjunction of these three conditions against the failing examples reveals that it is safe. However, the second condition of `is_cuda` constantly `True` is not violated in any failing examples; thus, it is pruned from the precondition. The final precondition is `CONSTANT(tensor_model_parallel, False) && UNEQUAL(meta_vars.TP_RANK)`

When the candidate precondition is unsafe, we are in an *under-constrained* situation. This can happen for three reasons: (1) the precondition is fundamentally not expressible in the condition types we support, (2) the information in the trace is not enough to infer the precondition, or (3) the invariant holds under multiple preconditions. In our experience, (3) happens most of the time. This indicates that local attributes and meta variables are sufficient for most invariants and do not need a complex grammar to express the preconditions.

We enhance an unsafe candidate precondition by adding conditions not considered previously to further constraint it, as described in § 3.6. We choose the conditions to add based on decreasing order of statistical significance, i.e., the conditions that cover the most passing examples. In Figure 5, the candidate precondition is the conjunction of the two fully-covering conditions, `cond1 && cond2`. However, since it is unsafe, we attempt to add `cond3` and `cond4`, resulting in a safe precondition of `cond1 && cond2 && (cond3 || cond4)`. If this precondition is still unsafe, we repeat the process until we find a safe precondition, or the computation budget is exhausted. The statistical significance based search helps reduce the search

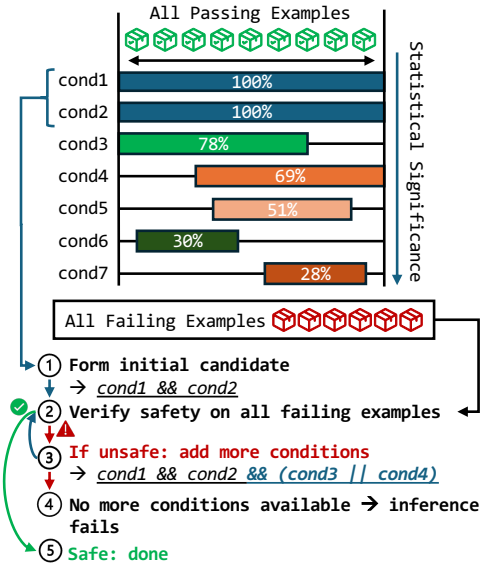

Figure 5: Deduce precondition in under-constrained situations.

space and find the majority scenarios that the invariant holds.

Our algorithm is not guaranteed to find strictly the weakest precondition, as the pruning strategy only looks at individual conditions, and we do not rely on any static program analysis to infer the preconditions. However, it provides a good trade-off between simplicity and effectiveness.

3.7 Filtering Out Superficial Invariants

One challenge in invariant inference is distinguishing meaningful invariants from superficial ones—those that appear valid due to the limited information available in a trace. For example, two irrelevant APIs `torch.cuda.is_available()` and `torch.jit.is_scripting()` can have consistent return values.

TRAINCHECK deems an invariant superficial if it cannot deduce a precondition for this invariant. Such invariants will not be deployed because they may not hold in the target training task. Even if they hold, they are not effective as runtime checks because we do not know when to apply them due to the lack of precondition. This is a key design choice to reduce false positives and enhance explainability.

Our approach differs significantly from traditional invariant mining solutions. They typically use the number of passing examples and the number of failing examples to estimate the statistical significance and select likely invariants. This approach has two drawbacks in our context. In DL training, having a large number of failing examples does not mean the invariant is superficial due to the diverse and intricate training process. Local semantics might not be statistically representative in the global context. For example, in tensor parallelism, all major parameters in the attention layer are partitioned across workers. Only the LayerNorm parameters are replicated, which accounts for less than 0.1% of the total parameters in representative transformer models like GPT [39]. During inference, the invariant that `torch.nn.Parameter` objects should be consistent has a passing/failing ratio of 1:38. This can be pruned by a statistical significance-based approach, but in reality, this turns out to be an important invariant for catching the Bloom-176B error.

3.8 Scalability

DL training produces large traces due to frequent API calls and variable updates, posing significant challenges for analysis. For example, instrumenting a 2-GPU, 70M-parameter pretraining run for BLOOM-176B (using Megatron-DeepSpeed's GPT-2 pipeline) generates approximately 92,000 trace records (50 MB) per training iteration.

TRAINCHECK adopts two key design choices to address this challenge. First, it restricts analysis to a predefined set of high-level semantic relations, significantly reducing the search space. Second, TRAINCHECK abstracts APIs and variables into *descriptors*. For variables, they are typically compound objects with multiple attributes. A variable descriptor consists of the variable's type (as returned by `type(obj)`), attribute name (*e.g.*, `data`, `grad`), and optional value constraints. This allows TRAINCHECK to reason over groups of variables sharing the same type and attribute, rather than enumerating individual instances. For example, when analyzing BLOOM-176B using a 2-GPU and 70M-parameter run, enumerating 104 variable instances such as `0.input_layernorm.weight` and `2.post_attention_layernorm.weight` would yield 5,356 pairs to consider. In contrast, TRAINCHECK considers only the available PyTorch variable types relevant to training state, where the primary type is `torch.nn.Parameter`. This dramatically reduces the number of invariant candidates while preserving the properties needed for error detection. Descriptors can also encode constraints (*e.g.*, requiring non-null values) to further generalize invariant specification.

3.9 Input Requirements

Importantly, while the inferred invariants are intended to validate large-scale training, generating them does not always require large-scale setups. In our experiments, effective invariants can often be inferred from small-scale runs. For example, although the original BLOOM training job spanned hundreds of GPUs, TRAINCHECK was able to infer the relevant invariant using only a 2-GPU run. All evaluated invariants in this paper were inferred from training jobs using at most 4 GPUs and 100 iterations. These results demonstrate that representative behaviors can be captured with lightweight workloads, making the inference phase practical and efficient.

4 Implementation

We implement TRAINCHECK in Python with 22.7 K lines of code. The system is composed of Instrumentor, Infer Engine, and Verifier. A key challenge in developing TRAINCHECK is to balance fine-grained trace collection for inferring effective invariants to detect silent errors and minimizing runtime overhead. We made extensive efforts to explore different techniques for achieving a good trade-off.

4.1 Instrumentor

Instrumentor collects traces from a training task for both Infer Engine and Verifier. It instruments a given DL training program to emit information as required by the relations we support (§ 3), specifically (1) *API invocation trace:* function entry, exit, arguments, and return values, (2) *variable state trace:* variable assignment, deletion, and modification, and (3) *meta variables:* steps, epochs, ranks, etc.

We implement it as a command-line tool that takes the path to the entry Python program and the libraries of interest (*e.g.*, `torch`, `deepspeed`) as arguments. Instrumentor automatically scans the `import` statements and model definitions in the program and instruments the necessary functions and variables. The user can also provide a shell script that sets up the environment and arguments for the program. Trace logs are written to a specified directory using JSON format.

Instrumentor is designed with three key goals: (1) non-intrusiveness, (2) low overhead, and (3) high coverage. Instrumentor also aims to be flexible in instrumentation granularity, as different relations require different levels of detail. For example, the `Consistent` relation only requires a periodic sampling of model states, whereas the `EventContain` relation requires an eager model state logging whenever the variable is modified, as accurate timing of events is crucial for it.

One option is to use Python's `sys.settrace` function, which installs a trace function that is invoked on every function call, return, and exception. However, this approach incurs prohibitively high overhead; we observed a 200× to 550× slowdown. It can also interfere with existing workflows that use tools relying on `sys.settrace`, such as `pdb` and `cProfile`.

Dynamic Monkey Patching To meet the above goals, we adopt a *monkey-patching* approach. Instrumentor is implemented as a Python package that dynamically instruments the target program by injecting hooks into relevant source code at runtime. It supports *selective* instrumentation, allowing users to specify which modules to instrument; only APIs defined in the specified modules are patched. During instrumentation, Instrumentor recursively traverses the namespace of each selected module and wraps identified methods. Each wrapper inserts logging and bookkeeping logic before and after invoking the original function. To minimize overhead, Instrumentor skips low-level internal functions, particularly those in `torch.jit` and `torch._C`, which are invoked frequently but rarely provide meaningful information for invariant inference.

Tracking Variables Instrumenting Python variables is more challenging than tracing APIs. In CPython, assignment operations occur at the C level and do not invoke any Python-level hooks, making it infeasible to efficiently track arbitrary variable state changes. Our study shows that most non-trivial silent errors, despite their diverse root causes, affect a small set of key objects, such as the model and optimizer. If a silent error does not impact model quality, it is often inconsequential for training correctness. This leads to a key insight: tracking the state of only the model and optimizer is sufficient to detect meaningful silent errors. These objects are typically long-lived, and updates to them occur through attribute modifications rather than object replacement, which simplifies tracking. Therefore, Instrumentor focuses on tracking models and optimizers rather than arbitrary local variables.

To achieve this, models and optimizers are wrapped with a `Proxy` that intercepts state-changing operations via overridden magic methods such as `__setattr__`. These changes are logged to the trace eagerly upon execution. During instrumentation, Instrumentor scans the program's AST to locate the initialization sites of these objects and replaces them with their corresponding `Proxy` instances. Alternatively, when precise timing of state changes is not required, Instrumentor supports a lower-overhead, sampling-based approach that registers a state-dump callback on `Optimizer.step`.

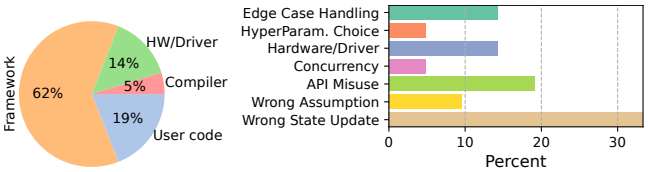
Logging Hashes of Tensors When dumping the model states, we are essentially doing checkpointing. The cost of this is unbearable as the model states are large and the overhead of serializing them, writing them to the log file, and reading them back is significant. Through our study, we observe that the actual values of the tensors are typically unimportant for inferring invariants. Silent errors typically arise from the shape, dtype, and the equality relationship between the tensors. Thus, Instrumentor only logs the hash of tensors.

Collecting Meta Variables Instrumentor also collects meta variables such as the current step, epoch, rank, *etc.* Whenever a trace record for a function call or variable state is dumped, Instrumentor walks through the call stack and finds the loop index local variable. This is a simple heuristic that works for most cases, as the loop index is usually a local variable in the outermost loop that is incremented in every iteration. Instrumentor further allows users to specify meta variables by calling the `set_meta` API. Users may also annotate the program into different phases, such as training, validation, and testing. The general idea for collecting meta variables is to provide context for the invariants to deduce preconditions.

4.2 Infer Engine

Infer Engine processes the trace files generated by Instrumentor to infer training invariants and their preconditions. One key challenge is handling large input traces produced by the data-intensive nature of DL training. Typical training pipelines can generate several hundred megabytes of trace data per epoch. Our algorithms, as described in § 3, are designed to efficiently deduce invariants with preconditions from large traces.

We implement Infer Engine in Python to leverage its rich ecosystem of libraries for data processing and deep learning. In addition, our traces cannot be conveniently represented with a fixed schema. We implement multiple trace backends, including Pandas, Polars, and built-in dictionaries. From experimenting with these backends, we choose Pandas DataFrames with Python dynamic typing as the default based



(a) Error locations. (b) Root cause types.

Figure 6: Root cause types of errors we reproduce for evaluation.

on its analysis performance and flexibility. We introduce optimizations with custom analysis functions that provide query caching, sampling, and pruning (*e.g.*, pruning candidates related to `torch.cuda.is_available`).

4.3 Verifier

During the online checking phase, TRAINCHECK consumes the stream of the trace generated by the instrumented program to detect silent errors in real-time. Different from the offline phase, the instrumentation is restrained to only the APIs and variables that are relevant to the deployed invariants and is thus lightweight. Verifier monitors the trace and triggers a check when a relevant piece of trace is available. It first evaluates whether the preconditions of an invariant are satisfied. If so, it checks whether the invariant holds. When an invariant violation is detected, Verifier reports the invariant and the corresponding trace to provide debugging help to developers.

5 Evaluation

We evaluate TRAINCHECK to answer several questions: (1) Can TRAINCHECK infer effective training invariants for detecting real silent errors? (2) How quickly can the invariants detect the errors? (3) Can TRAINCHECK help diagnose a detected silent training error? (4) Is the detection accurate? (5) What is the runtime overhead?

Our experiments are run on a server running Ubuntu 22.04, equipped with an Intel(R) Xeon(R) Silver 4310 CPU, 252 GB RAM, and one NVIDIA A40 GPU. For trace collection related to distributed training, we use another server with identical specifications but featuring 8 NVIDIA A2 GPUs. We use Python 3.10 and PyTorch 2.2.2 with CUDA 12.1.

5.1 Silent Error Detection

To assess TRAINCHECK's effectiveness, we collect and reproduce 20 *real-world* silent errors. Of these, 6 are drawn from our prior study (§ 2), while the remaining 14 are newly gathered from GitHub issues for popular libraries (PyTorch, DeepSpeed, etc.), StackOverflow, and social media. These errors span a broad range of root cause locations and types, as illustrated in Figure 6a and Figure 6b. The complete descriptions of these errors are available in our technical report [23].

We compare TRAINCHECK with four baselines that represent the current practices and state-of-the-art research:

- *Spike* detector is used to monitor numerical instability in training where the loss or accuracy spikes to a large value.
- *Trend* detector is used to monitor the training process where the loss or accuracy is not decreasing or increasing as expected. A tolerance factor is set to allow some fluctuation.
- *Anomaly Detection* detector applies common algorithms like LOF, Isolation Forest, and Z Score to detect anomalies on the same high-level metrics like loss and accuracy.
- *PyTea [22]* and *NeuRI [28]* are two recent research artifacts. PyTea specifies constraints on APIs used in the training process, primarily focusing on the shaping constraint of the input and output tensors. NeuRI automatically infers such constraints encoded in PyTea's syntax.

When implementing the first three detectors, we monitor signals as per industry practice [5] and apply the same configuration parameters to all errors for a fair and consistent comparison. For the spike detector, we set the threshold to 75, and for the trend detector, we set the tolerance to 3. The number of neighbors for LOF is set to 2, and the contamination factor is set to 0.1 for Isolation Forest. Other parameters use defaults provided by Scipy and Scikit-learn.

Methodology We prepare a reproduction script for each error and run them to emit (1) runtime trace for the checking of TRAINCHECK and PyTea/NeuRI, and (2) high-level metrics (loss, accuracy, gradient norm) for the anomaly detection-based detectors. We then run the detectors on the traces and metrics and collect the detection results. The invariants used by TRAINCHECK are inferred from PyTorch's official GCN, Autocast, and DDP examples, for PyTorch-related errors, and Megatron-DeepSpeed's official GPT pretraining examples for DeepSpeed-specific errors, and the official Transformers trainer examples for Transformers-specific errors.

We focus on *true detections* (true positives) to avoid rewarding detectors that indiscriminately raise many alarms. This ensures the result reflects real error-detection capability. For example, we observe that when using the anomaly detection detector, no matter how we tune it, it raises numerous alarms throughout the training process, *e.g.*, since the loss is dropping fast. To objectively determine the true positive, we run the fixed versions of each error and check if the detector also raises alarms in the error-free traces.

Detection TRAINCHECK successfully detects 18 out of the 20 errors. The invariants it infers and uses represent all five relations in Table 2. In all cases, detection occurs no later than one iteration after the root cause is triggered. For the motivating example, the incorrect gradient clipping logic is triggered in the second training iteration, and TRAINCHECK shortly detects it in the third iteration. Despite diverse root causes, TRAINCHECK achieves high detection coverage and timeliness. We attribute its effectiveness to our invariant checking approach and the precision of the inferred invariants.

TRAINCHECK fails to detect two errors: TF-33455 and TF-29903. TF-33455 involves the trainer stopping early due to an incorrectly calculated total number of training steps, while the training process itself is correct. Detecting this error would re-

Bug Id	Synopsis
AC-2665	Initializing the optimizer prior to wrapping the model with DDP causes training to not progress.
DS-6770	A mismatch between the model and the parameters held by the optimizer causes a KeyError during initialization.
DS-5489	Freezing parameters prior to initializing DeepSpeed causes incomplete model checkpoints.
DS-6714	Using heterogeneous MoE architecture with pipeline parallelism causes inconsistent usage of communication primitives, leading to training stuck.
DS-6772	DeepSpeed initialization silently overwrites "id" attributes on models, causing wrong model-GPU placement.
DS-6089	The program is stuck on communication due to consistent "capacity" value across workers.

Table 3: Six newly reported bugs that lead to silent errors, detected and diagnosed with the help of TRAINCHECK. AC: Accelerate. DS: DeepSpeed. Numbers refer to GitHub issue IDs.

quire monitoring the computed training steps and comparing them with the intended arguments. Currently, TRAINCHECK does not support tracking Python primitive variables, as doing so would incur prohibitive overhead and require modifications to the Python runtime. TF-29903 concerns a bug caused by a corrupted state dict constructed within the `safe_checkpoint` function. TRAINCHECK fails to detect this case because (1) this error is confined to the checkpoint function and does not impact the main training logic, and (2) TRAINCHECK does not analyze local variables.

In comparison, the signal-based detectors collectively only detect 2 errors, which are extreme cases where the model stops learning entirely and the loss is constant over epochs. The PyTea/NeuRI detector detects 1 error, which is from a bug in the transformers library where the processed data does not have the same batch size as the argument, falling into the shaping constraints supported by PyTea/NeuRI.

Diagnosis While diagnosis is not the primary goal of TRAINCHECK, we conduct analysis to understand whether invariant violations can aid in debugging. Among the 18 cases detected by TRAINCHECK, the violation reports can pinpoint the exact root cause in 10 cases and localize close to the root causes in 8 cases. The diagnosis hints for the one error detected by PyTea/NeuRI are on par with TRAINCHECK.

5.2 New Silent Errors

To further test TRAINCHECK's effectiveness, we monitor recent open GitHub issues in DeepSpeed and Transformers. We focus on issues that have silent symptoms, are unresolved with unknown root causes, and reproducible. We create reproduction scripts based on the reports to ensure the issues occur with the latest library. We then apply the invariants TRAINCHECK infers from the sample pipelines to the issues.

During this exercise, TRAINCHECK detects 6 new silent errors at an early stage and aid in diagnosing their root causes, as summarized in Table 3. Three of these root causes have since been confirmed and fixed.

Case Study: AC-2665 It causes the model to not learn effectively during training. In the original issue report, the user adapted their original pipeline into DDP, but the model stopped learning at all. The user did not know the root cause, but found a setting that fixed the error, `use_orig_param true`.

We applied the invariants inferred from the GCN example to the user's pipeline and inspected invariant violations. Below, we present three example true positives identified by the inferred invariants. Inv1: `zero_grad` should contain changing of `grad` attributes from a non-zero tensor to a zero tensor or None. Inv2: `step` should contain changing of `data` attributes of the model parameters. Inv3: `step` should contain a number of invocations of mathematical operations on the model parameters, such as `_foreach_add`. Inv2 and Inv3 indicate that the optimizer is not performing updates to the model, while Inv1 indicates that no gradient was computed. The three invariants combined point out that the optimizer is likely not initialized with parameters that are actually used during forward and backward passes. We then checked the model parameters and the optimizer's param_groups and confirmed the hypothesis. Upon investigation of the model and optimizer initialization process, we found out that DDP automatically flattens the original model parameters and creates a new model with the flattened parameters. However, the user initialized the optimizer with the original model parameters, and thus the optimizer did not have the correct parameters to update. We reported the issue both to the user and to the transformers team, and the issue has been confirmed. A pull request has been under review to fix the issue.

5.3 False Positive

To measure false positive, we collect 63 diverse training programs drawn from existing tutorials, all without known bugs. They span different training scales (*e.g.*, single-GPU vs. multi-GPU), frameworks (PyTorch, Transformers, Diffusers, *etc.*), tasks (image classification, language modeling, vision transformer pretraining, *etc.*), and configuration parameters (*e.g.*, precision, batch size, dataset, and model architecture).

To minimize confounding effects from applying invariants across unrelated tasks, we group programs into four classes based on training task type, as shown in Figure 7. Transferability across task classes is evaluated separately in § 5.4. For each class, we split the programs into a training set (used to infer invariants) and a validation set (used to assess false positives). Validation programs are further categorized as either *cross-configuration* (differing from the training set only in configuration parameters) or *cross-pipeline* (different code with similar semantics). This categorization allows us to assess how well the inferred invariants generalize across both minor and structural variations in training programs.

Figure 7 shows that TRAINCHECK achieves consistently low false positive rates. In the primary evaluation setting, where invariants are inferred from representative workloads using 5 or 6 input programs, false positive rates remain below

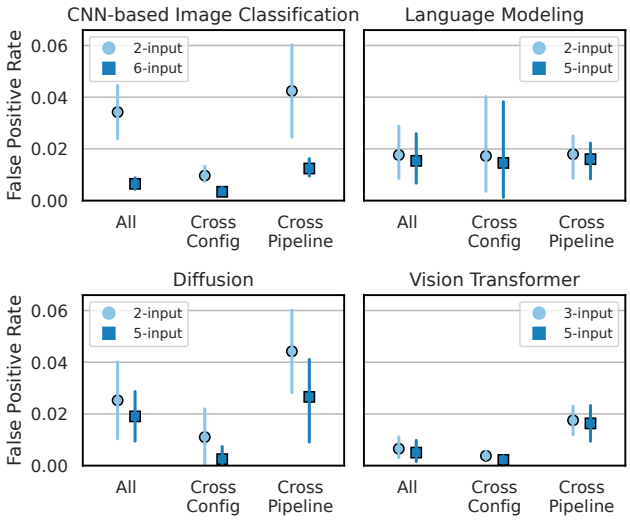


Figure 7: False positive rates across four program classes, broken down by cross-configuration and cross-pipeline settings.

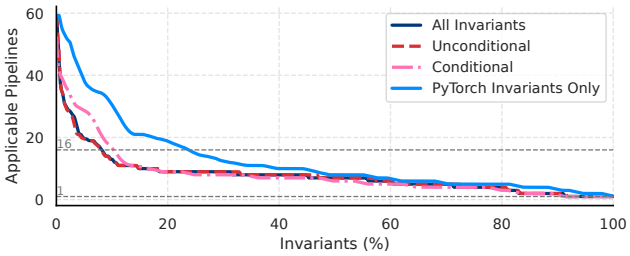

Figure 8: Invariant applicability across all collected pipelines. The y-axis shows how many pipelines each invariant applies to. "All Invariants" shows overall coverage; "PyTorch Invariants Only" isolates PyTorch-specific APIs. "Conditional" and "Unconditional" indicate whether preconditions are present.

2% across all classes. Even in constrained settings with only 2 or 3 input programs, the rate stays below 5%.

5.4 Invariant Transferability

TRAINCHECK infers transferable invariants, enabling those learned from a small set of input programs to generalize across different pipelines and library versions. To evaluate this transferability, we apply a set of *valid* invariants to all 63 collected pipelines. These invariants are inferred using a 5/6-input setup across all classes and exclude any that triggered false positives in § 5.3. For each invariant, we count how many pipelines it can be applied to without raising a false alarm.

As Figure 8 shows, many invariants exhibit broad transferability. All invariants apply to at least one additional pipeline beyond those used for inference. Notably, over 8% of invariants apply to more than 16 pipelines—the average number of pipelines per model class, demonstrating strong cross-class generalization despite semantic and structural differences. We also observe that invariants with preconditions are generally more transferable than unconditional ones, underscoring the importance of precise precondition inference.

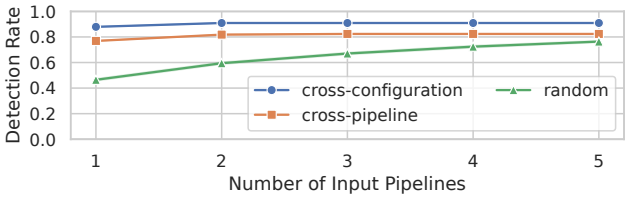

Figure 9: Detection rate as the number of input pipelines increases under cross-configuration, cross-pipeline, and random settings.

We expect the transferability to be even higher in practice, as developers typically apply invariants only within the same framework or library context. For example, invariants involving Transformers-specific APIs would not be applied to a program that only uses PyTorch. Since all pipelines in our dataset use PyTorch, we isolate 8,172 invariants that capture only PyTorch-specific semantics. These exhibit significantly higher transferability: 23% of them apply to more than 16 pipelines. This result suggests that framework-level behavior is a strong source of reusable invariants.

We also evaluate the false positive rate of applying invariants across model classes to assess TRAINCHECK's robustness in extreme transfer scenarios. Using the setup from § 5.3, we infer invariants from one class and apply them to all programs in the other classes, comparing the resulting false positive rate to the in-class baseline. Surprisingly, only the smallest-scale class, CNN, shows a higher false positive rate in the cross-class setting (2.62% vs. 0.65%). In all other cases, the rate is comparable or lower (*e.g.*, 0.93% vs. 1.54% for language modelling). This is because many invariants become inapplicable due to differing API usage and training context.

5.5 False Negative

To study the trade-off between false negative and the input programs used for invariant inference, we evaluate three settings: *cross-configuration*, *cross-pipeline*, and *random*. In the *cross-configuration* setting, invariants are inferred from historical runs of the same training pipeline executed under alternative configurations where the silent error was not observed. In the *cross-pipeline* setting, invariants are inferred from semantically similar training pipelines that do not exhibit the error. In the *random* setting, invariants are inferred from general tutorial pipelines collected from relevant frameworks.

For each silent error detected in § 5.1, we randomly sample k input pipelines for each setting and evaluate whether the error can be detected using the inferred invariants. The average detection rate for a given k is computed by repeating this process 100 times and averaging the results across all cases.

As Figure 9 shows, increasing the number of input pipelines consistently improves detection rates. Both the cross-configuration and cross-pipeline settings achieve high detection coverage (91% and 82%, respectively) even with only two input programs. The random setting starts with lower detection coverage, but improves steadily as more inputs are added (76% with five inputs). Further investigation of the

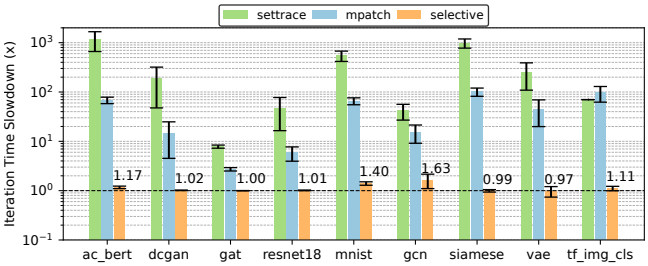

Figure 10: Overhead of different instrumentation techniques.

undetected silent errors reveals that the violated semantics often involve specialized features that are underrepresented in the available example pipelines or not exercised in cross-configuration or cross-pipeline inputs. For instance, detecting `DeepSpeed-5794` requires invariants about DeepSpeed's MoE features; however, only 1 out of 15 available DeepSpeed tutorial pipelines performs MoE training, making it infeasible to detect `DeepSpeed-5794` with random sampling.

5.6 Overhead

We evaluate the runtime overhead of invariant checking during training. TRAINCHECK uses *selective instrumentation*, which only instruments the APIs and variables relevant to the deployed invariants. We conduct experiments on a diverse set of training programs that vary in model size, task complexity, and framework usage. For each program, we deploy 100 randomly sampled invariants and compare the per-iteration training time before and after instrumentation. We compare our selective instrumentation against two baselines: (1) Python's *sys.settrace*, using a simple trace function that logs API calls and arguments without variable tracking, and (2) TRAINCHECK's *full instrumentation* mode, which instruments all API calls and variables regardless of invariant relevance.

Figure 10 shows the results. TRAINCHECK incurs low overhead in selective mode, typically less than 2%, and at most 1.6× slowdown across all workloads. `GCN` and `MNIST` exhibit higher relative overhead (1.6× and 1.4×, respectively), as they are toy workloads (*e.g.*, training a 2-layer CNN) where per-iteration execution time is minimal, and any instrumentation incurs a larger proportional cost. In contrast, for the more realistic workloads, overhead is significantly lower, as a larger portion of the time is spent on GPU-bound computation.

The primary sources of overhead stem from trace data serialization into JSON, conversion of objects into dictionary representations, and handling of tracked objects. These operations occur at the Python level and introduce runtime costs, especially in tight CPU-side loops. While our current implementation is synchronous and prioritizes correctness and modularity, there are clear opportunities for reducing overhead further. Potential engineering optimizations include asynchronous or batched logging and minimizing redundant instrumentation through static analysis. We leave the exploration of these optimizations to future work.

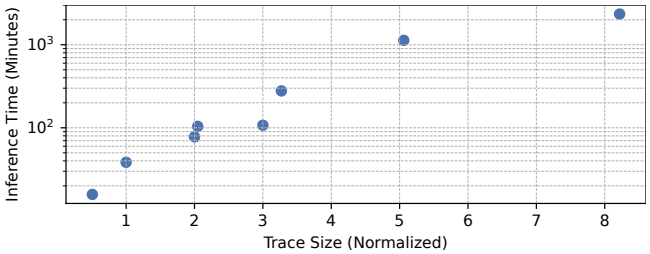

Figure 11: Inference time vs. trace size (normalized to ResNet-18 pretraining trace size).

5.7 Inference Efficiency

To quantify the invariant inference efficiency, we reuse the traces from the false positive experiments (§ 5.3) and measure the inference time across traces of varying size and structural complexity. For consistency, we normalize trace size by treating the trace from a ResNet-18 pretraining run with 20 training iterations and 10 testing iterations as a standard program trace, corresponding to 66.2 MB or 93,686 records.

Figure 11 shows that inference time grows roughly quadratically with trace size in this setting. While the inference algorithm itself is linear in both trace size and the number of hypotheses, larger traces typically expose more semantic behaviors, resulting in a larger hypothesis set. In the worst case, TRAINCHECK completes inference in 38 hours when processing traces from 8.2 standard programs. Since inference runs offline and our current implementation is single-threaded, the performance remains acceptable for practical usage.

5.8 Examining Invariant Violations

Despite a low false positive rate, false alarms do occur, and developers must examine violation reports to extract actionable diagnostic information. We find that violations can often be inspected structurally rather than treated in isolation. They tend to cluster around specific APIs or components, which makes the review process more manageable. In practice, true positives are frequently supported by multiple related violations that reinforce the underlying issue, while false positives follow recognizable patterns and are easy to dismiss.

For example, in the AC-2665 case study (§ 5.2), using invariants inferred from PyTorch's GCN pipeline alone, 100 violations were reported. Among these, 52 were true positives. Of those, 33 indicated that `torch.optim.adamw.adamw` was never invoked, highlighting a missing optimizer initialization. 18 showed that `optimizer.step` performed no mathematical operations, suggesting it was not linked to model parameters. The remaining 48 violations were quickly dismissed as irrelevant: 7 involved GCN-specific constants (e.g., `dropout_rate == 0.5`), and 26 flagged missing ReLU invocations, which do not apply to the T5-based model used in AC-2665. The rest followed similar, non-impactful patterns.

6 Limitations

TRAINCHECK has a few limitations. First, its instrumentation interferes with JIT compilation tools like `torch.compile`, preventing the analysis of optimized code paths. Second, it is restricted to Python code, limiting its ability to analyze components with significant logic implemented in lower-level languages, such as the Flash Attention algorithm [11]. Finally, representing tensors in hash form prevents fine-grained numerical analysis, limiting its applicability to detecting instabilities caused by inappropriate hyperparameters. However, this can be complemented by existing research on hyperparameter tuning [50] and numerical defect detection [25].

7 Related Work

Testing Pipeline Code, Libraries, and Compilers CRADLE [33], AUDEE [18], LEMON [44], and NNSmith [27] employ differential testing to detect and diagnose failures across frameworks and compilers. PyTea [22] detects tensor shape mismatches using pre-specified API constraints, while NeuRI [28] enhances this by automating constraint inference. RANUM [25] targets numerical defects in deep neural networks. TRAINCHECK goes beyond framework inconsistencies or isolated error categories by inferring runtime invariants tailored to the training process. It automates error detection and debugging with automated invariant inference from example pipelines, addressing a broader range of silent failures across diverse training pipelines.

Monitoring Frameworks for Training Dynamics Tools like TensorBoard [1] and Weights & Biases [5] log high-level metrics such as loss and accuracy, enabling developers to visualize and compare experiments easily. However, these tools require manual and active monitoring, as seen during the training of BloombergGPT [45], where loss plateaued for seven days before the developer noticed it. These metrics are often noisy and can lead to many false alarms when used for detecting silent errors. They also do not help with diagnosis.

In contrast, TRAINCHECK provides an automated solution that captures the precise semantics of training as training invariants and proactively checks them, enabling reduced manual effort, early and accurate detection of silent training errors, and providing diagnosis hints for root-cause analysis.

Testing DL Models Extensive work exists to test trained DL models for robustness and fairness, such as DeepXplore [32] and DeepTest [43]. They are orthogonal to TRAINCHECK given their focus on testing and uncovering errors in the final model weights rather than validating the training process.

Fault-Tolerance in DL Systems Fault-tolerance mechanisms have been proposed, such as elastic resource scaling, task reallocation, pipeline parallelism, and efficient checkpointing [3, 21, 26, 42]. While these approaches improve fault tolerance, they do not address silent errors that arise from misconfigurations, bugs, or subtle correctness violations.

Invariant Mining Much work has explored mining likely program invariants for traditional single-component software with tools such as Daikon [16] and DIDUCE [19]. These invariants focus on low-level program variable relations at certain points of the program, such as `idx < len` for two local variables in a loop. Recent work such as I4 [30], DistAI [49], and DuoAI [48] infer inductive invariants, which are used in the verification of distributed protocols. Oathkeeper [29] infers event rules to detect silent failures in distributed systems.

Inferring rules is a general approach for bug detection. Engler *et al.* [15] notably propose inferring rules about programmer beliefs and show its effectiveness in large systems code.

TRAINCHECK targets a new domain of deep learning training systems and addresses various challenges unique to this domain. To the best of our knowledge, it is the first work for systematic invariant checking in DL training pipelines to detect silent training errors. The training invariants TRAINCHECK infers capture high-level semantics tailored to DL training. TRAINCHECK also deduces precise preconditions for these invariants. Moreover, prior work mainly infers invariants from a single system, and these invariants only apply to that system. In contrast, TRAINCHECK invariants from diverse and seemingly unrelated training pipelines. Its inferred invariants are transferable to different pipelines.

8 Conclusion

Silent errors are detrimental to DL training and yet notoriously difficult to address. This paper presents a study on such errors to understand their characteristics. Informed by the study, we propose a principle approach that uses precise training invariants to detect and diagnose silent training errors. We present TRAINCHECK, an end-to-end framework that automates the process of inferring training invariants and proactively checking them. TRAINCHECK shows effective and quick detection capability for real-world silent training errors with diverse root causes. It also uncovers previously unknown bugs leading to silent errors in popular training libraries. Its tailored approach and the transferability of its inferred invariants make it readily applicable to existing DL training pipelines.

Abstract

As GPUs play an increasingly important role in computer systems in the scaling laws era, understanding fine-grained GPU runtime behavior is more crucial than ever. However, existing GPU kernel profilers, typically kernel-exclusive or hardware-dependent, often fail to capture fine-grained measurements. This paper presents NEUTRINO, a programmable interface for GPU kernel profiling that leverages assembly-layer probing to achieve instruction-level fine granularity, profiling versatility across time and value domains, and hardware independence. To better visualize the rich details captured by NEUTRINO, we introduce the Densified Memory Access Timeline (DMAT), a novel representation that offers new insights into GPU runtime behavior. We implement NEUTRINO in Linux for both NVIDIA and AMD GPUs and conduct extensive evaluations and analyses. The results demonstrate NEUTRINO's superior capabilities in GPU kernel profiling with low overhead. We envision NEUTRINO as a valuable tool for the community and have open-sourced it to facilitate future research at https://github.com/open-neutrino/neutrino.

1 Introduction

With the emergence of artificial intelligence under the scaling laws [41] in data, parameters, and computation, the underlying computer systems have been scaling rapidly, primarily driven by GPUs, parallelism-oriented computing devices that are heterogeneous from the traditional OS running on CPUs. The huge system scale and the unique parallelism-oriented design open many research challenges on GPU systems, such as communication [16, 36, 67, 70], memory efficiency [43, 78], computation pipelining [35, 46, 63, 65, 75], and GPU cluster scheduling [3, 37, 47, 52, 99]. To address these challenges, researchers would greatly benefit from comprehensive measurements and in-depth insights into the runtime behavior of real workloads on GPU systems. Demystifying the otherwise opaque GPU programs can promise new opportunities for optimizing machine learning (ML) systems.

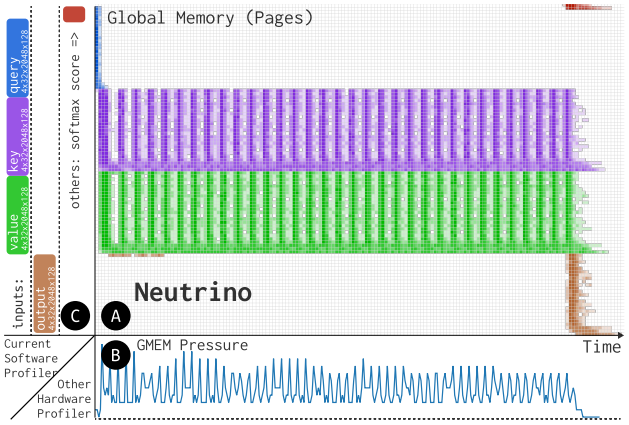

Figure 1: NEUTRINO's Densified Memory Access Timeline Plot. ❶ NEUTRINO expands new dimensions from previous ❷ hardware-dependent profilers and ❸ kernel-exclusive software profilers. Color depth in ❶ shows density from parallel threads, profiled from Flash-Attn-v2 [19] (non-causal).

However, profiling real GPU workloads at a fine granularity has been well-recognized as a significant challenge from previous attempts [5, 7, 23, 55, 58, 93]: ❶ The proprietary and heterogeneous hardware, coupled with the huge system scales (*e.g.*, 10,000+ cores), limits the capability to probe fine-grained information. ❷ GPU kernels are treated as atomic to the host OS, which largely prevents profiling GPU kernels through the mature OS profiling techniques [24]. ❸ Many profilers [12, 15, 18, 50, 74] rely on concurrency mechanisms like timer interrupts and locks, which are either unsupported or inefficient on GPUs due to the parallelism-oriented architecture. These challenges are further amplified by the rapid development of GPU systems with many new features introduced over the past few decades, such as matrix core [1, 73] in execution model and asynchronous copy [2] for memory access, which continuously introduce new runtime behaviors, performance issues, and profiling needs.

These unique challenges make existing GPU profilers ei-

ther *kernel-exclusive* [87], only capturing coarse-grained metrics like FLOP/s, or *hardware-dependent* [5,7,55,58], relying on physical hardware features such as Performance Monitor (PM) counters, as shown in Tab. 1. Additionally, these hardware profilers are *sampling-based*: They use hardware counter readings at certain intervals to capture statistics such as memory throughput, and cannot support more informative profiles like the page reference map [22] for capturing the spatial and temporal patterns of memory access. There are also explorations on GPU instrumentation [14, 77, 80, 82], such as NvBit [93] that manipulates proprietary machine code or HIPAnalyzer [21] that instruments compilers [44]. Yet these efforts still only focus on statistics such as memory access divergence among threads or reusable distance. To the best of our knowledge, there exist no tools for a fine-grained and general-purpose programmable interface of GPU profiling, just like eBPF [24] for Linux Kernel tracing.

To bridge this gap, we present NEUTRINO, a GPU assembly probing tool for *fine-grained*, *versatile*, and *programmable* GPU kernel runtime profiling. Inspired by eBPF [24], NEUTRINO's design aims to attach small snippets (probes) to GPU programs to expose runtime details of program executions. Specifically, NEUTRINO extracts, instruments, and reassembles GPU assemblies [4,30,60], rather than machine code [57] or compilers [44,45], allowing fine-granularity, versatility, and programmability in one framework:

■ **Fine-granularity:** NEUTRINO directly works on assemblies, the lowest software level, to offer the finest granularity at the instruction level that can be effectively mapped to particular hardware units such as tensor cores and memory I/Os.

■ **Versatility:** NEUTRINO supports GPU kernel profiling from both perspectives of *value*, *i.e.*, capturing runtime values such as memory addresses and of *time*, *i.e.*, recording event timestamps or even intra-kernel micro-benchmarking by differencing timestamps. By covering these two dimensions, NEUTRINO supports versatile profiling tasks from warp/block scheduling to memory access patterns.

■ **Programmability:** NEUTRINO extends the programmability of previous GPU instrumentation frameworks [14, 21, 77, 80, 82, 93] to cooperative probes by leveraging registers as the temporal storage between probes. By doing so, NEUTRINO enables more complicated and flexible profiling tasks by cooperating probes at different tracepoints and time.

NEUTRINO excels with its distinct probe design (§3) of three key components, namely snippet, tracepoint, and structured map, corresponding to the probe's target functionality, injection point, and output format, respectively. At runtime, NEUTRINO probes will be injected into tracepoints of the original program, and snippets use logically independent registers to place temporal results. This design, together with the GPU SIMT model, ensures the probes are virtual to the original program. Moreover, with eBPF-like structured maps, NEUTRINO probes can flexibly store metrics to one or more buffers via race-free saving without costly metadata.

We fully implement (§4) NEUTRINO for NVIDIA GPUs with the CUDA driver and AMD GPUs with the ROCm driver on Linux, consisting of three modules: the DSL compiler, the hook driver, and the probe engine. The DSL compiler compiles probes written in platform-independent Python Tracing DSL into raw low-level assembly probes wrapped in TOML [68]. The hook driver emulates symbolic links to the driver (shared library) to provide runtime support, including capturing GPU calls from the user, allocating probe maps, and saving results to the storage. The core probe engine validates, instruments, and reassembles the probed assembly code from wrapped low-level probes. Finally, NEUTRINO is encapsulated into an easy-to-use CLI similar to `bpftrace` [13] that can be run by `neutrino -p <probe> <user/program>`.

To better visualize the traces captured by NEUTRINO, we introduce a novel plot named Densified Memory Access Timeline (DMAT, §5), which improves the previous page reference map (strings) [11, 22] with physical time information and memory access density from parallelism. As illustrated in Fig. 1, DMAT expands new dimensions of observability compared with *hardware-dependent* profilers (Fig. 1B) and *kernel-exclusive* software profilers (Fig. 1C), enabling more comprehensive and intuitive GPU runtime analysis. For example, by comparing their DMAT profiles (Fig. 11), we can visually and quantitatively confirm that FlashAttn-v1 [20] improves memory efficiency and that FlashAttn-v2 [19] benefits from better pipelining.

We perform comprehensive evaluations (§6) to validate the trustworthiness, overhead, and applicability of NEUTRINO on profiling real GPU workloads. The results demonstrate that NEUTRINO ensures both execution correctness, *i.e.*, probing will not change the original execution flow, and profiling accuracy, *i.e.*, profiles are trustworthy. It also yields low overhead in both kernel slowdown (only 1.04x for most probes) and additional register usage (on average 4.11 more registers) Moreover, our extensive evaluations spotlight high system efficiency compared to other profilers and the capability to profile the whole model, even for LLMs. To showcase how NEUTRINO-profiled insights can help diagnose performance issues in GPU kernels, we conduct a case study (§7) on the impact of synchronization on GPU runtime behavior, which reveals an unnoticed tailing effect of shared GPU blocks on one compute unit and helps pinpoint different root causes of the performance bottlenecks.

NEUTRINO currently has limitations inherent to assembly-level probing, such as the inability to access unprogrammable hardware like caches. Nonetheless, as a fine-grained, versatile, and programmable framework for GPU kernel profiling, we envision NEUTRINO as a valuable tool for both research and industry communities. We have fully open-sourced NEUTRINO at https://github.com/open-neutrino/neutrino, and hope to foster a global community for its continuous development.

Table 1: **NEUTRINO vs. other GPU Profilers**. NEUTRINO is the only platform-independent runtime GPU kernel profiler and offers many unique features, *e.g.*, the DMAT, programmability via Python DSL or TOML, cooperative probes, eBPF-like maps, *etc*. PM stands for performance monitor, PC stands for program counter, and PRM stands for thread-local page reference map.

2 Background and Design Choice

GPU Profiling: Profiling builds roadmaps for performance engineering. Different from CPU profiling [12, 18] emphasizing sequential execution efficiency like branch prediction, GPU profiling prioritizes parallel execution scalability like compute unit utilization and throughput. Taking memory access as an example, CPU profiling cares about temporal locality like the working set [22], while GPU profiling focuses more on coalescing access among threads to utilize the bandwidth, opening unique challenges and research opportunities.

GPU Ecosystem: In modern computer systems, GPU has become a general-purpose computing unit (GPGPU) backed by a huge and complicated ecosystem covering numerous computing tasks, such as deep learning training [8, 27, 79] and inference [62, 94, 96]. However, from the perspective of compilation, the complicated ecosystem can roughly be divided into two branches: ❶ Ahead-of-Time (AOT) compiled operator libraries of hand-written codes [53] compiled by C++ compilers [6, 54], *e.g.*, ATen [8]; ❷ Just-in-Time (JIT) compiled domain-specific languages (DSLs) such as triton [91] compiled by LLVM [44] / MLIR [45]. As shown in Fig. 2, these two branches diverge only above the parallel assembly. Consequently, to build a general-purpose profiler, it has to be on or below the parallel assembly layer.

GPU Organization Hierarchy: As the *thread* and *memory* organization on GPU significantly varies from CPU for parallelism, we present some key differences between CPU and GPU below that are related to our design. First, parallelism on GPUs is hierarchical: 32 or 64[1] threads are grouped into a warp, the *scheduling unit* of GPU, *i.e.*, these threads share a single PC and must execute the same instruction at the same cycle. Warps are further grouped into blocks, the *concurrent execution unit*, *i.e.*, threads in the same block are executed in one physical compute unit (CU)[2] for communication and synchronization. Finally, blocks are grouped into grids mapped to the same GPU, which is the *management unit* for host side, and the measurement unit for kernel-exclusive profilers [87].

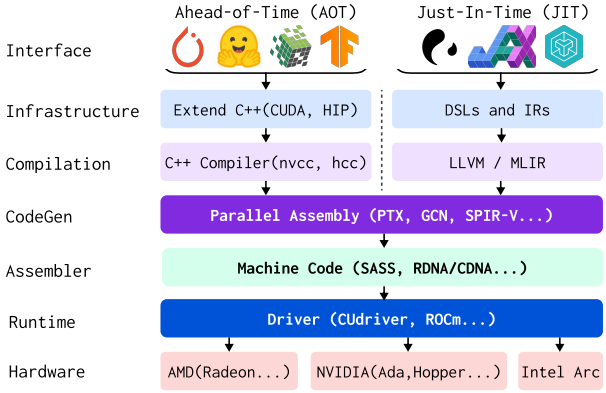

Figure 2: Complex GPU Ecosystem divided in two branches AOT (left) and JIT (right) unified at parallel assembly layer.

Similarly, the GPU memory is also hierarchically organized. First, each thread holds private registers (RMEM, at most 255 32-bit regs per thread on A100) as a primary resource. Blocks have CU-level shared memory (SMEM, at most 164KB on A100) as the temporary buffer for results and communications. Finally, there's GPU-level global memory (GMEM, 80GB on A100) for grid-level synchronization and kernel input/output.

GPU in the Operating System Paradigm: Positioned as an accelerator that communicates with the host OS via the driver, GPU programs are centralized with *kernel functions*, the entry for GPU computing whose content will be executed on the GPU while the rest of the program remains on the host CPU. Specifically, GPU kernel is considered *atomic* to the host OS, *i.e.*, the execution inside the kernel is managed by GPU hardware/firmware and is invisible and untouchable to the host OS, which prohibits observing GPU programs through mature OS technologies like ptrace or eBPF [24].

Apart from the host, profiling on GPU threads is also difficult as the systematic functionalities of GPU threads are

[1] NVIDIA GPUs group 32 threads into a warp, while AMD GPUs mostly group 64 threads into a wavefront (the different AMD's name of warp).

[2] Vendors may use different names for compute unit, *e.g.*, SM (Streaming Multiprocessor) for NVIDIA GPU or EU (Execution Unit) for Intel GPU.

highly limited. GPU programs are of direct execution without a management layer like the OS kernel. Particularly, there is no support for timer interrupts, a crucial feature for sampling-based profilers. Therefore, profiling techniques on traditional OSs, *e.g.*, sampling and scanning the stack frame, are not applicable to GPUs. Moreover, there are no commonly supported disk I/Os, making it troublesome to save results.

Assembly as a Probing Interface: The unique characteristics of GPU programming pose great challenges in building NEUTRINO, a fine-grained, versatile, and programmable GPU profiling tool that is *kernel-inclusive* and *hardware-independent*. The key question we need to answer is: at *which* layer should NEUTRINO be built and *how*? In this paper, among all the choices in Fig. 2, we choose the parallel assembly, such as PTX/GCNAsm [4, 60] designed to adapt to rapid changes in system and machine code, as the probing interface. Importantly, instead of static approaches, such as customizing profiling passes [21] via compilers or naive `asm()` in C, we employ a more capable but challenging approach, *attaching probe(s) at runtime*, which minimizes usage overhead (*e.g.*, recompiling) for changing or enabling/disabling probes. This design choice not only allows forward- and backward-compatibility, but also promises distinct advantages in various aspects:

❶ **Hardware-Oriented:** As a low-level interface, assemblies can capture hardware events that are important for performance analysis but hard to track with high-level languages. For example, there are only four related instructions in PTX for memory access, *i.e.*, `ld`, `st`, `cp.async`, and `tensormap`. In contrast, with objects and templates in CUDA C++, it is difficult to classify and capture all possible memory access.

❷ **Special Registers / Instructions:** Special registers of parallel assemblies contain useful runtime information for profiling. For instance, `hwreg` of GCNAsm tells which compute unit the thread is scheduled on, while PTX's special registers `%clock` (in CU-local clock cycles) and `%globaltimer` (in GPU-local nanoseconds) are helpful to measure the timestamp and can be used as instruction-level timers as shown in Fig. 3.

❸ **Compatibility:** As shown in Fig. 2, parallel assemblies are the *highest common layers* of the AOT and JIT compilations. For example, PTX is the common output of CUDA C++ compiled by gcc-based `nvcc` [54] and DSLs, *e.g.*, Triton backed by LLVM [86]. Thus, probing on assemblies can be compatible with most infrastructures, while compiler-based approaches are limited to the specific compiler or IR(s).

❹ **Coverage:** Compiler-based approaches require source code, assuming that users have located the poor-performing GPU kernel, which is uncommon as most programs have many kernels. Instead, runtime approaches can cover all user codes, capable of scanning poor-performing kernels.

The design choice of assembly-layer runtime probing also poses unique challenges, such as securing probes without compiler support, locating GPU code in the runtime, obtaining high-level contexts, *etc*. We overcome these challenges in NEUTRINO and enable it as a powerful GPU profiler.

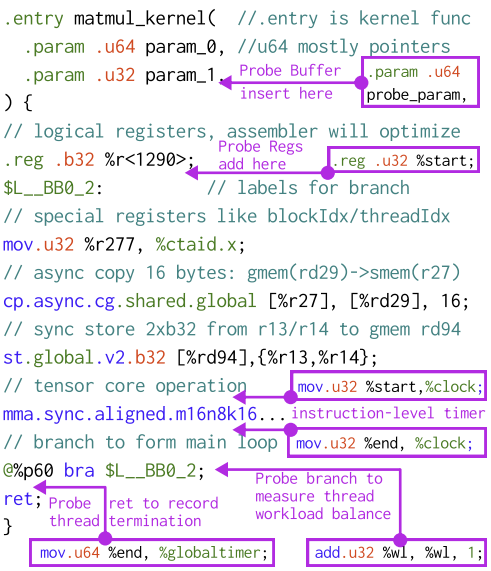

Figure 3: Parallel assembly example (PTX) with possible probing positions and corresponding functionalities.

3 NEUTRINO Design

NEUTRINO aims to formulate a simple yet powerful probe design like eBPF probe [24] to profile GPU kernels with the finest granularity to capture instructions, versatility to cover time- and value-profiling, and programmability for users to customize probe(s). Due to the massive parallelism of GPUs, NEUTRINO targets lightweight probes that only operate at tracepoints with the least disturbance to the remaining.

3.1 Programmable Probing Interface

As shown in Fig. 4, NEUTRINO features three key elements in its probe design: snippet, tracepoint, and structured map:

Snippet: Same as the probing target, NEUTRINO's snippet is assemblies, with some helpers such as `SAVE` for logging results and `OUT/IN1/IN2` for reading registers (instruction operands) for value profiling. Developers can also use other assembly features, especially `S_MEMTIME` for time profiling.

Tracepoint: NEUTRINO formulates probe tracepoints primarily at the finest instruction level, which assures both temporal accuracy and hardware granularity such as `wmma/mma` for tensor core operation. By grouping instructions, NEUTRINO's tracepoints can be extended to larger scales such as device function calls and thread start/end.

Map: Similar to eBPF [48], NEUTRINO's map explicitly structures the saving format to address the problem of persistence, a troublesome issue on GPU due to race conditions from parallelism and huge metadata from hierarchical organization. NEUTRINO mainly defines maps at two levels (§3.3): ❶ thread-level: *every thread* saves, for value profiling; ❷ warp-level: only *warp leader thread* saves, for time profiling.

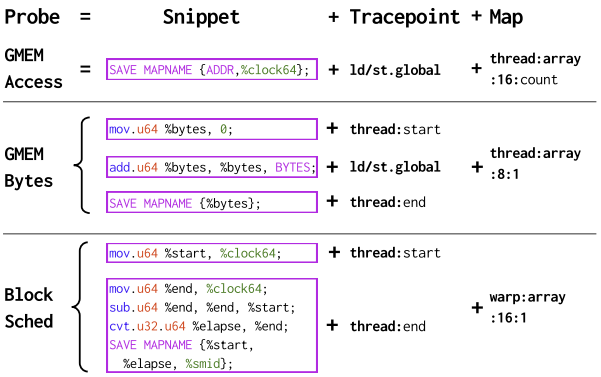

Figure 4: NEUTRINO programmable probing interface. Probes consist of snippet, tracepoint and structured map. Snippet can use helpers such as SAVE for storing values to NEUTRINO Map (§3.3). Multiple probes at different tracepoints can compose more comprehensive tasks like `block_sched`.

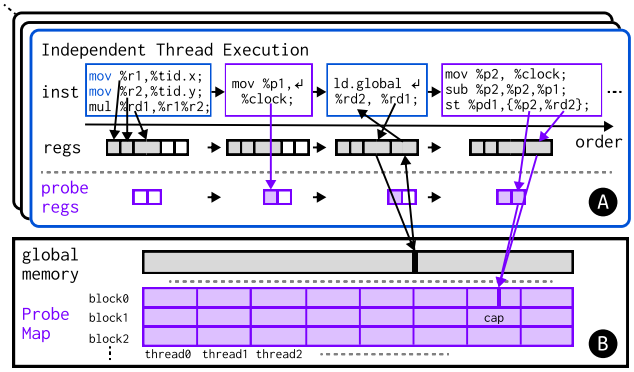

Figure 5: NEUTRINO probe execution model. ❶ Probes are executed virtually under time and resource (register and global memory) separation; ❷ NEUTRINO's Probe Map for race-free and metadata-efficient persistence: Each thread finds its segment of map via its `threadIdx` and `blockIdx`.

Beyond the three components for formulating customizable probes, the key design of NEUTRINO's programmability is *cooperativeness*: ❶ NEUTRINO probes of the same thread can cooperate by leveraging registers as temporal storage for advanced profiling tasks while maintaining efficiency as register usage is parallel in GPU cores. ❷ NEUTRINO probes can also cooperate with maps in GMEM, *i.e.*, different probes can contribute to and cooperate through the same map.

3.2 Virtualized Probe Execution Model

Since the GPU program is *static* to the OS, *i.e.*, all code (assembly) is loaded and known before execution, we choose to directly place probes in the original assembly without protection, *e.g.*, stack, to achieve cooperativeness. We identify that by doing so, NEUTRINO probes are still executed *virtually* from the original program. As shown in Fig. 5A, such virtualization is achieved via time and resource separation:

Time Separation: The time virtualization of NEUTRINO originates from the SIMT execution model of GPGPU, where parallelism happens among threads while execution within a thread is generally sequential with one instruction at a cycle. Thus, as probes are directly inserted into assemblies, their time separation from the original program will be guaranteed.

Resource Separation: Similar to CPU, GPU threads also have *thread-private* registers as their primary resources, which contain intermediate results from ALU, addresses of shared or global memories, *etc*. NEUTRINO virtualizes the probe registers by separating an independent register group, as well as other resources like GMEM. Thus, NEUTRINO probes can avoid affecting the original program's resources, and the execution flow. It is worth noting that NEUTRINO's probe register group is declared logically at the assembly level rather than physically. Therefore, NEUTRINO may not necessarily introduce extra physical register usage (Tab. 3) because the declared logical registers will be integrated into physical registers by the assembler in register allocation, with independence between probes and the original program preserved by dependency tracking algorithms [39, 72].

3.3 Structured Map for Persistence

Persistence is a critical challenge for GPU profiling. Although thread executions are parallel and independent, the underlying memory system is shared, leading to race conditions among concurrent savings. Thus, previous solutions [80, 93] widely use *atomics* for separating persistence spaces, which can become inefficient under massive parallelism. Moreover, the GPU hierarchical organization creates rich *metadata* such as `threadIdx` and `blockIdx` (24 bytes), which is informative for analysis but can be storage-hungry [93].

Inspired by the design of lock-free per-cpu eBPF maps [48] and event buffers of HIPAnalyzer [21], we explicitly structure NEUTRINO map to an `ndarray` layout, as shown in Fig. 5B, with the shape determined by launch configurations (`blockDim`, `gridDim`) and the map definitions (`level`, `type`, `size`, `cap`). This enables race-free saving as each thread has an independent segment and reduces storage pressure as most metadata can be inferred rather than directly saved. NEUTRINO mainly formulates maps at two levels:

Thread-Level: The thread-level map is mainly designed for *value profiling* where every thread independently saves data. Its layout is in the form of `[#Grid, #Block, cap]` and each element is of `size`. `#Grid` and `#Block` can be inferred by launch config `gridDim` and `blockDim`, respectively. `cap` specifies the maximum number of savings per thread, which can be set to a suitable value, or measured dynamically by running a counter probe[3] in the runtime.

[3] A probe of `count+=1` attached at tracepoints, and after execution, the value of `count` can be regarded as `cap` (only applies to *pure* kernel functions).

Warp-Level: The warp-level map simplifies the thread-level map for time profiling with layout `[#Grid, #Warp, cap]`. Because threads within the same warp are scheduled together for the same instruction, recording event timestamp only needs one thread inside the warp other than all, which can significantly reduce the memory and storage pressure.

Based on these two levels, NEUTRINO can extend different types of maps, such as the simplest `array`, or advanced `ring` (ring buffer) and `hash` to support versatile user needs.

3.4 Verification for Security

Verification [28, 84] has been proven vital for programmable probes [24] as unsafe probes can break the execution flow of the original program and invalidate the profiling. The verifier can also help guide developers in writing correct probes. In NEUTRINO, we identify and prevent three key security issues:

Overwrite Original Registers: As discussed in §3.2, GPU threads use registers as primary resources. Thus, modifications of registers used by the original program are unsafe. For example, modifying a register holding address to global memory could lead to illegal memory access (Fig. 6A). Thus, NEUTRINO requires probes to use independent register groups, and prohibit probes that modify original registers.

Program Misorder: Although the SIMT program model guarantees that instructions within the thread are executed linearly, there are flow control instructions, such as `S_BRANCH` (GCNAsm) or `bra` (PTX), that may change the execution order, which are unsafe for probes as they may break the original execution order (Fig. 6B). Thus, NEUTRINO prohibits probes from instructions that change the execution flow.

Shared Memory: As an important factor for acceleration, the shared memory has been highly optimized for storage [17, 91] and access efficiency [89]. Thus, additional shared memory usage from the probes may greatly affect or fail the execution if the original usage is already at the hardware limit. Thus, NEUTRINO prohibits probes from using shared memory.

4 NEUTRINO Implementation

We implement NEUTRINO in Linux for NVIDIA GPU with CUDA driver and AMD GPU with ROCm/HIP runtime. Our implementation consists of three major components: ❶ a hook driver (§4.1, ≈2,500 lines of C code) to provide runtime support for assembly tracking, code caching, *etc*; ❷ a probe engine (§4.2, ≈2,000 lines of Python code) to instrument parallel assemblies; ❸ a DSL compiler (§4.3, ≈1,000 lines of Python code) to translate probes in platform-agnostic Python Tracing DSL into platform-specific assemblies (PTX for CUDA and GCNAsm for ROCm/HIP). We implement the core probing engine and the DSL compiler in Python to make the infrastructure more approachable and extensible for developers. Besides, we also provide utilities (§4.4), such as ecosystem integrations, analysis code generations, *etc*.

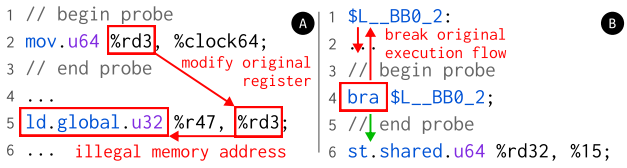

Figure 6: NEUTRINO verification against two unsafe operations: ❶ overwrite original regs; ❷ change execution flow.

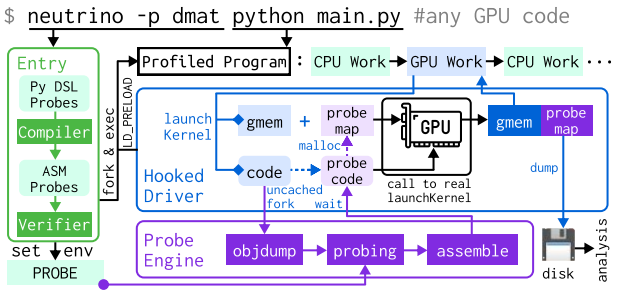

Figure 7: NEUTRINO workflow. Entry loads and JIT compiles (§4.3) probes, and injects hook driver. Hook driver (§4.1) captures GPU workloads, invokes probe engine (§4.2), allocates probe buffers, launches probed kernel, and dumps results.

Finally, we wrap these modules as a command-line interface similar to `bpftrace` [13] and `valgrind` [74]. As shown in Fig. 7, when a user invokes `neutrino` with the probe `dmat` via `-p/--probe` argument, the entry will load, compile, and verify the probe (`.py`) into platform-specific assembly (`.asm`) wrapped in TOML [68]. Then the entry will set environment variables, such as `NEUTRINO_PROBE` for probe contents and the special `LD_PRELOAD` to inject the hook driver, and `fork` a child process to launch the workload. Throughout the execution, the hook driver will continuously capture the GPU workload, particularly the GPU kernels launched. For each uncached GPU kernel, the hook driver will invoke the probe engine, which objdump, probe, and reassemble the kernel. After loading back the probed kernel, the hook driver allocates probe buffers on CPU and GPU, and launches the probed kernel. Upon completion, the hook driver will dump probe buffers containing metrics and give back control to user programs.

4.1 Hook Driver

Though drivers in OS are mostly referred to kernel extensions exposed via `read/write/ioctl` syscall, such as `nvidia.ko`, most vendors also maintain higher-level user-space drivers as shared libraries such as `libcuda.so` or `libamdhip.so` in Linux. These driver shared libraries are often highly complex and closed-source. However, given that symbols in ELF are resolved via their signatures, we can build a clever hook driver by defining all functions with matching signatures and using `dlfcn` internally to locate and call the real function from the actual driver (More details in Appendix B). Compared with

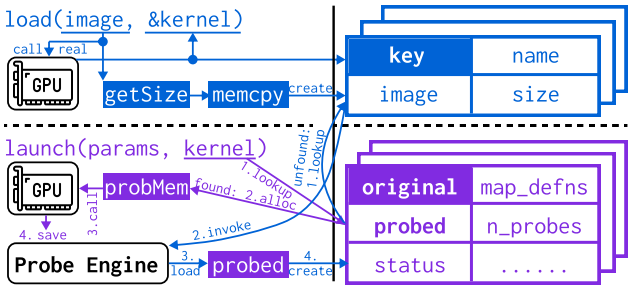

Figure 8: NEUTRINO hook driver infrastructure. Hook driver catches `load` and `launch` API for loading images and launching kernels on GPU, respectively. Hook driver maintains two hash-based [33] storage for image (upper) to map kernel to binary image, and kernel (lower) to avoid repeated probing.

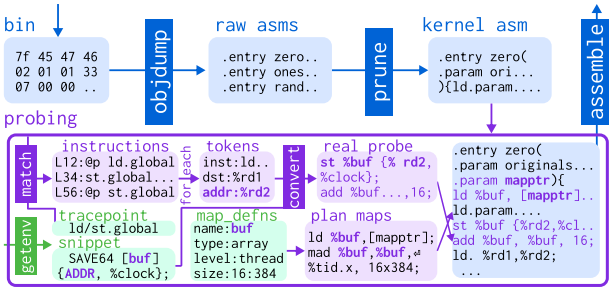

Figure 9: NEUTRINO probe engine workflow. Probe engine objdumps and prunes the binary, and finally reassembles it. In probing, it uses *map defns* to plan probe buffers and *tracepoints* to match instructions. It also fills helpers in *snippets* with tokens before injecting them into assemblies.

other approaches like eBPF `uprobe` [24], our hook driver is safer and more flexible as all code is executed in the user mode, supporting `fork/wait` that are important for interactions with the probe engine. We leverage the hook driver to provide the following supports:

Code Tracking: Compared with CPU code implicitly loaded by the OS, GPU code, in the ELF [25] or FatBinary [56] format, requires an explicit `load` via `cuModuleLoad`. Other functions, such as `cuModuleGetFunction` may also be applied to locate the specific kernel from the module. We hook these APIs (Fig. 8) to capture all images loaded, kernels extracted, and the mapping from kernels to code. Each image is `memcpy`ed into the *image storage* with size from its header to avoid being `free`d by resource management of user programs.

Runtime Probing: As the execution is non-local, launching GPU kernel functions is not simply adding stack frames but requiring an explicit driver call to `cuLaunchKernel` or `hipModuleLaunchKernel`. We hook these APIs to provide runtime support: ❶ It searches for the probed kernel in the *kernel storage* via the original kernel (a pointer); ❷ It `allocates` probe buffer(s) according to the metadata; ❸ It `launches` the probed kernel and `synchronizes` for the finish, *i.e.*, probe buffers on GPU are of metric readings; ❹ It `memcpy`s probe buffer back to CPU, then `fwrites` and `frees` probe buffers.

More importantly, when the probed kernel is not found in the *kernel storage*, the hook driver is also responsible for interacting with the probe engine: ❶ It searches for the binary containing the kernel in the *image storage*. ❷ It `fwrites` the binary in the directory and `forks` a subprocess to invoke the probe engine. ❸ After `waiting`, it looks up the directory and `loads` back the probed kernel and metadata, e.g., number of probes. ❹ Finally, the probed kernel and metadata will be added to *kernel storage*. Failed kernels will also be added to *kernel storage* with `status=false` to avoid repeating.

Other functions are unhooked and we auto-generate them by parsing the header `cuda.h/hip_runtime.h` and the symbol table of the shared library, such as `libcuda.so`.

4.2 Probe Engine

As shown in Fig. 9, NEUTRINO probe engine first `objdumps` the dumped GPU binary to extract parallel assemblies in text format. Then it will use the kernel name to match and prune the *many-kernel* raw assemblies into a *single-kernel* assembly while keeping global definitions and device functions.

Next, NEUTRINO will process and add the probes read from environmental variables, involving the following steps: ❶ It plans probe map(s) that directs each warp/thread to its segment(s) of map(s) according to the *map definition* (§3.3, `level/type/size/cap`) and thread indexes, *e.g.*, `threadIdx`, as detailed in Appendix C. ❷ It coarsely parses the kernel assembly into parameters, register declarations, and instructions. Then it matches the *tracepoints* to specific instruction(s). ❸ It thoroughly parses each matched line (e.g., `ld.global.u64 %rd1, [%rd2];//%rd1=*%rd2`) into tokens, such as opcode (`ld.global.u64`) and operands `%rd1, %rd2`. Then it fills the helpers in *snippets*, such as `ADDR`, to the real register `%rd2`. Finally, it places snippets before/after matched instructions, as well as the map addresses at the end of kernel parameters, and the assembly of map planning at the kernel beginning.

After probing, it converts the probed assemblies into machine code via assemblers such as `ptxas` [61]. The probe engine will also save kernel metadata useful for the hook driver, such as the probes, maps, callbacks, *etc*.

4.3 Probe DSL and Compiler

A practical issue of the probe engine is that probes are of assemblies, a low-level and hardware-dependent language. Direct assembly programming may be less friendly for general developers. Thus, to enhance NEUTRINO's hardware independence and usability, we propose a minimalistic Python domain-specific language (DSL) as the high-level interface for NEUTRINO probes, similar to bpftrace [13] for eBPF [24]. Note that DSL is optional for NEUTRINO, experienced developers can still handcraft assemblies for advanced usages.

As shown in Fig. 10, the NEUTRINO DSL closely follows the Python syntax, allowing users to declare probes with the `@probe` decorator over functions with tracepoints specified as decorator arguments and the snippet as the function body. Similarly, maps can be declared with `@Map` decorator with the structure defined as class members. Moreover, contexted probe registers shared across probes can be defined via value assignment syntax with types annotated in the global scope. NEUTRINO probes are not allowed to use other functions like `open`. Instead, we provide helper operands like `nl.addr` for reading registers and helper functions like `nl.clock()` and `Map.save()` for getting device-side clocks and saving results.

This DSL will be *just-in-time* compiled into the platform-specific assembly-based probes in two steps, with a compilation example of Fig. 10 in Appendix D: ❶ It uses Python's `ast` module to parse and transform the Tracing DSL to an intermediate representation (IR) similar to the eBPF ISA [90]. ❷ The IR will be translated into platform-specific assemblies, *i.e.*, PTX Assembly and GCNAsm, and helper operands will be preserved for the probe engine. We design the IR to be eBPF-like, potentially enabling reuse of mature eBPF toolchains, such as the reputable eBPF verifier [28].

```python
from neutrino import probe, Map
import neutrino.language as nl
CALLBACK = "block_sched.py" # for trace analysis
# declare maps for persistence
@Map(level="warp", type="array", size=16, cap=1)
class block_sched:
    start:   nl.u64
    elapsed: nl.u32
    cuid:    nl.u32
# declare probe registers shared across probes
start:   nl.u64 = 0 # starting clock
elapsed: nl.u64 = 0 # elapsed time, initialized to 0
# define probes with decorator
@probe(pos="kernel", level="warp", before=True)
def thread_start():
    start = nl.clock()
@probe(pos="kernel", level="warp")
def thread_end():
    elapsed = nl.clock() - start
    block_sched.save(start, elapsed, nl.cuid())
```

Figure 10: NEUTRINO DSL probe example. Each *warp* has probe register, *e.g.*, `start`, and saves a `block_sched`.

4.4 Utilities

Ecosystem Integration: Solely hooking onto the driver or probing at the assembly would lack high-level info like tensor shapes that are useful for analysis. Thus, we also implement utilities for ecosystem integrations like PyTorch [8] by Python `sys.settrace` to expose high-level tensor information.

Benchmarking Mode: To evaluate system overhead and provide time alignment for heavy probes, NEUTRINO provides a benchmark mode that launches both the probed kernel and the pruned kernel (stripped of probes and assembled with identical configurations) with CUDA/HIP event timers to benchmark the additional execution latency caused by probes.

Analysis Codegen and Callback: To facilitate analysis, NEUTRINO supports generating tracing parsing code in Python based on the map definition (such as Fig. 10) to facilitate users extracting information from traces, with an example in Appendix E. Moreover, NEUTRINO supports adding callbacks (such as Line 3 of Fig. 10) for automated posterior analysis.

Source Code Annotation: To give more precise control, we implement a source code annotation tool in NVTX-like API [59]. The probe engine can look up the lineinfo (special comments, e.g., `".file 1 example.py"` and `".loc 1 33 45"`) and cross-reference with the source code (line 33 of 1st file, *example.py*) to include or exclude the instruction.

4.5 Extending NEUTRINO to Other Platforms

Though the current implementation only supports NVIDIA and AMD GPUs, NEUTRINO can be extended to other platforms, such as Intel oneAPI [26]. NEUTRINO's hardware independence originates from its design on the two common components across platforms: parallel assembly to accommodate rapid architecture-level evolution, and the driver to control the execution from the host OS.

In practice, to extend NEUTRINO to other platforms, one needs to implement the hook driver, probe engine, and *(optional)* DSL compiler backend. For the hook driver, as most functionalities are standardized to platform-agnostic modules, we expect most changes to be around API renaming and debugging, *e.g.*, `cuLoadModule` to `hipLoadModule` for ROCm/HIP support. Regarding probe engine, a new parser and matcher for the different assembly syntax (*e.g.*, GCNAsm [4]) shall be needed, but the overall infrastructure (Fig. 9) remains unchanged. The DSL compiler needs a backend to translate our eBPF-like IR into assembly. We expect this would be similar to how Triton [91] supports new hardware with extended codegen (like our probe engine and DSL compiler) and launcher (like our hook driver).

4.6 Usage: Putting It All Together

The above components shape a user-friendly and easy-to-use profiling tool of NEUTRINO. Compatible with many frameworks such as PyTorch [8], Triton [91] and JAX [27], the usage of NEUTRINO is as simple as `bpftrace`, with many built-in tools such as `block_sched` (Fig. 10) to check the block scheduling cost of kernels. NEUTRINO's user-friendliness is best demonstrated through a simple example, where we try to profile the following line of PyTorch code and gain insights:

```
torch.zeros((4096,4096),torch.float16,device="cuda")
```

To do so, a user just needs to run the NEUTRINO CLI with the `-probe/-p` option:

```
$ neutrino -p block_sched python -c "torch.zeros(...
```

Then, when finished, traces will be placed in a directory with a print-out message from the analysis callback as follows:

```
vectorized_elementwise: # kernel name, truncated
No.block:32768 Exec:680869 Sched:142674 (cycle/SM)
```

Here the `vectorized_elementwise` kernel [88], widely used by unary tensor operations, is used for initializing allocated memory with zeros. We measure the scheduling time by simulating the block dispatching to CUs. For every recorded block on the CU, if its `start` clock is greater than any existing block's `end` clock (`start + elapsed`), then a block replacement happens with scheduling cycles estimated by *the next* `start` - *the previous* `end` and execution cycles measured by the previous `elapsed` (Complete code in Appendix E).

The profiling results reveal a surprising $\sim$ 20% time spent on scheduling blocks to physical SMs as the kernel launches a huge number (32,768) of blocks and the execution time of each block is relatively small. Based on the insights, one can optimize the performance by reducing the number of blocks launched by the kernel. To do so, we can use the CUDA `memset` or instruct LLMs to write a persistent kernel (examples in Appendix F) that fixes the number of blocks to the hardware limit. To apply customized initialization, we replace `torch.zeros` with `torch.empty` that allocates memory without initialization, and add a line of `cuMemset` or `zero_persistent`. This modification offers $\sim$ 28% speedup:

```
# Original kernel time: 34,493 ns
torch.zeros((4096,4096),torch.float16,device="cuda")
# Updated memset time: 24,630 ns
t=torch.empty((4096,4096),torch.float16,device="cuda")
driver.cuMemsetD16(t.data_ptr(), 0, 4096*4096)
# Updated zero_persistent kernel: 24,891 ns
zero_persistent(t) # code in Appendix F
```

The above one-line debugging example demonstrates the capability and simplicity of NEUTRINO to pinpoint performance bottlenecks within the kernel. Note that NEUTRINO also supports more advanced usage beyond the above example, including profiling the whole model with other interesting tools:

```
$ neutrino -p tensorop_count # number of tensor op
$ neutrino -p gmem_bytes # number of GEMM bytes used
$ neutrino -p dmat # draw DMAT Plot
$ neutrino -p <to/be/contributed/by/you>
```

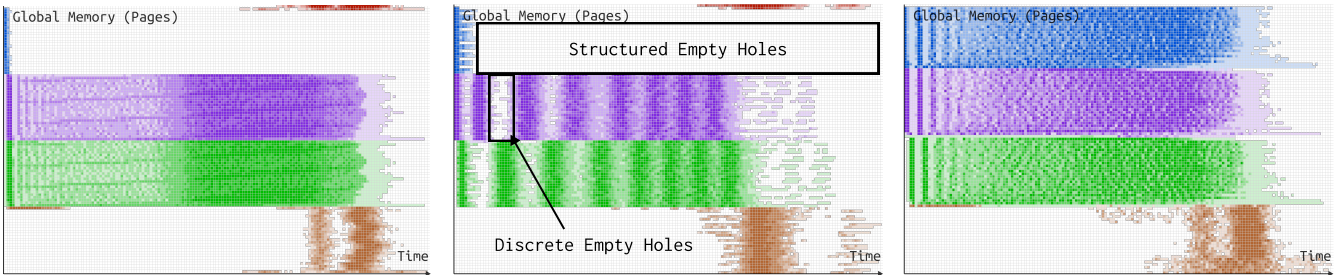
5 NEUTRINO Visualization

In this section, we introduce the Densified Memory Access Timeline (DMAT) plot, an insightful visualization of GPU runtime workload behavior, as presented in Fig. 1 and Fig. 11. DMAT plot is inspired by the *page reference map* [11, 22], which shows the virtual time as the x-axis and page accesses as the y-axis, where a point represents an access to the page at the time. As a reference standard, page reference maps have proven to be a useful tool for research on virtual memory management [11] and replacement algorithms [10].

To accommodate the massive parallelism of GPU, DMAT extends the original page reference map in two perspectives:
Physical Time: Page reference maps [11, 22] and general memory tracers [66, 74] commonly use a *thread-local* auto-incremental index as the virtual time denoting the access order. However, we find that the virtual time is insufficient under parallelism where each thread only holds part of the entire page reference map. Because starting times and execution paces of threads diverge, there will be unavoidable misalignment among the virtual time when aggregating page reference maps from individual threads to form the complete trace.

Hence, for DMAT we use the *device-side* physical time to provide reliable aggregation. Specifically, we provide two types of DMAT: ❶ Normalized to the starting clock (Fig. 1, Fig. 11) of unsynchronized CU-level clocks, suitable for analyzing algorithm behavior; ❷ Synchronized to a less accurate (MHz) GPU-local timer (Fig. 15), representing actual memory access for hardware/cache analysis (Appendix G).
Page Access Density: Previous page reference maps are in 2D, where a point denotes an access at the time to the page. However, for highly parallelized environments, there are likely many concurrent accesses to the same page at the same time from multiple threads. We record such parallel access intensity as *density* and mark it as color depth to distinguish it from the temporal frequency in traditional page reference maps [11, 22], highlighting the new informative dimension spanned for analyzing the effect of parallelism.

The proposed DMAT not only facilitates traditional memory analysis on GPU (*e.g.*, data races, access anomalies), but also features unique benefits for GPU runtime analysis:
■ **Color Depth:** The color depth in DMAT denotes the density of parallelization. When aligned to the GPU-local timer, it reflects the real memory load, with shallow regions pinpointing uncoalesced access among threads and excessive intensity indicating potential memory I/O contention. When aligned with the starting clock, color depth reflects the divergence among threads where pale patterns usually indicate divergent thread executions or imbalanced workloads that may waste the computing power.
■ **Empty Holes:** Empty holes in DMAT demonstrate that pages remain unused for a significant amount of time, which includes two cases (Fig. 11b): ❶ Discrete empty holes usually reflect computing within CUs. The duration reflects the operational intensity [95] per main loop, where a too long empty holes might be inefficient in pipelining [20]; ❷ Structured empty holes usually reflect algorithm improvements, while extra-large structural empty holes may reflect time fragmentation and optimization opportunities.



(a) Flash-Attn v2 (Triton) [19] with shared block (b) Flash-Attention-v1 [20] (c) Memory-Efficient-Attention [69]

Figure 11: NEUTRINO DMAT plot (captured on RTX3080, Appendix A) for different attention algorithms, which exhibit distinct memory access patterns. (a) differs from Fig. 1 with exclusive SM. By comparing the DMAT of different algorithms, we can visually identify the improvement of (b) FlashAttn-v1 [20] *w.r.t.* (c) Memory Efficient Attention [69] comes from I/O efficiency, while the gain of (a) FlashAttn-v2 (Fig. 1) comes from better pipelining, both consistent with their respective claims.

6 NEUTRINO Evaluation

We conduct evaluations to answer the following questions on the reliability and usability of NEUTRINO: Are NEUTRINO's results trustworthy (§6.1)? How much performance and resource overhead does NEUTRINO introduce (§6.2)? How effective is NEUTRINO in profiling real applications (§6.3)?

Our evaluation is performed on two platforms, NVIDIA A100 80GB GPU and NVIDIA RTX4090 24GB GPU. NEUTRINO is compiled with gcc-11.4.0. Other software used includes Python 3.11.4, CUDA 12.6, PyTorch 2.5.0, Triton 3.1.0, CUTLASS 3.5.0, and Ubuntu 22.04.

6.1 Correctness Validation

We identify and verify two types of correctness: ❶ **Execution Correctness** that ensures the probing will not alter the original execution flow; ❷ **Profiling Accuracy** that ensures the metric reading from NEUTRINO is reasonable and correct.

Execution Correctness: We validate the execution correctness by comparing output differences between the probed and original kernels, as any difference in execution flow will likely change the output or corrupt the system. To do so, we run each test twice, one with NEUTRINO probes and one without probes (*i.e.*, the original execution) under identical input and configurations. The results show no significant differences between the probed and original outputs.

Profiling Accuracy: We verify the profiling accuracy from two perspectives. For metrics overlapped with other profilers like Nsight Compute [58], (`block_sched`, `gmem_bytes`, and `tensorop_count`), we run the same program separately with NEUTRINO and Nsight Compute, and compare their metric readings. The captured results give consistent metric readings.

Regarding new metrics beyond the scope of existing profilers, particularly DMAT (§5), we validate their correctness by profiling carefully designed "micro-benchmarking" kernels having expected theoretical metric values, and comparing with the actual metric readings. We design micro-benchmarking kernels using `ld/st` instructions with L1 cache disabled, for memory access, and spin-based sleeping to controllably simulate computation inside CUs. We implement several memory access patterns: Linear, Strided, Gather, Scatter, and Random. We emulate these access patterns on the CPU, with addresses, normalized to base addresses, derived from the access pattern's code, and intervals (in cycles) between consecutive accesses estimated by the sleeping time and memory latency.

We compare theoretical estimations and actual readings to evaluate: ❶ Address Consistency: Calculated as Hamming distance between emulated and profiled address sequences; ❷ Clock Errors: Measured as the differences of intervals between consecutive accesses within threads; ❸ DMAT Similarity: Computed as RMSE between DMAT (treated as matrices). Tab. 2 demonstrates that DMAT can correctly capture memory addresses (with Hamming distances of zeros) and achieve *less than 200* cycles time resolution (< 7% of the loop time). Accumulated clock errors will lead to a misaligned timeline for DMAT, resulting in high RMSE errors, which are marginal for coalesced accesses (*e.g.*, `stride`), yet become considerable for uncoalesced accesses, *e.g.*, $\sim$ 60% error for `linear`. It is because uncoalesced accesses have a lower average intensity ($\sim$ 16) as normalization bases and experience more variable memory latencies ($\sim$ 190 cycles clock errors). As detailed in Appendix H, large DMAT errors are mainly due to the static emulation not considering memory system dynamics, *e.g.*, cache, rather than profiling, which we reserve for future work.

Table 2: DMAT micro-benchmark *w.r.t.* theoretical metrics.

Kernel	Address Consistency Hamming Distance	Clock Errors Mean (Normalized)	DMAT Similarity RMSE (Normalized)
`linear`	0	190.1 (6.30%)	9.54 (59.62%)
`stride`	0	96.20 (3.42%)	277.4 (5.21%)
`gather`	0	58.11 (2.70%)	33.80 (0.44%)
`broadcast`	0	65.19 (3.01%)	192.5 (2.64%)
`random`	0	179.8 (5.98%)	221.7 (4.86%)

Table 3: Kernel slowdown and additional physical register usage of NEUTRINO: Kernel slowdown is normalized to original kernel latency and additional register usages are averaged based on assembler [61] debug information. NEUTRINO might lead to kernel speedup on lightweight probes, *e.g.,* 0.9868x speedup of `gmem_bytes` on `GEMM`, and we discuss this abnormal effect in §8 and Appendix K. `dmat` probe leads to different degrees of slowdown on different kernels, as discussed in depth in Appendix I.

		`block_sched` `warp:array:16:1`		`gmem_bytes` `thread:array:8:1`		`tensorop_count` `thread:array:8:1`		`mem_trace` `thread:array:16:count`	
		Kernel Slowdown	Additional Registers	Kernel Slowdown	Additional Registers	Kernel Slowdown	Additional Registers	Kernel Slowdown	Additional Registers
CUTLASS	Standard GEMM	0.9997x	+4	0.9868x	+4	0.9873x	+4	8.8933x	+1
	Stream-K GEMM	1.0050x	+12	1.0022x	+12	1.0034x	+12	10.3709x	+6
	Conv2D	1.0327x	+0	1.0934x	+0	1.1061x	+0	2.7463x	+28 (spill)
Triton	Group-GEMM	0.9804x	+8 (spill)	0.9798x	+8 (spill)	0.9796x	+8 (spill)	8.3589x	+516 (spill)
	Flash-Attnv2	0.9999x	+2	1.0257x	+2	1.0256x	+2	2.9392x	+1.50
PyTorch	Batch/LayerNorm	1.0251x	+4.58	1.0951x	+3.54	1.0981x	+3.25	5.4392x	+4.67
	SoftMax	1.0004x	+4.5	1.0006x	+3.5	1.0006x	+3.5	13.1630x	+8
	Sum	1.0653x	+4	1.0389x	+2	1.0390x	+2.67	4.4597x	+8.67
	Max/AvgPool	1.0406x	+3	1.3882x	+2	1.3875x	+2	7.2559x	+4
	Embedding	1.0068x	+6	1.0009x	+4	0.9995x	+2	9.1155x	+6
	Gather	0.9596x	+5	0.9957x	+2	0.9782x	+2	5.5659x	+6

6.2 Profiling Overhead

We evaluate two types of profiling overhead: ❶ **Performance Overhead**: the kernel slowdown due to probes can compromise the accuracy of time-related profiling; ❷ **Resource Overhead**: additional registers from probes, which may affect block dispatching or even lead to register spilling.

Performance Overhead: We formulate the kernel overhead as the slowdown from probe instructions normalized to the execution time of the original kernels. For better accuracy, we evaluate the kernel execution time via device event timers (§4.4). Results presented in each left column of Tab. 3 demonstrate the efficiency of NEUTRINO with controllable latency (1.04x on average) on lightweight probes *i.e.*, `block_sched`, `gmem_bytes` and `tensorop_count`, while heavy probes such as `dmat` introduce considerable slowdown (7.12x on average). And our analysis (Appendix I) shows that DMAT's frequent memory I/O is the cause of the slowdown, and degrees of slowdown depend on the percentage of memory accesses and kernel execution time. Moreover, we identify that lightweight probes could *abnormally* accelerate the program, and our analysis (Appendix K) finds that it is because probe instructions can lead assemblers to better instruction flow (+5.88% IPC) and thus better performance (up to 0.94x faster).

Resource Overhead: We formulate the resource overhead as the difference in the number of *physical* registers used by the probed kernels compared to the original kernels. Results shown in each right column of Tab. 3 demonstrates the low overhead for NEUTRINO probes with 3.78 more registers used in lightweight probes and 5.09 more registers used in the heavy `dmat` probe. The phenomenon that each probe defines the same number of *logical* registers but uses varying and fewer *physical* registers also confirms the effectiveness of our design of using logical registers rather than physical ones, allowing potential optimization by the assembler.

6.3 Extensive Study

We further conduct two extensive studies evaluating NEUTRINO's applicability in evaluating real-world workloads:

GMEM Usage in Model Profiling: In practice, developers need to profile the whole model, rather than a single kernel, to locate potential performance issues. GMEM usage becomes a constraint here as most GMEM is occupied by model parameters. Thus, we conduct an intensive test on NEUTRINO's maximum GMEM usage in end-to-end profiling on the whole model inference pass. We select ResNet [34], Stable-Diffusion [71], Mamba-1.7B [31], and Llama3-1/3/8B [29].

The result shown in Fig. 12 demonstrates the efficiency of NEUTRINO's memory usage, with lightweight probes being at least an order of magnitude smaller of the original memory footprint, especially for transformers like Llama. GMEM usage of the heavy `dmat` is mostly remains within the original memory usage, even under a large batch size (256). Moreover, by comparing the results of Llama-1B/3B/8B, we observe that the proportion of NEUTRINO's GMEM usage relative to the original usage decreases surprisingly as the model scales. This finding demonstrates that the growth of NEUTRINO's memory requirements is slower than model size scaling and highlights the usability of NEUTRINO in profiling larger models.

Profiler Exposed Latency: In addition to *kernel slowdown*, profilers also expose other noticeable latencies, including *Prologue* for allocating probe maps and calling the probe engine and *Epilogue* for copying back probe maps and saving traces to disk. The sum of these is the latency exposed to the upper layer. To evaluate the overall profiling efficiency of NEUTRINO, we compare their exposed latency with Nsight Compute [58] on overlapped metrics via application benchmarkers [8, 89, 91]. Results presented in Fig. 13 highlight the reduction of exposed latency and the efficiency of NEUTRINO's system design and implementation.

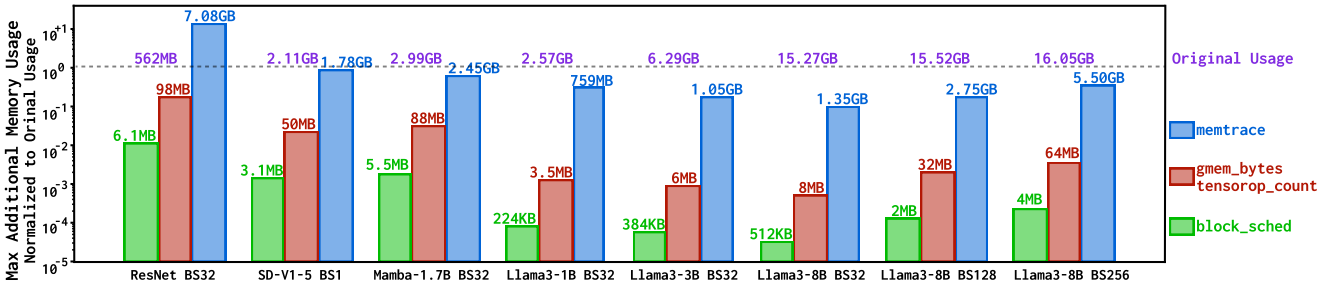


Figure 12: Max probe memory usage of NEUTRINO in profiling model forward. Probe memory usage is log-scaled to original memory usage ((labeled in purple). `gmem_bytes` and `tensorop_count` have the same map definition and the same usage.

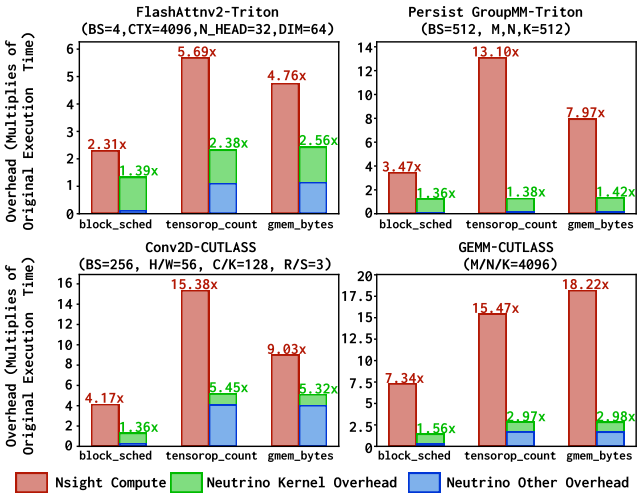

Figure 13: Exposed latency comparison: NEUTRINO and Nsight Compute [58]. NEUTRINO latency is decomposed into prologue (<1%), kernel and epilogue latency.

7 Case Study with NEUTRINO Insights

We envision NEUTRINO to be a useful tool for GPU performance engineering, paving the way for optimizing ML systems with fine-grained runtime insights. This paper mainly focuses on the design and implementation of NEUTRINO, and thus, how to leverage profiles is not our primary goal. Nevertheless, to showcase how one could exploit NEUTRINO and DMAT plots for previously unavailable insights, we carry out one case study on the impact of synchronization:

Similar to hyper-threading on CPU, GPU SM Sub-Partition (the execution unit) also maintains multiple candidate warps (the scheduling unit in GPU), and in each cycle, one warp will be selected by the warp scheduler to run. Such a design can reduce blocked waiting of instruction completion, particularly for non-local operations like memory I/O, as other candidates can be scheduled to utilize the core. In practice, there could be two cases for these warps: ❶ All warps belong to the same block that might need synchronization; ❷ Warps belong to different blocks that are mutually independent.

To identify the potential runtime difference with respect to the difference in synchronization, we create a controlled pair on Flash-Attn-v2 [19] implemented by Triton [91]. We leverage Triton auto-tuner to create two kernels: ❶ Exclusive blocks: 128x128 tile, 2 stages, 8 warps, 1 block per SM (2 warps on each SMSP are of the same block); ❷ Shared blocks: 128x64 tile, 2 stages, 4 warps, 2 blocks per SM (2 warps on each SMSP *can be* of different block). The DMAT plot (aligned with kernel start time) traced by NEUTRINO on A100 are presented in Fig. 1A and Fig. 11a, respectively. Although these two configurations impose the same computational load on the SM and offer similar throughput, we can find that their memory access patterns are significantly different.

For exclusive blocks (Fig. 1A) with frequent synchronization, the memory access pattern is structured with a regular access pattern to `K` and `V`, confirming that the algorithm [19] uses one load for both `K` and `V` per main loop. However, for shared blocks with independent synchronization (Fig. 11a), the memory access pattern is unexpectedly unstructured with many tailing blocks (light-colored parts on the right).

To validate the tailing effect, we conduct more in-depth analysis via the `block_sched` probe (Fig. 10) to analyze the elapsed time of blocks. From the CDF of elapsed time in Fig. 14A, we identify that the elapsed time of exclusive blocks is highly consistent, but varies significantly for sharing blocks (Fig. 14B) with a tailing effect of up to 24.69%[4].

To further explore the tailing latency, we take a closer look at the program execution progress via probing the `bra` instruction (Fig. 3) that redirects the program to form the *main loop*. This probe samples program execution via recording the timestamp at each `branching`, which can be used to recover the timeline of the block's working progress as shown in Fig. 14D. Furthermore, by taking the difference between sampled timestamps, we can further recover the intra-block-level throughput (TFLOP/s) timeline (presented in Fig. 14C).

From the sampled progress and throughput timeline, we observe an interesting phenomenon that every shared block

[4]The differences in completion cycles in Fig. 14A (∼220000) and Fig. 14B (∼430000) is from the FlashAttn-v2 algorithm that N is the sequential dimension, so the latency of two 128x128 tiles (Fig. 1) is equivalent to that of two 128x64 tiles (Fig. 11a), both handling 256 feature dimensions (M).

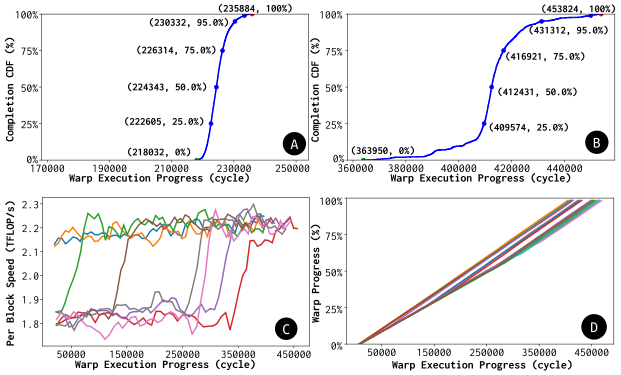

Figure 14: ❶ CDF of elapsed latency in exclusive blocks; ❷ CDF of elapsed latency in shared blocks; ❸ GFLOP/s distribution *w.r.t.* execution progress from left to right; ❹ Progress timeline of shared blocks, with slope denoting speed. Every warp in shared blocks first experiences a slow stage ($\sim$ 1.8 TFLOP/s) then jumps into a fast stage ($\sim$ 2.2 TFLOP/s).

experiences two stages: a *slower* stage at around 1.8 TFLOP/s followed by a *faster* stage at around 2.2 TFLOP/s till the termination. Moreover, by aligning the sampled timeline with start time and CU id, we identify that the transition from *slow* stage to *fast* stage is approximately when previously arrived shared block (executing at *fast* stage) terminates, suggesting an implicit FIFO-like prioritized scheduling policy. This finding explains the sparse-then-dense chaotic behavior in Fig. 11a and violates the common understanding of structured launch waves shown in Fig. 1A based on the algorithm [19]. Furthermore, we also identify similar effects on other kernels, *e.g.*, GEMM (Appendix J), with 50.93% tailing effect and jumping from $\sim$ 5 TFLOP/s to $\sim$ 7.5 TFLOP/s, spotlighting the prevalence of the tailing effect in shared blocks.

Regarding the performance, both exclusive and shared blocks are not optimal, yet have different performance statistics. Sharing blocks experience poor cache behavior due to the random-like memory access pattern, which can be verified by 5.85x higher stall cycles due to L1 miss from hardware profilers [55] in Tab. 4. Quite the opposite, exclusive blocks are so synchronized that they exhibit considerably peaked memory usage (Fig. 1B) and suffer from 4.47x higher exposed stall cycles due to memory bus busy and similarly, 1.45x more stall cycles for compute pipeline contention, both implying potential space for performance optimizations.

Table 4: Exposed stall cycles and reasons of FlashAttn-v2 under exclusive and shared blocks, collected from the Nsight Compute [58] PC Sampling.

Stall Reason	Exclusive Block	Shared Block
`long_scoreboard` (Waiting Global Memory)	41,055	268,941 (**5.85x**)
`mio_throttle` (Memory I/O High Pressure)	303,694 (**4.47x**)	68,005
`math_pipe_throttle` (Compute Unit Busy)	616,913 (**1.45x**)	425,026

8 Discussion and Future Work

NEUTRINO and GPU Scheduling: While we demonstrate the significance of NEUTRINO in revealing new insights from the runtime scheduling behavior in §4.6 and §7, current experiments are still far from completely understanding or reverse-engineering the GPU scheduling policies. This is because GPU scheduling is hardware-implemented, unlike OS schedulers like CFS or EEVDF [83,97], and is multi-level, including stream-, block-, and the finest warp-level instruction scheduling. Moreover, as a shared system, the behavior of the scheduler will be highly affected by runtime dynamics, which can also be reflected by the randomness of DMAT.

Impact of GPU Sharing: GPU sharing, *i.e.*, concurrently executing multiple kernels, is a practical solution to utilize the GPU. Such sharing can be intra-process via CUDA/HIP streams, inter-process via MPS (Multi-Process Service), or with resource isolation via MIG (Multi-Instance GPU). NEUTRINO is currently thread-local (*will block thread until kernel finishes*) and the scope is process-local (only profile the execution of the local process in MPS or MIG). We keep the impact of sharing as an interesting future direction.

Completeness of Probe Verification: We identified and prohibited three key factors of unsafe probes in §3.4, yet the current verification is not complete. ❶ There remain uncovered security factors, such as unreachable synchronization points that could pause programs. ❷ Current verification might be too strong, *e.g.*, `jmp` could be supported if the target is within the probe [24]. GPU-kernel verification itself remains an open research problem, and existing works only address several perspectives, such as synchronization [76] or data races [40]. Thus, we keep probe verification as future work.

Abnormal Speedup of Probed Kernel: As shown in Tab. 3, NEUTRINO's probed kernel might present better performance than the original kernel. Based on in-depth experiments (Appendix K), we attribute the speedup to the assembler optimization. In addition to translating assembly into machine code, modern assemblers also incorporate many optimizations, such as reordering instructions for better execution flow and merging reusable registers based on dependency tracking. Our analysis in Appendix K demonstrates that NEUTRINO probe's additional registers and instructions may change register dependencies and can lead to better execution flow (with 5.88% IPC improvement) and better performance (up to 0.94x faster). We believe this counterintuitive observation promises new opportunities since assemblers and machine code are not widely explored due to their hardware-oriented nature. For example, recently, DeepSeek's DeepGEMM [100] reported 10% speedup by flipping a control bit in machine code.

Towards Hardware-Software Profiler: As a pure-software profiling system primarily based on the assembly layer, NEUTRINO cannot profile unprogrammable hardware events such as the cache miss, although the DMAT trace can be used for cache simulation [98]. Furthermore, its profiling is based

on execution, so it is hard to trace stall cycles, *i.e.*, no instruction scheduled, but it can still help diagnose stall cycles caused by memory I/O. Despite these drawbacks, NEUTRINO can be an excellent complement to current hardware-dependent and kernel-exclusive kernel profilers by fusing the missing information on both sides. Moreover, from the big picture of observability, the multi-scale probing feature of NEUTRINO makes it an intermediate to bridge the gap between architecture-level hardware profilers [7, 55, 58] and application-level software profilers [12, 87]. Hence, we keep it as an exciting direction to integrate platform-specific hardware profilers and framework-specific software profilers to build a unified framework for GPU kernel profiling.

9 Related Work

GPU Hardware Profiler: Current GPU kernel profiling systems, such as NVIDIA NSight [58] / CUPTI [55] or AMD RGP [7] / GPA [5], are *hardware-dependent* that profiling features require corresponding hardware implementation support, such as performance counters like cache hit/miss rate. These features, though unique, are hard to adapt to new hardware, *e.g.*, async tensor core that makes utilization metric [81] less reliable as computation is offloaded from threads to tensor cores. Moreover, they cannot be flexibly customized to meet the needs of developers. For example, hardware profilers can only profile the entire program in a *sampling-based manner with low sampling frequency* to control overhead in performance and resources, limiting its capability to trace user-specified events. Instead, NEUTRINO limits the profiling targets to only the desired tracepoints, achieving both fine-grained event tracing and low system overhead.

GPU Software Profiler: Other framework-specific software profilers, such as the built-in profiler of PyTorch [87] and JAX [27], are *kernel-exclusive* and can only capture higher-level events, like measuring memory events (`alloc/free`) or timing the whole kernel (FLOP/s). Instead, NEUTRINO focuses on intra-kernel profiling at the instruction level.

GPU Micro-Benchmarking: Motivated to understand hardware design, GPU micro-benchmarking [1, 38, 51, 64, 85] tries to profile the *idealized performance* of specific hardware via *specially designed workloads* that only consist of interested instructions, such as `mma` to benchmark tensor core, without any other instructions (even those necessary in real workload, such as `ld` to read data) to reduce disturbance. Instead, NEUTRINO aims to measure the performance of real workloads, rather than idealized workloads.

GPU Simulation: Another way to understand the performance is to use simulators [9, 32, 42, 49, 92] that emulate GPU execution at the cycle level on a CPU. The major problems of these simulators lie in the speed of both running simulations (which might need several days) and support for new hardware features and instructions (which might take several years). Moreover, various runtime dynamics, *e.g.*, timing an instruction, may not be accurately profiled on simulators.

GPU Instrumentation: Binary instrumentation [15, 24, 50, 74] that injects *code, functions or interrupts*, with program states as parameters has been proven powerful in building performance tools on the CPU. There are also some GPU binary instrumentation tools in compile-time such as Ocelot [23], HIPAnalyzer [21], CUDAAdvisor [77], CUDAFlux [14], or in runtime such as SASSI [82], NVBit [93] and GTPin [80]. Though compiler-based approaches may benefit from additional information in compilation, they are bound to a specific compiler, module, or IR, lacking generalizability. They also require source codes, limiting its compatibility with existing frameworks. Runtime approaches directly operating on machine code lacks sufficient virtualization, so they mostly rely on the protection of the stack via injecting *pure device function*, which prohibits cooperation between probes for advanced usages, making them hard to perform tasks such as timing instruction (subtracting two clock readings) because the start time has been cleared on return and is not visible in the end timer's context. NEUTRINO persists runtime, rather than compiler, to advance its generalizability and targets parallel assemblies, other than machine code, to support more advanced and complex profiling tasks with cooperative probes.

10 Conclusion

The rapid development of AI systems has fostered an urgent need for comprehensive insights through advanced GPU kernel profiling. To address this, we present NEUTRINO, a GPU assembly probing infrastructure that enables fine-grained, versatile, and programmable GPU kernel runtime profiling with its distinct probe design of snippet, tracepoint, and map. We implement NEUTRINO, consisting of the hook driver, probe engine, and DSL compiler, for the CUDA and ROCm ecosystems. We introduce the novel Densified Memory Access Timeline (DMAT) to effectively visualize comprehensive GPU memory access patterns. We conduct extensive experiments, validating NEUTRINO's reliability, low overhead, and applicability. Additionally, we conduct a case study on the impacts of synchronization, successfully pinpointing performance bottlenecks with new insights gained by NEUTRINO. To maximize the potentials of NEUTRINO, we have open-sourced it at `https://github.com/open-neutrino/neutrino` and plan to build a collaborative community to support its continuous growth towards a unified framework for GPU kernel profiling.

A Artifact Appendix

A.1 Abstract

The artifact of NEUTRINO is hosted at GitHub (in branch `artifact`), containing the source code, installation/collection/analysis scripts, collected traces that reproduce all the evaluation results in our paper. We also package the artifact evaluation as Jupyter Notebooks hosted on Google Colab, offering one-click results reproduction without local runtime setup. In addition, we also maintain an online documentation of NEUTRINO containing project highlights, user guides, roadmaps, and references for evaluating the functionality.

Artifact Claim: The collected traces and the codes are identical to our paper's corresponding description. You can replicate all the major results using the traces and analysis codes we provided (details in the *Expected Results* section below). We also provide the trace collection code for you to collect your own traces on your own devices. It's worth noticing that customized traces, particularly DMAT, can only yield similar results due to hardware and runtime dynamics.

A.2 Scope (meta-information)

- **Design**: NEUTRINO is a GPU assembly probing tool designed to *attach small snippets (probes)* to *GPU kernels at runtime* to expose runtime execution details (profiling).
- **System**: NEUTRINO system consists of two parts, the probe engine to attach code snippets, and the hook driver to capture GPU kernels launched at runtime. The source code is available at GitHub and is installable as a Python package.
- **Probes**: NEUTRINO probes are small TOML files that define the profiling task via snippet, datamodel, position, and callback. Probes used in the paper are available at Github.
- **Output**: Fig. 1, Fig. 10 (A/B/C), Fig. 11, Fig. 12, Fig. 13, and Table. 2 in the paper.
- **Evaluation**: We arrange evaluations in notebooks structured linearly, allowing simple click `Runtime -> Run All` execution. Please refer to the README, and instructions in each Jupyter Notebook (Colab).
- **Special Requirements**: No special requirements for static trace analysis, For dynamic trace collection, a NVIDIA GPU, e.g., A100, and a PTX-included build of PyTorch v2.5.0 and CUTLASS v3.5.0 are required.
- **Disk Space Requiremetns**: Evaluating on Google Colab doesn't require any disk space. Regarding local evaluation, please arrange 3GB for static traces and at least 10GB for collecting dynamic traces.
- **Experiment Time** Less than 30 minutes for **static** evaluations analyzing collected traces on CPU, and ≈ 10 hours for **dynamic** evaluation collecting traces on GPU.
- **Environment Setup Time**: For **static** evaluation, it takes ≈ 2 minutes to download traces. For **dynamic** evaluation, it takes ≈ 15 seconds to build NEUTRINO. Setting up PyTorch and CUTLASS might take ≈ 3 minutes.
- **Publicly Available**: Yes.
- **License**: We use the Apache License, Version 2.0 for the system source code and the CC BY 4.0 license for probes used in the paper.

A.3 Contents

NEUTRINO's artifact evaluation is arranged in 6 parts, corresponding to different figures or tables in the paper:

1. `block_sched`: §4.6
2. `dmat`: Fig. 1, Fig. 11
3. `kernel_overhead`: Tab. 3
4. `max_mem`: Fig. 12
5. `exposed_latency`: Fig. 13
6. `warp_sched`: Fig. 14

We arrange each part to correspond to a section in the Jupyter Notebook. Moreover, each evaluation is provided in two modes: the **static** that parses collected traces, suitable for *Getting Started* on local CPU-only devices without special hardware/software requirements, and the **dynamic** that collects the traces on the real GPU-enabled environment, suitable for *Full Evaluation*.

A.4 Hosting and Requirements

A.4.1 How to access

Please choose one of the following to access the artifact:

- **Github**:
  1. **Static** evaluation: `artifact/static.ipynb`
  2. **Dynamic** evaluation: `artifact/dynamic.ipynb`
- **Colab**:
  1. **Static** evaluation (Use CPU as Runtime) is here.
  2. **Dynamic** evaluation (Use GPU as Runtime) is here.

A.4.2 Hardware Requirement

For **static** evaluation, only a CPU machine with Python 3 runtime is needed. You *don't need to install* NEUTRINO for static evaluation.

For **dynamic** evaluation, you will need a NVIDIA GPU with the CUDA driver installed. Please note:

1. The choice of hardware will significantly affect results:
   - Please use RTX3080 for all DMAT plot (Part. 2).
   - Please use A100 for all the rest (Part. 1, Part. 3-6).
2. Please make sure no other workload is executing on the same GPU.
3. Please arrange enough disk space, at least 10GB, for dynamic traces collection.

A.4.3 Software Requirements

NEUTRINO system only depends on GNU toolchain (`gcc`, `file`, `git`, `nm`), CUDA toolchain (`cuobjdump`, `ptxas`) and

Python 3.12 (`pip`, `toml`). But evaluation workload needs a PTX-included build of PyTorch and CUTLASS. We package the dependency checking and installation in `prepare_env.py` for one-click installation.

A.4.4 Installation

It's recommended to use virtual environments, e.g., `conda create -y -n ae_env python=3.11 && conda activate ae_env`, for installation when not using Colab.

Automatic Installation:: We provide a helper script `prepare_env.py` that one can `python prepare_env.py` to install all dependencies and `neutrino`. Jupyter Notebooks (also Google Colab) use this way.

Manual Installation::

1. Clone the Github repository: `git clone -b artifact https://github.com/open-neutrino/neutrino.git`
2. Build and install neutrino: `cd neutrino && python setup.py install && cd ..`
3. Test installation with `neutrino -help`

Please refer to the README file for detailed descriptions on installing PTX-included builds of PyTorch and CUTLASS.

A.5 Evaluation Workflow

A.5.1 Getting Started Instructions

Getting started instructions, taking <30 min, consist of:

1. All **static** evaluation that reproduces all figures and tables in the paper based on collected traces.
2. The `block_sched` section (1st part) of the **dynamic** evaluation that collects and analyzes the block scheduling traces. This part takes <1 minute and helps justify the correct environment setup for detailed instructions.

You can use Colab to execute the evaluation scripts. To do this, first select the correct Runtime (CPU or GPU as stated above), then click the Runtime button at the top of the Colab web page, and click the Run All button in the dropdown menu to execute the scripts. Each section (of several blocks) can be executed independently. Statistics or figures will be displayed below each cell when execution finishes.

If you choose to evaluate locally, please download the Jupyter Notebooks and follow the same steps as the Colab execution instructions above.

A.5.2 Detailed Instructions

The detailed instructions cover the rest five sections of the **dynamic** evaluation. They are also packaged in a Jupyter Notebook (also available on Colab), allowing one-click (`Runtime -> Run All`) execution and evaluation. Each section can also be executed independently. So you can clear up traces after each section to save disk space.

A.5.3 Expected Results

Static evaluation on collected traces are expected to closely fit the figures and tables presented in the paper. To save disk space, we mistakenly deleted the original traces for these results. And because these results capture the finest runtime dynamics of the GPU, exact reproduction will be impossible. Our later experiments can only reproduce similar results. Please accept our apologies for the inconvenience, and we will update the revised paper to include the latest results.

Dynamic evaluation on customized traces is expected to produce similar results, i.e., similar numbers or figure shapes.

A.5.4 Further Evaluation

After completing the above evaluation and reading the documentation, we recommend several ways for further evaluation:

1. **Test your workloads**: NEUTRINO supports most GPU workloads. You can import your GPU kernels (CUDA C++, Triton, etc) and test them via `neutrino <your workload>`. Check more on NEUTRINO's support here.
2. **Test your workloads**: First, read the Programmable Probe guide, write and save your probe in `.toml` locally, and apply it using `neutrino -p <path/to/probe>`.
3. **Investigate Implementation**: NEUTRINO's implementation is well organized, and it's a good entry to understand how GPU code dispatches from OS. You can find the implementation of hook driver in `neutrino/src/` and the probe engine in `neutrino/probe/`.

A.5.5 Experiments Added in Shepherding

In the shepherding process, we have added several more experiments to address technical comments by reviewers. Though not required by AE, we also prepare the reproduction code:

- Microbenchmark (Tab. 2): `microbench.ipynb`
- Global DMAT (Fig. 15): `dmat_global.ipynb`
- DMAT Slowdown (Fig. 16): `dmat_slowdown.ipynb`
- Abnormal Speedup (Appendix K): `speedup.ipynb`

B Hook Driver

Hook driver is implemented via exposing functions of the same signature and using `dlfcn` to call the original function with hooks (lines 6 & 8) left for adding functionalities.

```
#define REAL_DRIVER ...   // path to real driver
static void* dlib = NULL; // dlopen handle
CUresult cuInit(unsigned Flags){ //same signature
  if (!dlib) {dlib = dlopen(REAL_DRIVER, RTLD_LAZY);}
  CUresult (*real)(unsigned) = dlsym(dlib, "cuInit");
  // insert code here := eBPF uprobe
  CUresult ret = real(Flags);
  // insert code here := eBPF uretprobe
  return ret; }
```

Hook driver is injected into the program via `LD_PRELOAD` like above for dynamic loading, *e.g.,* PyTorch, or `LD_LIBRARY` for static linking, *e.g.,* Triton. This can also be extended to filter out proprietary products like `cublas` for legal safety.

```
#define REAL_DRIVER ... // filled in make
#define HOOK_DRIVER ... // filled in make
void* dlopen(const char *filename, int flags) {
  // RTLD_NEXT -> the real dlopen of libc
  real_dlopen = dlsym(RTLD_NEXT, "dlopen");
  if (strstr(filename, "libcuda.so.1") != NULL) {
    void* tmp[STACK_TRACE_SIZE];
    int size = backtrace(tmp, STACK_TRACE_SIZE);
    char** syms = backtrace_symbols(tmp, size);
    for (int i = 0; i < size; i++) {
      // filter proprietaries like cublas
      if (strstr(syms[i], "cublas") != NULL)
        return dlopen(REAL_DRIVER, flags);
    }
    return dlopen(HOOK_DRIVER, flags);
  }
  return dlopen(filename, flags);
}
```

C Probe Map Planning

Our probe engine will automatically plan the probe map according to the definition, *e.g.,* `thread:array:8:1`. Its mechanism is similar to the following CUDA/HIP C++:

```
#define NO_BYTES ... // filled by datamodel, 8*1 here
__global__ void tmp(void* buff) {
  int thr_idx = (blockDim.y * threadIdx.z + \
    threadIdx.y) * blockDim.x + threadIdx.x;
  int blk_idx = (gridDim.y * blockIdx.z + \
    blockIdx.y) * gridDim.x + blockIdx.x;
  int blk_size = blockDim.x * blockDim.y * blockDim.z;
  int buf_idx = blk_idx * blk_size + thr_idx;
  void* buf_loc = buff + buf_idx * NO_BYTES;
}
```

In practice, the probe engine achieves it via formatting a Python string of assemblies with `name` and `no_bytes` like the following example of PTX:

```
""".reg .b32  %loc<7>; // applies to all map
mad.lo.s32  %loc7, %ntid.y, %tid.z, %tid.y;
mad.lo.s32  %loc6, %loc7, %ntid.x, %tid.x;
mad.lo.s32  %loc5, %nctaid.y, %ctaid.z, %ctaid.y;
mad.lo.s32  %loc4, %loc5, %nctaid.x, %ctaid.x;
mul.lo.s32  %loc3, %ntid.x, %ntid.y;
mul.lo.s32  %loc2, %loc3, %ntid.z;
mad.lo.s32  %loc1, %loc2, %loc4, %loc5;
// following is unique for each map
.reg .b64 %map_{name}<5>;
mul.wide.s32  %map_{name}4, %loc1, {no_bytes};
ld.param.u64  %map_{name}3, [param_{name}];
cvta.to.global.u64  %map_{name}2, %map_{name}3;
add.s64 %map_{name}1, %map_{name}2, %map_{name}4;"""
```

D Probe DSL Compilation Example

Our compiler will first translate the DSL into eBPF-like IR:

```
callback="block_sched.py"
[map.block_sched]
type  = "array"
level = "warp"
size  = "16"
cap   = "1"
[probe.thread_start_thread_end]
position = "kernel"
level = "warp"
register = {"u32": 2, "u64": 3}
before = "clock PD0"
after = """clock PD1
sub PD1, PD0
cvt32 P0, PD1
cuid P1
SAVE [block_sched] {PD0, P0, P1}"""
```

This intermediate representation is inspired by the mature eBPF ISA [90] and can be translated into platform-specific assemblies like PTX:

```
[probe.thread_start_thread_end]
... # other metadata truncated
before = """.reg .b64 %PD<3>;
.reg .b32 %P<2>;
mov.u64 %PD0, %clock64;"""
after = """mov.u64 %PD1, %clock64;
sub.u64 %PD1, %PD1, %PD0;
cvt.u32.u64 %P1, %PD1;
mov.u32 %P2, %smid;
SAVE [block_sched] {%PD0, %P1, %P2};"""
```

and GCN Asm:

```
[probe.thread_start_thread_end]
... # other metadata truncated
register={"u32": 2, "u64": 3, "type": "sgpr"}
before = "s_memrealtime PD0"
after = """s_memrealtime PD1
SUB64 PD1, PD1, PD0
CVT32 P0, PD1
s_getreg_b32 P1, hwreg(HW_REG_HW_ID)
SAVE [block_sched] {PD0, P0, P1}"""
```

On AMD GPUs, scalar registers per warp and vector registers per thread are separated, which is reflected in the new `type` field in `reigster`. We also implement more helpers for AMD platform to cover the missing functionality, such as `SUB64` for 64-bit subtraction as AMD doesn't support 64bit add/sub for Scalar Registers [4] (We emulate it by `s_sub_u32`).

E Trace Analysis Code Example

Typical NEUTRINO trace analysis code consists of two parts: ❶ *(before line 32)* Trace reading code auto-generated by NEUTRINO probe engine, for reading binary traces into Python data structures via `struct`. ❷ *(after line 32)* Trace analysis code built upon read structures. The whole program can be registered to the hook driver as `CALLBACK` (Fig. 10), like the following example:

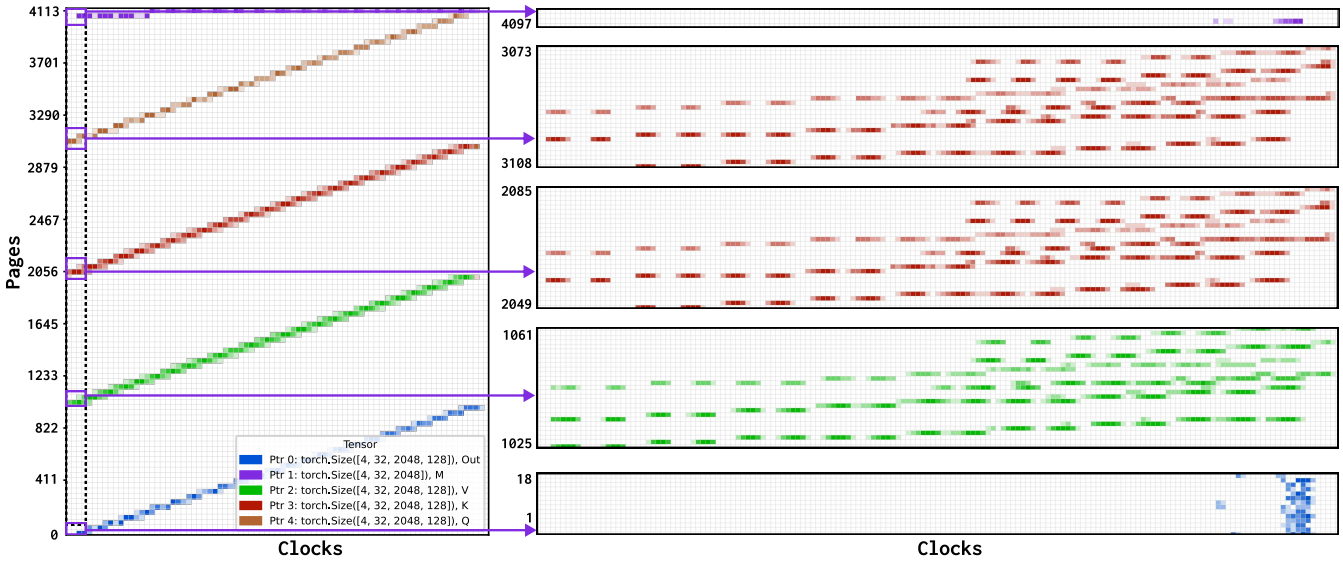

Figure 15: NEUTRINO DMAT aligned to the GPU-local clock. Left: The overview; Right: the Zoom-in view of selected small proportions highlighted in the red rectangles.

```
# Neutrino Generated Code for Reading Trace
import struct
from typing import NamedTuple, List, Tuple
from neutrino import TraceHeader, TraceSection
class block_sched(NamedTuple):
  start: int
  elapsed: int
  cuid: int
def parse(path: str):
  with open(path, "rb") as f:
    header: TraceHeader = TraceHeader(
      struct.unpack("iiiiiiii", f.read(32)))
    sections: List[TraceSection] = []
    for _ in range(header.numProbes):
      size, offset = struct.unpack("QQ", f.read(16))
      sections.append(TraceSection(size, offset))
    gridSize = header.gridDimX * header.gridDimY
                               * header.gridDimZ
    blockSize = header.blockDimX * header.blockDimY
                                 * header.blockDimZ
    records: List[List[block_sched]] = []
    for i in range(gridSize):
      records.append([])
      for j in range(blockSize):
        start, elapsed, cuid = struct.unpack(
                                 "QII", f.read(16))
        records[i].append(
                 block_sched(start, elapsed, cuid))
  return header, sections, records
# END OF GENERATED CODE
import numpy as np
header, sections, records = parse(sys.argv[1])
unique_cus = set()
for block in records:
  unique_cus.add(block[0].cuid)
cu_timelines = [[]] * len(unique_cus)
sched_times = [0.0] * len(unique_cus)
work_times = [0.0] * len(unique_cus)
for cur in records:
  sched_out = False
  for block in cu_timelines[cur[0].cuid]:
    if block.start+block.elapsed<=cur[0].start:
      sched_times[cur[0].cuid]+=cur[0].start
                 - (block.start + block.elapsed)
      cu_timelines[cur[0].cuid].remove(block)
      cu_timelines[cur[0].cuid].append(cur[0])
      work_times[cur[0].cuid] += cur[0].elapsed
      sched_out = True
      break
    if not sched_out:
      cu_timelines[cur[0].cuid].append(cur[0])
      work_times[cur[0].cuid] += cur[0].elapsed
print(np.array(sched_times).mean(),
      np.array(work_times).mean())
```

F Persistent Kernel for `torch.zeros`

Following code is generated by GPT4o with prompt: "Write a Persistent Kernel to initialize a torch tensor to 0":

```
import torch
import triton
import triton.language as tl
@triton.jit
def zero_persistent_kernel(output_ptr, numel,
  BLOCK_SIZE: tl.constexpr, NUM_SMS: tl.constexpr):
  start_pid = tl.program_id(axis=0)
  num_blocks = tl.cdiv(numel, BLOCK_SIZE)
```

```
  blocks_per_sm = num_blocks // NUM_SMS
  if start_pid < num_blocks % NUM_SMS:
    blocks_per_sm += 1
  block_id = start_pid - NUM_SMS
  for _ in range(blocks_per_sm):
    block_id += NUM_SMS
    offsets=block_id*BLOCK_SIZE+tl.arange(0,BLOCK_SIZE)
    mask = offsets < numel
    tl.store(output_ptr + offsets,
      tl.zeros([BLOCK_SIZE], dtype=tl.float16), mask)
def zero_persistent(x: torch.Tensor):
  numel = x.numel()
  NUM_SMS = torch.cuda.get_device_properties("cuda")\
                     .multi_processor_count
  BLOCK_SIZE = 128
  grid = lambda META: (min(NUM_SMS,
     triton.cdiv(numel, META['BLOCK_SIZE'])),)
  zero_persistent_kernel[grid](
    x, numel, BLOCK_SIZE, NUM_SMS)
t=torch.empty((4096,4096),torch.float16,device="cuda")
zero_persistent(t)
```

G Global Timer Aligned DMAT

NEUTRINO DMAT can also be synchronized to the GPU-local timer, *i.e.*, different compute units share the same synchronized timer, rather than CU-local cycle timer. DMAT of the same configuration as Fig. 1 under global synchronization becomes Fig. 15. Under global synchronization, DMAT becomes *terraced*-like and each *"step"* represents a launch wave of virtual blocks, 32x128 in this case, to physical compute units (108 SM on A100). We recommend zooming in on each *"step"*, for insightful analysis.

The zoomed-in view (right part of Fig. 15, note the y-axis value difference) reflects the actual memory access pattern applied to the hardware, and is insightful for hardware-level analysis and cache simulation.

H Micro-benchmarking Details

Here we present more details behind the theoretical estimation, and the reasons for the varying clock estimation. Take the most complicated `random` access as an example, we use the Fisher–Yates shuffle to create reproducible random index sequences in A. At runtime, each thread reads the random index from A and writes to B accordingly, like the following:

```
__global__ void random_kernel(
  const int* A, int* B, // A has been shuffled
  int M, int N, unsigned int NS) {
  int col = blockIdx.x * blockDim.x + threadIdx.x;
  if (col >= M) return; // boundary check
  int* src = A + col;
  for (int i = 0; i < M * N; i += M) {
    int idx  = src[i];  // get the random idx from A
    B[idx] = i;         // write to B[idx]
    device_sleep(NS);   // spinloop inside
  }
}
```

Then, in verification, we reconstruct the same random index and simulate the access as follows. We compare simulated addresses with collected addresses aligned to the base address.

```
arr = fisher_yates_shuffle(...)
for blockIdx in range(blocks):
  for threadIdx in range(threads):
    start = blockIdx * threads + threadIdx
    clock = LATENCY # 1st access doesn't sleep
    for recordIdx in range(records):
      index  = start + recordIdx * blocks * threads
      addr_A = (index * size) # >> 16 => page
      addr_B = (arr[index] * size) # >> 16 => page
      clock += NS + LATENCY
```

However, one critical challenge is the memory access latency (`LATENCY` in the above code), which, in practice, will vary from cache hit/miss. To be fair, we disable the L1 (via `cg` cache operator [60]) and choose the L1 disabled latency (570 cycles on A100) as `LATENCY`. Because different patterns have varying L1 hit rates (88% for linear and 0% for stride), resulting in unpredictable estimation errors.

I Evaluating NEUTRINO probe slowdown

As presented in Tab. 3, NEUTRINO's `dmat` probe leads to different degrees of slowdowns on different kernels, from 2.75x on Flash-Attn-v2 to 13.163x on SoftMax. We first analyze this effect from the perspective of memory I/O by sampling the DMAT access, *i.e.*, adding a sampling counter to make DMAT save only 1/2 (save only once in two memory accesses), 1/3, 1/4, 1/8, and measuring the kernel slowdown.

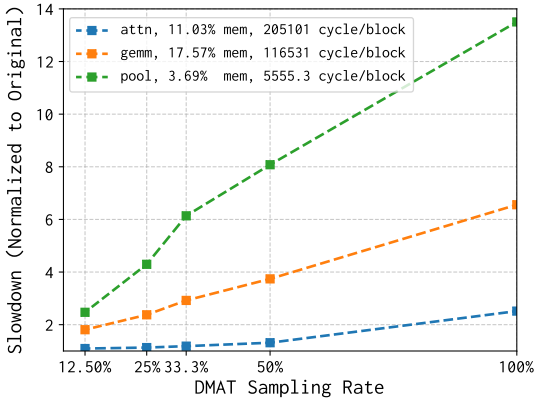

Figure 16: NEUTRINO DMAT Slowdown versus kernels and sampling frequency.

Results presented in Fig. 16 demonstrate that the slowdown of DMAT is mainly of a linear relationship *w.r.t.* the sampling

frequency, highlighting that most DMAT cost comes from the I/O. Moreover, we also identify two major factors contributing to the exact slowdown ratio. First, smaller kernels, *i.e.*, lower block time, suffer from larger slowdown as the proportion of `dmat`'s memory I/O would be larger *w.r.t.* the original block time (pool, ∼5555 cycles with 13x slowdown and attn, ∼205101 cycles with 2.75x slowdown). Second, for kernels of similar block time, the proportion of memory instructions significantly affects the slowdown (attn, 11.03% memory instructions with 2.75x slowdown, and gemm, 17.57% memory instructions with 6.55x slowdown).

J Case Study on GEMM Kernel

Here, we also formulate two configurations of GEMM kernel (`M=N=K=4096`) issuing the same burden to the physical SM: ❶ 128x256x64 tile, 3 stages, 8 warps, 1 block per SM on A100; ❷ 128x128x64 tile, 3 stages, 4 warps, 2 blocks per SM on A100. And we present the cumulative distribution function of block completion time in Fig. 17A and Fig. 17B, respectively.

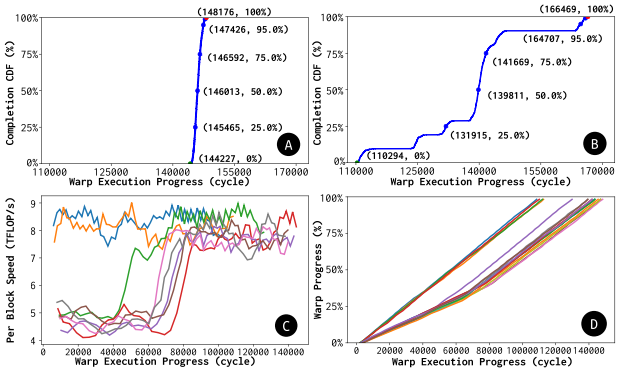

Figure 17: ❹ CDF of elapsed latency in exclusive blocks; ❺ CDF of elapsed latency in shared blocks; ❻ GFLOP/s distribution *w.r.t.* execution progress from left to right; ❼ Progress timeline of shared blocks.

We can identify the same pattern as §7 that shared blocks suffered from tailing blocks. Similarly, we plot the intra-block-level throughput timeline and the warp execution timeline in Fig. 17A and Fig. 17B, yielding similar finding as §7. But different from the previous, here `BLOCK_N`, 128 or 256, is a parallel dimension. Fig. 14 and Fig. 17 together demonstrate that the existence of tailing effects in shared blocks due to GPU synchronization and scheduling (§7) is general, regardless of kernels or tile organizations (parallel or sequential).

K Analyzing Abnormal Speedup

As shown in Tab. 3, NEUTRINO probes can lead to abnormal speedup. One significant case of such speedup is GEMM with `M=N=K=2048`, where `block_sched` can lead to up to 0.94x speedup on CUTLASS implementation and 0.96x speedup on Triton implementation. We pick the Triton implementation (`BLOCK_M=128`, `BLOCK_N=128`, `BLOCK_K=32`, `STAGES=3`, `WARPS=4`), and `block_sched` probe as it has the lowest interruption to the program (only thread start and end). We profiled the probed and original kernel (with the same `-O3`) with hardware profiler Nsight Compute [58] to validate their performance metrics, and the results suggest dramatic changes:

Metric	**Probed**	**Original**
`Executed IPC Elapsed`	1.08 (**+5.88%**)	1.02
`Issue Slots Busy`	30.41% (**+4.97%**)	28.97%
`long_scoreboard` (waiting global memory)	2,698,349 (**-10.22%**)	3,005,844
`mio_throttle` (waiting memory inst queue)	665,885 (**-32.8%**)	990,653
`no_instruction` (waiting instruction/register)	52,804 (**-17.32%**)	63,868
`short_scoreboard` (waiting shared memory)	1,311,106 (**+148%**)	528,495

Profiled metrics highlight a 5.88% IPC improvement with a 4.97% busier instruction scheduling. Moreover, we also identified that NEUTRINO probed kernel has 10.22% less waiting time for global memory, 32.8% less waiting time for memory instruction queue, and 17.32% less waiting time for instructions or register cache. To further address the improvement, we checked the assembled machine code, particularly the main loop with tensor core (`HMMA`) and async copy (`LDGSTS`):

```
/* Probed SASS */
LDGSTS.E.BYPASS ...
IMAD R132, R236 ...
HMMA.16816.F32  ...
HMMA.16816.F32  ...
HMMA.16816.F32  ...
IMAD.MOV.U32    ...
HMMA.16816.F32  ...
IMAD.MOV.U32    ...
IMAD R133, R236 ...
HMMA.16816.F32  ...
LDGSTS.E.BYPASS ...
HMMA.16816.F32  ...
HMMA.16816.F32  ...
HMMA.16816.F32  ...
IMAD R132, R236 ...
IADD3 R134, P0, ...
IMAD.MOV.U32    ...
HMMA.16816.F32  ...
```

```
/* Original SASS */
LDGSTS.E.BYPASS ...
HMMA.16816.F32  ...
LDGSTS.E.BYPASS ...
HMMA.16816.F32  ...
LDGSTS.E.BYPASS ...
HMMA.16816.F32  ...
IMAD.MOV.U32    ...
HMMA.16816.F32  ...
IMAD.MOV.U32    ...
HMMA.16816.F32  ...
LDGSTS.E.BYPASS ...
IMAD.X R251,    ...
ISETP.LE.AND P5 ...
HMMA.16816.F32  ...
LDGDEPBAR ;     ...
IADD3 R138,     ...
HMMA.16816.F32  ...
LDGSTS.E.BYPASS ...
```

From the above truncated and optimized machine code, we can find the probed kernel's `HMMA` instructions are more continuous, with more opportunities to reuse the register cache (as results are accumulated along `K`). Moreover, memory instructions `LDGSTS` are more distributed, possibly leading to a more balanced pressure on the memory system.

This experiment shows that new instructions from NEUTRINO probe(s) may lead the assembler [61] to better execution flow. Though the current experiment is not comprehensive (only one kernel), we believe that this abnormal speedup and our analysis spotlight there are still unexplored opportunities in low-level assembler optimization.

Principles and Methodologies for Serial Performance Optimization

Sujin Park Mingyu Guan Xiang Cheng Taesoo Kim
Georgia Institute of Technology

Abstract

Throughout the history of computer science, optimizing existing systems to achieve higher performance has been a longstanding aspiration. While the primary emphasis of this endeavor lies in reducing latency and increasing throughput, these two are closely intertwined, and answering the *how* question has remained a challenge, often relying on intuition and experience.

This paper introduces a systematic approach to optimizing sequential tasks, which are fundamental for overall performance. We define three principles—task removal, replacement, and reordering—and distill them into eight actionable methodologies: batching, caching, precomputing, deferring, relaxation, contextualization, hardware specialization, and layering. Our review of OSDI and SOSP papers over the past decade shows that these techniques, when taken together, comprehensively account for the observed sequential optimization strategies.

To illustrate the framework's practical value, we present two case studies: one on file and storage systems, and another analyzing kernel synchronization to uncover missed optimization opportunities. Furthermore, we introduce SysGPT, a fine-tuned GPT model trained on curated literature analysis, which offer context-aware performance suggestions. SysGPT's outputs are more specific and feasible than GPT-4's, aligning with core strategies from recent research without direct exposure, demonstrating its utility as an optimization assistant.

1 Introduction

Improving the performance of computer systems has been a pivotal objective within the field of computer science, profoundly influencing user experience, operational efficiency, and cost reduction. High-performance systems process tasks with greater speed and efficiency, thereby minimizing response times for user applications and enhancing the throughput of computational operations.

The optimization of sequential execution is particularly crucial, as Amdahl's law [8] highlights that the maximum potential speedup of a system is constrained by the fraction of the program that must remain sequential. Despite advances in parallel processing, addressing the sequential bottleneck remains foundational for achieving meaningful performance gains.

In response to this challenge, this paper proposes a structured approach to optimizing *sequential* performance. Our approach is founded on three key principles: the removal, replacement, or reordering of tasks within a sequence. The performance of sequential execution is inherently defined by the sequence itself, as each task's execution time directly contributes to the total runtime, and tasks must be completed in a specific order. This deterministic nature implies that modifying the sequence—either by removing tasks to reduce the overall sequence length, replacing slower tasks with faster alternatives, or reordering tasks for more efficient execution—constitutes the only practical means to improve sequential performance under a fixed hardware and execution environment.

Building upon these principles, we define eight actionable methodologies for sequential performance optimization: batching, caching, precomputing, deferring, relaxation, contextualization, hardware specialization, and layering. Each methodology can be systematically explained through one or more of the three fundamental principles, providing clear reasoning as to why and how it improves sequential performance.

While each methodology may be individually familiar to the systems community, our key contribution lies in synthesizing them into a unified framework that captures the full space of observed optimization opportunities for sequential execution. By distilling common optimization patterns into a systematic and actionable set of methodologies, our work clarifies the space of existing optimization opportunities and transforms the inherently open-ended challenge of performance optimization into a fully structured and tractable process.

To investigate the completeness of this framework, we conducted an empirical analysis by reviewing every system paper published at OSDI and SOSP over the past decade. Our goal was to examine whether the eight methodologies could sufficiently account for the diverse optimization techniques proposed in these papers, thereby demonstrating that the methodologies form a complete set of common patterns for sequential performance optimization. These eight methodologies are not intended to represent the *only* means of achieving sequential performance optimization, but rather to provide a comprehensive account of the common patterns observed over the past decade.

We envision these methodologies serving as a checklist for researchers and developers, helping them to systematically explore known optimization strategies, reduce the risk of overlooking opportunities, and recognize when a true algorithmic breakthrough may be required.

Finally, to bridge the gap between conceptual principles and practical application, we present SysGPT, a fine-tuned GPT model [2] trained on a curated analysis of a decade's literature. Through both qualitative and quantitative evaluation, we demonstrate that SysGPT consistently outperforms the base model and few-shot learning approaches. Our qualitative analysis shows that SysGPT generates more specific and actionable suggestions that better align with ground-truth solutions, while quantitative results demonstrate significant improvements in precision, recall, and F1-score across various temperature settings and sampling configurations. This combination of conceptual rigor and practical utility ensures that the insights gleaned from our analysis do not remain only theoretical, but instead become a tangible tool for improving system performance.

In summary, this paper has the following contributions:

- Formalizes the performance of sequential execution and defines three principles to optimize it. (§2)
- Establishes eight methodologies that systematically guide sequential performance improvements.(§3)
- Empirically validates the completeness of the framework through a comprehensive analysis of OSDI and SOSP papers over the past decade. (§3)
- Demonstrates the potential of AI-assisted performance optimization through the development of SysGPT. (§5)

2 Problem Definition

$$S_{parallel} = \frac{1}{F_{serial} + (F_{parallel}/\#\text{ threads})} \tag{1}$$

Optimizing sequential performance is a fundamental challenge in system design. Amdahl's law (Equation 1)[8] provides an insight into the potential speedup achievable through the utilization of multiple processors in a computing task. The law states that the maximum possible speedup from parallelizing a program ($S_{parallel}$) is limited by the fraction of the program that must be executed sequentially, denoted as the serial fraction (F_{serial}). In other words, it highlights the fact that not all parts of a program can be parallelized, so even with infinite additional resources, there will always be a limit to how much faster a program can run. It's obvious that augmenting $F_{parallel}$ (and diminishing F_{serial}) leads to better performance. However, there has been a lack of systematic approach to optimize F_{serial} of a program. Moreover, many problems (programs) cannot be parallelized due to computational dependencies among constituent tasks, making the optimization of F_{serial} the only way to accelerate programs.

$$S_n = \{t_i\}_{i=1}^{n} = \text{Sequence of tasks for one } \textit{epoch} \tag{2}$$

The serial fraction of a program plays a pivotal role in determining the overall runtime and is of significant importance in optimizing performance. We define the serial fraction of a program (F_{serial}) as a sequence of tasks, t_1, t_2, $\ldots t_n$ as represented in Equation 2.

$$latency = F(S_n) = F(\{t_i\}_{i=1}^{n}) \tag{3}$$

$$throughput = N, \text{ where } N \cdot F(S_n) < time \tag{4}$$

In many common scenarios, a sequence of tasks is executed iteratively, with the optimization of repetitive tasks being the primary focus for performance enhancement. Each iteration is referred to as an *epoch*, and Equation 3 signifies the elapsed time to execute one epoch, typically denoting *latency*. S_n represents the sequence of tasks defined above, and F represents the execution time required to process S_n, where n is the number of tasks (length of S_n). Equation 4 defines *throughput*, providing insight into the number of epochs that can be executed within a given time frame.

2.1 Principles for performance optimization

In pursuit of enhancing system performance for sequential workloads, the focus lies on optimizing the sequence of tasks, S_n, to ultimately reduce the runtime $F(S_n)$. Given that the optimization target is sequential, $F(S_n)$ is deterministically influenced by the sequence S_n and the hardware executing it. Aside from completely rewriting S_n, there are three strategic approaches: removal, replacement, or reordering of tasks within the sequence. The following three principles delineate these strategies:

- $\mathbf{P}_{rm}$**:** Remove t_i from S_n. Upon optimization, the length of the optimized sequence S'_m is shorter than the original sequence S_n, thereby satisfying $m < n$.
- $\mathbf{P}_{rep}$**:** Replace t_i with t_j within S_n. While the length of the sequence S_n may remain unchanged, the optimized sequence S'_n yields a better overall runtime performance, denoted as $F(S_n) > F(S'_n)$.
- $\mathbf{P}_{ord}$**:** Explore alternative permutations of S_n. Different permutations of S_n indicates different execution order of given tasks, which can impact overall runtime.

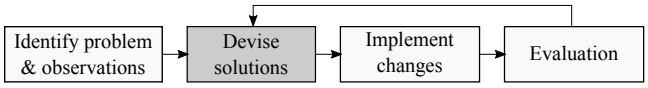

Figure 1: Steps in performance optimization.

2.2 Research scope

Our research targets optimizing the sequential fraction of system performance, focusing specifically on throughput and latency. Throughput reflects the system's capacity to process tasks within a given timeframe, such as request handling rates, model trainig speed, or data scanning speed. Latency measures responsiveness, including per-request or per-operation time, and offers insights into real-time performance and user experience. We focus solely on optimizing existing systems, excluding concerns such as security, energy use, space efficiency, fault tolerance, and maintainability. We also exclude the design of entirely new algorithms, as our goal is to optimize existing ones.

2.3 Steps in performance optimization

Performance optimization is a multi-step, iterative process involving inefficiency identification, solution design, implementation, and evaluation. While tools and benchmarks for problem identification and evaluation have matured over time, the intermediate steps—designing and implementing solutions—remain largely reliant on the researcher's expertise, creativity, and experience. These stages are often the most challenging, as they require both deep system knowledge and the ability to predict how changes will interact with the broader system dynamics. Within this context, this paper focuses on establishing a systematic approach for the second step: *devising solutions*.

3 The Eight Optimization Methodologies

The landscape of system optimization techniques is vast and often discussed informally, with little consensus on how many distinct strategies exist or how they relate to each other. In this section, we distill a decade of performance optimization research in the systems community and define eight actionable methodologies that together form a structured framework for sequential performance optimization: batching (§3.1), caching (§3.2), precomputing (§3.3), deferring (§3.4), relaxation (§3.5), contextualization (§3.6), hardware specialization (§3.7), and layering (§3.8). We explain each methodology through the principles of removal, replacement, and reordering, detailing its rationale and impact on sequential performance, and illustrating it with examples from representative system papers.

To empirically validate the coverage of our framework, we conducted a exhaustive review of 477 papers published at OSDI and SOSP over the past decade. Our analysis indicates that these eight methodologies collectively encompass all common patterns of sequential performance improvements observed in practice over the last ten years.

3.1 Batching

When the cost for computing a batch of items is lower than the total cost for computing each item individually, combining these items into batches will enhance overall efficiency. As shown in Table 1 (a), for every epoch, duplicate costs (x_2, x_4 and x_6) are incurred across epochs, and these costs are repetitively accrued with each iteration of epochs. With batching, depicted in Table 1 (b), these individual blocks are merged into one big block (x_7). To ensure the efficacy of batching, two conditions must be satisfied: the length of the optimized sequence should be shorter than that of the original sequence, and the running time for batched items should be shorter.

In terms of the three principles (§2.1), batching is a methodology which can effectively leverage all the three principles. First, batching commonly yields benefits through coalesced computation. By coalescing duplicate tasks together, particularly when each task incurs significant overhead, the overall runtime can be reduced. Upon comparing of the original and batched sequences, the latter removes x_2 and x_4 (P_{rm}), and replaces x_6 with x_7 (P_{rep}). Alongside P_{rm} and P_{rep}, the overall runtime improves. NEVE (①) is an example of this approach (see Table 2 for details).

Batching also inherently defers earlier tasks until a batch of tasks is gathered. Consequently, it has the potential to decrease the overall number of tasks to be processed by discarding stale tasks at the time of batched request (P_{rm}), thereby reducing the overall runtime. For instance, group commit and write buffer batch multiple updates and apply modifications in a deferred and batched manner, thereby some stale data that has already been deleted or updated does not need to be committed anymore. EAW (②) implements this approach by enabling applications to update batched items in the log prior to commit.

In addition, when batching is applied, the order of tasks is reordered (P_{ord}). For example, initially x_2 was located between x_1 and x_3, but after optimization, x_1 and x_3 will be executed consecutively. Therefore, batching might be employed to maximize the spatial and temporal locality of data. IX (③) efficiently adopts this strategy to batch requests at every stage of the network stack.

This concept is also closely interwined with caching (§3.2) as batching eventually provides greater caching opportunities with the improved locality.

In general, batched items can achieve higher bandwidth and throughput by eliminating redundant costs across tasks. Nevertheless, this approach can lead to extended latency, as initial earlier tasks in a batch might wait for subsequent tasks to arrive, and processing a batch usually takes longer than processing an individual task.

Methodology	P_{rm}	P_{rep}	P_{ord}	Visualization	Condition and Strategies
(a) Original					• Use below methodologies to reduce overall runtime.
(b) Batching	✓	✓	✓		$len(S_{before}) > len(S_{after})$ **AND** $F(x_2)+F(x_4)+F(x_6) > F(x_7)$ • Coalesce duplicate tasks together. • Discard stale tasks at the time of batched request. • Maximize spatial and temporal locality.
(c) Caching		✓			$F(x_4)+F(x_6) > F(x_7)+F(x_4')+F(x_6')$ • Introduce new caching layer on top of existing system. • Modify system to reveal more caching opportunities. • Develop caching policy to decide what to cache.
(d) Precomputing & Deferring	✓		✓		$len(S_{before}) > len(S_{after})$ **OR** $F(x_1,x_2) > F(x_2,x_1)$ • Move tasks out of a sequence and use resources in other time. • Reorder tasks within a sequence and seek for better locality. • Precomputing speculates a task will be required in near future. • Precomputing speculates future context. • Deferring expects the task will be shorter or not used at all. • Deferring creates an opportunity to exploit future contextual advantages such as caching or batching.
(e) Relaxation	✓	✓			$len(S_{before}) > len(S_{after})$ **OR** $F(x_k) > F(x_k')$ • Compromises other properties such as accuracy, consistency or durability. • Sampling is a common example of compromising accuracy.
(f) Contextualization		✓			$F(x_2)+F(x_4)+F(x_6) > F(x_7)+F(x_2')+F(x_4')+F(x_6')$ • Collect runtime context and make workload-specific decision. • Analyzing runtime characteristics can be done off the critical path then no need to pay extra cost.
(g) Hardware specialization		✓			$F(x_4) > F(x_7)+F'(x_4)+F(x_8)$ • Decide which tasks to execute on which hardware. • Tailored design for specific hardware.
(h) Layering	✓	✓	✓		Bypassing: $len(S_{before}) > len(S_{after})$ • Skip existing layer and take a fast-path. • The most common strategy is kernel bypass. Delayering: $len(S_{before}) > len(S_{after})$ **AND** $F(x_1)+F(x_2) > F(x_7)$ • Merge two tasks into one; singularity appraoch. Decoupling: $F(x_2) > F(x_2^1)+F(x_2^2)$ • Split one task into several fine-grained tasks. • Enable finer control and loosen dependencies. • Open more opportunities for other methodologies.

Table 1: Summary of the eight methodologies, detailing their underlying principles, visual representations, necessary conditions, and strategic applications.

3.2 Caching

While batching removes redundant costs across tasks, caching addresses redundant costs over time. The fundamental idea behind caching is to keep computational results in memory and reuse them at a later time, thereby avoiding redundant computation and leveraging previously computed values. Table 1 (c) illustrates how caching optimizes costs over time. For caching to be effective, the computational redundancy (x_4 and x_6) must outweigh the overhead of using and maintaining the cache. This overhead involves the cost for storing computed results in the cache (x_7) and retrieving old results from it (x_4' and x_6'). In other words, caching leverages P_{rep} by replacing redundant computation with cached results. Consequently, caching inherently reduces the overall runtime at the expense of increased memory usage.

Introducing a new caching layer on top of existing system involves identifying common operations that can be strategically cached for enhanced performance. Table 2 shows such examples to optimize stream processing (④) and VM allocation (⑤). Beyond introducing additional caching layer to the current system, it is also possible to reveal more caching opportunities by modifying existing structures (⑥).

Furthermore, numerous endeavors have been made to optimize caching policy, determining what to cache. The selective caching of frequently accessed (*hot*) data stands out as a particularly effective method for improving cache hit rates in environments having uneven access patterns (⑦).

		System	Description
Batching	①	NEVE [44]	Coalesce and defer traps to the hypervisor by logging to avoid context switch overhead between a VM and the hypervisor.
	②	EAW [13]	Exclude outdated data from the batch by allowing modifications in the log before committing.
	③	IX [11]	Apply batching at every stage of the network stack, including system calls and hardware queues to enhance instruction and data locality.
Caching	④	Drizzle [60]	Reuse scheduling decisions across micro-batches as computation is largely static and undergoes infrequent changes.
	⑤	Protean [27]	Cache previous virtual machine allocation result and reuse the placement across multiple requests.
	⑥	Tasi *et al.* [58]	Decouple permission checking from locating a directory and memoizes permission check resuls to enable fast path.
	⑦	NetCache [32]	Let programmable switches to cache hot data for key-value store architectures.
Precomputing	⑧	Duet [9]	Reorder storage maintenance to prioritize data already cached in memory.
	⑨	Itasks [18]	Proactively trigger memory reclaiming upon detecting the first sign of memory pressure to reduce garbage collection during critical path.
	⑩	Correctables [26]	Prefetch dependent objects based on preliminary view instead of waiting for fully consistent one to hide the latency of strong consistency.
Deferring	⑪	Sparrow [51]	Delay assignment of tasks to worker machine until workers are prepared, mitigating race conditions among multiple distributed schedulers.
	⑫	PACTree [35]	With optimistic version lock, perform an operation optimistically without holding a lock and then check the version number.
	⑬	SKYROS [23]	Defer expensive ordering and operation execution until their effects are externalized.
Relaxation	⑭	KnightKing [65]	Allow for sampling the next edge in random walk algorithms without scanning all out-edges at the walker's current vertex.
	⑮	RSS and RSC [28]	Relax certain real-time guarantees of strict serializability for causally unrelated transactions or operations.
	⑯	SAUCR [6]	Relax durability and availability when most servers crash simultaneously to achieve performance comparable to memory-durable one.
Contextualization	⑰	MemLiner [61]	Let application threads notify garbage collection tracing threads about accessed objects for better alignment of memory accesses.
	⑱	Syrup [34]	Use eBPF to have customized scheduling policies defined by applications.
	⑲	CLoF [15]	Automatically generates various hierarchical combinations of locks and selects the most performant configuration.
Hardware	⑳	Nap [62]	Introduce NUMA-aware layer over existing persistent memory (PM) indexes to manage hot items and avoid costly remote PM access.
	㉑	FAERY [66]	Adopt FPGA to accelerate embedding-based retrieval system which requires both high memory bandwidth and pipeline parallelism.
	㉒	KV-Direct [40]	Use programmable NICs to extend RDMA primitives and directly handle key-value operations in the host memory.
Layering	㉓	The nanoPU [29]	Route incoming messages directly to the running threads' registers, bypassing traditional memory hierarchies.
	㉔	TinyNF [55]	Simplify buffer management layers by removing buffer pool. Merge reception, processing and transmission into a single logical flow.
	㉕	RackSched [69]	Two-layer scheduling framework decouples inter-server scheduling in top-of-rack switch and intra-server scheduling in each server.

Table 2: List of example papers adopting each methodology to improve either latency or throughput.

3.3 Precomputing

Precomputing optimizes performance by strategically moving tasks to an earlier time, allowing them to be executed in advance of their actual need. Tasks can be moved to earlier time even before epochs start, as illustrated in Table 1 (d). Although moving a task forward may not directly reduce its execution time, it can optimize the performance of future performance-sensitive executions by moving the task off the critical paths (P_{rm}) and leverages resources that would otherwise be idle or less contended. On the other hand, task can be rearranged within an epoch to seek better opportunity for locality and reduce their execution time (P_{ord}). Duet (⑧) in Table 2 serves as an exemplary case which reorder tasks to better utilize caching.

Executing work earlier relies on two types of speculations. Firstly, it involves speculating that the task will be required in the near future. For example, proactive task execution serves as a preventive measure against unexpected overhead during critical operations, ensuring better control over their execution (⑨). Secondly, precomputing speculatively executes tasks based on current information, rather than waiting until a complete view of information is available (⑩). This proactive approach can significantly enhance system performance by ensuring the tasks are ready when needed, thus minimizing waiting times and accelerating overall workflow. However, to fully leverage the benefits of precomputing, it is crucial to make precise decisions about when and which tasks to execute ahead of time, as incorrect speculation may introduce overhead.

3.4 Deferring

In contrast to precomputing, deferring postpones a task to a later time, employing a lazy approach. Tasks can either be delayed to beyond an epoch (P_{rm}) or shifted to a later time within an epoch (P_{ord}).

One primary motivation for deferring a task is the anticipation of its eventual reduction of runtime when postponed. For instance, deferring a task allows it to make better decisions with the most up-to-date information available (⑪). Furthermore, as previously mentioned, the strategy of deferring tasks can be effectively combined with batching opportunities, since multiple deferred tasks can be executed together. NEVE (①), given as a batching example, also exploits deferring, demonstrating the close relation between these two methodologies (§4.2).

Some deferring examples even anticipate that the task

may eventually be canceled. If there's a possibility that a task could be useless, it can be considered to be deferred. Should it indeed prove unnecessary, the task can then be skipped, thereby preventing the system from wasting resources on tasks that were never required. *Optimistic decision* exemplifies this scenarios, rooted in the assumption that certain events such as concurrency conflicts (⑫) or crash will not occur, thereby deferring their handling until they actually happen.

Another rationale for deferring tasks is to prioritize the performance-sensitive sequence S_n, even if it may compromise later performance. In scenarios where a task within the S_n isn't immediately necessary and can be deferred, it can be executed lazily after S_n has been completed (⑬).

3.5 Relaxation

In some cases, precise or thorough answers are unnecessary while a reasonably accurate approximation suffices. When the workload and context can tolerate a modest degree of inaccuracy or inconsistency, existing system can be modified to reduce task size through approximate execution, thus delivering faster results. As depicted in Table 1 (e), relaxation substitutes existing tasks with significantly shorter tasks (P_{rep}), or even completely skips them (P_{rm}).

For example, sampling, a prevalent method of relaxation, analyzes a small subset of data instead of the entire dataset (⑭). Despite working with a smaller portion of the data, sampling aims to provide insights that reflect the overall dataset, thereby facilitating faster analysis and decision-making. In addition to the accuracy, other software requirements such as consistency (⑮) or availability (⑯) may be compromised in pursuit of performance.

3.6 Contextualization

There is typically a semantic gap between system design and the execution of real workloads. Design decisions often aim to meet general requirements due to uncertainty about future usage, but this lack of workload awareness can hinder optimal performance. To bridge this gap, existing systems are often customized by incorporating runtime context into their decision process. This context is often obtained by collecting data available during execution (⑰). Table 1 (f) illustrates a case where a system performs additional tasks to inform future decisions. While these may incur runtime overhead (denoted as x_7), the resulting performance (P_{rep}) improvements generally justify the cost. Alternatively, profiling workload characteristics off the critical path enables specialization without runtime penalties (⑱). eBPF also helps bridge the semantic gap by letting applications guide the kernel toward more efficient, workload-aware behavior (⑲).

3.7 Hardware specialization

Customizing the general system design for specific hardware configurations is another common approach. Optimization for hardware primarily involves determining which tasks should be executed on which hardware, taking into account the workload characteristics and hardware specifications. For example, numerous studies tailor existing general systems for specific hardware requirements such as non-volatile memory, non-uniform memory access (⑳), FPGA (㉑), or SmartNIC (㉒). In Table 1 (g), task x_4 is executed on different hardware (F') which can execute it more efficiently, resulting in reduced runtime ($F(x_4) > F'(x_4)$). When optimizing an existing system for particular hardware, the advantage of utilizing the hardware must outweigh the software overhead (x_7, x_8) incurred in transitioning to that hardware.

3.8 Layering

A layer is a logical division or abstraction defined during system design to organize and structure a system's components. Each layer encapsulates a specific set of functionalities or services, helping to modularize the system and making it easier to understand, maintain, and scale. While layers provide clear structural benefits, they also introduce performance overhead, stemming from additional processing, communication, or indirection across layers.

Layering, the final methodology, optimizes sequential performance by reducing the overhead associated with layers—through merging multiple layers, decomposing layers more efficiently, or selectively bypassing layers where appropriate.

Bypassing. It involves creating shortcuts or alternative paths in a system to avoid unnecessary steps or processes, thus reducing latency and improving overall performance. In Table 1 (h), x_4 is completely skipped through a fast-path (P_{rm}). Many existing works bypass the kernel stack [5, 16, 19, 21, 29, 37, 40, 46, 48, 54, 57, 68] and handle operations within the user space to eliminate context switching overhead between user and kernel, thereby having more flexible control for runtime requirements (㉓).

Delayering. It reduces the number of layers in a system's architecture. This simplification consolidates multiple abstraction layers and removes software overhead between them (㉔). Delayering often sacrifices generality, flexibility or functionality to achieve improved performance in specific scenario. Table 1 (h) shows a scenario where two tasks are merged into a single, larger layer, effectively reducing overall runtime. Delayering not only combines existing layers into one but also minimizes the intermediate overhead, leveraging both P_{rm} and P_{rep}.

While both delayering and bypassing aim to reduce the number of layers being executed, their approaches differ. Delayering restructures the system architecture itself to have fewer layers, thereby simplifying the system. In contrast, by-

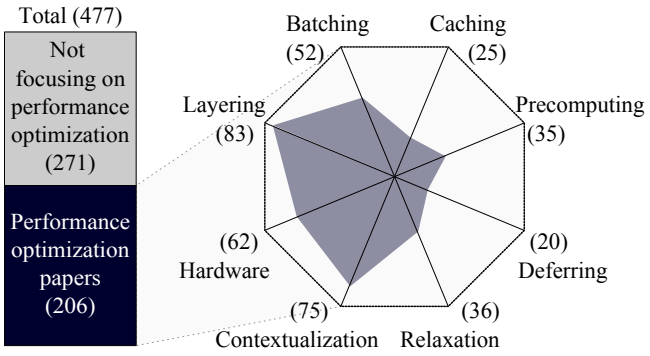

Figure 2: Number of papers leveraging each methodology. Since each paper may employ multiple methodologies, the cumulative count of methodologies exceeds the total number of papers within our scope.

passing selectively skips over existing layers without modifying the underlying architecture—the skipped layers remain present and may still be executed in other contexts.

Decoupling. In contrast to delayering, decoupling splits one layer into multiple ones. Decoupling aims to minimize dependencies between different components or modules within a system. This strategy enhances finer control and execution by loosening the coupling between parts, allowing changes to be made to one component without affecting others. Furthermore, by loosening dependencies between layers, it opens more opportunity for parallelization. In Table 1 (h), x_2 is decoupled into x_2^1 and x_2^2. Despite the potential for additional overhead between the layers due to having more layers, the benefit arises from the finer control it provides. For example, it becomes possible to execute either x_2^1 or x_2^2 individually rather than executing the larger x_2, or to implement different logic for each task (㉕).

4 Case Study

4.1 Statistics

To empirically evaluate the completeness of the eight methodologies in enhancing system performance, we systematically analyzed entire papers from the OSDI and SOSP conferences over the last decade, from 2013 to 2022. The review process was rigorously conducted, with each paper independently reviewed by two different reviewers to ensure accuracy and minimize bias. Papers from 2023 and 2024 were intentionally excluded from this analysis to serve as a fresh dataset for evaluating our fine-tuned model, as discussed in Section §5.

As depicted in Figure 2, our analysis of 477 papers reveals that 271 do not focus on performance optimization of sequential tasks. Among the remaining 206 performance-related papers, every technique employed to enhance existing performance aligns with one of our eight methodologies. Furthermore, these methodologies are often used in tandem. On average, research papers utilize approximately 2.01 methodologies, demonstrating the necessity of a multidimentional approach for improving system performance.

Table 2 provides a detailed breakdown of file and storage system papers presented at SOSP 2021, serving a case study to illustrate the practical application of the methodologies within the given domain. It provides insights into how the eight methodologies are leveraged in practice to address challenges within file and storage systems. Additionally, we provide suggestions for further performance optimization directly derived from the methodologies.

4.2 Relations between methodologies

The optimization of system performance through the eight methodologies is not isolated; rather, these strategies often interrelate and amplify one another when applied together.

Batching and deferring are closely interwined optimization strategies. Batching aggregates multiple operations to execute them collectively, inherently modifying their execution timing. For instance, a write buffer exemplifies the combined use of batching and deferring, as it accumulates multiple write operations to execute them together at a later time, improving data transfer and write efficiency. This approach not only minimizes repetitive, immediate operations but also strategically defers execution to a more opportune moment, thereby leveraging both batching and deferring for enhanced performance.

Decoupling separates tightly integrated components into finer-grained subtasks, enhancing modularity and flexibility. This separation facilitates a more targeted optimization of individual components. Often, specialization tailored for specific hardware configurations or software requirements necessitates initial decoupling of integrated mechanisms. This ensures that modifications are minimal and do not inadvertently impact any other system components. For example, Akkio [10] introduces an intermediary layer between client applications and the datastore systems to separate the allocation of shard data from its management. Consequently, this allows application to specify their own shard sizes much smaller than existing one, and determines the distribution of data across shards, facilitating customized shard assignment tailored to the needs of each application. Similarly, decoupling can enable more effective caching opportunities, especially when only a subset of a task's output is reused over time. For instance, Tsai *et al.* [58] first decouple permission checking from directory lookup, allowing permission results to be cached and reused independently, creating a fast path for common operations.

4.3 Applying methodologies to real problem

In exploring practical applications of the methodologies to improve system performance, we bring one case study for

Paper	Methodologies used in the paper	Suggestions for further optimization
ccNVMe [43]	❶ Instead of having per-request communication, batch requests and ring doorbell per transaction to reduce MMIOs and better utilize the write combining buffer. ❼ Leverage data dissemination mechanisms of NVMe for crash consistency.	❻ Instead of always chaining the completion doorbell to order transactions, enforce it only for dependent transactions.
Kangaroo [49]	❶ Batch multiple objects in log-structured cache first and move objects to set-associative cache as a group to reduce write amplification.	❽ Objects are always written twice: once in KLog and once in KSet. Having additional fast-path to bypass KLog and write directly to KSet could be beneficial in certain scenarios.
IODA [41]	❸ Proactively reclaim enough space via garbage collection to guarantee it is not triggered during predictable window. ❻ To reduce semantic gap between host and SSD for predictable latency, add new fields to I/O submission command and quickly get contextual status.	❷ Introduce a caching layer to serve hot items while the underlying flash storage is busy.
HeMem [56]	❶ Sampled memory events are processed in batches. ❶ Migrate memory pages in batches. ❺❻❼ Monitor applications' memory usage by sampling and make memory management decisions based on these patterns and hardware characteristics.	❸ Based on the memory access pattern, speculatively prefetch memory page from NVM to DRAM to lower the access latency.
J-NVM [39]	❽ Decouple object into proxy and data to directly access NVMM without runtime garbage collection. ❽ Remove the cost of converting data back and forth between NVMM and Java representation.	❷ Since persistent objects are separated into persistent data and a proxy in J-NVM, cache only the persistent data to hide access latency to NVMM.
PACTree [35]	❸ A reader optimistically performs a read on a data node. ❽ Decouple search layer and data layer and asynchronously execute structural modification operations. ❼ Take into account the specific characteristics of Non-Volatile Memory (NVM) to design an efficient persistent index.	❶ Given that allocating persistent memory incurs significant costs, preallocate memory in batches to hide allocation latency in critical path.
Aurora [59]	❽ Instead of having volatile memory and persistent storage separately, transparently persists all application states at regular intervals.	❶ Aurora can leverage batching to persist relevant POSIX objects together and reduce the latency of persistence.
WineFS [33]	❶ More huge pages to have less number of TLB entries ❸ Proactively take actions to prevent future fragmentation. ❻ Collects more runtime information for better allocation.	❷ Instead of traversing red-black trees repeatedly to find unaligned free space, cache the results of the traversals for faster allocation of small memory requests.
uFS [46]	❽ The uFS servers are implemented on userspace and bypass existing operating system stack.	❸ Preemptively reads more data than requested when the data access patterns are predictable.
FragPicker [52]	❶ Rather than issuing multiple small I/O requests due to fragmentation, consolidate them by migrating data to contiguous storage locations. ❻ Monitor applications' I/O activities and selectively migrate data for defragmentation.	❷ To efficiently address defragmentation, FragPicker should operate periodically. Caching previously observed I/O patterns might expedite the analysis phase in subsequent executions, for instance, predict which data blocks are more prone to fragmentation.
Witcher [22]	Propose automatic testing framework to detect correctness and performance bugs in NVM-based persistent key-value stores.	The goal of the paper is out of our scope.

Table 3: A complete list of file and storage system papers presented at SOSP'21. Each paper is annotated with the corresponding methodologies employed to improve performance: (1) batching, (2) caching, (3) precomputing, (4) deferring, (5) relaxation, (6) contextualization, (7) hardware, and (8) layering. Suggestions for further optimizations, derived from these methodologies, are also provided.

a paper, *Application-informed kernel synchronization primitives* [53] from OSDI'22. The paper introduces SynCord, a framework enabling application developers to deploy custom behaviors for kernel locks. Kernel locks are synchronization primitives within the kernel, to ensure that concurrent threads do not simultaneously access shared resources or critical sections of code. When multiple threads simultaneously request the same lock to enter a critical section, the lock implementation internally organizes these threads into a waiting queue. This process ensures orderly lock acquisition and allows only one thread to enter the critical section at any moment. Consequently, the critical section and the lock implementation are fundamentally serial (F_{serial}) and cannot benefit from parallelization. Optimizing these serial components, therefore, holds the potential to significantly improve performance.

Figure 3 demonstrates the strategies employed by SynCord to enhance lock performance and how they align with our methodologies. Primarily, SynCord maintains concurrent threads in a waiting queue and allows dynamic rearrangement of the waiters. A key contribution of SynCord is its decoupling of the reordering policy from lock mechanism, allowing the policy part to be managed in userspace (❶). Consequently, it allows userspace to create its own rule for lock acquiring order, facilitating the specialization of kernel lock behaviors to meet specific workload demands or requirements (❷). With user-defined policy, SynCord dynamically reorders threads in a waiting queue instead of conventional

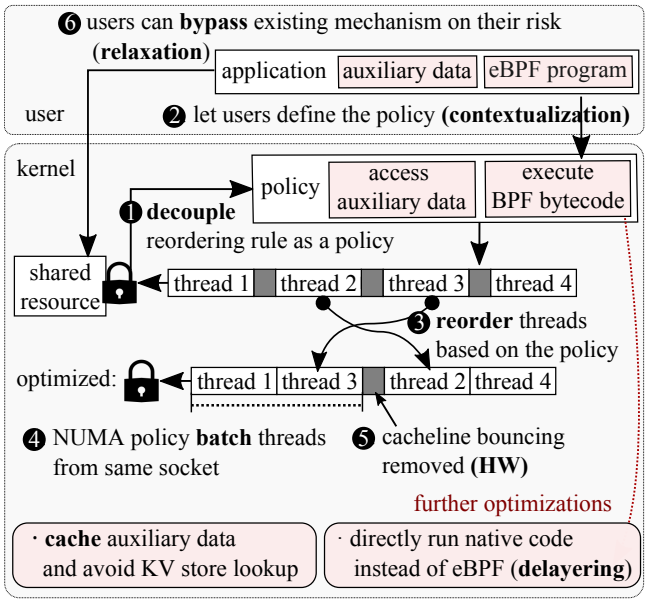

Figure 3: SynCord [53]'s strategies with integration of our methodologies. SynCord leverages most of the methodologies to optimize the performance of kernel locks. Moreover, using the methodologies, we identified two potential optimization opportunities: caching and delayering.

first-in-first-out policy (❸). For instance, a thread may be prioritized and moved to the front if it has a short critical section, or it can be deferred to the back if it operates on a slower core. This strategic reordering is carried out with the underlyig hardware in mind, as illustrated by batching threads from the same NUMA node together (❹) to remove cacheline bouncing between them (❺). Moreover, SynCord provides an API to completely bypass the kernel lock, allowing it to be redefined in userspace at the user's own risk (❻). While this approach relaxes the safety guarantee, it unveils opportunities for performance enhancements.

While SynCord incorporates the majority of our methodologies, two methodologies are still not directly adopted in their work, which hold potential for further optimization. The first one is caching. To accommodate various user-defined lock policies, SynCord provides auxiliary data through shadow variables [45], stored as a key-value store in the kernel. In scenarios where lock performance is crucial, it is common for threads to repeatedly acquire and release locks aggressively. Therefore, introducing a caching mechanism for this auxiliary data would allow for the reuse of previously accessed data upon subsequent accesses, thereby further reducing the overhead associated with repeatedly searching the key-value store every time using a lock.

Another overlooked opportunity is delayering. To protect the kernel from potentially faulty user code, SynCord compiles user-defined policies into eBPF [20] bytecode, allowing for static analysis through the eBPF verifier. However, the execution of eBPF program introduces additional overhead with each use of a lock. One potential optimization involves compiling user-defined policy programs into native code once they pass the static verifier, enabling their direct execution. This approach would eliminate the intermediary overhead between lock mechanism and user-provided policies.

In summary, this case study illustrates a successful application of methodologies. Moreover, exploring additional methodologies such as caching and delayering presents potential avenues for further optimization. It not only demonstrates that these methodologies are applicable in real research works, but also highlights its role as a checklist to maximize performance optimization and minimize any potential opportunities to be missed.

5 SysGPT: Hints for System Performance

Devising effective solutions for system performance optimization remains an open-ended and intuition-driven, often relying on experience rather than structured guidance. While tools for identifying bottlenecks and evaluating outcomes are mature, the intermediate step—formulating an actionable solution—often lacks systematic support. To address this gap, we introduce SysGPT, a fine-tuned [4] large language model (LLM) that provides context-aware optimization suggestions.

Our goal is to make our methodologies more applicable to real-world optimization workflows. While standard LLMs like GPT-4 [3] are trained on broad corpora, they often produce vague or overly verbose outputs that lack the specificity required for system-level decisions. We thus investigate whether a model that internalizes the distilled insights from a decade of systems research can provide more targeted and practically feasible suggestions.

5.1 Implementation

To build SysGPT, we first constructed a fine-tuning dataset based on our comprehensive review of all SOSP and OSDI papers published from 2013 to 2022. This corpus contains a wide range of system performance problems, each annotated with a problem description, observations, and the solution strategy employed in the original paper. The solution is annotated with both the applicable methodology from our taxonomy defined in §3, and a concise explanation of how it was used to address the problem. The dataset spans diverse systems domains, including file and storage systems, databases, machine learning infrastructure, and more. Notably, we excluded papers from 2023 and 2024 to use them exclusively for evaluation purposes, as described in §5.2 and §5.3, ensuring that SysGPT is tested on unseen examples.

Using this dataset, we fine-tuned GPT-4o [2] to produce SysGPT, a domain-specialized LLM that provides structured suggestions for optimizing sequential system performance.

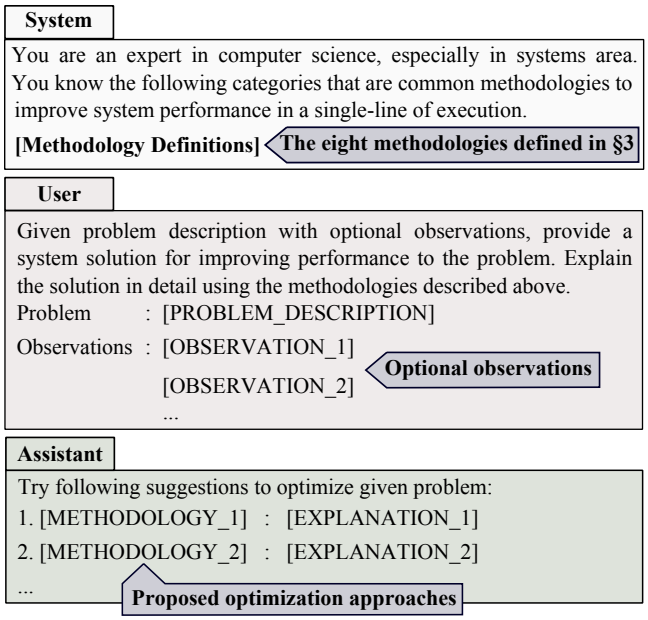

Figure 4: The prompt used for fine-tuning SysGPT. Observations can include background, existing challenges, related work, and more. Based on the descriptions provided by *system* and *user*, the *assistant* proposes multiple suggestions for optimizing system performance. Each suggestion is explicitly tied to the eight methodologies, accompanied by a brief explanation of its application.

The prompt format used during training is illustrated in Figure 4. Once fine-tuned, SysGPT can be used interactively. Given a system performance problem and context, the model returns a set of optimization strategies, each rooted in our methodology and supported by brief justifications.

To support reproducibility and facilitate future research at the intersection of systems and LLMs, we release our complete dataset and evaluation benchmark [1].

5.2 Qualitative results

We first examine whether SysGPT produces more feasible and meaningful suggestions than baseline models. Evaluating the *quality* of optimization suggestions is inherently challenging. There is currently no well-established benchmark for this task, and much of the utility of a suggestion depends on how it is interpreted and applied in practice. Since the effectiveness of a response often becomes clear only when a user reads and reasons about the suggestion in context, we include in this section the actual outputs generated by SysGPT and baseline GPT-4 for direct inspection and comparison.

Table 4 compares responses from SysGPT and baseline GPT-4. The test set consists of all database-related papers from SOSP and OSDI in 2023, which were excluded from our training data. To ensure comprehensive coverage and

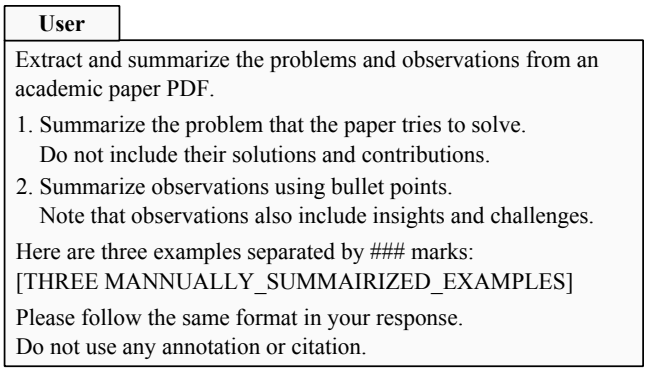

Figure 5: The prompt to automatically extract *problem descriptions* and *observations* from uploaded papers. The prompt explicitly instruct the model to identify and extract only the relevant problems and observations, while excluding any proposed solutions.

eliminate selection bias, we include the complete list of database papers, even those that do not primarily focus on performance optimization. Among the 10 papers, six address performance-related problems, while the remaining ones focus on topics such as security, privacy, or maintainability. To ensure scientific rigor, we use only the first model output for each case, with the temperature set to 0 to ensure deterministic behavior. Due to space constraints, the table contains summarized sentences, although most are directly extracted from the full model outputs.

To eliminate human bias in preparing inputs for test set, we automatically extracted problem statements and observations from each paper using a separate GPT-4o model with knowledge retrieval capabilities. The extraction prompt shown in Figure 5 explicitly instructs the model to include only the problem and relevant observations, while omitting any solutions or contributions described in the paper. This setup ensures that both models are evaluated solely based on their own reasoning given the same input, and that the evaluation pipeline is fully automated without any human intervention.

Since the problems and observations are directly derived from the original papers, a strong model should generate suggestions that meaningfully align with the solutions proposed by the authors. In this context, SysGPT consistently produces outputs that exhibit a high degree of correspondence with the ground-truth solutions, often matching not only the methodology but also specific implementation details.

Examples include concrete recommendations such as "set different lifetimes for hot/cold data by storing them separately in cache" or "decouple range index into frontend staging buffers and backend index update". In contrast, GPT-4 tends to produce more generic responses, such as "leverage runtime heuristics" or "implement an in-memory caching layer", which are less specific and often lack actionable guidance.

DeToX [12]	**P+O**	Traditional caching policies focus on object hit rate, but transactional workloads need to cache all concurrently requested objects to reduce latency. Transactions modeled as DAGs require scoring for eviction, which is costly, infeasible, and complicated by overlapping object usage.
	GPT-4	Design a caching policy that prioritizes key groups in transactional DAGs, leveraging runtime heuristics to balance latency and computational complexity.
	SysGPT	Infer transactional DAGs using dynamic profiling to capture transaction locality (❻). Pre-fill the cache with keys (❸) based on dependency tracking.
	Solution	To limit the number of groups scored, keys interchangeable in reducing critical length are treated as one group. Dynamically infer groups when DAGs are inaccessible (❻). Preemptively cache related items based on dependency tracking (❸).
VBASE [67]	**P+O**	Relational databases rely on strict monotonicity, while vector systems use approximate top-K, lacking this property. This division forces hybrid queries, like finding top-K vectors meeting relational conditions, to handle similarity search and relational filtering separately, resulting in inefficiencies.
	GPT-4	Dynamically adjust indices based on query patterns and embedding techniques. Employ adaptive sampling strategies to balance precision and computation. Integrate scalar and vector constraints to minimize computational overhead.
	SysGPT	Integrate vector search with relational databases by developing a query engine tailored for hybrid workloads (❽). Cache tentative results to avoid redundant computation (❷) while incrementally exploring new data. Use an adaptive search model that allows early termination based on the size of the result set during the search (❻).
	Solution	Instead of having two separate phases—one for finding top-K vectors and another for applying relational query filters—unify these steps into a single execution engine (❽) that incrementally expands traversal and terminates early once the query conditions are met. Use runtime information to traverse high-quality indices more frequently (❻).
Falcon [30]	**P+O**	The introduction of persistent cache challenges existing designs of online transaction processing engines on non-volatile memory. Cache-NVM granularity mismatch causes write amplification, and out-of-place updates increase NVM writes and require frequent index updates.
	GPT-4	Eliminate traditional logging by ensuring atomic updates directly in persistent cache. Employ fine-grained in-place updates to minimize NVM writes and integrate cache-aware index structures.
	SysGPT	Eliminate explicit cache line flushing by introducing persistent cache (❼). Set different lifetimes for hot/cold data by stroing them separately in cache (❷). Align cache eviction policies with NVM write block sizes (❶).
	Solution	With persistent cache, no need to explicitly flush logs for persistency (❼). To reduce write amplification from granularity mismatch, multiple cache lines are merged into one NVM write (❶). A small LRU cache absorbs hot tuples, avoiding manual flushing and reducing NVM writes (❷).
SPFresh [64]	**P+O**	Updating high-dimensional vector indices is challenging due to the cost of maintaining index quality during frequent updates. Existing methods rely on costly periodic global rebuilds, result in fluctuating query latency and accuracy.
	GPT-4	Adopt a hybrid approach combining cluster-based local updates with lightweight graph pruning. Cluster-based indexing minimizes the cost of local modifications, while periodic, asynchronous graph pruning ensures global quality without frequent full rebuilds.
	SysGPT	Incrementally update graph indices with minimal distortion on global indices (❺). Only manage short range connections accurately at runtime (❻) and move partition maintenance tasks off the critical search path (❸). Batch updates locally (❶).
	Solution	Perform incremental updates by reassessing only vectors affected by local changes, rather than rebalancing the entire index (❺). Accumulate small updates locally in partitions (❶) and use existing centroids and data distribution to expedite rebalancing (❷). Move the background split-reassign off from the critical path of update (❸).
Chardonnay [17]	**P+O**	Existing systems rely on two-phase commit for atomicity, causing performance limitations due to high RPC and log flushing latencies. Modern hardware with μs-level latency alleviates these issues, shifting the bottleneck to disk read. This creates contention during lock-holding periods, particularly under high workloads.
	GPT-4	Implement an in-memory caching layer for frequently accessed data. Leverage low-latency storage and fast RPCs to asynchronously synchronize disk-based storage.
	SysGPT	Relax synchronization for reads and eliminate dependencies between transactions (❻). Preemptively aggregate information about transaction participants and prefetch data (❸). Group read and write operations requesting same locks (❶, ❻).
	Solution	Use fast RPCs to read a counter for strict serializability without locks (❼). Dry run transactions to approximate read sets and prefetch them (❸). Reorder lock acquisition order based on the precomputed read/write sets to avoid deadlocks (❻).
ScaleDB [50]	**P+O**	Scaling in-memory databases on multi-core architectures is hindered by contention on range-index structures like B+ trees, caused by synchronous updates for consistency. However, range scans typically operate on stale data and read a few records.
	GPT-4	Decouple updates and reads by leveraging append-only logs for write operations. Large read-only range scans can bypass the index to directly access the underlying data.
	SysGPT	Decouple range index into staging buffers for front-end and backend index update (❽). Apply index updates in batches while caching them in the staging buffers (❶, ❷). Delay updating index from the critical path of transaction processing (❹).
	Solution	Decouple transaction execution from updating the affected range index (❽). Asynchronously apply batched updates to range indexes with optimistic concurrency control (❶, ❹). Cache recently committed transactions separately (❷).
Trubo [36]	**P+O**	The goal of the paper is user privacy, which is out of our scope.
TxCheck [31]	**P+O**	The goal of the paper is finding transactional bugs, which is out of our scope.
K9db [7]	**P+O**	The paper focuses on tracking data ownership in database and easier maintenance based on it.
HEDB [42]	**P+O**	The goal of the paper is security and maintainability, which are out of our scope.

Table 4: A complete list of database papers from SOSP'23 and OSDI'23, showing the problem and observations (P+O), suggestions from standard GPT-4 and SysGPT, and the actual solution. Solutions and suggestions are tagged with corresponding methodologies: (1) batching, (2) caching, (3) precomputing, (4) deferring, (5) relaxation, (6) contextualization, (7) hardware, (8) layering.

User

Evaluate two answers to a system performance problem by comparing them to the standard solution. Your goal is to determine which answer aligns more closely with the standard solution and explain your reasoning.

Problem statement : `[problem description]`

Observations : `[observations]`

Standard solution : `[Actual solutions used in the paper]`

Answer to evaluate : `Answer 1 = [Answer from GPT-4]`
`Answer 2 = [Answer from SysGPT]`

Figure 6: Prompt. LLM-based comparative evaluation.

To further validate this distinction, we conducted an LLM-based comparative analysis following standard practices in language model evaluation. In this setting, GPT-4o [2] serves as an independent evaluator, tasked with judging which of the two model outputs more closely aligns with the actual solution from the paper. The prompt for this evaluation is shown in Figure 6.

For 37 out of 42 papers (88%) in the test set (§5.3.2), the evaluator preferred SysGPT's output over that of the baseline. This strong preference stems from SysGPT's ability to provide more relevant and detailed suggestions that better align with the actual solutions devised by systems researchers. For example, in the case of Nomad [63], the evaluator noted that SysGPT's response "directly addresses two of the three key strategies: contextualization and deferring, with a clear focus on optimizing memory management based on application behavior and reducing unnecessary migrations." This demonstrates how SysGPT's methodologies enable it to generate more targeted and actionable suggestions for real system problems.

For the remaining 5 papers where GPT-4o's output was preferred, the evaluator's rationale primarily focused on broader strategy coverage rather than suggestion quality. For instance, in the case of CHIME [47], the evaluator noted that while GPT-4o's response covered all three components (batching, contextualization, and precomputing), it lacked critical implementation details like RDMA usage and hotspot buffer design. In contrast, SysGPT provided more practical and detailed suggestions for batching and precomputing, though it missed the contextualization aspect. This highlights SysGPT's strength in delivering concrete, actionable recommendations, even if it occasionally prioritizes depth over breadth in its coverage of optimization strategies.

5.3 Quantitative results

While the qualitative results in §5.2 highlight the specificity and feasibility of model-generated suggestions, it is inherently interpretive. To provide more objective evidence, we also include a quantitative evaluation that assesses how accurately models can identify applicable optimization methodologies given a system performance problem.

5.3.1 Task definition

We frame the evaluation as a multi-label classification task: given a system performance problem and its associated observations, the model must predict a set of applicable methodologies from the eight defined in §3. We then evaluate how well these predictions align with the methodologies actually used in the corresponding paper.

This formulation enables measurable evaluation using standard classification metrics such as precision, recall, and F1-score. It also helps reduce the subjectivity involved in open-ended solution generation by focusing on whether the model correctly identifies the underlying optimization principles.

5.3.2 Evaluation setup

The test set consists of all performance-related papers published at OSDI and SOSP in 2024 (42 out of 96). These papers were not only excluded from the fine-tuning dataset, but also released after the knowledge cutoff date (September 30, 2023) of both the base GPT-4o model [2] and SysGPT. As a result, neither model has access to the content of these papers, ensuring a fair evaluation on truly unseen examples.

Each paper is annotated with ground-truth methodologies based on the actual solution described by the authors. We compare three approaches: (1) the baseline GPT-4o model, (2) GPT-4o with few-shot prompting using 3, 5, and 10 examples, and (3) our fine-tuned SysGPT.

Few-shot examples are drawn from our training set and are carefully selected to cover all eight methodologies when 10 examples are given ($N = 10$). Each prompt builds on the structure shown in Figure 4. It includes a brief description of the taxonomy in the system prompt, along with N representative input-output examples and formatting instructions for the model's output.

All models are evaluated using the same inputs—problem descriptions and observations—automatically extracted as described in Figure 5. This ensures that any performance differences reflect the models' reasoning capabilities rather than differences in prompt quality, output format, or prior exposure to the test cases.

Metrics. We report micro-averaged precision (the fraction of predicted methodologies that are correct), recall (the fraction of ground-truth methodologies that are correctly identified), and F1-score (the harmonic mean of the precision and recall) over the eight methodology labels. Partial matches are accounted for; for example, if the ground truth is (batching, caching) and the model predicts (batching, precomputing), this counts as one true positive, one false negative, and one false positive.

Model	N	Output	Precision	Recall	F1-score
GPT-4o	0	-	0.277	0.934	0.426
GPT-4o	0	Top-2	0.476	0.377	0.421
GPT-4o	3	-	0.342	0.840	0.486
GPT-4o	3	Top-2	0.560	0.443	0.495
GPT-4o	5	-	0.344	0.802	0.482
GPT-4o	5	Top-2	0.547	0.434	0.484
GPT-4o	10	-	0.345	0.868	0.479
GPT-4o	10	Top-2	0.536	0.425	0.474
SysGPT	-	-	**0.758**	**0.651**	**0.701**

Table 5: Methodology prediction evaluation on the SOSP/OSDI'24 test set. We compare SysGPT and GPT-4o under few-shot prompting ($N = 0, 3, 5, 10$) with/without top-2 output constraint.

5.3.3 Results

Table 5 summarizes the results of our evaluation. SysGPT clearly outperforms all GPT-4o configurations in F1-score, demonstrating that fine-tuning with methodology-aware supervision leads to more accurate and relevant predictions. In its default form, GPT-4o tends to enumerate nearly all methodologies regardless of input context, resulting in an average of 6.23 suggestions per query. This behavior leads to a high number of false positives—resulting in low precision and high recall—and ultimately producing noisy and unhelpful outputs.

To compensate for GPT-4o's tendency to overgenerate, we added a constraint limiting its output to the top-2 most promising methodologies. While this adjustment improves GPT-4o's precision, now the recall drops significantly, and the overall F1-score remains lower than that of SysGPT. We believe this improvement stems from SysGPT's exposure during fine-tuning to realistic solution patterns with properly labeled methodologies. This training enables SysGPT to more effectively filter out irrelevant suggestions and focus on feasible strategies grounded in the problem and observations.

To assess robustness under non-deterministic sampling, we evaluate performance (Best@k) across multiple temperature settings ($T = 0.1, 0.3, 0.5, 0.7$) and trials ($k = 1, 3, 5, 10$), reflecting what an average user might expect from multiple trials. For each temperature, we generate k samples and report the best-scoring prediction relative to ground truth. As shown in Figure 7, SysGPT consistently achieves higher scores across all temperature settings and trial counts, with an average F1-score improvement of 39.1% over GPT-4o. This demonstrates that SysGPT's methodology-aware training enables more stable and reliable predictions even under varying sampling conditions.

These results validate that SysGPT's performance gains are not simply due to stylistic alignment with the training data, but stem from its improved capability to identify relevant optimization principles. The methodology-aware fine-tuning improves both precision (fewer irrelevant suggestions) and recall (more comprehensive coverage), and generalizes to unseen papers from a later publication year. This demonstrates that SysGPT is not merely reproducing past solutions, but learning transferable reasoning patterns applicable to new system performance problems.

6 Discussion

6.1 Complementing causal profiling

Performance optimization is a multifaceted challenge. Optimizing sequential code is not a panacea, and improvements on one task do not always translate to end-to-end performance gains. As demonstrated by Coz [14] paper, accelerating a component may have little or no effect on overall performance if it is not on the critical path. Coz introduces causal profiling, a technique that quantifies the potential impact of speeding up different parts of a program to identify *where* optimizations will be most effective. Once such regions are identified, however, the challenge becomes *how* to optimize them effectively. This is where our work contributes. While Coz identifies high-impact optimization targets, our methodology provides a systematic framework for realizing those optimizations. Together, they form a complementary performance optimization pipeline guiding both where to focus and how to proceed.

6.2 Coordination between tasks

While our framework models performance in terms of individual sequences, coordinating multiple tasks is often crucial for achieving system-wide performance improvements. In multi-threaded and distributed environments, interactions between tasks—such as contention for shared resources, scheduling delays, or communication overhead—can dominate execution time, even when individual operations are optimized. Strategies that align task execution to reduce contention, schedule work based on hardware topology, or overlap communication and computation are widely-recognized techniques for improving throughput and latency.

These coordination strategies, however, typically require reasoning across multiple execution contexts, extending beyond the assumptions of our sequential model. Although some coordination effects—such as improved locality or deferred execution—can be partially captured through batching or reordering, a full treatment of inter-task dynamics remains beyond the current scope. Extending our methodology to incorporate coordination-aware techniques represents a promising direction for future work.

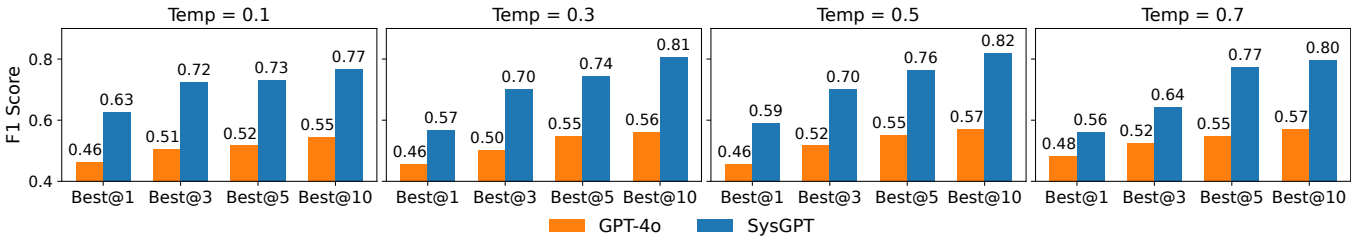

Figure 7: F1-scores under non-deterministic sampling with temperature values set to 0.1, 0.3, 0.5 and 0.7. For each temperature, we generate k responses and report the best score among the k trials (Best@k).

6.3 Limitations of SysGPT

SysGPT targets the second step of performance optimization: devising solutions. Its effectiveness therefore depends on input quality and the subsequent implementation. Well-defined problems and detailed observations yield precise, actionable suggestions, whereas vague inputs can lead to generic ones. SysGPT offers conceptual guidance in natural language but does not directly modify code. As such, implementation and evaluation still require developer expertise.

We envision a future where the entire optimization pipeline—from performance monitoring and solution design to code generation and evaluation—is automated. Realizing this vision will require significant advances across program analysis, synthesis, and systems tooling. Our work takes a step toward this goal, providing a foundation for automated performance optimization.

7 Related Work

Optimizing system performance has been a longstanding aspiration of computer systems research. Alongside countless studies aimed at enhancing performance across various systems through diverse strategies, there have also been some efforts to explore high-level methodologies for performance optimization.

Lampson [38] provides hints and principles for computer system design, suggesting principles such as simplicity, timeliness, efficiency, adaptability, dependability and desirability. While Lampson's discussion of *efficiency* partially aligns with our goal of system performance optimization, it largely relies on intuition and high-level ideas. In contrast, our work takes a systematic approach to optimize system performance in terms of sequential execution, by defining fundamental principles and empirically validating the completeness of the four methodologies with scrutiny over a decade. We illustrate how these methodologies can be practically applied to solve real-world problems efficiently, with case study and SysGPT, significantly extending the existing literature on performance optimization.

The Systems Performance book [25] also provides methodologies to improve performance and reduce latency. However, it targets system administrators and explains practical tools for better system monitoring. Based on the introduction of various performance analysis tools and background to understand them, the book guides how to use existing system and tools better, rather than fundamentally optimizing system designs itself, as our work does.

Similar to the CAP theorem [24], which states that a distributed system can optimize only two of consistency, availability, and partition tolerance, our methodologies define the boundaries of system performance optimization. Both frameworks help narrow the scope of exploration, guiding developers toward feasible and practical improvements.

8 Conclusion

Optimizing sequential system performance remains a fundamental yet often understructured task in systems research. We proposed a systemized framework based on three core principles—removal, replacement, and reordering—and distilled them into eight actionable methodologies commonly used across a decade of systems literature. This taxonomy clarifies the space of optimization opportunities and offers a systematic language for reasoning about performance. Built on this foundation, we introduced SysGPT, a fine-tuned LLM trained to suggest strategies grounded in this methodology. Evaluated on unseen papers, SysGPT significantly outperformed GPT-4 baselines in both qualitative and quantitative evaluations, demonstrating its superior ability to generate targeted, actionable suggestions for real-world system performance problems.

9 Acknowledgment

We thank our shepherd and the anonymous reviewers for their valuable feedback. We are also grateful to Changwoo Min and Sanidhya Kashyap for insightful discussions during the early stages of this work. This research was supported by ONR under grant N00014-23-1-2095, DARPA V-SPELLS N66001-21-C-4024, and gifts from Facebook, Mozilla, Intel, VMware, and Google. This work was also supported by IITP grant funded by the Korean government Ministry of Science and ICT (MSIT) under the project titled RISC-V based system software development for open ecosystem of SDR (No.RS-2024-00459774).

Söze: One Network Telemetry Is All You Need for Per-flow Weighted Bandwidth Allocation at Scale

Weitao Wang T. S. Eugene Ng

Rice University

Abstract

Weighted bandwidth allocation is a powerful abstraction that has a wide range of use cases in modern data center networks. However, realizing highly agile and precise weighted bandwidth allocation for large-scale cloud environments is fundamentally challenging. In this paper, we propose Söze, a lightweight decentralized weighted bandwidth allocation system that leverages simple network telemetry features of commodity Ethernet switches. Given the flow weights, Söze can effectively use the telemetry information to compute and enforce the weighted bandwidth allocations without per-flow, topology, or routing knowledge. We demonstrate the effectiveness of Söze through simulations and testbed experiments, improving TPC-H jobs completion time by up to 0.59× and 0.79× on average.

1 Introduction

As a fundamental building block of the modern data center, the transport layer provides accurate and reliable data delivery between machines. Transport solutions in use by data center networks today [12, 33, 35, 62] aim to achieve a fixed goal, where the bandwidth resource sharing is generally fair and the actual allocation only depends on the traffic pattern. Unfortunately, since modern cloud applications' performance goals [3, 4, 8, 25, 43] for data transmissions are diverse and may change over time [49], such a rigid resource allocation strategy clearly cannot suit every application's need perfectly.

To better serve the various and evolving applications, weighted allocation can be a powerful abstraction [37, 44]. For example, when a flow with weight 3 shares a bottleneck link with another flow with weight 1, the bandwidth is allocated 75% and 25%. Weighted allocation has many potential use cases. For example, important jobs or latency-sensitive jobs can be prioritized for shorter waiting time [17, 26]; within a job, resources can be prioritized for critical paths to reduce the job completion time [48]; service-level objectives can be achieved by carefully assigning weights [42].

Although weighted bandwidth allocation can be extremely helpful and provide unique benefits for applications [37, 44], the reason that blocks its wide deployment is the scale of the cloud data center [10, 15]. Realizing the flow rates that conform to a weighted bandwidth allocation policy at scale is challenging. Existing systems try to implement and enforce the policies through either packet scheduling [21, 52] on switches or using a logically centralized bandwidth allocator together with rate shapers [32, 51]. On one hand, packet scheduling-based implementation is limited by the small number of per-flow queues and the coarse granularity of weight parameters supported by switch hardware [41, 61]. On the other hand, a logically centralized bandwidth allocator-based implementation has high communication latency to gather and dispatch information and high computation cost to calculate the optimal allocation [27, 32]. Thus, realizing weighted bandwidth allocation for cloud networks with fine granularity, high agility, and high scalability remains an open challenge.

In this paper, we provide all the above properties for weighted bandwidth allocation with our approach called Söze. Our insight is that we need only one network telemetry along a flow's path, regardless of the number of hops, to solve the weighted bandwidth allocation problem at the bottleneck. Furthermore, instead of using this telemetry to gauge congestion levels like in traditional use cases of network telemetry, this telemetry is cleverly repurposed to signal the correct weighted fair share at the bottleneck.

With Söze, every flow can be associated with a weight regardless of the number of flows or the size and topology of the network (scalability, generality), each flow's weight can be fine grain adjusted instantaneously at the host (granularity, flexibility), and the weighted bandwidth allocation is realized in a matter of several RTTs (agility). These capabilities provide a building block for supporting various application scenarios such as critical path prioritization, coflow straggler mitigation, intelligent bandwidth sharing across jobs, altruistic bandwidth sharing, shortest flow prioritization, etc.

Our contributions can be summarized as follows:

- Söze shows that one network telemetry is enough to reflect the network sharing status and serve as a channel

to coordinate multiple flow senders, thus offering an effective control knob for weighted bandwidth allocation.
- Söze provides a novel decentralized framework to enforce the weighted max-min fair allocation for different flows across the network with high precision and agility, without per-flow, topology, or routing information.
- We show that Söze can be seamlessly incorporated into existing transport layer mechanisms such as TCP and eRPC. In the evaluation, we show that Söze reduces the job completion time for the TPC-H benchmark up to 0.59× and 0.79× on average.

This paper is organized as follows. §2 motivates weighted bandwidth allocation and discusses challenges in designing an ideal weighted bandwidth allocation system in a large-scale cloud. §3 introduces our proposal Söze with thorough design details and proves that leveraging the network telemetry feature can achieve highly accurate weighted bandwidth allocation. §4 and §5 provide implementation details and extensive experiments to demonstrate the effectiveness of Söze. §6 discusses related work and we conclude in §7.

2 Motivation

In this section, we firstly introduce the benefits of weighted bandwidth allocation for the network (§2.1); Next, we list the essential requirements for an efficient and powerful weighted allocation solution (§2.2); Lastly, we motivate that the in-network telemetry (INT) can be a low-cost and efficient solution to achieve weighted bandwidth allocation (§2.3).

2.1 Weighted Bandwidth Allocation

Instead of a rigid bandwidth allocation strategy, weighted bandwidth allocation can give modern applications extra flexibility to adapt the underlying bandwidth allocation intentionally for better performance, which benefits many applications, like ML training, Spark/Hadoop, databases, and RPCs. With the increasing demand for giant applications [11, 55] and low-cost function services [24, 57], modern cloud applications tend to rely on the data center network for efficient data exchange under distributed execution. Take distributed training with data parallelism as an example, the tensors at different layers can be assigned different priorities for accessing the bandwidth resource, in order to overlap the communication and computation process and accelerate the overall training process [28, 29, 47]. For map-reduce applications such as Spark and Hadoop, prioritizing the straggler flow over others during the shuffle operation is a common technique to shrink the job competition time [18, 19].

2.2 Challenges

As the key infrastructure for interconnecting hardware in the cloud, one would expect the network to provide efficient and fine-grained weighted bandwidth allocation services to meet the various requirements from the applications. However, networks in the production environment only provide coarse-grained differentiation, such as traffic aggregate classes with bandwidth reservations or strict priorities. The challenges in providing efficient and fine-grained weighted bandwidth allocation services for the network come from multiple aspects:

Bottleneck resource recognition. Unlike many other computational and storage resource, the data center network has multiple layers and each layer contains multiple alternative connections, where the routing of each flow is determined with random seeds and is difficult to predict. For the flow that utilizes such networks, its path will travel multiple hops where every hop has a bandwidth capacity. On different hops, the flow will contend and share the bandwidth resources with an unpredictable group of other flows, but only one of the hops will become the bottleneck and limit its sending rate. Recognizing the bottleneck resource is therefore crucial for determining the weighted allocation of bandwidth resource but the bottleneck resource is highly unpredictable.

High scalability with large network size and high concurrency. Besides recognizing bottleneck resources, the intended system size adds another dimension of challenge: 1) Massive information: the amount of information we can collect from the network is massive, including the network topology, link bandwidth, and each flow's sender/receiver/routing. How to filter and pick the most useful information and reduce the input to the algorithm can be challenging. 2) Global optimality: since the weighted bandwidth allocation needs to be enforced at the bottleneck resource to be effective, how to reach this global optimal state with low cost and consistently fast solving time is also challenging.

Fine-grained weighted allocation. To support fine-grained policy changes, the weighted bandwidth allocation system should accommodate flow weight with fine granularity and enforce the desired allocation with high precision. However, due to the network's scale, fine granularity and high accuracy are hard to obtain cost-effectively through high-precision computations in switch ASICs. Fine-grained weighted bandwidth enforcement must require careful algorithm design instead of relying on switch hardware capability.

High agility in updates and changes. A weighted bandwidth allocation policy needs to be realized quickly, but this is challenging because the network environment dynamics can affect the allocations, and the solution must react quickly. Firstly, the network condition may change due to updates, like new flow arrivals, existing flow finishes, link failures, and routing changes. Secondly, the application may update the task weight based on the runtime information or user input.

2.3 Use Telemetry for Coordination

In-network telemetry (INT) is a common feature in switch ASICs today [5–7] that enables better network visibility by in-

serting the fine-grained switch-local information (e.g., queueing delay, timestamp, transmitted bytes, etc.) into the packet headers. The typical usage for the INT data is network monitoring, informing the network operator about the current network status, such as the queue depth or the link utilization. INT data is quantitative so that it can describe the status of the network accurately in a timely manner. In this paper, we want to use the INT feature to help achieve weighted bandwidth allocation. To start, we introduce the INT with a realistic example and demonstrate why the INT function can be used for information exchange and coordination.

Typical INT data include queueing level, link utilization, etc. As a concrete example, let us use queueing delay for demonstration: 1) Multiple senders create an incast scenario on one link, and this link collects the queueing delay as the INT and informs all senders through packet headers. 2) The queueing delay may change if any sender changes its sending rate, but the actual change of queueing depends on the behavior of all senders together. 3) All flow senders will have the same observation about the queueing delay, such as the queueing increases if every sender increases its rate. 2) and 3) imply that if flow senders change their behavior, the changes may be reflected in the queueing delay, and all the senders will sense the change at the same time. In this way, an information exchange channel can be constructed using queueing delay. Thus, we argue for a distinctly different usage for INT: using passive INT data to coordinate different hosts.

Such an information exchange channel through INT data has many unique benefits. First, the in-network telemetry feature on switches is simple and low-cost compared to other types of information exchange, which preserves deployability and scalability. Second, the in-network telemetry data is inherently quantitative, which can be used to achieve fine-grained goals with precision. Thirdly, the in-network telemetry feature can operate on a per packet granularity at full line rate, therefore timely information exchange can be achieved at very high speed. All of the above properties of in-network telemetry are favorable for designing a low-cost scalable system for bandwidth allocation, but we still need to design an algorithm to make the best use of the INT data.

3 Design

Driven by the observations in §2, we propose Söze, a decentralized weighted bandwidth allocation system for large-scale and highly dynamic cloud environments. Given the flow weights, Söze can identify the bottleneck and enforce the weighted max-min fair bandwidth allocation with only one network telemetry. In this section, we firstly show how Söze achieves the weighted allocation on a single switch, where the bottleneck is always the switch egress (§3.1); Then, we show that Söze can be applied to arbitrary data center networks, where the bottleneck can be any hop (§3.2); Lastly, we summarize our system design (§3.3) and discussions (§3.4).

3.1 A Single Switch Scenario

In this subsection, we show step-by-step how we derive a decentralized resource allocation algorithm from a straw-man algorithm. For the goal proposed in §3.1.1, we first give a simple decentralized algorithm where a lot of information needs to be collected and exchanged in §3.1.2; then we try to reduce the amount of information to be very tiny in §3.1.3; finally, we pick only one piece of information and transform it into a different format, to make telemetry easy and practical on the switches in §3.1.4.

3.1.1 Goal: Decentralized Weighted Allocation

Denote the flows on one link are $\{f_0, f_1, ..., f_n\}$, their specified weights are $\{w_0, w_1, ..., w_n\}$, and the hop bandwidth is B. After converging to weighted bandwidth allocation, the weighted fair-share should be $\frac{B}{w_0+w_1+...+w_n}$, and flow f_k's rate, r_k, should be:

$$r_k = \frac{w_k}{w_0 + w_1 + ... + w_n} \cdot B \tag{1}$$

However, calculating this weighted allocation requires obtaining the sum of all flows' weights, where a centralized controller is usually required. No matter when a new flow joins or an existing flow wants to change the weight, the centralized controller needs to be notified. Thus, this could become the bottleneck of the whole system and prevent the weighted service from being agile, accurate, and scalable.

3.1.2 Straw-man: Massive Information Exchange

A straw-man decentralized solution can be given as follows: **each flow f_i could send its weight specification w_i to every other flow**, then every flow sender is able to calculate its rate with Equation 1 directly.

However, the problem with this straw-man solution is that the communication overhead is too high for data center networks. If there are n numbers of flows on the link, the total amount of information that needs to be exchanged is $O(n)$ for each flow sender.

3.1.3 Reduce the Information Exchange

To reduce the information exchange for achieving the weighted resource allocation, Söze splits Equation 1 into two equations. And those two equations are achieved if and only if Equation 1 is achieved (proved in Appendix B of [59]):

$$\begin{cases} r_0 + r_1 + ... + r_n = B \\ \frac{r_0}{w_0} = \frac{r_1}{w_1} = ... = \frac{r_n}{w_n} \end{cases} \tag{2}$$

For the first equation in Equation 2, Söze finds that the sum of all flows' rates is the arrival rate of the link; For the second equation in Equation 2, Söze further reformats the equation

with respect to $\max(\frac{r_i}{w_i})$ and $\min(\frac{r_i}{w_i})$. Interestingly, now we are able to rewrite Equation 2 from any single flow k's view in a decentralized manner:

$$\begin{cases} link_arrival_rate = \sum_{i=0}^{n} r_i = B \\ \frac{r_k}{w_k} = \min_{i\in[0,1,...,n]}\left(\frac{r_i}{w_i}\right) = \max_{i\in[0,1,...,n]}\left(\frac{r_i}{w_i}\right) \end{cases} \quad (3)$$

If and only if every flow individually observes that Equation 3 has been achieved, the weighted allocation is achieved for all flows. Thus, potentially, **only the information about whether $\sum_{i=0}^{n} r_i = B$ and $\frac{r_k}{w_k} = \min(\frac{r_i}{w_i}) = \max(\frac{r_i}{w_i})$ are satisfied is required to be exchanged**. In this way, Söze largely reduced the exchanged information from $O(n)$ to $O(1)$ for each flow sender.

3.1.4 Conduct Information Exchange with a Convergence Algorithm and In-network Telemetry

Although the information's content is determined, how to conduct the exchange remains a problem. In this subsection, Söze leverages the in-network telemetry and designs a convergence algorithm for every flow to converge to the equilibrium in Equation 3 with zero coordination between flows.

❶ **Use the link itself for information exchange.** Previous methods usually exchange information only among servers (flow senders), either in a master-slave architecture or an all-reduce architecture. However, the information exchange among servers is always off-path and leads to extra overhead. Thus, Söze uses an on-path device for information exchange: the link. Since flows compete for the link bandwidth resource, they must travel this link, which makes it the best channel to deliver information among servers or flow senders.

A specific new technique for links: **in-network telemetry.** Söze leverages a new and common feature of the commodity switches: In-network Telemetry (INT), which allows the switch to tag some information on the packet. Specifically, Söze only uses one of the telemetry data — **queueing delay**. The queueing delay is tagged in the data packet header on the forwarding path and reflected back to the sender with the ACK packet header on the reverse path. Only the queueing delay on the forwarding path is required and it is represented by a single 2-byte field in each packet header. This operation is simple and does not require the use of programmable switches.

❷ **Queueing delay inherently implies link arrival rate.** The queueing delay's dynamic inherently reflects the link arrival rate, more specifically, the first derivative of the queueing delay is the difference between the link arrival rate and the link bandwidth. Denote the queueing delay as D, link arrival rate as R, and link bandwidth as B:

$$\frac{dD}{dt} = \frac{R-B}{B}, \forall D > 0 \quad (4)$$

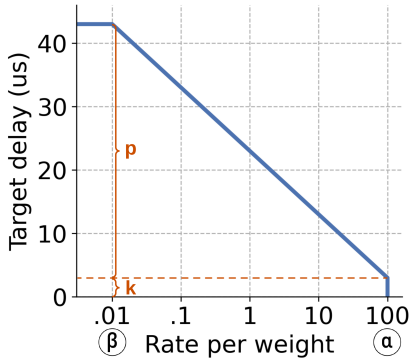

Figure 1: Target function must be monotonically decreasing. p is the queueing delay scaling and k is always > 0 for full utilization; α and β should be set to the highest and lowest rate-per-weight, depending on the scenarios.

As shown in Equation 4, as long as the queueing delay is stabilized around a non-zero value, the link arrival rate is equal to the bandwidth. Since each flow could individually observe queueing delay, the first equation in Equation 3 can be verified in a decentralized manner.

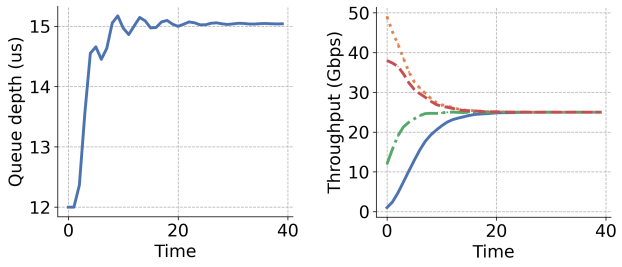
❸ **Design different queueing delays to represent different weighted fair-share.** Since the queueing delay can be stabilized around any value to indicate the link arrival rate, the actual value of the queueing delay can be used to represent another selected property. In Söze, different queueing delays represent different weighted fair-share with a unique one-to-one mapping, where the weighted fair-share wfs is defined as $wfs = \frac{r_i}{w_i}$ from Equation 2. Specifically, the larger the weighted fair share, the smaller the queueing delay. In addition, we denote a flow's rate divided by its weight as its "rate-per-weight". For networks in weighted allocation status, each flow's rate-per-weight is equal to the wfs.

$$target_delay = T(\frac{r_i}{w_i})$$
$$T(x) < T(y), \forall\, x,y \text{ where } x > y \quad (5)$$

With this relation between the queueing delay and the weighted fair share, each flow could compare its rate-per-weight with the wfs value from the queueing delay and find out if it is smaller or larger than the indicated value. In this way, a possible convergence algorithm can be created to converge to the second equation in Equation 3.

❹ **Provide a convergence algorithm that uses insights ❷ and ❸ simultaneously.** The convergence algorithm will converge to a final steady state indicated by Equation 1, where the weighted fair share is $\frac{B}{w_0+w_1+...+w_n}$, and the queueing delay on that link is a function of the weighted fair share.

The target function differentiates flows with larger $\frac{r}{w}$ from flows with smaller $\frac{r}{w}$, so that the function is monotonically-decreasing as in Figure 1. With this, each flow



(a) Convergence to the target queueing delay.

(b) Convergence to weighted fair-share.

Figure 2: Convergence for 4 flows on a single switch.

calculates a queueing delay according to their own $\frac{r}{w}$.

$$T\left(\frac{r}{w}\right) = p \cdot \frac{ln(\alpha) - ln(\frac{r}{w})}{ln(\alpha) - ln(\beta)} + k \tag{6}$$

In Equation 6, k is the minimal queueing delay when the link is saturated by one flow; p is the queueing delay scaling to differentiate between different flows. α and β indicate the most frequent range of weighted fair share: α is the highest rate-per-weight, which is usually the link bandwidth divided by the smallest weight; β is the lowest rate-per-weight, which can be determined with the traffic pattern. The update interval is referred as Δt, where $\Delta t = \frac{RTT}{CWND}$ for per-packet update.

The update function tries to change a flow's sending rate so that its target delay can match the observed queueing delay.

$$U\left(\frac{r}{w}, D\right) = \left(\frac{T^{-1}(D)}{\frac{r}{w}}\right)^{m} \tag{7}$$

In Equation 7, m is a smoother parameter smaller than 2, which is tunable to achieve either faster convergence or more stable final state.

In Algorithm 1, we give an incredibly simple decentralized algorithm for each flow sender to adjust their rate and converge to weighted allocation. After receiving the queueing delay information from the link, each flow calculates a *ratio* based on its current rate-per-weight and the received queueing delay, then updates the rate accordingly. From any initial bandwidth allocation, the final allocation will always comply with the weighted fair share as in Equation 1.

3.1.5 Proof of Convergence to Weighted Allocation

Although the above decentralized algorithm has no explicit information exchange, the queueing delay that contributed by all the flows is also observed by all the flows, which conducts an efficient information exchange towards the weighted bandwidth allocation. With the above design, we are able to have the following two lemmas:

Lemma 3.1: Convergence to Weighted Fairness

Söze converges to the weighted fairness on a link if and only if $0 < m < 2$ in the update function.

Algorithm 1: Söze's Rate Adjustment Algorithm

Input: w_k, r_k: weight and rate for flow f_k;

Function `MainFunctionForFlowK()`**:**

  $signal$ = `RecvPktWithINT()`

  if $now - last_update > rtt$ **then**

    $ratio = \mathtt{U}\left(\frac{r_k}{w_k}, signal\right)$

    $r_k = r_k \cdot ratio$

Lemma 3.2: Convergence to Target Queueing

Söze converges to the target queueing delay level, if and only if $p > \frac{\Delta t}{2} \cdot [\ln(\alpha) - \ln(\beta)]$

The idea for proving the above two lemmas is that all the flows together contribute to the queueing and maintain the queueing at the target delay level. The observed delay is the same across all flows, which provides a guidance for achieving fairness; The observed delay is maintained at a certain level, which provides the guarantee of achieving full utilization. The complete proof is in Appendix C and Appendix D of [59].

3.2 Arbitrary Network Scenario

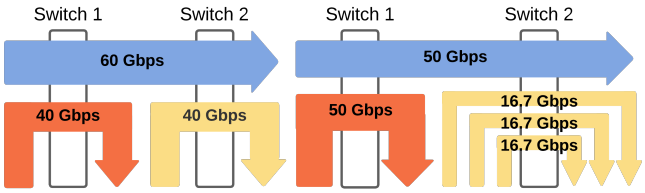
Based on the weighted allocation in a single-switch scenario (§3.1), Söze also achieves weighted bandwidth allocation in the arbitrary network scenario, such as the widely used multi-layer network architecture in production data centers. In this section, we firstly introduce the goal of the weighted resource allocation in §3.2.1; Then, to accommodate the complex scenario, we explore the properties of the flow bottleneck in §3.2.2; Lastly, we extend the collected INT signal to be the maximum queueing delay from all links on the path in §3.2.3.

3.2.1 Goal: Weighted Max-min Allocation

For the network-wide scenario, a flow may travel multiple links along the path and contend with different sets of other flows. However, for any flow traveling multiple hops, there will be at least one bottleneck link, which determines the flow rate. Thus, the weighted allocation should happen on the bottleneck link for any flow, which is also the goal of weighted max-min fair allocation. According to the previous papers, the weighted max-min fair is defined as follows:

Definition 3.1: Weighted Max-min Fair [14, 38]

For all flows $\{f1, ..., fn\}$ in the network, denote their weight to be $\{w_{f1}, ..., w_{fn}\}$. A rate allocation $\{r_{f1}, ..., r_{fn}\}$ is weighted max-min fair when for each flow f, any increase in r_f would cause a decrease in the



(a) Bottleneck for blue: Switch 1 (b) Bottleneck for blue: Switch 2

Figure 3: Bottleneck changes in weighted max-min fair: blue flow weight: 3, red flow weight: 2, yellow flow weight: 1.

transmission rate for some flow f' satisfying $\frac{r_{f'}}{w_{f'}} \leq \frac{r_f}{w_f}$.

In the weighted max-min fair, each hop divides the bandwidth to let each bottleneck flow have the same "rate-per-weight". As Figure 3 shows, the "rate-per-weight" is the same for the blue flow and the red flow, and the rate allocation is equivalent to having "weight" number of individual flows.

With the above analysis, we realize that recognizing the bottleneck becomes the new challenge when achieving the weighted max-min fair in arbitrary networks. In the next subsection, we will show how to simply recognize the bottleneck hop and obtain the INT signal from the bottleneck.

3.2.2 The Bottleneck Hop Properties

In §3.1, Söze already achieves the weighted bandwidth allocation on a single switch in a decentralized manner. Thus, in order to achieve the weighted max-min fair, the major challenge is to recognize the bottleneck hop for each flow, then achieve weighted allocation on the bottleneck hop. According to the definition, achieving fair allocation on the bottleneck hop for every flow is just achieving weighted max-min fair.

From the definition, we could derive a lemma that could help us identify each flow's bottleneck hop, namely, the hop that prevents the flow from increasing the rate further.

Lemma 3.3: Bottleneck Hop Properties

When achieving weighted max-min fair, each flow will have the largest rate-per-weight among all flows on its bottleneck hop and not on any other saturated hop.

Intuitively, a flow must have the largest rate-per-weight on its bottleneck hop, otherwise, it could take more bandwidth from the flows on this hop who has a higher rate-per-weight; a flow cannot have the largest rate-per-weight on a non-bottleneck saturated hop, since there must be some other flow on that hop could steal more bandwidth from it. The full proof of the above lemma is in Appendix E of [59].

With Lemma 3.3, we could easily know that if a flow has the largest rate-per-weight only on its bottleneck hop, then among all hops that this flow travels, the bottleneck hop must have the highest queuing delay. Because on non-bottleneck hops, there must be a flow with larger rate-per-weight, and And our target function is monotonically decreasing. Thus, the queueing delay on any other hops is lower than the bottleneck queueing delay. The proof is included in Appendix E of [59].

3.2.3 Recognize Bottleneck with *maxQD* Signal

With the above properties, we could know that a flow does not have the largest rate-per-weight on hops other than the bottleneck hop. Thus, the bottleneck hop always has the highest queueing delay for that flow. In the single-switch scenario, we use the queueing delay (*QD*) signal from one hop to achieve the weighted allocation on that hop. Similarly, for a flow that travels multiple hops in an arbitrary network, we can use the maximum per-hop queueing delay (*maxQD*) signal to achieve weighted allocation on the bottleneck hop of that flow.

The algorithm does not need to know on which hop the *maxQD* signal was collected, switches simply compare and replace the packet header to keep the *maxQD* signal is enough to achieve weighted max-min fair on the bottleneck hop. With this solution, *maxQD* becomes the signal in Algorithm 1.

With this new INT signal, we could derive our theorem on achieving weighted max-min fairness with Söze. The full proof is given in Appendix E of [59].

Theorem 3.1: Weighted Max-min Fairness

For every flow in an arbitrary network, Söze converges to a weighted max-min fair allocation, if and only if $0 < m < 2$ in the update function and $p > \frac{\Delta t}{2} \cdot [\ln(\alpha) - \ln(\beta)]$ in the target function.

3.3 System Design Summary

With all the above analysis on how to achieve weighted max-min fairness in arbitrary networks, we are able to give our system design in this section.

Collect *maxQD* in data packet and reflect in ACK packet. As shown in Figure 4, each packet contains a fixed-length packet header to store the *maxQD* INT data, which usually takes 2 bytes in the field. When the data packet travels the forwarding path, it compares and keeps the highest per-hop queueing delay on each hop. After reaching the receiver side, the receiver host will attach the *maxQD* information to the ACK packet and send it back to the sender. Thus, the *maxQD* signal is collected at the sender side for every ACK packet.

Host control with the INT signal. The rate control is conducted at the sender host. Firstly, after receiving the INT signal from the packet, the host will parse the *maxQD* data from the packet header and use it to determine the multiplicative rate update ratio. Then, the rate can be controlled with either a traditional *CWND* specification or with a rate-based specification, such as the pacing in some CC algorithms [35]. Note that, when using the window-based protocol, we are still using the "rate" rather than the congestion window directly. The

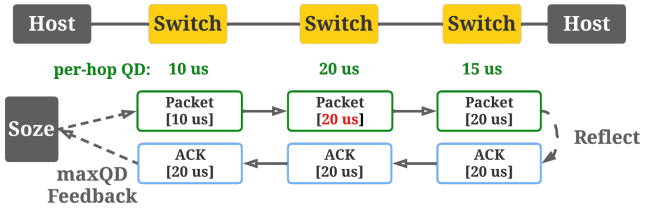


Figure 4: System design of Söze.

rate of the flow needs to be calculated with $CWND$ and RTT by $rate = \frac{CWND \cdot pktsize}{RTT}$. Lastly, Söze serves both as congestion control and as a weighted resource allocation protocol. Thus, Söze should be on the networking stack, either in the kernel or running on the NIC hardware. The applications should give the weight specification through an API.

Conduct rate update in per-packet manner. Typical CC algorithm conducts rate update for each RTT, because they are using AIMD-based algorithm for convergence. In Söze, the convergence to weighted fairness is performed with a new adaptive-update algorithm in Algorithm 1. Moreover, each individual $maxQD$ signal can reflect the network condition and calculate the rate update. Thus, achieving a per-packet rate update becomes beneficial to weight enforcement, making the convergence faster and stabilizing the rate enforcement.

3.4 Discussion

Weight distribution policy. With Söze, each application could individually determine the weight of its flows and obtain the corresponding bandwidth from the network. However, if each application increases its weight to maximum blindly, the weighted fairness will not benefit any application. For practical usage, there should be guidelines for weight determination and restrictions on the application's behavior.

The network operator could define any usage policy based on their specific workloads and service-level objectives, which, we emphasize, is not the focus of this paper. We use one simple idea for a discussion as follows: 1) Each application has a total weight that it can distribute across different hosts and flows, but the application can pay the service provider to get more total weight. 2) An application can decrease the weight of any flow when possible, namely, not fully utilize all the weights. 3) When an application wants to increase the weight of flows, some other flows in the same application need to decrease their weight so that the sum of the weights in an application is generally the same. This simple policy gives applications the ability to be altruistic to others, but when the application wants to benefit themselves, some penalties will be added to regularize their behavior.

Policy enforcement monitor. For applications inside the cloud, Söze expects them to follow the policy for weight distribution from the cloud provider. However, there is still the possibility that an application does not follow the policy. To monitor whether all the applications' behavior follows the policy, a logging system could be used. 1) Whenever the networking stack receives a weight specification from the application through the API, Söze will log the timestamp, flow ID (e.g., 5-tuple), and the specified weight. 2) Periodically, each application's weight update logs will be gathered to a policy checker, where the policy will be verified through the logs from multiple machines.

Queuing as INT signal. Although in this paper we use queuing delay as the feedback signal, the queuing level is controlled by the target function in Equation 6. Thus, the queue can be maintained at a relatively low level, as shown in Figure 13. Besides queuing delay, the design of Söze also applies to other INT signals, such as link utilization or ECN marking ratio. For different signals, the properties of the system also vary, which will be discussed in future studies.

4 Implementation

We implemented Söze with both the Linux kernel module to replace Linux's default Cubic transport and kernel-bypassing network transport — eRPC. We also provide simulator implementation on the NS-3 simulator for large-scale experiments.

Switch implementation. We implement the queueing delay signal on Tofino switches [9] with 9 lines of code. When every packet reaches the exit point of the switch, the switch uses the low-pass filter $LPF()$ function to collect the queueing signal in the "sampling mode". By controlling the sampling interval, we can adjust the signal to be each individual packet's queueing delay or smoothed queueing delay over multiple packets. In Söze, the default setting is to output the smoothed queueing delay over 10 μs.

```
1 Lpf<bit<32>, bit<10>>(size=1) lpf_queue;  # type="SAMPLE"
2 queue_input = (bit<32>) eg_intr_md.deq_timedelta;
3 queue_output = lpf_queue.execute(queue_input, 0);
```

Host implementation 1: kernel module. We implemented a prototype of Söze as a Linux kernel module with 241 lines of code, which can be installed on Linux without recompiling the kernel. By replacing the kernel module for congestion control, we could receive the maximum per-hop queueing signal in a TCP option field. For the functions $exp()$ and $log()$ in Söze, we implemented efficient approximation functions without using the STL library. For application integration, we added one TCP socket option and used that field to configure the weight for this specific TCP socket. To deliver the weight specification, we allow the application to modify the value of the TCP socket option field as the weight value. For Söze, the parameters are set to: $p = 20\mu s$, $k = 3\mu s$, $m = 0.25$. As a baseline, the default algorithm for Linux is TCP-Cubic. The switch port bandwidth is set to 25 Gbps.

Host implementation 2: eRPC. Alternatively, we also implemented Söze in an RPC library — eRPC [31], an open source RPC library that supports Ethernet, InfiniBand, and RoCE.

We add an additional field in the erpc header to carry the max queueing delay information, and use the same Tofino switches to attach those signals to each data packet. We replace the Timely CC algorithm in erpc with Söze and added supporting features, such as packet header changes and queueing signal processing, in 1972 lines of code. For application integration, eRPC uses userspace networking with polling, so applications can directly communicate with eRPC through the API and reconfigure the weight parameter for eRPC connections. The parameters for Söze are set to: $p = 20\mu s$, $k = 3\mu s$, $m = 0.25$. The bandwidth is 25 Gbps.

NS-3 simulator implementation. We also implement Söze in NS-3 [2]. The switches in the simulator have been customized to provide the maximum per-hop queueing delay. The packet header with "maxQD" will be updated on every hop to keep the maximum queueing delay so far. This *maxQD* information is sent back to the sender through the ACK packets. For Söze, unless otherwise noted, the default parameters in the target function are set as $p = 20\mu s$, $k = 3\mu s$, $m = 0.25$. For DCQCN, we use all the parameters suggested in [62, 63]. For HPCC, all the original settings from [35] are kept unless noted: $W_{AI} = 80$ Bytes, $maxstage = 5$, and $\theta = 95\%$.

Principles for choosing parameters. The choice of the parameters is based on the following principles: p controls the granularity of the INT signal, a higher p value leads to higher queuing delay but less rate oscillation, so we tend to choose the minimal p value that gives a relatively low rate enforcement oscillation. k controls the base queuing delay, which may cause the utilization to be less than 100% if k is too small. Thus, we choose the minimal k that provides full link utilization. m controls the convergence speed, higher m leads to faster convergence but worse rate oscillation. So, there is a wide spectrum of m that may suit different workload patterns.

5 Evaluation

We will evaluate Söze on both the testbed and the large-scale simulator. Firstly, we demonstrate application use cases for Söze on the eRPC testbed in §5.1; Secondly, we also evaluate the efficiency of Söze as the congestion control protocol alone and compared with existing industry solutions in §5.2; Lastly, in §5.3, we conduct micro-benchmark experiments in the simulator to show that Söze can achieve fine-grained weighted max-min fair allocation rapidly on a large scale.

eRPC testbed setup. For the eRPC testbed, we connect four servers with DPDK-capable CX-4 NIC to a Tofino-1 programmable switches in a star topology. The flow is the RPC write request sent from one host to another, where the request size is 7 MB and the response size is 32 bytes. When multiple hosts send write requests to the same host, the switch egress port to that destination host will become the bottleneck. In the eRPC testbed, we compare our scheme with Timely [39], the default CC used in eRPC.

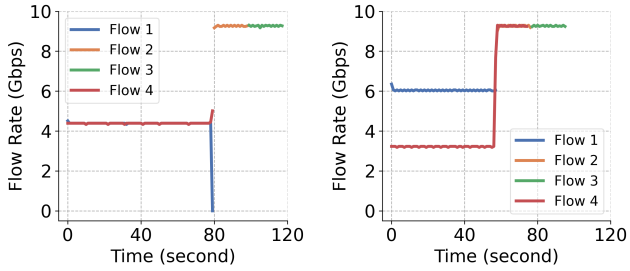
Figure 5: Scenario for critical path acceleration.



(a) Fair allocation. (b) Weighted: f1:f4=2:1.

Figure 6: Reduce completion time by prioritizing critical path.

NS-3 simulator setup. In the NS-3 simulator, we built a network with 1024 servers and 320 switches in a fat-tree topology. The simulator uses 100 Gbps links with 1 μs link delay, 32 MB buffer size, and 1000 bytes packet payload size. In the simulator, we compare Söze with DCQCN and HPCC. All the parameter settings are adopted from their original paper.

5.1 Application Case Study

Firstly, we evaluate the application benefits from Söze in several scenarios on the eRPC testbed. The scenarios below are a small subset of the benefits for demonstration. We then evaluate Söze on the TPC-H jobs in the NS-3 simulator.

5.1.1 Prioritize Critical Path inside a Job

Consider stage-based applications such as map-reduce, distributed matrix multiplication, DNN training, etc., where there are several computation and communication phases. The end-to-end application performance depends on the performance of the critical path. Enabled with modern application-level abstractions and critical-path analysis [36, 45, 58], relative priorities between flows of different paths can be determined prior to execution, and Söze can allocate bandwidths between flows according to those priorities.

As shown in Figure 5(a), a job consists of 4 flows: flow f1 has 20 GB of data, flow f2 has 10 GB, flow f3 has 10 GB, while flow f4 has 20 GB. As shown in Figure 5(b), f2 can only start when flow f1 finishes, and f3 can only start when f2 finishes. And flow f1 and flow f4 share the same bottleneck.

When fairly sharing the resource between flow 1 and flow 4 as in Figure 6a, the start of flow 2 will be delayed, and the job completion time is 117 seconds. Once we recognize the

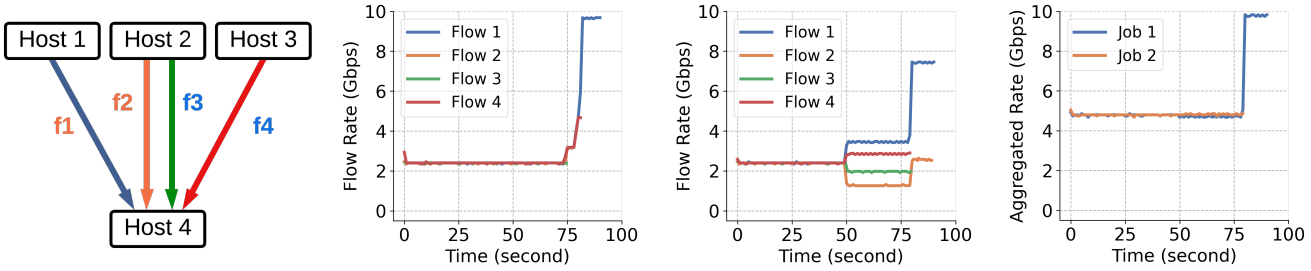
Figure 7: Mitigate straggler.



(a) Experiment setup. (b) Fair allocation. (c) Weighted allocation. (d) Aggregated rates.

Figure 8: a) The flows f1 and f2 belong to job 1, and the flows f3 and f4 belong to job 2; b) The fair allocation equally allocates the bandwidth among all four flows, and rebalances when any flow finishes. Under the fair allocation, job 2 finishes at 82 seconds. c) The weighted allocation will update the weights at time 50 s, letting f3 and f4 finish at the same time and reducing the completion time for job 2 to 79 seconds; d) For the weighted allocation, each job always has the same aggregated bandwidth as before the weight changes, so that the bandwidth rebalancing only happens within a job.

critical path, we can prioritize flow 1 over flow 4 by setting their weight to be $\frac{4}{3}$ and $\frac{2}{3}$, so that flow 1 gets twice bandwidth than flow 4 and the sum of their weights still add to 2. As shown in Figure 6b, prioritized allocation reduces the job completion time to 96 seconds.

5.1.2 Identify and Mitigate Stragglers inside a Coflow

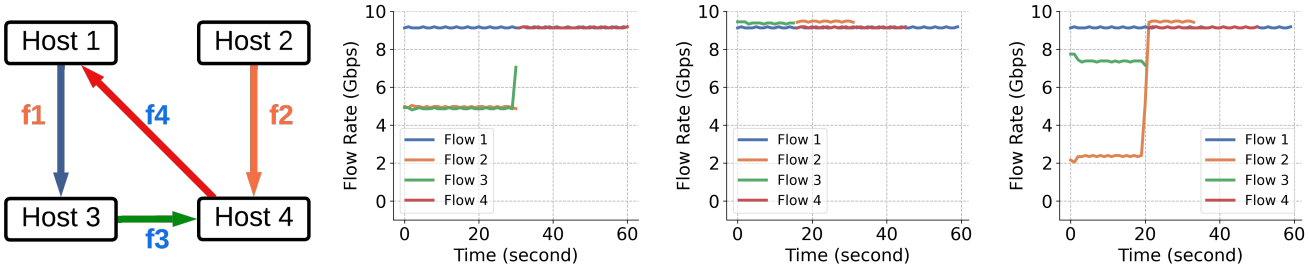
A common technique for mitigating stragglers in a coflow is to dynamically change the inter-flow priority. Such a scenario can be an interesting use case for Söze. Due to the zero-coordination and fast-convergence properties, Söze can implement the weighted bandwidth allocation with arbitrary granularity among the flows of a coflow to mitigate stragglers, and thus minimize the coflow-completion time.

This experiment tries to identify the straggler for an all-shuffle job. The figure focuses on two flows inside one coflow, where flow f2 is twice as large as flow f1. When the resources are fairly shared by f2 and background flows, flow f2 will decrease the rate as shown in Figure 7a; To mitigate the straggler and make flow f2 finish around the same time as flow f1, we monitor the progress of flow f2, if the progress cannot catch up with f1 under current sending rate, the weight of flow f2 will increase as in Figure 7d, and flow f2 will take more bandwidth from the background traffic and maintain the same rate as flow f1 as shown in Figure 7b and Figure 7c.

5.1.3 Share Resource on Common Bottleneck

Another great property of Söze is that we can reallocate the resource among flows within the same application, while the application generally keeps the same total bandwidth utilization and minimizes the effect on other applications' behavior. This property can be helpful, especially when some jobs share the same bottleneck in the network, such as the firewalls or load balancers. When applications share the same bottleneck, the resource allocation for each application can be perfectly isolated if the sum of weights remains the same.

In this experiment, we have two jobs in total. As shown in Figure 8, one job has two parallel flows f1 and f2, while the other job has two other parallel flows f3 and f4. Both jobs need data from every parallel flow for further computation, so we want them to finish at the same time to minimize waiting time. Because all the flows have different sizes, we change the weight of every flow at time 100 seconds. However, to keep the same job-level resource allocation, we choose the weight carefully so that the sum of all the flows' weights within one application remains the same. As you can see in Figure Figure 8d, no matter before or after the weight changes, the bandwidth that each job occupied in total is always around 5 Gbps, while each individual flow's bandwidth has been updated depending on the size. In summary, by restricting the sum of all flows' weights insides one job to be a constant, each job reduce the interference with other jobs' resource;



(a) Experiment setup. (b) Fair allocation. (c) Optimal allocation. (d) Altruistic allocation.

Figure 9: a) The flows f1 (28 GB) and f2 (7 GB) belong to job 1, where f1 f2 start simultaneously. The flow f3 (7 GB) and f4 (14 GB) belongs to job 2, where f4 can only started when f3 finishes; b) With the fair allocation, f2 and f3 fairly share the bandwidth and job 2 finishes at time 60 s; c) Under the optimal allocation, f2 will initially give all bandwidth to f3. Thus, job 2 finishes at time 45 s; d) With the altruistic allocation, f2 shares the bandwidth with the guarantee that it can still finish on time with its bandwidth. The job 2 finishes at around time 50 s.

Only when different jobs shares the same bottleneck, there is no interference among different jobs.

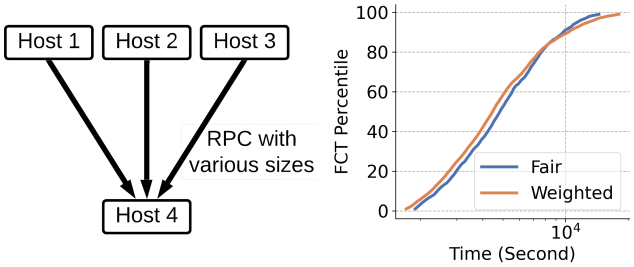
5.1.4 Altruistic Scheduling among Multiple Jobs

Although the weighted allocation could help us prioritize the critical execution path, sometimes the critical path cannot be accelerated due to resource limitations and job characteristics. In such cases, other non-critical execution paths could be altruistic by giving up some resources to other jobs, as long as the non-critical execution paths can finish at the same time as the critical path, the job completion time is not harmed. However, the bandwidth altruistically given to other jobs may benefit their completion time.

In the example of Figure 9, we have two jobs: one job has two parallel flows, f1 and f2, while the other job has two sequential flows f3 and f4. In the fair allocation case, flows f2 and f3 fairly share the inbound bandwidth at host 4, and both finish at around 30 seconds. Then, flow f4 starts and finishes at 60 seconds. However, because flow f1 is much larger than flow f2, we could let flow f2 give up some bandwidth without hurting the job completion time. In the optimal allocation scenario, flow f2 can give all the bandwidth to flow f3 and achieve the minimum job completion time. However, this is not safe because one job does not know the size of the other job's flow. Thus, in the altruistic allocation case, we let f2 get only 25% of the bandwidth, because this is the minimum bandwidth to guarantee completion at the same time with flow f1. With this altruistic behavior, flow f3 finished much earlier at 20 seconds, so that its job also finished at time 60 seconds, which is 10 seconds earlier than the fair allocation.

5.1.5 Shortest-flow Prioritization

In this experiment, we create an in-cast scenario where three hosts send RPC write requests to one host. Note that this experiment is not under the assumption that all flows come from the same job and need to follow the weight distribution policy. The size of the RPC write varies based on the workload, from



(a) Experiment setup. (b) Flow completion time.

Figure 10: Shortest flow prioritization.

around 700 MB to 7000 MB. Because the three senders may send RPCs of different sizes at the same time, prioritizing the RPCs with the smallest size could approximate shortest job first scheduling and reduce the overall average flow completion time. Thus, based on the flow size, we calculate a specific weight for flow with the equation $weight = \frac{max_flow_size}{flow_size}$.

As we can see in Figure 10, when we update the weight according to the flow size, smaller flows finish faster than the fair allocation case. As a trade-off, only a small portion of large flows suffer from longer completion time than fair allocation, while more than 80% of the flows benefit from the approximately shortest-flow first allocation. Moreover, unlike a strict shortest-flow first policy, like the preemption-based schedulers, Söze never starves the large flows.

5.1.6 TPC-H Benchmark Acceleration

Furthermore, we also test the 22 jobs from the TPC-H benchmarks [1] in our NS-3 simulator, in which each job is an execution DAG with tasks. Each task is randomly placed on a host within a fat-tree topology. For every flow in the DAG, we calculate the longest distance from this flow to the end of the DAG and use this distance to determine the flow's weight. This simple policy is designed based on the insight that the longer execution path needs more resources. In Figure 11, with Söze providing the weighted allocation, the average job completion time is reduced by 0.79×, and the maximum reduction is 0.59×. Only jobs that have only one execution path

(a) Timely. (b) Söze.

Figure 12: Step-in & step-out experiment on eRPC testbed. Söze achieves higher utilization and faster convergence to the optimal state than Timely.

do not receive benefits from Söze.

5.2 Efficient Congestion Control

5.2.1 Step-in & Step-out Experiment in Testbed

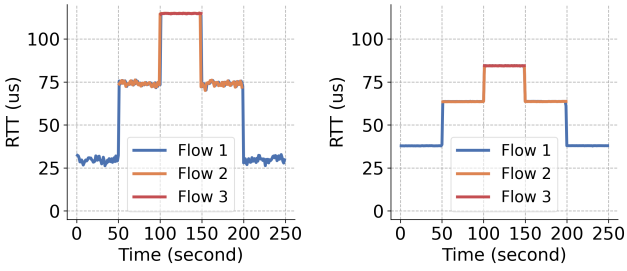
To show that Söze can serve as an efficient congestion control algorithm, we conduct a step-in and step-out experiment on the eRPC testbed with three hosts sending traffic to one host. Every 50 seconds, a new flow was added to the incast host from a different sender until time 100 seconds, then every 50 seconds, one flow will terminate and give bandwidth back.

As shown in Figure 12, Söze outperforms Timely, the default congestion control algorithm in eRPC. When there is only one flow, Söze achieves higher utilization than Timely; and when a new flow arrives or an existing flow completes, Söze converges to the new optimal allocation faster than Timely because of the proposed adaptive MIMD algorithm.

In Figure 13, we also show the round-trip time (RTT) for both Timely and Söze. The RTT of Söze increases with more number of flows competing on the link, because our target function is monotonically decreasing as the fair-share rate of the link increases. Nevertheless, Söze still achieves lower RTT than Timely, because we use a range of queueing delay to indicate different levels of congestion, and the maximum queueing delay in Equation 6 bounds the RTT of Söze.

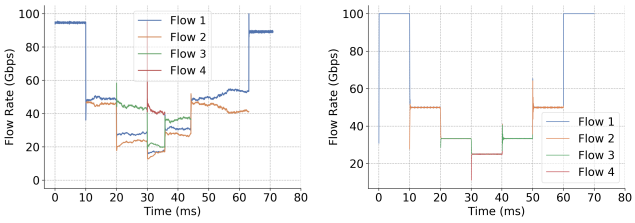
5.2.2 Step-in & Step-out Experiment in NS-3

In the NS-3 simulator, we also conducted a step-in and step-out experiment with hosts under different ToRs sending traffic



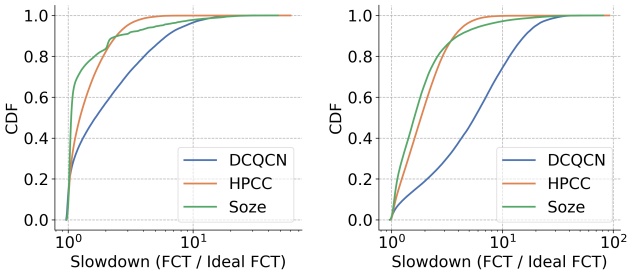
(a) Timely. (b) Söze.

Figure 13: Söze achieves lower RTT than Timely by using queueing level as the signal to indicate congestion.



(a) HPCC. (b) Söze.

Figure 14: Step-in & step-out experiment in NS-3 simulator. Compared with HPCC, Söze achieves a more stable and accurate rate allocation.



(a) 40% load. (b) 80% load.

Figure 15: FCT slowdown under different network loads.

to the same destination. We compared Söze with one recent data center congestion control algorithm using in-network telemetry — HPCC. In this set of experiment, 4 flows are added every 10 milliseconds, and each flow completes every 10 milliseconds in sequence.

Compared to HPCC, the bandwidth allocation in Söze is very accurate and stable in Figure 14. Because Söze uses the queueing delay as the signal to indicate the level of congestion, more specifically, the fair-share rate of the link. While for HPCC, the in-network signal is only used to indicate whether the link is congested or not, so that the bandwidth allocation is not accurate nor stable for HPCC due to the binary status provided by its in-network signal.

5.2.3 FCT Slowdown

In order to evaluate the performance of Söze under high network load with a large amount of flows, we run the Google RPC workload [53] with randomly selected sender and re-

ceiver. And we compare with two datacenter congestion control solutions — HPCC and DCQCN.

In Figure 15, under both 40% and 80% load, Söze achieves lower FCT slowdown than HPCC and DCQCN, especially for the short flows. Because Söze could grab bandwidth rapidly with fast convergence. As shown in Figure 16, Söze provides more benefits for flows with less than 1000 packets. While for flows with larger data size (> 100k packets), Söze also provides comparable performance with DCQCN and outperforms HPCC, leading to shorter tail FCT slowdown in Figure 15.

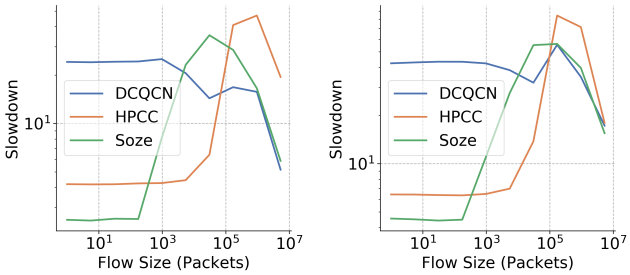
5.3 Micro-benchmark

In this subsection, we compare Söze with alternative solutions with a set of micro-benchmark experiments on the NS-3 simulator to demonstrate Söze's weighted max-min fairness, high agility, fine granularity, and scalability.

5.3.1 Weighted Max-min Fairness

In the experiment for weighted max-min fairness, we create a scenario where flow 1 only travels switch 1; flow 2, 3, and 4 travel switch 1 and switch 2; flow 4 and 5 only travel switch 2. The link bandwidth is 100 Gbps and the default weight for every flow is 1, so that flow 1 get 40 Gbps at the beginning. Every 10 milliseconds, the weight of flow 1 will be increased by 1. When the weight is 2, flow 1 still gets 40 Gbps because the bottleneck hop for flow 2, 3, and 4 is still switch 2. Only when the weight increases to be higher than 3, the bottleneck hop becomes switch 1 and flow 1 will take more bandwidth from other flows on switch 1.

As we described in §3.2, the weighted max-min fairness for every flow is determined by its bottleneck hop. In Figure 17, we show that the bottleneck hop for flow 2, 3, and 4 changes with the increase of flow 1's weight. With this micro-benchmark experiment, we demonstrate that Söze can recognize the bottleneck hop for every flow and achieve weighted max-min fairness rapidly after the weight is changed for any flow in the network. Moreover, the bottleneck hop changes at time 20 ms, and Söze handles the changing bottleneck rapidly within 10 RTTs. For comparison, we test how weighted round-robin (WRR) scheduling in switches combined with AIMD rate control would perform in this scenario. WRR enforces weighted sharing of bandwidth at the packet scheduling level but senders must still discover the achievable bandwidth at the end-to-end level. The AIMD control uses queuing delay as the explicit feedback signal: when the queuing delay is below 20 μs (this value is chosen to ensure good link utilization in the experiment), the CWND is increased by 1; when the queuing delay exceeds 20 μs, the CWND is reduced by 20% (this value is chosen to limit oscillation). In the results in Figure 17c, we can see that the rate for each flow is maintained correctly around the weighted max-min fair allocation by WRR scheduling. However, the link utilization is lower than with Söze because the oscillation due to AIMD is larger.



(a) 40% load. (b) 80% load.

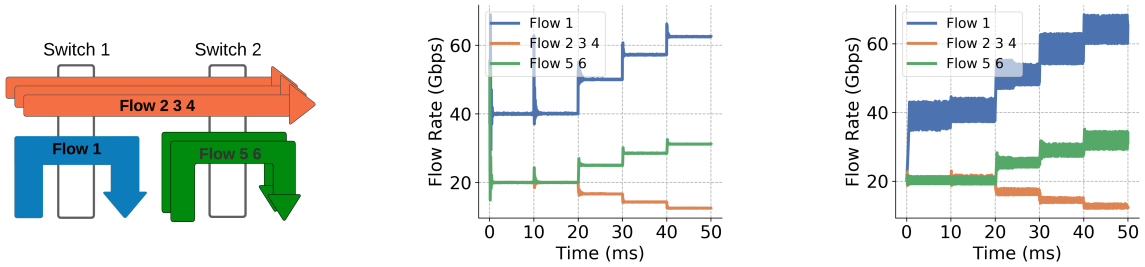
Figure 16: FCT slowdown for different flow size under different network loads.

5.3.2 Granularity Micro-benchmark

To show the granularity of the weighted allocation, we make use of a coflow scenario, where each coflow is consist of 10 flows, and the flow size is randomly chosen from a range of [1 GB, 3 GB]. In Söze, according to the size of each flow, the flow will be assigned with a certain weight to complete at the same time with other flows: in Söze's scenario, the weight is equal to the flow size. For the multi-connection solution, we will choose the closest integer number with the flow size. For instance, there will be 2 connections for a flow with 2.4 GB data size and there will be 3 connections for a flow with 2.6 GB data size. For the switch-based weighted round-robin solutions, we test on a scenario where each switch has 4 physical queues. We try to pack the 10 different flows into 4 physical queues and set a certain weight for each physical queue. The flows with similar data size will be packed into the same queue, and they will fairly share the bandwidth from that physical queue. The sum of the flow data size within a queue will be used to calculate the weight of each queue.

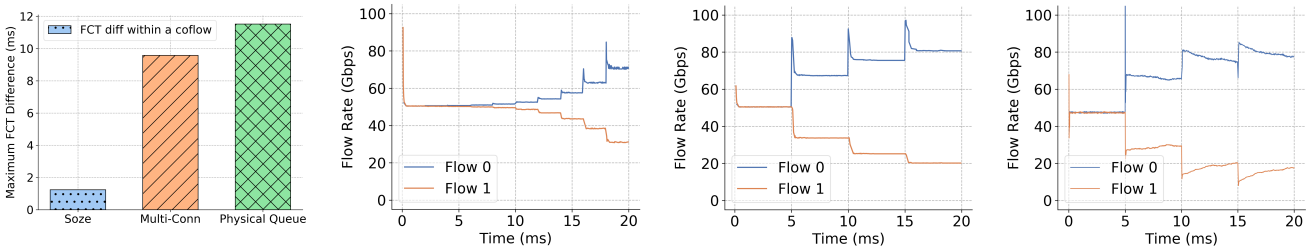
In Figure 18a, Söze allows all the flows within a coflow to finish at nearly the same time, so that it has the minimum FCT difference among all the alternative solutions. In contrast, the multi-connection solution ("Multi-Conn") only provides integer number of concurrent connections, which makes the weight enforcement rigid and cannot support non-integer weight; the switch-based weighted round-robin ("Physical Queue") relies on limited number of physical queues, and weight enforcement granularity will degrade when the number of flows exceeds the number of queues.

In addition, we also compare different schemes by changing weights or the number of connections. We create a simple in-cast scenario, where two flows are sent to the same destination host. In Figure 18b, we increase the weight for flow 0 every 2 milliseconds by 5‰, 10‰, 20‰, etc. The figure shows that the rate allocation can be accurately stabilized around any level, even when the weight difference is relatively small. In contrast, we also let both Söze and HPCC have multiple connections to change the rate allocation. In Figure 18c, Söze adds one connection for flow 0 every 5 milliseconds. The rate allocation changes accurately accordingly



(a) Experiment scenario. (b) Söze with increasing weight. (c) WRR with AIMD.

Figure 17: a) Flow 1 and flow 2, 3, 4 compete on switch 1; flow 5 and 6 compete with flows on switch 2. During time 0 ms to time 50 ms, we increase the weight of flow 1 from 1 to 5 every 10 ms. b) Söze achieves accurate weighted sharing. When the weight of flow 1 is smaller than 2, flow 1 remains at 40 Gbps since switch 2 is the most congested hop; but when the weight is higher than 2, flow 1's rate increases because the congested hop has become switch 1. c) For comparison, we repeat the experiment using weighted round-robin (WRR) scheduling in switches to achieve flow 1's increasing weight; AIMD rate control is used to adapt to the weight changes.



(a) Granularity comparison. (b) Söze with weight updates. (c) Söze multi-connection. (d) HPCC multi-connection.

Figure 18: Granularity and agility comparison.

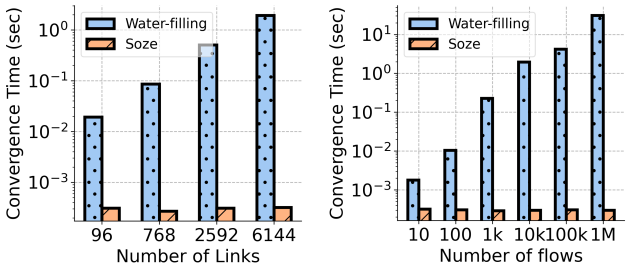
to the number of connections, but the allocation granularity is limited to weights with integer numbers. For HPCC with multi-connection in Figure 18d, the flow rates are also maintained around the weighted allocation, but the rate enforcement is less accurate and also suffers from coarse-granularity due to integer weights.

5.3.3 Agility Micro-benchmark

With the same experiment in 18b that changes the weights for Söze, we also demonstrate the agility achieved by Söze. As shown in Figure 18b, on average, it only takes less than 10 RTTs for Söze to converge to the new rate under the new weight. We can observe that there is a rate surge right after each weight change and before convergence. This is because we are increasing the weight of flow 0, thus the new converged queueing delay is higher than before, so the rate needs to exceed the line rate briefly to stack the switch queue.

5.3.4 Scalability Micro-benchmark

Scalability is the key to supporting large-scale systems with consistent performance despite increasing scale. Söze is a fully distributed system and can inherently scale to datacenters of any size; in contrast, the water-filling algorithm is a centralized solver, which needs to gather all the information to one master node and use its resources for computation. In the following experiments, we test the convergence time of



(a) Increasing topology size. (b) Increasing flow count.

Figure 19: The solving time for the water-filling algorithm increases drastically with either increasing topology size or increasing number of flows; while Söze provides consistent convergence speed toward the global weighted allocation state despite of the increasing topology size or flow count.

Söze and the solving time of the water filling to demonstrate the capability to scale for those two solutions.

Firstly, we maintain the same number of flows and change the fat-tree network topology sizes by parameter K. We chose the number of flows to be 10k so there are roughly 10 flows per server when $K = 16$. In Figure 19a, when the topology size increases from $K = 4$ (16 hosts) to $K = 16$ (1024 hosts), the solving time of the water filling algorithm increases drastically. In contrast, for Söze, once applications have determined the weights, the convergence time towards the global weighted bandwidth allocation is always around the same magnitude.

The average convergence time for Söze is 0.3 milliseconds, which is around 10 RTTs.

Moreover, we also tested the convergence time for Söze and the water filling algorithm with increasing number of flows under the same topology. As shown in Figure 19b, the network topology is always a fat-tree with 1024 servers ($K = 16$), and the number of flows in the network increases from 10 flows to 1 million flows. As more and more flows are added to the network, the solving time for the water filling algorithms increases from 1.81 milliseconds with 10 flows to 31.1 seconds with 1 million flows. While Söze still provides consistent convergence towards the global weighted allocation within 10 RTTs. Thus, the water-filling algorithm has inherent drawbacks to support large-scale data center; while Söze benefits from the decentralized design and can be scale up with nearly no performance degradation.

6 Related Work

One line of work focuses on using weighted fair queueing (WFQ) on the switches to achieve weighted allocation. NumFabric [42] assumes switches support WFQ in hardware, then provides algorithms for setting the weight parameters in switches to optimize for a utility objective. NumFabric is complementary to Söze, because Söze replaces switch WFQ; weight parameters provided by NumFabric can be used to implement the desired utility objective on Söze even more easily, because there is no talking to switches' control planes.

Besides using weighted fair-queueing algorithms on switches [16, 21, 23, 46, 52] to allocate bandwidth, a recent trend is to use programmable switches to approximate weighted fair-queueing [22, 50, 54, 60, 61]. Such switch-based solutions are hard to scale because of the resource limitations on the switches. To enforce the per-flow weighted allocation accurately among many flows, the switch data plane needs to keep a large amount of information, which may exceed the memory capacity. Moreover, the delay and the complexity of the control plane for such a scheme are both high, which leads to a lack of agility. To add a new flow or to change the weight, the flow sender needs to inform all the switches along the flow's path individually. Besides, those works heavily rely on programmable switches, which are not widely used in production, and those switches are usually less cost-effective than commodity switches with fixed telemetry functions. PERC [30] proposes an alternative approach that departs from the existing DCN service model; it requires switches to run a distributed algorithm to continuously compute the max-min fair shares for all flows and communicate them to end hosts; the algorithm requires control packets that must be processed by switches, requiring multiplication and division operations. In contrast, Söze only requires INT from the switches, and end hosts can do the rest.

As for solutions that do not rely on switches, a bandwidth allocator [27, 32, 34, 51] is also capable of achieving weighted max-min fairness for all flows. By aggregating the sources, destinations, and demands of all flows, the allocator can calculate a rate allocation plan for each flow. However, this solution requires aggregating information and calculating the allocation plan at the controller, which may lead to a long solving time when the scale of the network increases. Moreover, such solutions are not agile. Each time a flow needs to change weight or a new flow arrives, the whole rate allocation algorithm may need to be executed, leading to high overhead and long control plane delay.

There are also proposals that aim to manipulate the congestion window to allow a flow to take up more bandwidth when needed. For example, D2TCP [56] proposes to adjust the congestion window size more or less aggressively based on how close the time is to the deadline. MulTCP [20] heuristically lets a flow act like N flows in adjusting its congestion window more aggressively. Both solutions build on top of the TCP algorithm, but suffer from the inherited drawbacks, like slow convergence and throughput jitter. Weighted allocation is not the goal of D2TCP, while in MulTCP the effect of increasing the N parameter is not linear and may change for different situations. In contrast, Söze achieves fast convergence, low throughput jitter, and accurate weighted fair allocation.

Besides weighted allocation, priority-based allocation solutions [13, 40] are also used to provide service differentiation between flows, but such solutions have some intrinsic disadvantages over weighted bandwidth allocation, such as head-of-line blocking if preemption is not allowed, and starvation risk. Moreover, priority-based differentiation schemes are a larger departure from the existing DCN service model that's based on fair allocation. Söze represents a potentially more compatible evolutionary direction with flexible and controllable allocation for general-purpose DCN.

7 Conclusion

In this paper, we propose Söze, a simple and efficient weighted bandwidth allocation system for data center networks. Söze designs the maxQD INT signal to not only indicate network status but also provide a control knob to coordinate multiple flow senders. Furthermore, Söze co-designs the decentralized rate update algorithm with the maxQD signal, which allows each flow to independently move toward the weighted max-min fair allocation in arbitrary networks. We prototype Söze across various platforms and demonstrate that Söze can achieve weighted bandwidth allocation with fine granularity, high agility, and high scalability.

Decouple and Decompose: Scaling Resource Allocation with DEDE

Zhiying Xu[†] Minlan Yu[†] Francis Y. Yan[𝕀]
[†]*Harvard University* [𝕀]*University of Illinois Urbana-Champaign*

Abstract

Efficient resource allocation is essential in cloud systems to facilitate resource sharing among tenants. However, the growing scale of these optimization problems have outpaced commercial solvers commonly employed in production. To accelerate resource allocation, prior approaches either customize solutions for narrow domains or impose workload-specific assumptions. In this work, we revisit real-world resource allocation problems and uncover a common underlying structure: the vast majority of these problems are inherently *separable*, i.e., they optimize the aggregate utility of individual resource and demand allocations, under separate constraints for each resource and each demand. Building on this observation, we develop DEDE, a scalable and theoretically rooted optimization framework for large-scale resource allocation. At the core of DEDE is a *decouple-and-decompose* approach: it decouples entangled resource and demand constraints and thereby decomposes the overall optimization into alternating per-resource and per-demand subproblems that can be solved efficiently and in parallel. We have implemented and released DEDE as a Python package with a familiar modeling interface. Our experiments on three representative resource allocation tasks—cluster scheduling, traffic engineering, and load balancing—demonstrate that DEDE delivers significant speedups while generating higher-quality allocations.

1 Introduction

Resource allocation remains a critical and challenging problem today, especially as cloud providers operate multi-tenant systems on an unprecedented scale—these systems must ensure efficient and fair allocation of computing, storage, and networking resources across a large number of clients, in order to maintain the quality of cloud services.

Common scenarios of resource allocation include cluster scheduling [28,45,47,63,66], traffic engineering [1,24,32,51,69], and load balancing [14,38,49,53]. To meet diverse and dynamic user demands (jobs, traffic flows, and queries), these systems extensively employ commercial optimization solvers like Gurobi [22] to solve linear programs (LP) or mixed-integer linear programs (MILP) that determine the allocation of valuable cloud resources (compute units, network links, and data nodes) worth millions to billions of dollars.

However, as cloud environments continue to expand and diversify, the sheer scale of modern resource allocation problems has exceeded the capabilities of commercial solvers.

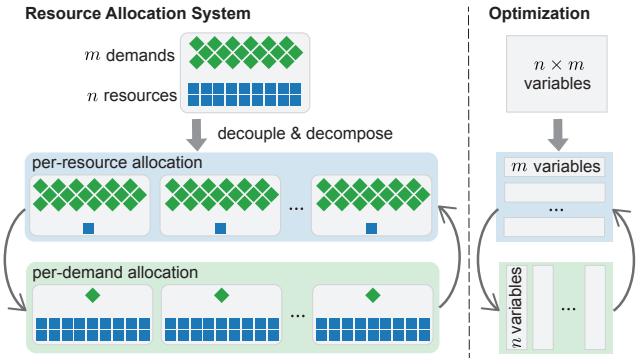

Figure 1: Overview of DEDE.

These problems may involve millions of variables and take tens of minutes or even hours to solve, whereas fast allocation is necessary to meet service-level objectives. This "scalability crisis" has spurred a flurry of studies [1,43,48,65] that trade off solution quality for computational speed, using heuristics, approximate algorithms, or machine learning. Nevertheless, these approaches are typically restricted to specific domains (e.g., wide-area network traffic engineering) or particular optimization objectives (e.g., max-min fairness), limiting their broader applicability. While POP [44] accelerates assorted allocation tasks, it hinges on a "granular" assumption that each demand requests only a small fraction of interchangeable resources. This premise proves brittle under realistic workloads, leading to degraded solution quality (§7).

In this study, we revisit real-world resource allocation problems through a different lens, avoiding domain-specific designs or workload-dependent assumptions. We introduce DEDE[1], a practical and scalable optimization framework for solving resource allocation problems. Rooted in optimization theory, DEDE allows the global allocation problem to be decomposed into alternating per-resource and per-demand subproblems (Figure 1), which can be solved more efficiently and in parallel without compromising solution quality.

This decomposition is enabled by an intrinsic, workload-agnostic problem structure that we identified after surveying dozens of real-world resource allocation problems in the literature (Table 1). We find that the vast majority of these problems are inherently *separable*: they optimize the total utility of individual resource and demand allocations, subject to separate constraints for each resource and demand to ensure feasibility. To be more concrete, we illustrate this problem structure using a simplified job scheduling example.

[1] DEDE encapsulates our core technique "**De**couple and **De**compose."

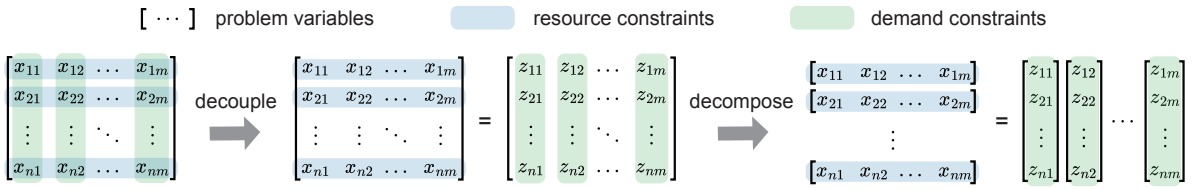

Figure 2: DEDE decouples constraints using an auxiliary variable, thereby decomposing optimization into subproblems.

▶ **Example:** Each hour, we aim to determine—as soon as possible—the optimal allocation of a set of large language model inference jobs (e.g., GPT-4, Llama 3, and DeepSeek-V3) on a heterogeneous GPU cluster composed of various hardware types (e.g., Nvidia H100, A100, and V100). Jobs may divide their execution time across multiple GPU types, and due to differences in hardware specifications (e.g., memory capacity, bandwidth, and FLOPS), each job may require a different number of GPUs for each GPU type and achieve varying levels of throughput, measured in tokens per second (TPS). For instance, a job might run for 0.4 hours on 2×A100 at 50 TPS, and for 0.6 hours on 4×V100 at 20 TPS.

Formally, let x_{ij} denote the fraction of the hour that job j (demand) runs on GPU type i (resource). Naturally, we have the demand constraints: $\forall j, \sum_i x_{ij} \leq 1$. On the other hand, for each GPU type, the total GPU hours requested by all jobs must not exceed the available GPU capacity. Thus, the resource constraints are: $\forall i, \sum_j \text{req}_j \cdot x_{ij} \leq \text{capacity}_i$. The objective is to maximize the total weighted average throughput, $\sum_j w_j \cdot (\sum_i \text{tput}_{ij} \cdot x_{ij})$, reflecting different job priorities. □

This example demonstrates the "separable" structure frequently encountered in practical resource allocation problems: resource constraints are specified for *each* resource and its associated demands, demand constraints are specified for *each* demand and its contributing resources, and the objective function sums the utility achieved by *each* demand (or resource). Despite this seemingly modular structure, however, such optimization problems remain computationally challenging for commercial solvers to solve at scale. The difficulty arises from each allocation variable x_{ij} simultaneously affecting both resource and demand constraints, precluding straightforward decomposition and parallel optimization.

To address this challenge, DEDE first *decouples* entangled resource and demand constraints through a mathematical reformulation. It introduces a copy of the allocation matrix x as an auxiliary variable z, and rewrites the demand constraints (and per-demand terms in the objective) in terms of z, while adding a new constraint $x = z$. This transformation is mathematically equivalent, preserving the optimal solution. Moreover, it also lends itself to ADMM (Alternating Direction Method of Multipliers) [8], a constrained optimization method based on Lagrange multipliers [6]. By incorporating constraints into the objective via multipliers and constructing the (augmented) Lagrangian (see §3.1), ADMM provides a theoretical framework that allows DEDE to alternatively and iteratively optimize the Lagrangian with respect to each block of variables—x or z—while holding the other fixed.

Building on the reformulation, DEDE further *decomposes* the optimization into subproblems along each resource and each demand. This step capitalizes on the identified separable structure, wherein the introduced Lagrangian can be partitioned across individual resources and demands (see §3.2). Consequently, instead of solving a monolithic optimization over all n resources and m demands, DEDE breaks the problem into n per-resource subproblems, each with only m demand variables, and m per-demand subproblems, each with only n resource variables. These smaller subproblems are amenable to independent and parallel optimization using off-the-shelf solvers. Figure 2 depicts the decouple-and-decompose workflow of DEDE.

To demonstrate DEDE's practical utility, we have implemented DEDE as a Python package, installable via `pip install dede`. Built on the popular open-source modeling language `cvxpy` [3, 15], DEDE provides familiar APIs (§6) aligned with `cvxpy`. Moreover, unlike prior efforts that simulate parallelism [1, 44], our implementation is optimized for *real* parallel execution using Ray [41], enabling efficient utilization of many CPU cores with minimal overhead.

We evaluate DEDE on three representative resource allocation tasks—cluster scheduling, traffic engineering, and load balancing, demonstrating its faster speed and higher allocation quality relative to the state of the art (§7). Compared with the best variant of POP [44] in each domain, DEDE achieves a 7.3% improvement in allocation quality and a 3.1× speedup for cluster scheduling, 5.3% and 7.6× for traffic engineering, and 12.6% and 2.2× for load balancing.

2 Real-World Resource Allocation Problems

In modern cloud systems, resources such as CPUs, memory, and network bandwidth are shared among numerous users and applications. A central resource allocator often casts the distribution of resources as an optimization problem (e.g., LP or MILP) and repeatedly computes feasible solutions using solvers to accommodate changing demands.

However, these solvers are struggling to keep up with the increasing problem sizes that frequently occur in fast-growing systems. They may take up to *several hours* to solve an allocation problem that attempts to assign thousands of resources to thousands of demands. This is several orders of magnitude

slower than desired (e.g., service-level objectives measured in seconds). This challenge of scaling up resource allocation has prompted a series of recent works [1, 43, 44, 48, 65], but they either rely on domain-specific customizations or workload-dependent assumptions. In this work, we instead seek to take a general (i.e., domain- and workload-agnostic) approach to scaling resource allocation.

Separable problem structure. Upon surveying real-world resource allocation problems from the literature (Table 1), we find that nearly all these formulations can be transformed into a *separable* structure (§1) formally described as follows. (We discuss the generality and limitations in §4.)

- *Variables.* An allocation matrix $x \in \mathcal{X}$ specifies the allocation of n resources among m demands, where x_{ij} indicates the amount or fraction of resource i assigned to demand j (or vice versa). Accordingly, the i-th row of x, denoted as $x_{i*} = (x_{i1}, x_{i2}, \ldots, x_{im})$, constitutes the allocation vector of resource i, while the j-th column $x_{*j} = (x_{1j}, x_{2j}, \ldots, x_{nj})$ encodes the allocation of demand j. The constraint set $\mathcal{X}$ is the Cartesian product of the individual domains $\mathcal{X}_{ij}$, but it is often just non-negative real numbers or integers.
- *Objective.* The objective defines a metric to be maximized or minimized over an allocation matrix x, consisting of a sum of utilities or costs that quantify the outcome from allocating each resource x_{i*} or demand x_{*j}:

$$\sum_i f_i(x_{i*}) + \sum_j g_j(x_{*j}), \tag{1}$$

  where $f_i(\cdot) : \mathbb{R}^m \to \mathbb{R}$ and $g_j(\cdot) : \mathbb{R}^n \to \mathbb{R}$ are utility or cost functions. These functions are typically convex (by nature or by choice), facilitating tractable optimization. A variety of objectives can be transformed into this form using standard optimization techniques. E.g., maximizing the minimum utility can be converted into maximizing an auxiliary "min utility" variable, with additional constraints ensuring that each utility is at least as large as this variable.
- *Constraints.* To enforce feasible allocation, one or more constraints can be imposed on each resource and each demand (e.g., to prevent oversubscription of resources and overprovisioning of demands). For computational tractability, these constraints are typically linear. Following standard optimization practices, we transform inequality constraints into equivalent equality constraints using slack variables. Thus, without loss of generality, we express the $rc_i \geq 1$ resource constraints on each resource i as

$$R_i x_{i*} = r_i, \quad \forall i, \tag{2}$$

  where $R_i \in \mathbb{R}^{rc_i \times m}, r_i \in \mathbb{R}^{rc_i}$ are constraint parameters. Likewise, each demand j is subject to $dc_j \geq 1$ linear constraints:

$$D_j x_{*j} = d_j, \quad \forall j, \tag{3}$$

  where $D_j \in \mathbb{R}^{dc_j \times n}, d_j \in \mathbb{R}^{dc_j}$ are constraint parameters.

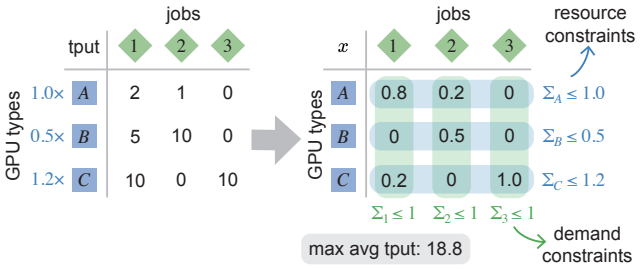

Figure 3: Toy scenario of the job scheduling example.

Despite the separable objective and separate constraints over each resource and each demand, large resource allocation problems (e.g., with millions of variables) still remain painfully slow to solve as they cannot actually be separated into smaller, concurrent subproblems. The main obstacle is that resource and demand constraints are fundamentally entangled. As shown in Equations 2 and 3, each $x_{i,j}$ not only participates in the resource constraints (over x_{i*}) but also in the demand constraints (over x_{*j}).

► **Example:** The example introduced in §1 clearly fits into this formulation. For a more specific example, consider a toy scenario in Figure 3, where three language model inference jobs are scheduled across three types of GPUs. For simplicity, we assume each job fits in a single GPU of any type ($\text{req}_j = 1$), and all jobs have equal priority ($w_j = 1$).

The left panel of Figure 3 shows the capacity of each GPU type (capacity_i) in GPU hours, alongside the throughput table (tput_{ij}). E.g., GPU type C has a total capacity of 1.2 GPU hours, and assigning job 1 to it yields a throughput of 10 TPS.

The right panel shows the optimal allocation matrix (x_{ij}), which satisfies all resource and demand constraints. E.g., the optimal solution schedules job 1 on (one unit of) GPU type A for 0.8 hours, and on GPU type C for 0.2 hours. The maximum average throughput achieved is 18.8 TPS. □

3 DEDE: Decouple and Decompose

We present DEDE, a practical and theoretically rooted optimization framework for solving large-scale, real-world resource allocation problems. By exploiting the inherently separable structure of these problems as described earlier, DEDE achieves massive parallelism while producing near-optimal solutions through a *decouple-and-decompose* approach.

3.1 Decouple

The interdependence between resource and demand constraints is a core complexity in resource allocation. Achieving an optimal solution requires jointly allocating all resources to all demands; otherwise, local, greedy strategies likely result in suboptimal or infeasible solutions.

Existing solutions do not address this intertwined structure of constraints in resource allocation. In practice, production

systems tend to simply rely on commercial solvers and employ linear programming (LP) or mixed-integer linear programming (MILP) algorithms (e.g., simplex methods [46], barrier methods [31], or branch-and-bound methods [7]) to navigate a high-dimensional search space, which is induced by the coupling of resource and demand constraints.

A recent work, POP [44], naively breaks entangled constraints by partitioning resources and demands into a handful of subsets (e.g., 4–64), and then independently allocates a subset of resources to a subset of demands. Doing so ignores the dependencies across subsets and leads to suboptimal solutions in practice (§7). Meanwhile, it only enables limited parallelism because finer-grained decomposition would render the allocation infeasible and unusable.

Instead of disregarding the constraints across subproblems, we tackle the root cause of constraint entanglement. Specifically, without sacrificing solution quality, our high-level goal is to decouple demand constraints from resource constraints, transforming the global allocation into alternating per-resource and per-demand subproblems.

Reformulation. Consider the minimization of the objective in Equation 1 (the signs of f_i and g_j can be simply reversed for maximization problems), subject to resource constraints in Equation 2 and demand constraints in Equation 3.

First, we introduce an auxiliary variable z as a duplicate of the allocation matrix x, and rewrite all demand constraints and all demand-related terms in the objective using z. Meanwhile, we add a new constraint $x = z$. This transformation clearly leads to an equivalent optimization problem:

$$\begin{aligned} \min_{x\in\mathcal{X}} \quad & \sum_i f_i(x_{i*}) + \sum_j g_j(z_{*j}), \\ s.t. \quad & R_i x_{i*} = r_i, \quad \forall i, \\ & D_j z_{*j} = d_j, \quad \forall j, \\ & x - z = 0. \end{aligned} \tag{4}$$

In this formulation, all resource constraints remain on x, while all demand constraints (and related utilities) are moved to z.

Although introducing z appears to separate the problem structurally, the (necessary) constraint $x = z$ still tightly couples the variables and thus prevents straightforward decomposition. In fact, jointly optimizing x and z (e.g., using penalty methods [4] or augmented Lagrangian [23]) will forfeit the benefits of this reformulation, as we will show in §7.3.

ADMM background. Nevertheless, this reformulation lends itself to ADMM (Alternating Direction Method of Multipliers) [8], a classical method for solving constrained optimization problems of the form: minimize $f(x)+g(z)$, subject to $Ax+Bz=c$. Note that Equation 4 conforms to this form.

ADMM is based on augmented Lagrangian [23], a method that converts constrained optimization into a sequence of unconstrained optimization problems using Lagrange multipliers [6] (a well-known technique in optimization). These unconstrained problems are defined over the Lagrangian function, constructed from the objective and constraints: $L_\rho(x,z,y) = f(x)+g(z)+y^\mathsf{T}(Ax+Bz-c)+(\rho/2)\|Ax+Bz-c\|_2^2$, where y is (an estimate of) the Lagrange multiplier, and the last quadratic term with parameter ρ serves as a penalty [4] for improving convexity and stability.

The theory of ADMM enables partial, alternating optimization of the Lagrangian with respect to x and z—iteratively solving for x with z fixed, and solving for z with x fixed. This "two-block partial optimization" guarantees convergence to an optimal solution for convex problems [20, 21]. In non-convex settings (including those involving integers), empirical results indicate that ADMM can still effectively solve many of these problems [54, 64, 70]. Theoretical convergence results are established under certain conditions [39, 57, 61].

By introducing the auxiliary variable $u = (1/\rho)y$, the augmented Lagrangian can be further rewritten as: $L_\rho(x,z,u) = f(x)+g(z)+(\rho/2)\|Ax+Bz-c+u\|_2^2-(\rho/2)\|u\|_2^2$, leading to a more convenient *scaled form* of ADMM. Next, we present the ADMM iterates for updating x, y, and u directly in the context of resource allocation problems.

Applying ADMM. DEDE applies the scaled form of ADMM to solve the reformulated optimization problem (Equation 4). First, it constructs the augmented Lagrangian:

$$\begin{aligned} \mathcal{L}_\rho(x,z,\alpha,\beta,\lambda) &= \sum_i f_i(x_{i*}) + \sum_j g_j(z_{*j}) \\ &+ \frac{\rho}{2}\Big(\sum_i \|R_i x_{i*} - r_i + \alpha_i\|_2^2 + \sum_j \|D_j z_{*j} - d_j + \beta_j\|_2^2 \\ &+ \|x - z + \lambda\|_F^2\Big) - \frac{\rho}{2}(\|\alpha\|_2^2 + \|\beta\|_2^2 + \|\lambda\|_F^2), \end{aligned} \tag{5}$$

where $\alpha_i \in \mathbb{R}^{rc_i}$, $\beta_j \in \mathbb{R}^{dc_j}$, $\lambda \in \mathbb{R}^{n\times m}$ are the introduced auxiliary variables. $\|\cdot\|_2$ still denotes the ℓ^2-norm of a vector, while $\|\cdot\|_F$ is the Frobenius norm of a matrix, i.e., the ℓ^2-norm of the matrix when flattened into a vector.

The ADMM iterates are given by:

$$x^{(k+1)} := \arg\min_{x\in\mathcal{X}} \mathcal{L}_\rho(x, z^{(k)}, \alpha^{(k)}, \beta^{(k)}, \lambda^{(k)}) \tag{6}$$

$$z^{(k+1)} := \arg\min_{z} \mathcal{L}_\rho(x^{(k+1)}, z, \alpha^{(k)}, \beta^{(k)}, \lambda^{(k)}) \tag{7}$$

$$\begin{aligned} \alpha_i^{(k+1)} &:= \alpha_i^{(k)} + R_i x_{i*}^{(k+1)} - r_i, \forall i \\ \beta_j^{(k+1)} &:= \beta_j^{(k)} + D_j z_{*j}^{(k+1)} - d_j, \forall j \\ \lambda^{(k+1)} &:= \lambda^{(k)} + x^{(k+1)} - z^{(k+1)} \end{aligned}$$

We will show in §3.2 that both the optimization subproblems in Equations 6 and 7 are amenable to decomposition owing to the previously identified separable problem structure.

3.2 Decompose

Up to this point, we have reformulated the original resource allocation problem into alternating minimization steps of the

augmented Lagrangian with respect to x and z. Next, we take the x-minimization step as an example to describe how the optimization is decomposed (z-minimization is similar).

Because the x-minimization step solves for x only, we can ignore all terms in the augmented Lagrangian without x (such as demand constraints). Thus, we rewrite Equation 6 as

$$\begin{aligned} x^{(k+1)} &= \arg\min_{x\in\mathcal{X}} \mathcal{L}_\rho(x, z^{(k)}, \alpha^{(k)}, \beta^{(k)}, \lambda^{(k)}) \\ &= \arg\min_{x\in\mathcal{X}} \sum_i f_i(x_{i*}) + \frac{\rho}{2}\sum_i \left\|R_i x_{i*} - r_i + \alpha_i^{(k)}\right\|_2^2 \\ &\quad + \frac{\rho}{2}\left\|x - z^{(k)} + \lambda^{(k)}\right\|_F^2 \\ &= \arg\min_{x\in\mathcal{X}} \sum_i \Big(f_i(x_{i*}) + \frac{\rho}{2}\left\|R_i x_{i*} - r_i + \alpha_i^{(k)}\right\|_2^2 \\ &\quad + \frac{\rho}{2}\left\|x_{i*} - z_{i*}^{(k)} + \lambda_{i*}^{(k)}\right\|_2^2\Big). \end{aligned} \tag{6}$$

Given that the new objective is a sum of disjoint terms across index i, its minimization can be decomposed into independent, per-resource subproblems over each x_{i*}:

$$\begin{aligned} x_{i*}^{(k+1)} = \arg\min_{x_{i*}\in\mathcal{X}_{i*}} \Big(&f_i(x_{i*}) + \frac{\rho}{2}\left\|R_i x_{i*} - r_i + \alpha_i^{(k)}\right\|_2^2 \\ &+ \frac{\rho}{2}\left\|x_{i*} - z_{i*}^{(k)} + \lambda_{i*}^{(k)}\right\|_2^2\Big), \quad \forall i. \end{aligned} \tag{8}$$

This decomposition is made possible by the separable structure: (1) the original objective is separable, with a utility $f_i(x_{i*})$ defined for allocating each resource i, and (2) the resource constraints are likewise separable, as each constraint $R_i x_{i*} = r_i$ pertains only to the corresponding resource i.

As a result, the original optimization problem over $n \times m$ variables is broken down into n independent subproblems, each involving only m variables. DEDE solves each subproblem using off-the-shelf solvers, which return either exact or approximate solutions depending on the nature of f (convex or not), whether $\mathcal{X}$ contains integers, etc. Since this decomposition allows up to n parallel computations—often numbering in the thousands in large-scale settings—DEDE is capable of delivering substantial speedups assuming sufficient CPUs.

For linear programs, the original problem has a worst-case time complexity of approximately $O((n\cdot m)^{2.373})$ [13, 44]. After decomposition, DEDE processes n subproblems, each with a complexity of $O(m^{2.373})$, reducing the overall complexity to $O(n\cdot m^{2.373})$. Nonetheless, this theoretical improvement assumes that ADMM converges within a constant number of iterations. In practice, the number of iterations depends on the choice of the penalty parameter ρ (which acts like a "learning rate") and other factors that influence convergence.

Similarly, the z-minimization step decomposes into independent, per-demand allocation subproblems over each z_{*j}:

$$\begin{aligned} z_{*j}^{(k+1)} = \arg\min_{z_{*j}} \Big(&g_j(z_{*j}) + \frac{\rho}{2}\left\|D_j z_{*j} - d_j + \beta_j^{(k)}\right\|_2^2 \\ &+ \frac{\rho}{2}\left\|x_{*j}^{(k+1)} - z_{*j} + \lambda_{*j}^{(k)}\right\|_2^2\Big), \quad \forall j. \end{aligned} \tag{9}$$

4 Generality and Limitations

In this section, we discuss the generality of DEDE (conditions under which it applies) and its limitations (scenarios that may result in limited parallelism or suboptimal solutions).

4.1 Generality

DEDE is applicable to a wide range of real-world resource allocation problems. Table 1 summarizes these problems that appear in recent literature such as OSDI, SOSP, NSDI, and SIGCOMM. Below, we explain why DEDE is applicable.

- *Variables.* As an ADMM-based framework, DEDE natively supports continuous (real-valued) allocation variables. Empirical evidence [54] and theoretical proofs [39, 57, 61] on ADMM further indicate that DEDE should effectively handle boolean and integer variables by projecting real-valued solutions onto the appropriate domains during iterations.
- *Objective.* Most objectives in real systems are defined as the sum, max, or min of utility functions over the individual allocation of resources and demands. They also exhibit convexity. Examples include weighted sums [45, 65], logarithmic utilities [2], and quadratic costs [60, 66].
- *Constraints.* DEDE assumes linear constraints on resources and demands—a condition that holds across all the surveyed use cases. These constraints are commonly expressed at the per-resource or per-demand level. Even for constraints that do span multiple resources or demands, DEDE can turn them into disjoint constraint groups and apply decomposition at the group level (at the cost of reduced parallelism).

Unlike POP [44], DEDE works with any workload, not only "granular" ones. In POP, the demands in each subproblem can only access a subset of resources, assuming each demand only requests a small fraction of interchangeable resources such that a resource subset suffices. This granular assumption can be unrealistic in practice, due to uneven demand distributions [29, 58] or specific resources that each demand is allowed to utilize [34, 59]. In contrast, each subproblem in DEDE can still access all the resources or demands, resulting in generalization to various workload distributions.

4.2 Limitations

While DEDE applies to a variety of resource allocation tasks, it might not always be the optimal approach for all scenarios.

Limited parallelism. DEDE's parallelism relies on its ability to decompose the problem into independent subproblems. When such decomposition is not fully achievable, the degree of parallelism diminishes. Although this limitation does not manifest in the set of real-world problems we surveyed, we come up with some examples below.

- *Non-separable objectives.* An objective is non-separable when utility depends on the interaction between different

	Variables			Objective
